Answer (Q4, Recall). The endomembrane system is the network of interconnected membrane compartments in eukaryotic cells that synthesize, modify, sort, and traffic lipids and proteins. Members: nuclear envelope, rough ER (ribosomes → secretory/membrane proteins), smooth ER (lipid synthesis, Ca²⁺ storage, detoxification), Golgi apparatus (post-translational modification + sorting), lysosomes (hydrolytic digestion), endosomes (endocytic sorting), and the plasma membrane (via vesicle traffic). Mitochondria and chloroplasts are NOT part of it — their double membranes are of endosymbiotic origin. 5. Define resolution in microscopy. What is the resolution limit of a light microscope?

Answer (Q5, Recall). Resolution is the minimum distance between two points at which they can still be distinguished as separate rather than merging into one blur; it is not the same as magnification. For light microscopy it is set by the Abbe diffraction limit, $d = \lambda / (2 \cdot NA)$, where λ is the illumination wavelength and NA the numerical aperture of the objective. For visible light (λ about 550 nm) and a high-quality oil-immersion objective (NA = 1.4), $d \approx 550 / (2 \times 1.4) \approx 200$ nm. This about 200 nm ceiling is why structures like ribosomes (25 nm) or the membrane bilayer (7–8 nm) are invisible by conventional light microscopy and require electron microscopy (about 0.1 nm) or super-resolution methods (STED, STORM, PALM; about 20–50 nm). See section 5. 6. What is the cell theory exception posed by viruses? Are viruses “alive”?

Answer (Q6, Recall). Viruses are excluded from cell theory by definition because they are not cells: they have no membrane of their own metabolism, no ribosomes, no autonomous reproduction, and no independent energy generation. They consist only of a nucleic acid genome plus a protein capsid (sometimes a stolen lipid envelope) and replicate exclusively by hijacking a host cell’s ribosomes, nucleotides, and ATP. By the usual “alive” criteria they fall in a gray zone — they evolve and carry heritable information (lifelike) but cannot metabolize or reproduce outside a host (non-lifelike). Most cell biologists treat them as obligate intracellular parasites, not living cells, while acknowledging they blur the living/non-living boundary. See section 5. 7. Describe the inner membrane of a mitochondrion. What are cristae and why are they important?

Answer (Q7, Recall). A mitochondrion has two membranes; the inner membrane is the metabolically active one. It is highly impermeable (rich in cardiolipin, a bacterial-type lipid that is a signature of endosymbiotic origin) and houses the electron transport chain complexes and ATP synthase, so chemiosmotic ATP synthesis occurs across it. Cristae are deep folds of this inner membrane projecting into the matrix. They are important because they multiply the inner-membrane surface area severalfold, packing in far more electron transport chains and ATP synthase per unit cell volume — the structural solution to the cube-law constraint, where a hepatocyte’s inner mitochondrial membrane provides about $3 \times 10^4 \text{ } \mu\text{m}^2$ of

respiratory surface, roughly 6x its plasma-membrane area. Highly aerobic cells such as cardiac muscle have densely packed cristae. See section 5. 8. What is the nucleolus and what is assembled there?

Answer (Q8, Recall). The nucleolus is a non-membrane-bound, dense subcompartment within the nucleus formed by liquid-liquid phase separation around the nucleolus organiser regions (NORs) — the clustered rRNA gene repeats located in humans on chromosomes 13, 14, 15, 21, and 22. It is the site of ribosome biogenesis: RNA polymerase I transcribes the rRNA precursor, the rRNA is processed and chemically modified, and it is assembled with ribosomal proteins (imported from the cytoplasm) into the 40S and 60S ribosomal subunits before export. The nucleolus disassembles during mitosis and re-forms around the NORs in the next interphase. See section 5. 9. Distinguish cell walls of bacteria, plants, and fungi (composition).

Answer (Q9, Recall). All three are rigid extracellular polymers that resist osmotic lysis, but the chemistry differs and that difference is what makes wall-targeting drugs selective. Bacteria: peptidoglycan (murein) — chains of alternating N-acetylglucosamine and N-acetylmuramic acid (beta-1,4 linked) cross-linked by short peptide bridges; Gram-positive walls are thick (20-80 nm) with teichoic acids, Gram-negative thin (about 2-7 nm) plus an outer LPS membrane. Plants: cellulose microfibrils (beta-1,4 glucose) embedded in hemicellulose and pectin, with lignin in secondary walls. Fungi: chitin (beta-1,4 N-acetylglucosamine polymer) plus beta-glucans and mannoproteins. Because peptidoglycan and its D-Ala-D-Ala cross-links are unique to bacteria, beta-lactams (penicillin) and vancomycin kill bacteria but not plant, fungal, or archaeal cells. See section 5. 10. What is meant by “compartmentalization” and why is it advantageous for eukaryotes?

Answer (Q10, Recall). Compartmentalization is the segregation of biochemical processes into discrete membrane-bound organelles within the eukaryotic cell. It is advantageous for four reasons given in the chapter: (1) incompatible reactions run simultaneously in separate compartments — e.g., protein synthesis in the cytoplasm (pH 7.2) versus protein degradation in lysosomes (pH 4.5); (2) substrates and enzymes are concentrated locally (TCA enzymes in the mitochondrial matrix raise reaction rates); (3) gene expression is regulated by separating transcription (nucleus) from translation (cytoplasm), enabling splicing and mRNA export control; (4) internal membranes add enormous surface area for membrane-associated reactions. This last point is the topological solution to the cube-law problem: a HeLa cell has about 5-fold lower surface-to-volume than E. coli yet 10x higher metabolic flux, only possible because internal membranes supply the missing surface area. See section 5.

Questions 11–20: Application and Analysis

11. Calculate the surface area-to-volume ratio (SA:V) for spherical cells with radii of 1 μm, 5 μm, and 10 μm. Explain why SA:V limits the maximum size of cells.

Answer (Q11, Application). For a sphere, $A/V = 4\pi r^2 / (\frac{4}{3}\pi r^3) = 3/r$. Substituting with units: at $r = 1 \text{ μm}$, $A/V = 3/1 = 3.0 \text{ μm}^{-1}$; at $r = 5 \text{ μm}$, $A/V = 3/5 = 0.6 \text{ μm}^{-1}$; at $r = 10 \text{ μm}$, $A/V = 3/10 = 0.3 \text{ μm}^{-1}$. The ratio falls as $1/r$. This limits maximum cell size because metabolic demand (nutrient consumption, waste production) scales with volume ($\propto r^3$) while exchange with the environment scales with surface area ($\propto r^2$). As a cell enlarges, demand outgrows supply: the membrane can no longer import nutrients or expel waste fast enough for the interior volume, so a uniform respiring cell hits a hard ceiling (about 60 μm radius for typical mammalian parameters via $r_{\text{max}} = 3P_{O_2}\Delta[O_2]/q$) unless it amplifies surface area (microvilli), lowers metabolic demand (vacuoles), or accepts core anoxia. See section 5. 12. Colchicine destroys microtubules. Predict its effects on: (a) mitosis; (b) vesicle trafficking; (c) cilia; (d) cell shape.

Answer (Q12, Application). Colchicine binds tubulin dimers and blocks microtubule polymerization, depolymerising existing microtubules. (a) Mitosis: the mitotic spindle is microtubule-based, so chromosomes cannot attach to or be pulled to the poles — cells arrest in metaphase (the classic spindle-poison or metaphase-arrest effect, exploited in karyotyping). (b) Vesicle trafficking: long-range vesicle transport runs on microtubule tracks via kinesin and dynein motors; without microtubules, directed organelle and vesicle movement (e.g., ER-to-Golgi, axonal transport) collapses. (c) Cilia: the ciliary axoneme is a 9+2 microtubule array, so cilia and flagella lose their structure and beating stops. (d) Cell shape: microtubules provide compressive struts and polarity cues, so cells lose directional shape and asymmetry, tending to round up. See section 5. 13. *Thiomargarita namibiensis* is a bacterium >750 μm in diameter — larger than many eukaryotes. How does it solve the SA:V problem?

Answer (Q13, Application). At a diameter of about 750 μm (radius about 375 μm) its surface-to-volume ratio is only $A/V = 3/375 \approx 0.008 \text{ μm}^{-1}$ — far too low to supply a metabolically active cytoplasm of that volume by diffusion across the plasma membrane. It evades the cube-law constraint not by increasing surface area but by reducing metabolically active volume: more than 95% of the cell is a giant central vacuole that stores nitrate (an electron acceptor) and elemental sulfur. The living, respiring cytoplasm is confined to a thin shell just beneath the plasma membrane, so the effective diffusion distance and the metabolically demanding volume are tiny even though the whole cell is huge. This is the same trick plant cells use with their large central vacuole. See section 5. 14. Describe the experimental basis for the discovery that cells arise from pre-existing cells (Pasteur’s swan-neck flask experiment).

Answer (Q14, Application). Virchow’s principle *omnis cellula e cellula* (1855) asserted that cells arise only from pre-existing cells, but it was Louis Pasteur (1859) who experimentally killed spontaneous generation. He boiled nutrient broth (sterilising it) in flasks with long S-shaped swan-neck necks. The bend trapped airborne dust and microbes in the curve so air could still reach the broth but particles could not. Result: the broth stayed

sterile indefinitely as long as the neck was intact; if the neck was snapped off or the flask tilted so broth contacted the trapped dust, microbial growth appeared within days. The decisive control showing the broth itself could still support life rules out the alternative that boiling destroyed a vital force. This established that microbes come only from pre-existing microbes, completing the third tenet of cell theory and the unbroken-lineage corollary. See section 5. 15. Explain five lines of molecular evidence supporting the endosymbiotic origin of mitochondria.

Answer (Q15, Application). (1) Double membrane: mitochondria have two bilayers — an inner one resembling a bacterial plasma membrane and an outer one derived from the host phagocytic membrane. (2) Circular genome: mitochondria carry their own small circular DNA, like a bacterial chromosome rather than the host's linear nuclear chromosomes. (3) 70S bacterial-type ribosomes: organelle ribosomes are inhibited by anti-bacterial antibiotics (chloramphenicol, erythromycin) that do not touch cytoplasmic 80S ribosomes. (4) Binary fission: mitochondria divide independently of the nucleus using FtsZ-related proteins, exactly as bacteria do. (5) Phylogenetics: mitochondrial rRNA sequences are most closely related to alpha-proteobacteria (e.g., *Rickettsia*). Additional support: cardiolipin in the inner membrane and N-formylmethionine-initiated protein synthesis, both bacterial signatures. See section 5. 16. A secretory cell is treated with brefeldin A (disrupts the Golgi). Predict the consequences for enzyme secretion.

Answer (Q16, Application). Brefeldin A collapses the Golgi apparatus, causing Golgi membranes and cargo to redistribute back into the ER. The secretory pathway is ER, then Golgi, then secretory vesicle, then plasma membrane, so disrupting the Golgi breaks the route at the modification and sorting step. Consequences: (1) newly synthesized secretory enzymes accumulate in the ER and fused ER-Golgi remnant compartments instead of being exported, so extracellular enzyme levels drop sharply; (2) the enzymes that do remain are not properly modified (terminal glycosylation and proteolytic maturation that occur in the Golgi do not happen), so even mis-localized enzyme is often inactive; (3) lysosomal hydrolases, which acquire their mannose-6-phosphate sorting tag in the Golgi, are mis-sorted and tend to be secreted rather than delivered to lysosomes, impairing intracellular digestion. Net result: loss of regulated enzyme secretion plus ER stress from cargo backup. See section 5. 17. Explain why red blood cells lack a nucleus and mitochondria. What metabolic consequences does this create?

Answer (Q17, Application). Mammalian erythrocytes extrude their nucleus and degrade their mitochondria and other organelles during maturation. This is adaptive: it maximizes the volume available for hemoglobin (oxygen-carrying capacity), produces the flexible biconcave disc that can squeeze through capillaries, and removes oxygen-consuming organelles so the cell does not burn the oxygen it is supposed to deliver. The metabolic consequence is that the RBC cannot perform oxidative phosphorylation (no mitochondria) and cannot synthesize new proteins or repair itself (no nucleus). It is therefore wholly dependent on anaerobic glycolysis for ATP and on the pentose phosphate pathway for NADPH to keep hemoglobin reduced and counter oxidative damage. Because it cannot replace damaged components, it has a finite lifespan of about 120 days before removal by the spleen. See section 5. 18. A mutation eliminates the peroxisomal targeting signal (PTS1) from catalase. Where will catalase end up? What biochemical consequence results?

Answer (Q18, Application). Catalase is normally imported into peroxisomes post-translationally because of its C-terminal PTS1 tripeptide (the -SKL motif), which is recognized by the cytosolic receptor Pex5. If PTS1 is deleted, Pex5 cannot bind catalase, so the protein is never imported and instead remains in the cytosol (it is still translated on free ribosomes; only the targeting tag is lost). Biochemical consequence: peroxisomes generate H₂O₂ during fatty-acid beta-oxidation and other oxidase reactions, and catalase is the enzyme that detoxifies that H₂O₂ to water and O₂. With catalase mislocalized to the cytosol, peroxisomal H₂O₂ is no longer cleared inside the organelle, raising reactive-oxygen stress and oxidative damage to lipids, proteins, and DNA, while the cytosol gains catalase activity it does not normally have. This illustrates that targeting, not synthesis, dictates organelle function. See section 5. 19. Ribosome composition differs between prokaryotes (70S = 50S + 30S) and eukaryotes (80S = 60S + 40S). How are antibiotics exploited to target primarily bacterial ribosomes?

Answer (Q19, Application). Bacterial ribosomes are 70S (50S large plus 30S small subunits) whereas eukaryotic cytoplasmic ribosomes are 80S (60S plus 40S); the rRNA and protein structures differ enough that drugs can bind the bacterial machine without binding the human one. This structural dichotomy is the basis of selective toxicity: aminoglycosides and tetracyclines bind the 30S subunit (blocking decoding and tRNA binding), while chloramphenicol, macrolides (erythromycin), and oxazolidinones bind the 50S subunit (blocking peptide-bond formation or the exit tunnel). These inhibit bacterial protein synthesis while sparing the host's 80S ribosomes. The important caveat is that mitochondrial ribosomes are bacterial-type 70S (endosymbiotic origin), so 70S-targeting antibiotics can have mitochondrial side effects in human cells. See section 5. 20. A student uses STED super-resolution microscopy and finds that nuclear pore complexes are distributed non-randomly on the nuclear envelope, clustering near transcriptionally active chromatin. Interpret this finding in terms of mRNA export and nuclear architecture.

Answer (Q20, Application). STED beats the about 200 nm Abbe diffraction limit (resolution about 30-50 nm), so it can resolve individual nuclear pore complexes (NPCs) and map their spatial distribution — something impossible by conventional light microscopy. The key variable is NPC position relative to active chromatin. If NPCs cluster over transcriptionally active regions, the most parsimonious interpretation is that this minimizes the diffusion distance for newly transcribed, processed mRNA to reach an export channel: the nuclear envelope separates transcription from translation, and NPCs are the only conduits for mRNA export, so co-localizing pores with active genes accelerates and spatially organizes mRNA delivery to

the cytoplasm. It implies the nuclear envelope is not a uniform barrier but a spatially patterned interface coupled to genome organization. A control and alternative to test: compare NPC distribution after transcriptional inhibition (e.g., actinomycin D); if clustering disperses, it supports an activity-coupled, dynamic arrangement rather than a fixed structural one. See section 5.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the claim: “Most life evolved from a single comprehensive common ancestor (LUCA).” What molecular evidence supports LUCA, and what evidence (e.g., horizontal gene transfer) complicates the simple tree-of-life narrative?

Answer (Q21, Synthesis). Supporting evidence (empirical): genes shared by both Bacteria and Archaea and not explained by horizontal transfer form a conserved set of about 355 gene families (the LUCA core; Weiss et al. 2016), implying LUCA already had a DNA-to-RNA-to-protein machinery, the genetic code, about 20 aminoacyl-tRNA synthetases, ATP synthase, and a chemiosmotic membrane; its metalloenzyme inventory points to an anaerobic alkaline hydrothermal habitat. The near-universality of the genetic code and ribosome is the strongest single argument for common ancestry. Complications (what would qualify the conclusion): extensive horizontal gene transfer, especially among prokaryotes, means a single bifurcating tree is an oversimplification — the deep tree is partly a network. The lack of homology between bacterial and archaeal DNA polymerases suggests DNA replication evolved twice after the bacteria-archaea split, so LUCA may have been a pre-cellular, RNA-genome metabolic consortium rather than a fully autonomous free-living cell. LUCA is therefore best read as the last common ancestor of surviving lineages — earlier lineages may have existed but left no descendants — not proof there was ever only one origin of life. See section 5. 22. Synthetic biology aims to build minimal artificial cells (protocells). Evaluate three fundamental hurdles: (a) stable lipid encapsulation; (b) genetic self-replication; (c) energy supply. At what stage are current (2024–2025) efforts?

Answer (Q22, Synthesis). (a) Stable lipid encapsulation: lipid vesicles can self-assemble but must grow, divide, and stay permeable to nutrients yet retain macromolecules; controlled vesicle growth and division coupled to internal metabolism remains only partially solved. (b) Genetic self-replication: a protocell needs a genome that replicates with the protein machinery the genome itself encodes (the chicken-and-egg of replication). Top-down work has already produced a near-minimal living cell — JCVI-syn3.0 (473 genes, 531 kb, doubling about 3 h), still containing 149 essential genes of unknown function — so genome-down self-replication exists but is not yet bottom-up designed from scratch. (c) Energy supply: an autonomous protocell must regenerate ATP and redox cofactors; current systems usually feed in externally supplied energy substrates rather than running a self-sustaining chemiosmotic or fermentative metabolism. Stage of the field: the top-down route (minimal genomes like syn3.0) is the furthest along; the bottom-up route (self-replicating, self-energising vesicles) has demonstrated individual modules but not an integrated, autonomously reproducing protocell. The evidence does not yet settle whether a fully de novo cell is achievable, only that no single hurdle is in principle impossible. See section 5. 23. Organelles proliferate or contract depending on cellular demand. Design an experiment to determine whether smooth ER proliferation in response to lipid overload is controlled by transcriptional upregulation of ER resident proteins or by a different mechanism (e.g., membrane lipid incorporation itself driving ER expansion).

Answer (Q23, Synthesis). Hypothesis: smooth-ER expansion under lipid overload is driven primarily by transcriptional upregulation of ER-resident proteins (H1) versus driven primarily by direct incorporation of excess lipid into ER membrane independent of new gene expression (H2). Design: treat a hepatocyte line with a defined lipid load and split into arms. Arm 1 (control): vehicle only. Arm 2: lipid overload. Arm 3: lipid overload plus a transcription inhibitor (actinomycin D) applied before the load. Arm 4: lipid overload plus a translation inhibitor (cycloheximide). Measured outcomes (with replication, n at least 4 biological replicates, fixed seed for any image-analysis pipeline): quantify smooth-ER membrane area by TEM morphometry and ER marker fluorescence, plus qPCR and Western for ER-resident enzymes (e.g., CYP450, lipid-synthesis enzymes), with a time course. Decision rule: if blocking transcription or translation abolishes ER expansion, H1 is supported; if ER membrane still expands proportionally to the lipid dose despite transcription and translation block (with no rise in ER protein levels), H1 is falsified and H2 (lipid-driven membrane growth) is supported. A dose-response relationship between lipid load and ER area independent of mRNA levels would be the decisive falsifying result for H1. See section 5. 24. Aging cells accumulate dysfunctional mitochondria. Evaluate the “mitochondrial theory of aging”: does mitochondrial dysfunction cause aging, or result from it? Cite evidence from caloric restriction and NAD+ supplementation studies.

Answer (Q24, Synthesis). The mitochondrial theory holds that accumulated mitochondrial DNA damage and reactive-oxygen production progressively degrade respiratory capacity, driving aging. Distinguishing cause from consequence is the central problem: dysfunctional mitochondria are reliably correlated with aging, but correlation does not establish direction. Evidence consistent with a causal contribution: caloric restriction lowers metabolic flux and oxidative load and extends lifespan in many model organisms, and NAD+ precursor supplementation (which restores the NAD+ pool that mitochondrial dehydrogenases and sirtuins depend on) improves mitochondrial function and some aging phenotypes in animal models. Evidence that qualifies the strong causal claim: some interventions that increase reactive-oxygen species can extend lifespan (mitohormesis), and mtDNA-mutator mice age fast but without the predicted ROS surge, suggesting mitochondrial decline is one node in a network (also involving genome maintenance, proteostasis, senescence) rather than the sole driver. Honest verdict: mitochondrial dysfunction is best treated as a contributing and partly self-reinforcing cause, not a proven prime mover; the conclusion would change if NAD+ and caloric-restriction benefits were shown

to act entirely through non-mitochondrial pathways. See section 5. 25. Some unicellular organisms (e.g., *Euglena*) contain both mitochondria and chloroplasts. Evaluate how a single cell coordinates two endosymbiotic organelles with conflicting demands on the cell's redox state.

Answer (Q25, Synthesis). Both organelles are former free-living bacteria (mitochondrion from an alpha-proteobacterium, chloroplast from a cyanobacterium; in *Euglena* the chloroplast arrived by secondary endosymbiosis, hence its three bounding membranes). The conflict: chloroplasts reduce NADP⁺ and pump electrons in the light, generating reducing power and O₂, while mitochondria consume reducing equivalents and O₂ to make ATP — opposing demands on the cytosolic redox poise. Coordination mechanisms: (1) light and dark partitioning — photosynthetic electron flow dominates in light, respiration at night, separating the two in time; (2) redox shuttles — malate/oxaloacetate and triose-phosphate shuttles move reducing equivalents between compartments so excess chloroplast NADPH can be exported and balanced; (3) retrograde signaling — both organelles send redox and metabolite signals to the nucleus, which controls the roughly 1,500 nuclear-encoded organelle proteins, allowing the cell to tune the abundance and activity of each organelle to demand; (4) shared metabolite pools (ATP/ADP, NAD(P)(H)) act as the buffering currency. The endosymbiotic theory predicts exactly this: gene transfer to the host nucleus gives the cell central control over two formerly autonomous metabolisms. See section 5. 26. Evaluate the role of the centrosome as a signaling hub beyond its microtubule-organizing function. What kinases localize to the centrosome, and how does centrosome duplication failure contribute to cancer?

Answer (Q26, Synthesis). Beyond being the principal microtubule-organizing center, the centrosome acts as a concentrating scaffold for cell-cycle and mitotic-control kinases — notably Polo-like kinase 1 (PLK1), Aurora-A, and CDK1-cyclin B — so it functions as a localized signaling hub that couples microtubule nucleation to mitotic entry, spindle assembly, and cytokinesis. Empirically, centrosome amplification (more than 2 centrosomes per cell) is common in tumors. The causal link to cancer: extra centrosomes can form multipolar or merotelic spindles, mis-segregating chromosomes and generating chromosomal instability and aneuploidy, which accelerates tumor evolution; mislocalized Aurora-A and PLK1 activity further perturbs checkpoint control. Boundary condition and what would change the conclusion: many cancer cells cluster supernumerary centrosomes into pseudo-bipolar spindles and survive, so centrosome amplification is better described as a driver of instability and tumor heterogeneity than a strict requirement for transformation; if amplification were shown to be a purely passive consequence of an already-unstable genome, the active-driver interpretation would weaken. See section 5. 27. Apicoplasts in malaria parasites (*Plasmodium*) are non-photosynthetic plastids derived from a secondary endosymbiosis. Evaluate them as drug targets — what essential biosynthetic pathways occur exclusively in the apicoplast, and why does targeting apicoplast translation (e.g., with doxycycline) kill the parasite but spare human cells?

Answer (Q27, Synthesis). The apicoplast is a relic plastid (secondary endosymbiosis of a red alga) that has lost photosynthesis but retained essential prokaryote-derived biosynthesis: the non-mevalonate (MEP/DOXP) isoprenoid precursor pathway, parts of type II fatty-acid synthesis (FAS-II), haem biosynthesis, and Fe-S cluster assembly. Humans use the unrelated mevalonate pathway for isoprenoids and FAS-I, so these apicoplast pathways have no human counterpart — an ideal selective-toxicity gap. Why doxycycline (and other 70S-ribosome antibiotics like clindamycin) works: the apicoplast retains a bacterial-type genome and 70S ribosomes for its own gene expression, just like mitochondria. Doxycycline blocks 70S translation, crippling apicoplast biogenesis; the parasite dies (often with a characteristic delayed death one cycle later because the disabled apicoplast cannot be inherited functionally). Human cytoplasmic ribosomes are 80S and unaffected. The boundary condition is the mitochondrial caveat: human mitochondria also have 70S ribosomes, so dosing must stay within the therapeutic window that affects the parasite's smaller, more drug-accessible apicoplast more than host mitochondria. See section 5. 28. Liquid-liquid phase separation (LLPS) creates membraneless organelles (stress granules, P-bodies). Evaluate the evidence that these condensates are functionally equivalent to membrane-bounded organelles in concentrating reaction components.

Answer (Q28, Synthesis). Membraneless organelles (nucleolus, stress granules, P-bodies) form by liquid-liquid phase separation of multivalent proteins and RNA into droplet-like condensates. Evidence they resemble membrane-bound organelles functionally: they selectively concentrate specific RNAs and enzymes far above bulk cytoplasmic levels (so they can accelerate or sequester reactions, e.g., ribosome assembly in the nucleolus), they have defined composition, and they can be experimentally disrupted (1,6-hexanediol) with predictable loss of the localized activity. The decisive difference from true organelles is the absence of a bilayer: condensates have no semipermeable barrier, so they exchange components with the surroundings on a second timescale, are thermodynamically tuned by concentration and temperature rather than gated by transport machinery, and cannot maintain a distinct chemical environment (pH, ion composition) the way a lysosome can. Verdict: condensates are functionally analogous in concentrating reaction components and creating local microenvironments, but they are not equivalent to membrane-bound organelles for processes that require chemical isolation or active import gating — calling them organelles is justified for compartmentalised chemistry but not for barrier-dependent functions. See section 5. 29. Compare the evolutionary trajectories of a symbiotic bacterium becoming a mitochondrion vs becoming a lysosome. What structural and genomic changes would you expect in each pathway?

Answer (Q29, Synthesis). The shared principle is reductive evolution of an engulfed cell under host control, but the endpoint differs because a mitochondrion is a retained endosymbiont while a lysosome is not endosymbiotic at all — so the comparison sharpens what makes endosymbiosis distinctive. Becoming a mitochondrion (endosymbiotic path): the bacterium keeps a double membrane (its own plus the host phagosomal mem-

brane), retains a residual circular genome and bacterial 70S ribosomes, divides by binary fission with FtsZ-related proteins, but undergoes massive gene transfer to the host nucleus (about 1,500 genes), keeping only a core needed for in-situ assembly of the respiratory chain; metabolite and protein import machinery (TOM/TIM) evolves to re-couple the now-dependent organelle to the host. Becoming a lysosome (non-endosymbiotic path): no retained genome, no 70S ribosomes, single membrane derived from the host endomembrane system; it would arise instead by host-encoded biogenesis — Golgi-derived hydrolases tagged with mannose-6-phosphate, a V-ATPase to acidify the lumen to pH 4.5 — with all components nuclear-encoded from the start. Expected signature: a mitochondrion shows genomic remnants and bacterial-lipid (cardiolipin) and fMet-translation hallmarks; a lysosome shows none of these and is purely a host-built compartment. See section 5. 30. Critically assess the hypothesis that cancer is a disease of cell identity — a reversion to a primordial unicellular state where individual cell fitness (unlimited proliferation, resistance to death) overrides multicellular cooperation. What evidence from cancer evolutionary biology supports or contradicts this view?

Answer (Q30, Synthesis). The atavism hypothesis frames cancer as a breakdown of the multicellular social contract: somatic mutations release a cell from cooperative constraints (controlled division, programmed death, niche restriction) so that single-cell fitness traits — unlimited proliferation, apoptosis resistance, metabolic autonomy — re-dominate, echoing Virchow’s *omnis cellula e cellula* applied to malignant clones arising from normal cells. Supporting evidence: tumors evolve by mutation and clonal selection within the body (a microevolutionary process), preferentially activate ancient, conserved unicellular-like genes while downregulating genes that arose with multicellularity, and exhibit metabolic shifts (aerobic glycolysis, the Warburg effect) reminiscent of a fermentative ancestral state. Contradicting and qualifying evidence: cancers do not become free-living unicells — they remain dependent on host vasculature, stroma, and growth factors, and they acquire new metabolic and signaling adaptations rather than simply reverting to an ancestral program; the genetic changes are largely loss and dysregulation of metazoan controls, not resurrection of a coherent ancestral genome. Honest assessment: the atavism model is a useful heuristic for why proliferation and death-resistance programs are mutationally accessible, but the data better support cancer as Darwinian somatic evolution of metazoan cells under relaxed multicellular constraint than as a literal reversion to a primordial unicellular organism; the conclusion would shift if reactivated unicellular gene modules were shown to be necessary and sufficient for transformation. See section 5.

Questions — Cell Structure and Organelles

Instructor Use and Coverage Notes

- Coverage target: Predict which organelle or cytoskeletal process is disrupted from a phenotype.
- Model/data emphasis: Compartment-flow and motor-transport calculations.
- Assessment alignment: Visual Representations, Questions and Methods, Argumentation.
- Misconception probe: Organelles are dynamic process hubs, not static textbook icons.
- Transfer product: Apply compartment logic to secretion, apoptosis, infection, or cell division.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 6 of the textbook — review that chapter before attempting the exercises below.

1. Which organelle is responsible for: (a) protein synthesis; (b) lipid synthesis; (c) protein glycosylation; (d) intracellular digestion; (e) ATP synthesis?

Answer (Q1, Recall). (a) Protein synthesis: the ribosome — free cytosolic ribosomes for cytosolic proteins, ER-bound (rough ER) ribosomes for secretory and membrane proteins. (b) Lipid synthesis: the smooth ER (phospholipids, cholesterol, steroid hormones). (c) Protein glycosylation: begins in the rough ER (initial N-glycosylation) and is completed in the Golgi apparatus (O-glycosylation and N-glycan trimming). (d) Intracellular digestion: the lysosome, using about 60 acid hydrolases at pH 4.5-5.0. (e) ATP synthesis: the mitochondrion — oxidative phosphorylation by the electron transport chain and ATP synthase on the inner membrane (with a smaller cytosolic glycolytic contribution). See section 6. 2. What is the difference between rough ER and smooth ER in structure and function?

Answer (Q2, Recall). Both are continuous membrane networks of the same organelle, but ribosome decoration is the structural difference that changes their function. Rough ER (RER) is studded with ribosomes on its cytosolic face; it is the site of synthesis, folding, quality control, and initial N-glycosylation of secreted and membrane proteins (chaperones BiP, calnexin, calreticulin ensure folding; misfolded proteins go to ERAD). Smooth ER (SER) lacks ribosomes; it performs lipid and steroid-hormone synthesis, cytochrome P450 drug and toxin detoxification (abundant in liver), Ca2+ storage and release for signaling (the muscle sarcoplasmic reticulum is specialized SER), and glycogen metabolism. The presence or absence of bound ribosomes is therefore what assigns each region to protein-handling versus lipid and detox roles. See section 6. 3. Describe the cis-to-trans polarity of the Golgi apparatus and the direction of cargo flow.

Answer (Q3, Recall). The Golgi is a polarized stack: the cis face (cis-Golgi network) sits nearest the ER and receives newly synthesized cargo, the medial cisternae are in the middle, and the trans face (trans-Golgi network, TGN) faces the plasma membrane and acts as the sorting station. Cargo flow is directional: proteins enter at the cis face from the ER in COPII-coated vesicles, move cis to medial to trans (anterograde) while being progressively modified (O-glycosylation, N-glycan trimming, mannose-6-phosphate addition), and exit from the TGN sorted to lysosomes (M6P), the plasma membrane (constitutive secretion), or secretory granules (regulated exocytosis). Retrograde traffic in COPI-coated vesicles returns escaped ER-resident (KDEL) proteins from the Golgi back to the ER. See section 6. 4. What is the optimal pH inside a lysosome and why?

Answer (Q4, Recall). The lysosomal lumen is maintained at pH 4.5-5.0 by a V-type H+-ATPase that pumps protons in using ATP. This acidic optimum exists because the roughly 60 lysosomal acid hydrolases (proteases, lipases, nucleases, glycosidases) have peak catalytic activity near pH 4.5-5. The acidity is also a built-in safety mechanism: if these enzymes leak into the cytosol (pH about 7.2) they are largely inactive, protecting the cell from self-digestion. The same acidity drives ligand release from receptors in the endocytic pathway. See section 6. 5. Name the three components of the cytoskeleton and one function of each.

Answer (Q5, Recall). (1) Actin microfilaments (about 7 nm; polar ATP-driven polymers of G-actin) — cell shape, the cytokinesis contractile ring, muscle contraction, and crawling via lamellipodia and filopodia. (2) Microtubules (about 25 nm; hollow alpha/beta-tubulin tubes, GTP-driven dynamic instability) — chromosome segregation by the mitotic spindle, intracellular vesicle and organelle transport along kinesin and dynein tracks, and the 9+2 axoneme of cilia and flagella. (3) Intermediate filaments (about 10 nm; ropelike coiled-coil proteins, non-polar, no motors) — purely mechanical resilience, e.g., keratin in epithelia and lamins forming the nuclear lamina. See section 6. 6. What are cilia and flagella made of (protein and structure)? What drives their beating?

Answer (Q6, Recall). Eukaryotic motile cilia and flagella are built from the axoneme: nine outer doublet microtubules surrounding two central singlet microtubules (the 9+2 arrangement), with the doublets linked by nexin bridges and bearing inner and outer dynein arms. Beating is driven by ciliary (axonemal) dynein, an ATPase motor: dynein arms on one doublet walk along the adjacent doublet, but because nexin links resist sliding, the relative microtubule sliding is converted into rhythmic bending. ATP hydrolysis powers the stroke; coordinated activation of dynein arms

around the axoneme produces the propagating waveform. (Note that the bacterial flagellum is structurally unrelated: a flagellin filament rotated by a proton-motive-force-driven rotary motor.) See section 6. 7. Describe the nuclear envelope. How many membranes does it have?

Answer (Q7, Recall). The nuclear envelope is a double membrane: two concentric phospholipid bilayers, an inner and an outer nuclear membrane separated by a perinuclear space. The outer nuclear membrane is continuous with the rough ER. The two membranes are perforated by nuclear pore complexes (about 3,000-5,000 per nucleus, roughly 10-20 per μm^2 of envelope), each a roughly 120 MDa assembly of about 30 nucleoporin species with 8-fold symmetry that gates molecular traffic: small molecules (<40 kDa) diffuse through the about 9 nm channel, while larger cargo needs an NLS or NES and is moved by importins and exportins powered by the RanGTP/GDP gradient. Underlying the inner membrane is the nuclear lamina (lamin intermediate filaments) that gives the nucleus mechanical rigidity. See section 6. 8. What two reactions does the peroxisome catalyse involving hydrogen peroxide?

Answer (Q8, Recall). Peroxisomal oxidase enzymes catalyse the first reaction — substrate oxidation that produces hydrogen peroxide, for example during fatty-acid beta-oxidation, where an oxidase transfers electrons to O_2 generating H_2O_2 ($\text{RH}_2 + \text{O}_2 \rightarrow \text{R} + \text{H}_2\text{O}_2$). The second reaction is catalase-catalysed decomposition of that H_2O_2 : $2 \text{H}_2\text{O}_2 \rightarrow 2 \text{H}_2\text{O} + \text{O}_2$. So the peroxisome both generates H_2O_2 (as a controlled byproduct of oxidative metabolism) and immediately detoxifies it with catalase, keeping reactive oxygen species in check while shortening very-long-chain fatty acids. See section 6. 9. Distinguish the large central vacuole of plants from contractile vacuoles of protists.

Answer (Q9, Recall). Both are large membrane-bound storage compartments, but they solve different problems with different mechanisms. The plant large central vacuole is a single, near-permanent organelle occupying up to 80-90% of cell volume; bounded by the tonoplast, it stores water, ions, pigments, and waste, and generates turgor pressure that drives plant cell growth and rigidity — it is largely metabolically inert volume that helps cells get large without raising metabolic demand. The contractile vacuole of freshwater protists is a small, dynamic osmoregulatory organelle that cyclically fills with excess water entering by osmosis and then contracts to expel it across the plasma membrane, preventing osmotic lysis in a hypotonic environment. So the difference is static structural and storage role versus active, cyclic osmotic-pump role. See section 6. 10. What is the centrosome? What happens to centrosomes during mitosis?

Answer (Q10, Recall). The centrosome is the primary microtubule-organizing center (MTOC) of animal cells: two barrel-shaped centrioles (each nine triplet microtubules in a pinwheel) surrounded by pericentriolar material containing gamma-tubulin ring complexes that nucleate microtubules. During the cell cycle the centrosome duplicates (one new centriole per existing one) in S phase; at mitosis the two centrosomes separate and migrate to opposite poles, where each nucleates the microtubules of the bipolar mitotic spindle that captures and segregates chromosomes. Centrosome amplification (more than 2 per cell) causes multipolar spindles and chromosomal instability, a common feature of cancer. See section 6.

Questions 11–20: Application and Analysis

- Trace the complete path of a secretory protein from its gene to the extracellular space, naming every organelle and vesicle type it passes through.

Answer (Q11, Application). A secretory protein follows the SRP and endomembrane route. (1) The gene is transcribed in the nucleus; mRNA exits through a nuclear pore complex. (2) Translation begins on a free cytosolic ribosome; the emerging signal peptide is bound by the signal recognition particle (SRP), which pauses translation and docks the ribosome at the SRP receptor on the rough ER. (3) The polypeptide is co-translationally threaded through the Sec61 translocon into the ER lumen, the signal peptide is cleaved, and the protein folds and is N-glycosylated under chaperone (BiP, calnexin) quality control. (4) Correctly folded cargo buds in COPII-coated vesicles to the cis-Golgi (via the ERGIC). (5) It moves cis to medial to trans through the Golgi stack, where it is further glycosylated and processed. (6) At the trans-Golgi network it is sorted into a secretory vesicle. (7) The vesicle traffics to and fuses with the plasma membrane (constitutive or Ca^{2+} -triggered regulated exocytosis), releasing the protein to the extracellular space. See section 6. 12. A mutation disables the signal recognition particle (SRP). Predict the fate of a lysosomal enzyme without functional SRP.

Answer (Q12, Application). SRP normally recognizes the signal peptide of a secretory or lysosomal protein as it emerges from the ribosome, pauses translation, and delivers the ribosome-nascent-chain complex to the SRP receptor and Sec61 translocon on the rough ER. If SRP is disabled, this co-translational targeting step fails for the lysosomal enzyme. The chain is therefore not paused and not delivered to the ER; translation completes in the cytosol, so the protein is synthesized as a cytosolic polypeptide instead of entering the ER lumen. Consequently it never gets its signal peptide cleaved, is not N-glycosylated, never reaches the Golgi to acquire the mannose-6-phosphate lysosomal tag, and is not delivered to the lysosome. The mistargeted, unmodified protein typically misfolds in the cytosol and is degraded by the ubiquitin-proteasome system; lysosomal hydrolase activity is lost. See section 6. 13. Colchicine prevents microtubule polymerization. Would it disrupt: (a) chromosome segregation; (b) ER-Golgi trafficking; (c) cell migration; (d) axonal transport? Justify each.

Answer (Q13, Application). Colchicine binds free tubulin and prevents microtubule polymerization, so every microtubule-dependent process is disrupted. (a) Chromosome segregation: YES — the mitotic spindle is microtubule-based, so chromosomes cannot be captured or moved and cells arrest in metaphase. (b) ER-Golgi trafficking: YES — long-range vesicle transport between ER and Golgi runs on microtubule tracks via kinesin and

dynein; the Golgi also disperses without microtubules. (c) Cell migration: YES (partly) — directed migration needs microtubule-based polarity and trafficking even though the protrusive force is actin-driven, so persistent directional crawling is impaired. (d) Axonal transport: YES — fast axonal transport of vesicles and organelles is kinesin/dynein movement along axonal microtubules, which collapses without microtubules. See section 6. 14. Gaucher disease results from a deficiency of the lysosomal enzyme glucocerebrosidase. What accumulates, in which cells, and why does this cause splenomegaly and bone marrow infiltration?

Answer (Q14, Application). Glucocerebrosidase normally hydrolyses glucocerebroside (glucosylceramide), a sphingolipid generated mainly from the turnover of membranes of senescent blood cells. With the enzyme deficient, undigested glucocerebroside accumulates inside the lysosomes of macrophages, because macrophages phagocytose large numbers of aged erythrocytes and leukocytes and depend on lysosomal degradation to recycle their membranes. The engorged lipid-laden macrophages (Gaucher cells) accumulate in the spleen, liver, and bone marrow. Splenic infiltration by these cells causes massive splenomegaly (and hypersplenism, cytopenias); bone marrow infiltration displaces normal hematopoiesis and erodes bone, causing anemia, thrombocytopenia, and bone disease. It is a lysosomal storage disease treatable by enzyme replacement therapy targeted to lysosomes via the M6P receptor. See section 6. 15. If a cell's mitochondria were removed, which metabolic pathways would be abolished and which would remain functional? Calculate the maximum ATP yield from 1 glucose in a cell without mitochondria.

Answer (Q15, Application). Removing mitochondria abolishes every pathway housed in or on them: the pyruvate dehydrogenase reaction, the TCA cycle, fatty-acid beta-oxidation, and oxidative phosphorylation (electron transport chain plus ATP synthase). Pathways that remain functional are the cytosolic ones: glycolysis, the pentose phosphate pathway, glycogen metabolism, and lactate fermentation (needed to regenerate NAD⁺). Maximum ATP yield from one glucose without mitochondria: glycolysis yields a net 2 ATP per glucose by substrate-level phosphorylation (4 made, 2 invested = net 2 ATP) plus 2 NADH that must be reoxidised by lactate dehydrogenase to sustain glycolysis. So the answer is 2 ATP per glucose, versus about 30-32 ATP with full oxidative phosphorylation — a roughly 15-fold loss of energy efficiency, which is why mitochondria-free cells (e.g., red blood cells) depend wholly on glycolysis. See section 6. 16. Clathrin-coated vesicles mediate receptor-mediated endocytosis. Describe the sequence from receptor-ligand binding to delivery of cargo to endosomes. Name two other coat protein systems and their functions.

Answer (Q16, Application). Clathrin-mediated endocytosis sequence: (1) an extracellular ligand binds its transmembrane receptor at the plasma membrane; (2) the adaptor complex AP2 links the receptor cytoplasmic tails to clathrin triskelions, which polymerize into a lattice and curve the membrane into a coated pit; (3) the GTPase dynamin assembles at the neck and pinches off a clathrin-coated vesicle; (4) the clathrin coat is removed (uncoating by Hsc70 and auxilin) and the naked vesicle fuses with the early endosome (pH about 6.0); (5) the acidic endosome dissociates ligand from receptor — receptors recycle to the plasma membrane while cargo is sent to late endosomes and lysosomes (pH about 4.5). Two other coat systems: COPII (Sar1, Sec23/24, Sec13/31) buds vesicles anterograde from ER to cis-Golgi; COPI (coatamer, Arf1) mediates retrograde Golgi-to-ER retrieval of escaped KDEL ER-resident proteins. See section 6. 17. Motor proteins kinesin (moves to + end) and dynein (moves to – end) both use microtubule tracks. How does a cell ensure organelles are delivered to the correct destination — axon terminal vs cell body?

Answer (Q17, Application). Microtubules are polar, with minus ends anchored at the centrosome/MTOC (cell body) and plus ends toward the periphery; in an axon they are uniformly oriented plus-end-out. Directionality of delivery is set by motor identity plus cargo-specific adaptors. Kinesin-1 walks toward the plus end (anterograde, about 0.8 $\mu\text{m/s}$), carrying newly synthesized synaptic-vesicle precursors, mitochondria, and membrane proteins from the cell body to the axon terminal. Cytoplasmic dynein walks toward the minus end (retrograde, about 1.0 $\mu\text{m/s}$), returning endosomes, signaling endosomes, autophagosomes, and damaged components from the terminal to the cell body. The cell ensures correct destination by attaching the appropriate motor (and regulatory adaptors that activate one motor and inhibit the other) to each cargo, so cargo identity selects the motor and the motor selects the direction along the oriented track. See section 6. 18. The rough ER membrane is studded with ribosomes, while the smooth ER is ribosome-free. A mutation eliminates the ribosome-binding site on the ER translocon (Sec61). Predict the consequence for: (a) membrane protein insertion; (b) secretory protein signal peptide cleavage.

Answer (Q18, Application). Co-translational targeting to the rough ER requires the ribosome to dock onto the Sec61 translocon (handed off from SRP/SR) so the nascent chain is threaded into the ER as it is made. If the ribosome-binding site on Sec61 is destroyed, ribosomes cannot dock, so secretory and membrane proteins are no longer co-translationally translocated. (a) Membrane protein insertion: fails — without ribosome docking the nascent chain cannot be threaded into or laterally released into the ER membrane, so type-I/II/multipass membrane proteins are not inserted (they are mistranslated in the cytosol and degraded). (b) Secretory protein signal-peptide cleavage: fails — signal peptidase acts on the luminal side of the translocon during translocation; if the chain never enters the translocon it is never presented to signal peptidase, so the signal peptide is not cleaved. Net effect: collapse of the secretory pathway with cytosolic accumulation and proteasomal degradation of these proteins. See section 6. 19. Zellweger syndrome (peroxisome biogenesis disorder) causes progressive neurological deterioration. Identify two specific metabolic functions of peroxisomes in neurons that would be disrupted, and explain the mechanism of neural damage.

Answer (Q19, Application). Zellweger syndrome results from PEX-gene mutations that abolish functional peroxisomes, so peroxisomal metabolism collapses. Two neuron-relevant functions disrupted: (1) Very-long-chain fatty acid (VLCFA, >C22) beta-oxidation — peroxisomes are the only site

that shortens VLCFAs; without it, VLCFAs accumulate and are incorporated into and destabilise neuronal and myelin membranes. (2) Plasmalogen biosynthesis — the early steps of ether-phospholipid (plasmalogen) synthesis occur in peroxisomes, and plasmalogens are essential structural lipids of myelin; their deficiency prevents normal myelination. Mechanism of neural damage: failure to make myelin plus toxic VLCFA accumulation produces dysmyelination and demyelination, neuronal migration defects, and oxidative or membrane damage, manifesting as severe hypotonia, seizures, and progressive neurological deterioration. See section 6. 20. A researcher fuses a nuclear localization signal (NLS) to a cytoplasmic protein (GFP). Describe the molecular events leading to the protein's nuclear import, including the roles of importin- α , importin- β , RanGTP, and the nuclear pore complex.

Answer (Q20, Application). GFP-NLS is imported by the classical importin pathway powered by the Ran gradient. (1) In the cytoplasm, importin- α binds the basic NLS (the adaptor) and importin- β binds importin- α and provides the affinity for the nuclear pore complex. (2) Importin- β interacts with the FG-repeat nucleoporins lining the NPC central channel, allowing the cargo complex to translocate through the roughly 9 nm gated channel. (3) Inside the nucleus, RanGTP (kept high in the nucleus by chromatin-bound RanGEF/RCC1) binds importin- β , causing a conformational change that releases importin- α and the GFP-NLS cargo into the nucleoplasm. (4) The importins are recycled back to the cytoplasm bound to RanGTP; cytoplasmic RanGAP then hydrolyses RanGTP to RanGDP, releasing the importins for another round. The roughly 10^4 :1 nuclear:cytoplasmic RanGTP ratio makes import vectorial; it is GTP-hydrolysis-powered, not driven by a translocation ATPase. See section 6.

Questions 21–30: Synthesis and Evaluation

21. Primary cilia are now recognized as signaling organelles for Hedgehog, Wnt, and PDGFR pathways. Evaluate why concentrating receptors in a small ciliary compartment (0.1% of total cell surface) enhances signaling sensitivity compared to distributing receptors over the entire plasma membrane.

Answer (Q21, Synthesis). The primary cilium is a 9+0 microtubule-based antenna making up only about 0.1% of total cell surface, into which specific receptors (Smoothed/Patched for Hedgehog, Frizzled for Wnt, PDGFR- α) are actively concentrated by intraflagellar transport. Concentrating receptors and their downstream machinery in this tiny compartment enhances sensitivity for several causal reasons: (1) the small volume means even a few activated receptors and second messengers reach a high local concentration, raising the signal-to-noise ratio relative to the same molecules diluted over the whole $1,300\text{ }\mu\text{m}^2$ plasma membrane; (2) co-localizing receptor, transducer (e.g., GLI processing machinery for Hedgehog), and effectors in one diffusion-limited space speeds productive collisions and reduces off-target dilution; (3) the ciliary membrane has a distinct lipid and protein composition and a diffusion barrier at the base (the transition zone) that retains active components and excludes inhibitors. Boundary condition: this gain depends on regulated trafficking into and out of the cilium; if intraflagellar transport or the transition-zone gate fails (ciliopathies), the concentrating advantage is lost and signaling becomes both insensitive and dysregulated. See section 6. 22. Design an experiment to determine whether a newly discovered organelle in a marine protist is related to the peroxisome or the lysosome, using: (a) proteomic analysis; (b) membrane lipid analysis; (c) fluorescent marker trafficking; (d) inhibitor sensitivity.

Answer (Q22, Synthesis). Hypothesis: the unknown organelle is peroxisome-related (H1) versus lysosome-related (H2). The discriminating expectations: peroxisomes import folded matrix proteins post-translationally via PTS1/PTS2 (PEX5/PEX7), contain catalase and beta-oxidation oxidases, have a near-neutral lumen, and arise by growth/division or from ER; lysosomes contain acid hydrolases, maintain pH about 4.5 via a V-ATPase, receive cargo by M6P-receptor sorting from the trans-Golgi, and are degradative. Tests, each with the matched control: (a) Proteomics — isolate the organelle by density-gradient fractionation and identify proteins; PEX proteins, catalase, and acyl-CoA oxidase support H1, whereas cathepsins and other acid hydrolases support H2 (control: co-fractionate with known peroxisome and lysosome markers). (b) Membrane lipid analysis — assay for plasmalogen-synthesis intermediates (peroxisomal) versus lysosomal-membrane-specific lipids (control: known organelle lipidomes). (c) Fluorescent marker trafficking — express GFP-SKL (PTS1) versus an M6P-tagged hydrolase and see which is delivered (control: wild-type markers in normal cells). (d) Inhibitor sensitivity — treat with bafilomycin A1 (V-ATPase): loss of luminal acidification and hydrolase activity supports H2; insensitivity supports H1. Decision rule: assign to the lineage matching the majority of independent assays; a falsifying result for H1 is an acidic, M6P-targeted, bafilomycin-sensitive compartment lacking PEX import. Replicate each assay (n at least 3) with fixed seeds for any image quantification. See section 6. 23. Autophagy (macro, micro, chaperone-mediated) degrades cytosolic material. Evaluate the selective vs non-selective aspects of each type, and propose why cells might preferentially use CMA (chaperone-mediated autophagy) rather than macroautophagy for long-lived soluble proteins.

Answer (Q23, Synthesis). All three deliver cytosolic material to the lysosome but differ in selectivity. Macroautophagy: a double-membrane phagophore engulfs bulk cytoplasm or, when tagged by receptors (p62/SQSTM1, NBR1) reading ubiquitin, specific cargo (mitophagy, ER-phagy); it is non-selective by default but can be made selective by receptors. Microautophagy: the lysosomal/vacuolar membrane directly invaginates and engulfs small portions of cytosol; largely non-selective, good for steady-state turnover. Chaperone-mediated autophagy (CMA): highly selective — Hsc70 recognizes a KFERQ-like pentapeptide motif in soluble substrate proteins and delivers them one by one across the lysosomal membrane via the LAMP-2A translocation receptor; no vesicle is formed. Why a cell would prefer CMA for long-lived soluble proteins: CMA targets individual proteins by sequence motif without sequestering and destroying neighboring organelles or bulk cytosol, so it allows precise removal of damaged

or regulatory soluble proteins (and selective amino-acid mobilization in prolonged starvation) while sparing functional structures — a precision tool versus the bulk demolition of macroautophagy. See section 6. 24. Reticulophagy (selective ER autophagy) is triggered by ER stress. Trace the molecular pathway from misfolded protein accumulation → IRE1 α /PERK/ATF6 activation → reticulophagy receptor induction → ER-phagy. What would happen if reticulophagy were completely blocked?

Answer (Q24, Synthesis). Pathway: accumulation of misfolded proteins in the ER lumen titrates the chaperone BiP away from the three stress sensors, activating them. IRE1- α dimerises and its endoribonuclease splices XBP1 mRNA to XBP1s, a transcription factor driving ER-expansion, ERAD, and lipid-synthesis genes; PERK phosphorylates eIF2- α to attenuate global translation (reducing new client load) while selectively translating ATF4; ATF6 traffics to the Golgi, is cleaved by S1P/S2P, and its fragment transcribes ER chaperones (BiP, GRP94). These outputs induce reticulophagy receptors (e.g., FAM134B, RTN3, CCPG1, SEC62) that bind LC3 on the phagophore, so excess and damaged ER is selectively engulfed and delivered to the lysosome (ER-phagy), restoring ER size and quality. If reticulophagy were completely blocked: damaged and surplus ER cannot be cleared, so misfolded-protein and expanded-ER load persists, the UPR stays chronically activated, and the PERK-ATF4-CHOP arm (plus IRE1 RIDD) biases the cell toward apoptosis; secretory cells (e.g., pancreatic beta-cells) are especially vulnerable, paralleling ER-stress-driven beta-cell loss in type 2 diabetes. See section 6. 25. The Golgi apparatus disperses into ministacks during mitosis and reassembles in each daughter cell after division. Evaluate the mechanism of Golgi fragmentation (role of mitotic kinases) and reassembly (role of p97 ATPase), and explain why Golgi inheritance must be coordinated with chromosome segregation.

Answer (Q25, Synthesis). Golgi fragmentation: at mitotic entry, CDK1-cyclin B and Polo-like kinase phosphorylate Golgi structural proteins (GRASP65/55, golgins), severing the cisternal stacking and tethering links; ongoing membrane fission (and inhibited fusion) converts the ribbon into dispersed tubulovesicular ministacks/clusters that partition stochastically with the cytoplasm to both daughters. Reassembly: after anaphase, mitotic kinases are inactivated and their sites are dephosphorylated; the AAA+ ATPase p97/VCP (with cofactors p47 and the SNARE machinery) uses ATP hydrolysis to drive homotypic fusion of Golgi membranes, and GRASP/golgin-mediated tethering rebuilds the stacked ribbon in each daughter cell. Why coordination with chromosome segregation matters: the Golgi has no template and cannot be synthesized de novo quickly, so each daughter must inherit roughly half of it; fragmentation into many small units makes inheritance statistically even, and tying disassembly/reassembly to the same CDK1-driven mitotic clock that controls chromosome segregation ensures the Golgi is partitioned in step with the genome rather than being lost or unequally divided. See section 6. 26. Compare endocytosis mechanisms: clathrin-mediated endocytosis, caveolae-mediated endocytosis, macropinocytosis, and phagocytosis. For each: what cargo is internalised, what signaling events initiate it, and how is cargo processed after internalization?

Answer (Q26, Synthesis). The shared principle is internalization by membrane invagination and vesicle formation; the mechanism-defining differences (coat, cytoskeleton, trigger, cargo, fate) change the interpretation. Clathrin-mediated endocytosis: small (about 100 nm) clathrin/AP2-coated vesicles internalise specific receptor-ligand pairs (LDL, transferrin, EGF) after ligand binding clusters receptors; dynamin scission; cargo to early then late endosome/lysosome, receptors recycled. Caveolae-mediated: about 50-80 nm caveolin/cavin flask-shaped invaginations of cholesterol/sphingolipid rafts; internalise certain toxins (cholera toxin), some viruses (SV40), and GPI-anchored proteins; signaling-platform regulated; cargo to caveosomes/endosomes, often bypassing lysosomal degradation. Macropinocytosis: large (0.5-5 μ m) actin-driven ruffle-derived vacuoles internalising bulk extracellular fluid and solutes; triggered by growth-factor (PI3K/Rac) signaling; cargo to macropinosomes that mature into lysosomes. Phagocytosis: very large (>1 μ m) actin-dependent engulfment by professional phagocytes; triggered by opsonin receptors (Fc, complement) recognizing microbes/apoptotic cells; cargo enclosed in a phagosome that fuses with lysosomes (phagolysosome) for destruction. The decisive contrast is coat-and-cytoskeleton: clathrin/dynamin and small cargo versus caveolin-raft versus large actin-driven uptake, which sets cargo size and post-internalization fate. See section 6. 27. COPI-coated vesicles mediate retrograde transport from Golgi back to ER (retrieval of escaped ER-resident proteins). How do KDEL-bearing ER-resident proteins get retrieved? What is the KDEL receptor, and what happens to its affinity for KDEL at Golgi pH vs ER pH?

Answer (Q27, Synthesis). ER-resident luminal proteins (BiP, PDI, calreticulin) carry a C-terminal KDEL tetrapeptide. They escape the ER by bulk flow into COPII vesicles and reach the cis/medial Golgi. There the KDEL receptor (KDEL R , a multipass Golgi membrane protein) binds them and is packaged into COPI-coated vesicles for retrograde transport back to the ER, where the proteins are released. The pH-dependent affinity switch makes this a cycle: the slightly acidic Golgi lumen (about pH 6.2-6.7) protonates key histidine residues in KDEL R , giving it high affinity so it captures KDEL ligands in the Golgi; on return to the more neutral ER lumen (about pH 7.2) those residues deprotonate, lowering KDEL R affinity so it releases the cargo back into the ER and the empty receptor recycles forward again. Thus KDEL R has high KDEL affinity at Golgi pH and low affinity at ER pH, producing vectorial retrieval that keeps ER-resident enzymes from being secreted. See section 6. 28. The nuclear lamina (lamin intermediate filaments) underlies the inner nuclear membrane. Mutations in lamin A cause laminopathies including Hutchinson-Gilford progeria syndrome (HGPS) — a premature aging disease. Evaluate how nuclear structural failure leads to an accelerated-aging phenotype at the cellular level.

Answer (Q28, Synthesis). The nuclear lamina is a meshwork of lamin A/C and B intermediate filaments underlying the inner nuclear membrane that gives the nucleus mechanical rigidity, anchors heterochromatin, and organizes the genome. In HGPS a point mutation activates a cryptic splice site in LMNA, producing progerin, a permanently farnesylated lamin A lacking 50 residues that cannot be processed and incorporates into the lamina abnormally. Causal chain to accelerated aging at the cellular level: progerin stiffens and distorts the nuclear lamina, producing misshapen, mechanically fragile nuclei; this disrupts lamina-associated heterochromatin and gene-expression programs, impairs DNA-damage repair (persistent double-strand breaks), and increases sensitivity to mechanical stress in load-bearing tissues (vasculature). The accumulating genomic damage and chromatin disorganization drive premature replicative arrest and cellular senescence (and apoptosis) in vascular smooth muscle and other cells, manifesting organismally as accelerated atherosclerosis and the progeroid phenotype. The interpretation generalizes: a structural nuclear protein failure becomes a genome-maintenance and senescence problem. See section 6. 29. Cells in developing lungs must convert from secreting surfactant (lipid-rich, packaged in lamellar bodies — lysosome-related organelles) to absorbing alveolar fluid at birth. Evaluate the signaling mechanisms controlling this switch and what organelle remodeling is required.

Answer (Q29, Synthesis). Before birth, alveolar type II cells are secretory: they synthesize surfactant lipids and proteins, package them into lamellar bodies (lysosome-related organelles), and release them by regulated exocytosis to line the airspaces. At birth the lung must rapidly switch from secreting fluid and surfactant to absorbing the alveolar liquid so gas exchange can begin. Signaling control: the perinatal surge in glucocorticoids and thyroid hormone (and the labor-associated catecholamine/beta-adrenergic surge, plus rising oxygen tension) reprogrammes the epithelium — beta-adrenergic and steroid signaling switch on apical epithelial Na⁺ channels (ENaC) and basolateral Na⁺/K⁺-ATPase, so the cells now drive vectorial Na⁺ (and osmotically obligated water) absorption out of the airspace. Organelle remodeling required: the secretory machinery is down-regulated (fewer lamellar bodies and reduced regulated-exocytosis apparatus) while the cell up-regulates ion-transport membrane proteins and the supporting endomembrane/trafficking and mitochondrial (ATP for the Na⁺ pump) capacity, converting a secretion-specialized cell into an absorption-specialized one. See section 6. 30. Evaluate the concept of “organelle crosstalk”: mitochondria-ER contact sites (MAM — mitochondria-associated membranes) facilitate Ca²⁺ and lipid exchange. How does disruption of MAM contact alter: (a) mitochondrial Ca²⁺ buffering; (b) phosphatidylserine transfer; (c) mitochondrial morphology? Cite evidence from neurodegenerative disease models.

Answer (Q30, Synthesis). Organelle crosstalk means organelles communicate through membrane-contact sites rather than working in isolation. Mitochondria-ER contact sites (MAMs) are zones where the ER and outer mitochondrial membrane are tethered about 10-30 nm apart, enabling local Ca²⁺ and lipid exchange. Empirical predictions of disrupting MAM tethering: (a) Mitochondrial Ca²⁺ buffering — MAMs deliver IP₃-receptor-released ER Ca²⁺ directly to the mitochondrial VDAC/MCU uniporter; loss of contact lowers mitochondrial Ca²⁺ uptake, blunting Ca²⁺-stimulated TCA dehydrogenases (less ATP) yet, paradoxically, can also dysregulate apoptotic Ca²⁺ signaling. (b) Phosphatidylserine transfer — PS made in the ER is handed to mitochondria at MAMs for conversion to phosphatidylethanolamine; disruption impairs mitochondrial PE supply and membrane composition. (c) Mitochondrial morphology — MAMs mark DRP1-mediated fission sites (the ER pre-constricts mitochondria); losing contacts reduces proper fission, shifting the network toward aberrant elongation or fragmentation and impairing quality control. Disease evidence (what would strengthen or weaken the causal claim): MAM proteins are perturbed in neurodegeneration — mutant presenilins/APP processing enrich at MAMs in Alzheimer disease, alpha-synuclein and PINK1/Parkin link MAM dysfunction to Parkinson disease, and VAPB mutations (ALS) disrupt ER-mitochondria tethering. These are largely correlative model-system findings; the conclusion that MAM disruption is causal would be strengthened by showing that restoring physiological tethering rescues the cellular phenotype and weakened if the defects persisted independent of contact-site status. See section 6.

Questions — Membrane Structure and Transport

Instructor Use and Coverage Notes

- Coverage target: Calculate or predict ion movement and explain which force dominates.
- Model/data emphasis: Nernst, Goldman, osmotic, and facilitated-transport calculations.
- Assessment alignment: Visual Representations, Questions and Methods, Argumentation.
- Misconception probe: Equilibrium does not mean equal concentration; charge and permeability matter.
- Transfer product: Transfer gradient logic to neurons, kidneys, roots, and mitochondrial membranes.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 7 of the textbook — review that chapter before attempting the exercises below.

1. Describe the fluid-mosaic model of the plasma membrane (Singer-Nicolson, 1972). What are the two major components?

Answer (Q1, Recall). The fluid mosaic model (Singer & Nicolson, *Science* 1972) describes biological membranes as a two-dimensional fluid of phospholipids in which proteins are embedded like mosaic tiles, both components free to diffuse laterally. Two major components: (1) phospholipid bilayer — amphipathic phosphoglycerolipids (phosphatidylcholine, phosphatidylethanolamine, sphingomyelin) spontaneously organizing into a ≈ 4–5 nm thick bilayer with hydrophobic tails inward and polar heads at the aqueous interfaces, providing the fluid matrix; and (2) membrane proteins (integral/transmembrane such as GLUT1, ion channels, Na⁺/K⁺-ATPase; peripheral proteins docked via electrostatics), which account for about 50% of membrane mass and carry out transport, signaling, and recognition. A lipid molecule diffuses laterally at about 10^{−8} cm²/s (about μm-scale in seconds) but “flip-flops” between leaflets extremely rarely (hours without flippases) — asymmetry is *biological*, not physical. Canonical example: red blood cell membrane, where Band 3 (anion exchanger) and spectrin cytoskeleton give the lipid mosaic its characteristic deformability. See section 7. 2. What is a phospholipid bilayer? Explain why it forms spontaneously in an aqueous environment.

Answer (Q2, Recall). A phospholipid bilayer is a two-layer sheet of amphipathic phospholipids with hydrophobic fatty-acid tails facing inward and polar phosphate head groups facing the aqueous solutions on both sides, about 4-5 nm thick. It forms spontaneously because the hydrophobic effect: nonpolar tails minimize unfavorable contact with water by self-associating, while polar heads remain hydrated, so the bilayer is the lowest-free-energy arrangement and even seals into closed vesicles. See section 7. 3. Define selective permeability. Which types of molecules cross membranes freely and which require assistance?

Answer (Q3, Recall). Selective permeability means the membrane allows some substances to cross readily while restricting others, controlled by the lipid bilayer and specific transport proteins. Small nonpolar molecules (O₂, CO₂, N₂) and small polar uncharged molecules (water, urea, glycerol) cross freely by simple diffusion; large polar molecules (glucose, amino acids) and all ions (Na⁺, K⁺, Ca²⁺, Cl[−]) cannot cross the hydrophobic core and require channel or carrier proteins. See section 7. 4. Distinguish simple diffusion, facilitated diffusion, and active transport.

Answer (Q4, Recall). All three move solutes across membranes but differ in energy and protein use. Simple diffusion: solute moves down its electrochemical gradient directly through the lipid bilayer, no protein, no energy. Facilitated diffusion: still down-gradient and energy-free, but through a channel or carrier protein (saturable). Active transport: moves solute against its electrochemical gradient and therefore requires energy (ATP hydrolysis or a coupled ion gradient). The decisive difference is the direction relative to the gradient and whether energy is consumed. See section 7. 5. What is the sodium-potassium ATPase (Na⁺/K⁺-ATPase)? How many ions does it move per ATP?

Answer (Q5, Recall). The Na⁺/K⁺-ATPase is a primary active transport pump (P-type ATPase) in the plasma membrane that uses ATP hydrolysis to move Na⁺ and K⁺ against their gradients. Per ATP hydrolysed it exports 3 Na⁺ and imports 2 K⁺, a net movement of +1 charge outward, making it electrogenic. It maintains high intracellular K⁺ (about 140 mM) and low Na⁺ (about 12 mM) and consumes about 25% of body ATP (up to 70% in neurons). See section 7. 6. Define osmosis. In which direction does water move — toward high or low solute concentration?

Answer (Q6, Recall). Osmosis is the net diffusion of water across a semi-permeable membrane in response to a difference in solute concentration. Water moves toward the side of higher solute concentration (lower water concentration/activity), because added solute lowers water activity, so water flows from the dilute (hypotonic) side toward the concentrated (hypertonic) side until water chemical potential is equalised. See section 7. 7. What is a membrane potential? What is the typical resting membrane potential of a mammalian cell?

Answer (Q7, Recall). Membrane potential is the voltage difference across the plasma membrane, arising because ions are unequally distributed and the membrane is selectively permeable to them (largely K⁺ at rest, read out by the Goldman equation). A typical mammalian resting membrane potential is about −70 mV (inside negative), lying close to E_K (about −89 mV) because the resting membrane is about 25× more permeable to K⁺ than Na⁺. See section 7. 8. Distinguish primary from secondary active transport. Give one example of each.

Answer (Q8, Recall). Both move solutes against their gradient (active), but differ in energy source. Primary active transport hydrolyses ATP directly (e.g., the Na^+/K^+ -ATPase moving 3 Na^+ out / 2 K^+ in per ATP; also SERCA, H^+/K^+ -ATPase). Secondary active transport uses the electrochemical gradient of one ion (usually the Na^+ gradient set up by the primary pump) to drive uphill movement of another solute (e.g., SGLT1 symport: 2 Na^+ + glucose into intestinal cells). The decisive difference is direct ATP use versus exploiting a previously stored ion gradient. See section 7. 9. What is endocytosis? Distinguish phagocytosis, pinocytosis, and receptor-mediated endocytosis.

Answer (Q9, Recall). Endocytosis is the uptake of extracellular material by invagination of the plasma membrane to form an internal vesicle. Phagocytosis: actin-driven pseudopod engulfment of large particles ($>0.5\ \mu\text{m}$ — bacteria, debris) by professional phagocytes. Pinocytosis (here macropinocytosis): non-specific bulk uptake of extracellular fluid in large ($0.2\text{--}5\ \mu\text{m}$) actin-ruffle vesicles. Receptor-mediated (clathrin-mediated) endocytosis: specific cargo receptors cluster in AP2/clathrin-coated pits and are internalised in small (about $60\text{--}120\ \text{nm}$) coated vesicles (e.g., LDL receptor). See section 7. 10. What is the role of cholesterol in membrane structure? How does it affect fluidity at high and low temperatures?

Answer (Q10, Recall). Cholesterol intercalates between phospholipids with its rigid steroid ring near the head groups and acts as a fluidity buffer. At high temperature it restrains phospholipid motion and reduces fluidity (condensing effect); at low temperature it disrupts tight crystalline packing and prevents the membrane from becoming a rigid gel (fluidising effect). The net result is that membrane fluidity is stabilized across a physiological temperature range. See section 7.

Questions 11–20: Application and Analysis

11. A cell is placed in a hypertonic solution. Describe, at the molecular level, what happens to: (a) the direction of water movement; (b) cell volume; (c) the cytoskeleton if shrinkage is severe; (d) membrane potential due to increased ion concentration.

Answer (Q11, Application). (a) The external solution is hypertonic (higher solute, lower water activity), so water moves out of the cell down its chemical-potential gradient. (b) Cell volume decreases (the cell shrinks/crenates). (c) Severe shrinkage causes the cytoskeleton (actin cortex/spectrin) to crumple and buckle as membrane area exceeds the reduced volume. (d) As water leaves, intracellular ion concentrations rise; this alters the Nernst potentials in the Goldman equation, but the membrane potential is buffered by the dominant K^+ permeability and active pumping rather than tracking concentration linearly. See section 7. 12. The Na^+/K^+ -ATPase pumps 3 Na^+ out and 2 K^+ in per ATP hydrolysed. Explain why this creates an electrogenic current. Calculate the charge moved per pump cycle and predict how ouabain (a pump inhibitor) would affect membrane potential.

Answer (Q12, Application). Per ATP: +3 Na^+ extruded – 2 K^+ imported = net +1 charge out, so each pump cycle moves +1 elementary charge ($+1.60 \times 10^{-19}\ \text{C}$) outward — the pump is electrogenic. Current: typical neuron density $\approx 1000\ \text{pumps}/\mu\text{m}^2$, cycling at about $100\ \text{s}^{-1} \rightarrow$ surface current density $\approx 16\ \mu\text{A}/\text{cm}^2$. This direct contribution accounts for roughly -5 to $-10\ \text{mV}$ of the resting potential ($\approx 10\text{--}15\%$ of the total); the remaining $-60\ \text{mV}$ comes from the K^+ gradient read out by the Goldman–Hodgkin–Katz equation. Ouabain prediction: inhibiting Na^+/K^+ -ATPase abolishes the electrogenic component — immediate depolarization of about $5\text{--}10\ \text{mV}$. Over seconds-to-minutes, intracellular $[\text{Na}^+]$ rises and $[\text{K}^+]$ falls, collapsing the Nernst gradients that set the resting potential \rightarrow further, profound depolarization and failure to repolarise after an action potential. Secondary consequence: the Na^+ -gradient-driven $\text{Na}^+/\text{Ca}^{2+}$ exchanger reverses, intracellular Ca^{2+} rises, boosting cardiac contractility — the basis of ouabain/digoxin’s positive inotropic effect on the failing heart. See section 7. 13. Glucose enters intestinal epithelial cells via SGLT1 (Na^+ -glucose co-transporter) on the apical membrane and exits via GLUT2 (passive facilitated diffusion) on the basolateral membrane. Explain: (a) which transport is primary active and which is secondary active; (b) why this arrangement allows glucose to be absorbed against its concentration gradient.

Answer (Q13, Application). (a) Neither transporter hydrolyses ATP directly, so neither is primary active here; SGLT1 is secondary active transport (it uses the inward Na^+ electrochemical gradient — itself maintained by the primary Na^+/K^+ -ATPase on the basolateral membrane — to co-transport glucose), while GLUT2 is passive facilitated diffusion. (b) SGLT1 couples glucose uptake to favorable Na^+ entry, so glucose is dragged into the cell even when intracellular glucose already exceeds luminal glucose (uphill); accumulated glucose then exits down its gradient through GLUT2 into blood. The Na^+/K^+ -ATPase keeps intracellular Na^+ low, sustaining the gradient that powers net transcellular glucose absorption against its own gradient. See section 7. 14. CFTR is a Cl^- channel mutated in cystic fibrosis. The ΔF508 deletion causes CFTR misfolding and ER retention. Explain how this affects: (a) epithelial Cl^- secretion; (b) mucus viscosity; (c) bacterial colonization of airways.

Answer (Q14, Application). ΔF508 CFTR misfolds and is retained/degraded in the ER, so functional CFTR Cl^- channels never reach the apical membrane. (a) Epithelial Cl^- secretion is lost, so accompanying water secretion onto the airway surface falls. (b) The airway surface liquid becomes dehydrated, so mucus becomes thick and viscous and cannot be cleared by cilia. (c) Stagnant viscous mucus impairs mucociliary clearance, allowing chronic bacterial colonization (e.g., *Pseudomonas aeruginosa*) and recurrent infection. See section 7. 15. A cell biologist measures the fluorescence recovery after photobleaching (FRAP) of a fluorescently labeled membrane protein. Recovery takes 30 seconds in normal cells but 5 minutes in cells with disrupted actin cortex. Interpret this result using the fluid-mosaic model and the concept of membrane protein diffusion constraints.

Answer (Q15, Application). FRAP measures lateral mobility of membrane proteins, a core prediction of the fluid mosaic model. Normal cells recover in 30 s because labeled proteins diffuse laterally in the fluid bilayer into the bleached spot. With a disrupted actin cortex recovery should reflect free diffusion, but here it slows to 5 minutes — indicating the actin cortex normally is not what slows diffusion; instead its disruption alters the picket-fence corrals or traps proteins, showing that membrane protein diffusion is not free but constrained by cytoskeletal fences (Kusumi corrals, about 40-300 nm). The result demonstrates the membrane is more mosaic and compartmentalised than the original 1972 ‘free diffusion’ picture. See section 7. 16. Explain how the membrane potential arises from differences in ion permeability (Goldman equation). If a cell becomes 10× more permeable to Na⁺ (e.g., during an action potential), predict the direction of change in membrane potential and apply the Nernst equation to estimate the equilibrium potential for Na⁺.

Answer (Q16, Application). The Goldman equation makes V_m a permeability-weighted log average of the ion Nernst potentials, so the most permeable ion dominates; at rest P_K is high and V_m sits near E_K (about −70 mV). If the cell becomes 10× more permeable to Na⁺, the Na⁺ term grows and V_m shifts toward E_{Na}, i.e., the membrane depolarizes (toward positive). Estimate E_{Na} from the Nernst equation at 37 °C with [Na⁺]_{out} = 145 mM, [Na⁺]_{in} = 12 mM, z = +1: $E_{Na} = 61.5 \text{ mV} \cdot \log_{10}(145/12) = 61.5 \cdot \log_{10}(12.08) = 61.5 \cdot 1.082 \text{ approx} + 67 \text{ mV}$. So increased Na⁺ permeability drives V_m up toward about +60 mV (the basis of the action potential upstroke). See section 7. 17. Vesicle fusion requires SNARE proteins. Explain the zipper model of SNARE complex assembly and how this drives membrane fusion. Why does botulinum toxin (which cleaves SNARE proteins) block neurotransmitter release?

Answer (Q17, Application). SNARE complexes form a four-helix bundle from a v-SNARE (VAMP/synaptobrevin) on the vesicle and t-SNAREs (syntaxin + SNAP-25) on the target membrane. In the zipper model the bundle zippers progressively from the membrane-distal N-terminus toward the membrane-proximal C-terminus; this releases about 35 kBT per complex, more than the about 25 kBT barrier to fusion, pulling the two membranes together until their bilayers merge. Botulinum toxin is a zinc protease that cleaves VAMP, SNAP-25, or syntaxin, so the SNARE bundle cannot assemble or zipper; without a functional SNARE complex synaptic vesicles cannot fuse, blocking acetylcholine release and causing flaccid paralysis. See section 7. 18. Aquaporin-1 (AQP1) is absent in red blood cells from certain individuals, yet these individuals are healthy. AQP1 knockout mice have impaired urinary concentrating ability. Explain this discrepancy — what does it reveal about the relative importance of aquaporin vs lipid bilayer water permeability in different tissues?

Answer (Q18, Application). Both reflect AQP1’s role in water transport, but the importance of aquaporins versus the lipid bilayer differs by tissue. Red blood cells without AQP1 stay healthy because the bilayer itself provides enough baseline water permeability for the modest osmotic challenges erythrocytes normally face. The kidney, however, must move very large water volumes rapidly to concentrate urine; here bilayer permeability is far too slow, so AQP1 (proximal tubule/descending limb) is essential and its loss impairs urinary concentrating ability. The discrepancy shows aquaporins are critical only where fast, high-throughput water flux is physiologically required, while elsewhere lipid bilayer permeability suffices. See section 7. 19. LDL receptor-mediated endocytosis concentrates LDL receptors in clathrin-coated pits. FH (familial hypercholesterolaemia) patients lack functional LDL receptors. Explain: (a) why plasma LDL rises dramatically; (b) why heterozygous FH is less severe than homozygous; (c) why statins partially compensate for LDL receptor deficiency.

Answer (Q19, Application). (a) LDL is normally cleared when LDL receptors concentrate in clathrin-coated pits and internalise LDL by receptor-mediated endocytosis; without functional receptors LDL is not removed from plasma, so circulating LDL cholesterol rises dramatically. (b) Heterozygous FH patients have one working LDL-receptor allele, so roughly half-normal receptor activity gives intermediate LDL elevation, whereas homozygotes have essentially no functional receptors and far more severe hypercholesterolaemia/early atherosclerosis. (c) Statins inhibit HMG-CoA reductase, lowering intracellular cholesterol; cells respond by upregulating any residual LDL receptors, so statins partially compensate only when some functional receptor remains (heterozygotes respond; receptor-negative homozygotes respond poorly). See section 7. 20. Membrane asymmetry: phosphatidylserine (PS) is normally on the inner leaflet but is exposed on the outer leaflet of apoptotic cells. Explain: (a) the enzyme (flippase) that normally maintains PS on the inner leaflet; (b) the enzyme (scramblase) that destroys asymmetry during apoptosis; (c) the physiological consequence of outer-leaflet PS exposure (phagocyte recognition).

Answer (Q20, Application). (a) Flippases (ATP-dependent P4-ATPases) normally translocate phosphatidylserine (and PE) from the outer to the inner leaflet, keeping PS confined to the cytoplasmic face. (b) During apoptosis, Ca²⁺-activated scramblases (TMEM16F) bidirectionally and non-selectively randomize lipids across the bilayer (and flippases are inactivated), so PS moves to the outer leaflet. (c) Externalised PS is an ‘eat me’ signal recognized by phagocyte receptors (TIM-4, BAI-1, Stabilin-2), so the apoptotic cell is engulfed and cleared without releasing inflammatory contents. See section 7.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the thermodynamic basis of lipid raft formation. What causes certain lipids (sphingomyelin, cholesterol, saturated phospholipids) to phase-separate into liquid-ordered domains? Evaluate the evidence that lipid rafts are real functional domains vs artifacts of cold detergent extraction.

Answer (Q21, Synthesis). Liquid-ordered raft domains form because cholesterol packs tightly against the long, saturated acyl chains of sphingomyelin/saturated phospholipids, maximizing favorable van der Waals contacts and lowering free energy, so these lipids preferentially segregate from the disordered, unsaturated bulk bilayer — a lipid-driven phase separation. The evidence that rafts are real functional domains rather than cold-detergent artifacts is the key judgement: detergent-resistant membrane fractions alone are weak evidence because cold detergent can itself induce domains, but live-cell single-molecule and STED super-resolution imaging (Eggeling et al. 2009) shows transient nanoscale (about 10-20 nm, about 10-20 ms) confinement of sphingolipids/GPI-anchored proteins, supporting a dynamic raft model. What would change the conclusion: if super-resolution/live-cell methods showed no preferential confinement and domains appeared only after detergent extraction, rafts would be artefactual. See section 7. 22. The membrane potential (typically -70 mV, inside negative) represents stored electrochemical energy. Calculate the energy available per mole of Na^+ flowing inward across a neuron membrane using $\Delta G = zF\Delta\Psi + RT \ln([\text{Na}^+]_{\text{in}}/[\text{Na}^+]_{\text{out}})$. How does this compare to the energy of ATP hydrolysis (about -57 kJ/mol at physiological concentrations)?

Answer (Q22, Synthesis). Model: electrochemical free energy for an ion crossing the membrane, $\Delta G = zF\Delta\Psi + RT \ln([\text{Na}^+]_{\text{in}}/[\text{Na}^+]_{\text{out}})$. Substitute for Na^+ entering a neuron ($z = +1$; $\Delta\Psi = -0.070$ V; $[\text{Na}^+]_{\text{in}} = 12$ mM, $[\text{Na}^+]_{\text{out}} = 145$ mM; $F = 96\,485$ C/mol; $R = 8.314$ J/mol·K; $T = 310$ K): electrical term = $(1)(96485)(-0.070) = -6754$ J/mol *approx* -6.8 kJ/mol; chemical term = $(8.314)(310) \ln(12/145) = 2577 \cdot \ln(0.0828) = 2577 \cdot (-2.49) = -6418$ J/mol *approx* -6.4 kJ/mol. Total ΔG *approx* $-6.8 + (-6.4) = -13.2$ kJ/mol (energy released as Na^+ flows in). Compared with ATP hydrolysis (about -57 kJ/mol at cellular concentrations), one inward Na^+ releases only about 23% as much energy, so the cell needs to couple several Na^+ entries (secondary active transport) to do work equivalent to one ATP, and about 4 Na^+ worth of gradient is recharged per ATP by the Na^+/K^+ -ATPase — consistent with the pump's 3 Na^+/ATP stoichiometry plus voltage cost. See section 7. 23. Ionophores are small molecules that carry specific ions across lipid bilayers. Valinomycin is a K^+ -selective ionophore; gramicidin is a non-selective cation channel. Compare their effects on: (a) membrane potential; (b) mitochondrial function; (c) cell viability at therapeutic vs toxic concentrations. How are they used experimentally as tools?

Answer (Q23, Synthesis). Valinomycin selectively shuttles K^+ , gramicidin forms a non-selective monovalent-cation channel. (a) Membrane potential: valinomycin clamps V_m toward E_K (can hyperpolarise or, by collapsing the K^+ gradient, depolarize depending on gradients); gramicidin lets Na^+ and K^+ flow freely and collapses V_m toward about 0. (b) Mitochondrial function: both dissipate the inner-membrane electrochemical gradient — valinomycin collapses the membrane potential component (K^+ uniport), gramicidin collapses both, so the proton-motive force needed for ATP synthase is lost and oxidative phosphorylation uncouples. (c) Cell viability: at low/therapeutic doses gramicidin is a useful topical antibiotic (kills bacteria by ion leak) while host cells tolerate brief exposure; at higher concentrations both are cytotoxic because gradient collapse halts ATP synthesis. Experimentally they are used as tools to clamp membrane potential, set defined K^+ diffusion potentials, and deliberately uncouple mitochondria. See section 7. 24. Membrane curvature is actively generated during endocytosis, vesicle budding, and tubule formation. Evaluate the mechanisms: (a) BAR domain protein scaffolding; (b) asymmetric lipid composition; (c) protein insertion into the cytoplasmic leaflet. Which mechanism is most critical for clathrin-mediated endocytosis at the cell's flat plasma membrane?

Answer (Q24, Synthesis). (a) BAR-domain proteins are banana-shaped dimers whose curved concave face binds the membrane and imposes its curvature as a rigid scaffold (and tubulates membranes). (b) Asymmetric lipid composition bends the bilayer when one leaflet has bulkier head groups or more area than the other, creating spontaneous curvature. (c) Amphipathic helix/protein insertion into the cytoplasmic leaflet acts as a wedge, expanding that leaflet locally and driving the membrane to curve away. For clathrin-mediated endocytosis starting from the flat plasma membrane, the dominant curvature generator is the clathrin coat itself (triskelions assembling into a curved polyhedral lattice via AP2 adaptors), with BAR proteins (e.g., at the neck) and dynamin assisting; coat-driven scaffolding is most critical for initiating the invagination from a flat membrane. See section 7. 25. Osmotic stress responses in bacteria involve membrane sensors (e.g., EnvZ osmosensor) that activate two-component signaling systems. Compare bacterial osmosensing to mammalian cell osmosensing via volume-sensitive ion channels (VSOR). Which system responds faster and why?

Answer (Q25, Synthesis). Bacterial osmosensing uses the membrane histidine kinase EnvZ, which detects osmotic change and autophosphorylates, then transfers phosphate to the response regulator OmpR, which alters gene transcription (porin expression) — a two-component signaling cascade requiring new gene expression and protein synthesis (minutes). Mammalian osmosensing via volume-sensitive outwardly rectifying anion channels (VSOR) is a direct mechanical/volume response: cell swelling opens the channels in seconds, allowing regulatory ion (and osmolyte) efflux for volume recovery without any transcription. The mammalian channel system responds faster because it is a direct conformational gating of pre-existing channels, whereas the bacterial response depends on the slower transcription-translation loop. See section 7. 26. Fatty acid composition of membrane phospholipids changes with temperature (homeoviscous adaptation). Design an experiment to determine whether *E. coli* adjusts membrane fluidity in response to temperature via: (a) transcriptional regulation of fatty acid desaturases; (b) selective incorporation of exogenous fatty acids; or (c) lipid flip-flop remodeling. What lipid analysis technique would you use?

Answer (Q26, Synthesis). Hypothesis: *E. coli* maintains membrane fluidity at low temperature mainly by transcriptionally upregulating fatty-

acid desaturase to add double bonds (vs. exogenous-fatty-acid incorporation or flip-flop remodeling). Experiment: shift cultures from 37 °C to a low temperature; controls are constant-37 °C cultures and a desaturase-deletion (or inhibitor) strain. Manipulate one variable at a time — (a) measure desaturase mRNA/activity and test the desaturase mutant; (b) supply isotopically labeled exogenous unsaturated fatty acids and test their incorporation; (c) test a flippase-deficient strain for impaired remodeling. Measured outcome: phospholipid acyl-chain unsaturation and membrane fluidity (fluorescence anisotropy / DPH probe), with replicates. If only desaturase induction tracks the fluidity change and the desaturase mutant fails to adapt, that mechanism is supported; if adaptation persists without desaturase or only with exogenous fatty acids, the hypothesis is falsified. Lipid analysis technique: gas chromatography-mass spectrometry of fatty-acid methyl esters (and/or LC-MS lipidomics). See section 7. 27. P-glycoprotein (MDR1) is an ABC transporter that pumps hydrophobic drugs out of cancer cells, causing multidrug resistance. Evaluate: (a) why hydrophobic drugs are its substrates; (b) why inhibiting MDR1 has largely failed clinically; (c) an alternative strategy (e.g., prodrug activation inside the cell) that bypasses MDR1.

Answer (Q27, Synthesis). (a) MDR1/P-glycoprotein has a large hydrophobic substrate cavity and extracts substrates from within the lipid bilayer, so lipophilic, membrane-partitioning drugs (taxol, doxorubicin, vincristine) are exactly the molecules it can grab and pump out using ATP hydrolysis. (b) Clinical MDR1 inhibition has largely failed because broad pump inhibitors are non-specific (P-gp also protects normal tissues like the blood-brain barrier and gut), causing toxicity and altered pharmacokinetics of co-administered drugs, and resistance is often multifactorial — so blocking one efflux pump rarely restores sensitivity at tolerable doses; what would change this judgement is a truly tumor-selective, potent inhibitor. (c) An alternative strategy is an inactive prodrug that freely enters cells and is converted to the active cytotoxic drug only intracellularly (or a non-substrate drug/nanocarrier delivery), so the toxic species is generated past the pump and is not a P-gp substrate, bypassing efflux. See section 7. 28. The mitochondrial inner membrane maintains a proton gradient ($\Delta\mu_{H^+} = -200$ mV, $\Delta pH = 1$ unit = -59 mV, electrical = -141 mV). Using the chemiosmotic equation $\Delta G = nF\Delta\Psi + 2.303RT\Delta pH$, calculate the total proton-motive force. How does this compare to the energy needed to synthesize ATP from ADP + Pi (about +37 kJ/mol at physiological [ATP]/[ADP])? Assume 3 H⁺ per ATP (c-ring H⁺/ATP coupling ratio).

Answer (Q28, Synthesis). Chemiosmotic equation (per mol H⁺): $\Delta G_{H^+} = F\Delta\Psi + 2.303RT\Delta pH$. At 37 °C, $F = 96.5$ kJ/(V·mol); $2.303RT = 5.92$ kJ/mol per pH unit. Substitute: $\Delta G_{H^+} = (96.5)(-0.141\text{ V}) + (5.92)(-1) = -13.60 - 5.92 = -19.5$ kJ/mol H⁺. Equivalent PMF in volts: $\Delta G/F = -19.5/96.5 = -0.202\text{ V} \approx -200$ mV (matches stated $\Delta\mu_{H^+}$). For 3 H⁺ transported per ATP synthesized: $\Delta G_{3H^+} = 3 \times (-19.5) = -58.5$ kJ. Energy needed per ATP at cellular [ATP]/[ADP]·[Pi] $\approx +50$ to $+57$ kJ/mol (higher than standard +30.5 because cells hold [ATP]/[ADP] $\approx 500:1$). Verdict: $58.5 > 50 \rightarrow$ thermodynamically favorable, but with about 6–8 kJ/mol margin only. This is why mitochondrial ATP synthesis is tightly coupled (F_0F_1 operates near equilibrium, c-ring stoichiometry 8–10 H⁺ per rotation \times 3 ATP per rotation = about 2.7–3.3 H⁺/ATP) and why small uncoupler doses (2,4-DNP, thermogenin in brown fat) convert PMF directly to heat rather than ATP. Intervention: DNP (protonophore) at 50 μ M; assay: oxygen-consumption rate + ATP:O₂ ratio (Seahorse XF) — predicts respiration \uparrow , ATP output \downarrow . See section 7. 29. Nanoparticle drug delivery systems exploit endocytosis for intracellular drug delivery. Evaluate the barriers nanoparticles face: (a) being taken up via endocytosis rather than direct membrane fusion; (b) endosomal escape before lysosomal degradation; (c) targeting specificity via surface ligands. What design features address each barrier?

Answer (Q29, Synthesis). (a) Nanoparticles are too large to cross the bilayer by fusion, so they enter via endocytosis and become trapped inside membrane-bound endosomes — the cargo is internalised but not yet in the cytosol where it must act. (b) Endosomes mature and fuse with lysosomes; without timely endosomal escape the drug/nucleic acid is degraded by acidic hydrolases. (c) Without targeting, uptake is non-specific, so off-target cells take up the particle. Design features: PEGylation and about 50-150 nm size to favor productive endocytic uptake and circulation; ionisable/cationic lipids or pH-buffering ('proton sponge') or fusogenic peptides to rupture/escape the endosome before lysosomal fusion; and surface ligands/antibodies (e.g., transferrin, folate, anti-receptor) to drive receptor-mediated uptake selectively into target cells. See section 7. 30. Stretch-activated ion channels (SACs) open when the plasma membrane is mechanically deformed. Design a complete research program to: (a) identify the molecular identity of a SAC in cardiac myocytes; (b) determine its role in cardiac arrhythmia during myocardial stretch; (c) develop a selective SAC inhibitor and evaluate its anti-arrhythmic potential in a relevant animal model.

Answer (Q30, Synthesis). (a) Identify the molecular SAC: patch-clamp isolated cardiac myocytes under membrane stretch to characterize the current, then use candidate mechanosensitive channels (e.g., Piezo1, TREK-1) — knock down/out each and test loss of the stretch current, and reconstitute the candidate in a heterologous system to confirm it is sufficient (controls: non-stretched cells, scrambled siRNA). (b) Role in arrhythmia: in a stretched-myocyte or isolated-heart preparation, apply controlled mechanical stretch and record stretch-induced depolarisations/ectopic beats with and without the channel present, establishing whether SAC activity causes mechanically induced arrhythmia (mechanism: stretch \rightarrow SAC opens \rightarrow depolarization \rightarrow triggered activity). (c) Develop and evaluate a selective inhibitor: screen for compounds that block the identified SAC without affecting other cardiac channels, confirm selectivity by patch-clamp, then test anti-arrhythmic efficacy in a relevant animal model (e.g., volume-overload or stretch-induced arrhythmia) versus vehicle controls, with replication and a predefined falsifying result (no reduction in arrhythmia despite target engagement disproves the SAC hypothesis). See section 7.

Questions — Cell Signaling and Communication

Instructor Use and Coverage Notes

- Coverage target: Predict the outcome of perturbing one pathway component and justify the causal chain.
- Model/data emphasis: Ligand-receptor occupancy and dose-response reasoning.
- Assessment alignment: Visual Representations, Questions and Methods, Argumentation.
- Misconception probe: A pathway diagram is a causal model, not a memorization chart.
- Transfer product: Apply signaling logic to hormones, neurotransmitters, immune receptors, or cancer mutations.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 8 of the textbook — review that chapter before attempting the exercises below.

1. List the three stages of cell signaling. Give a brief description of each stage.

Answer (Q1, Recall). Cell signaling has three stages. Reception: a signaling molecule (ligand) binds a specific receptor, which detects the signal. Transduction: the receptor triggers an intracellular cascade (e.g., G-protein activation, kinase phosphorylation, second-messenger production) that amplifies and relays the signal. Response: effectors produce the cellular outcome — altered enzyme activity, gene transcription, or ion flux — followed by termination. See section 8. 2. Name four chemical classes of signaling molecules. Give one biological example of each.

Answer (Q2, Recall). Four classes are: proteins/peptides (e.g., insulin, growth factors), steroids/lipophilic hormones (e.g., cortisol, estrogen), amino-acid derivatives/amines (e.g., epinephrine, thyroid hormone), and gases/small molecules (e.g., nitric oxide). Peptide and amine signals are usually hydrophilic and bind cell-surface receptors, whereas steroids cross the membrane to bind intracellular receptors. See section 8. 3. Distinguish autocrine, paracrine, endocrine, and contact-dependent signaling.

Answer (Q3, Recall). The four modes differ by the distance between sending and receiving cell. Autocrine: a cell secretes a signal that acts on itself (e.g., IL-2 in T cells). Paracrine: local diffusion to nearby cells (<1 mm; growth factors, prostaglandins). Endocrine: hormones travel meters through the bloodstream (insulin, cortisol). Contact-dependent (juxtacrine): membrane-bound ligand binds a receptor on a touching cell (Notch-Delta, ephrin-Eph). See section 8. 4. What is a G protein-coupled receptor (GPCR)? Name the three subunits of the heterotrimeric G protein.

Answer (Q4, Recall). A GPCR is a cell-surface receptor with seven transmembrane alpha-helices, an extracellular N-terminus and intracellular C-terminus; it is the largest receptor superfamily (about 800 in humans). Ligand binding changes its conformation so it acts as a GEF for an associated heterotrimeric G protein. The three subunits are G-alpha, G-beta, and G-gamma (Gβγ acting as a functional unit). See section 8. 5. Describe the second messengers cAMP and IP₃/DAG and name the enzymes that produce each.

Answer (Q5, Recall). cAMP is produced from ATP by adenylyl cyclase, activated downstream of Gs; it activates protein kinase A (PKA). IP₃ and DAG are produced together when phospholipase C-beta (Gq pathway) cleaves PIP₂: IP₃ releases Ca²⁺ from the ER via IP₃ receptors, while DAG stays in the membrane and activates protein kinase C (PKC). See section 8. 6. What is a receptor tyrosine kinase (RTK)? Name two growth factor receptors of this type.

Answer (Q6, Recall). An RTK is a single-pass transmembrane receptor with an extracellular ligand-binding domain and a cytoplasmic tyrosine kinase domain; ligand binding causes dimerization and trans-autophosphorylation that recruits SH2/PTB adaptors. Two growth-factor receptors of this type are EGFR (HER1) and HER2 (also the insulin receptor, VEGFR2, FGFR are RTKs). See section 8. 7. Define signal amplification. Give a numerical example from a GPCR cascade.

Answer (Q7, Recall). Signal amplification is the production of many active downstream molecules per single activated upstream molecule; total gain is the product of per-step gains, $G_{\text{total}} = \prod_{i=1}^n A_i$. In the epinephrine→glycogenolysis GPCR cascade there are 4 enzymatic steps each with $A_i \approx 10^{1.5}$, giving $G_{\text{total}} \approx (10^{1.5})^4 = 10^6$, so one epinephrine molecule releases about 10⁸ glucose molecules. See section 8. 8. What is a MAP kinase cascade? List the three kinases in the Ras-MAPK pathway.

Answer (Q8, Recall). A MAP kinase cascade is a three-tier kinase relay in which each kinase phosphorylates and activates the next, providing amplification and ultrasensitivity. In the classical Ras-MAPK (ERK) pathway the three kinases are RAF (MAPKKK), MEK1/2 (MAPKK), and ERK1/2 (MAPK); ERK requires dual Thr/Tyr phosphorylation for activity. See section 8. 9. Define receptor downregulation. What cellular mechanism drives it?

Answer (Q9, Recall). Receptor downregulation is a sustained reduction in the number of surface receptors that lowers cell sensitivity during prolonged stimulation. It is driven by GRK phosphorylation of the active receptor, β-arrestin recruitment, and clathrin-mediated internalization;

receptors sorted to lysosomes are degraded, so restoring response requires hours-to-days of new receptor synthesis. See section 8. 10. What is the role of protein phosphatases in signal termination?

Answer (Q10, Recall). Protein phosphatases terminate signaling by removing the phosphate groups that kinases add, reversing activation of pathway components. Examples include PP1 and PP2A (dephosphorylate PKA substrates), calcineurin/PP2B (Ca^{2+} -dependent), MKPs/DUSPs (dephosphorylate MAPKs), and PTEN (removes the 3-phosphate from PIP_3 , opposing PI3K). See section 8.

Questions 11–20: Application and Analysis

11. Adrenaline binds β -adrenergic receptors (Gs-coupled). Trace the complete signaling cascade from ligand binding to glycogen phosphorylase activation, naming every molecule. How many molecules of glycogen phosphorylase are activated per initial adrenaline molecule?

Answer (Q11, Application). Adrenaline binds the β_2 -adrenergic receptor → receptor activates Gs → $\text{G}\alpha\text{s}$ -GTP dissociates and activates adenylyl cyclase → adenylyl cyclase converts ATP to cAMP → cAMP binds PKA regulatory subunits, releasing active PKA catalytic subunits → PKA phosphorylates and activates phosphorylase kinase → phosphorylase kinase activates glycogen phosphorylase. The 4-step enzymatic cascade has gain $\approx 10^6$ ($\prod A_i$, each $A_i \approx 10^{1.5}$), so one adrenaline molecule activates on the order of 10^6 glycogen phosphorylase molecules (releasing about 10^8 glucose). See section 8. 12. Steroid hormones (e.g., cortisol) exert their effects via intracellular receptors that act as transcription factors. Compare the timescale, reversibility, and specificity of steroid signaling vs adrenaline signaling via GPCR. Which is more suitable for rapid physiological responses, and why?

Answer (Q12, Application). Cortisol is lipophilic, diffuses through the membrane, binds the cytoplasmic glucocorticoid receptor, and acts as a ligand-activated transcription factor: slow (minutes-to-hours, requires transcription/translation), long-lasting, and highly gene-specific. Adrenaline via a GPCR acts in seconds through pre-existing enzymes and second messengers, is rapidly reversible upon termination. The GPCR pathway is more suitable for rapid physiological responses because it modifies existing proteins instead of waiting for new gene expression. See section 8. 13. Explain how Ca^{2+} acts as a second messenger. What keeps resting cytoplasmic $[\text{Ca}^{2+}]$ so low (about 100 nM)? What is the role of calmodulin as a Ca^{2+} sensor, and which kinase does Ca^{2+} -calmodulin activate?

Answer (Q13, Application). Ca^{2+} acts as a second messenger because resting cytoplasmic $[\text{Ca}^{2+}]$ is held about 100 nM by SERCA pumps (into the ER), plasma-membrane Ca^{2+} -ATPases/ Na^+ - Ca^{2+} exchangers, and cytoplasmic buffering (about 99% bound by calbindin/calretinin), so a small influx produces a large fractional rise. Calmodulin binds 4 Ca^{2+} ions and the Ca^{2+} -calmodulin complex changes conformation to act as a sensor; it activates CaMKII (Ca^{2+} /calmodulin-dependent protein kinase II), important in synaptic plasticity. See section 8. 14. Trastuzumab (Herceptin) is a monoclonal antibody that targets HER2 (an RTK overexpressed in about 25% of breast cancers). Explain its mechanism of action: how does receptor blockade inhibit downstream MAPK and PI3K-Akt signaling, and why does HER2 dimerization (with HER3) make it particularly potent?

Answer (Q14, Application). Trastuzumab binds the extracellular subdomain IV of HER2; in HER2-amplified cells it sterically blocks HER2 self-dimerization, so the receptors cannot trans-autophosphorylate, which shuts off recruitment of Grb2/SOS→RAS→MAPK and PI3K→Akt signaling. It also accelerates HER2 internalization/degradation and triggers antibody-dependent cellular cytotoxicity via NK cells. HER2-HER3 heterodimers are the strongest mitogenic pair, so blocking HER2 dimerization is particularly potent at silencing the dominant proliferative/survival drive. See section 8. 15. An inhibitor blocks PLC- β (phospholipase C- β). Predict the effects on: (a) IP_3 production; (b) DAG levels; (c) PKC activation; (d) intracellular Ca^{2+} release from the ER; (e) smooth muscle contraction downstream of M3 muscarinic receptor activation.

Answer (Q15, Application). PLC- β cleaves PIP_2 into IP_3 and DAG, so blocking it cuts both messengers. (a) IP_3 production falls; (b) DAG levels fall; (c) PKC activation falls (no DAG, and no IP_3 -driven Ca^{2+}); (d) IP_3 -receptor-mediated Ca^{2+} release from the ER is lost, so cytoplasmic Ca^{2+} does not rise; (e) M3 muscarinic (Gq-coupled) smooth muscle contraction is blocked because contraction depends on the $\text{IP}_3/\text{Ca}^{2+}$ signal. See section 8. 16. Cross-talk between signal pathways allows integration of multiple inputs. Describe two specific examples where activation of one signaling pathway inhibits or potentiates the response of another pathway. How might this cross-talk produce distinct cellular outcomes depending on context?

Answer (Q16, Application). Example 1: PKA (cAMP pathway) phosphorylates and inhibits RAF, so a Gs/cAMP signal dampens RTK-MAPK proliferative signaling — context determines whether a cell proliferates. Example 2: PI3K-Akt survival signaling phosphorylates and inactivates the pro-apoptotic protein BAD, so a growth-factor survival input potentiates resistance to a death signal. The same death or growth ligand therefore produces opposite outcomes (survival vs apoptosis) depending on which other pathways are concurrently active, because the cell responds to the integrated sum of all pathways. See section 8. 17. Wnt signaling inhibits the destruction complex (APC/Axin/CK1/GSK3 β), allowing β -catenin to accumulate and enter the nucleus. Explain how mutations in APC (found in >80% of colorectal cancers) constitutively activate Wnt signaling and promote cell proliferation.

Answer (Q17, Application). Normally the destruction complex (APC/Axin/CK1/GSK3 β) phosphorylates β -catenin, marking it for β -TrCP ubiquitination and proteasomal degradation, keeping target genes off. APC mutations (in >80% of colorectal cancers) disable the destruction complex, so

β -catenin is no longer degraded; it accumulates, enters the nucleus, binds TCF/LEF, and constitutively activates proliferative target genes (c-Myc, cyclin D1) — mimicking a permanent Wnt signal and driving uncontrolled proliferation. See section 8. 18. Nitric oxide (NO) is produced by nitric oxide synthase (NOS) and diffuses freely across membranes to activate soluble guanylate cyclase (sGC) in smooth muscle cells, producing cGMP. Explain: (a) why NO is unusual as a paracrine signal; (b) how sildenafil (Viagra) potentiates the NO-cGMP pathway; (c) what happens to cGMP without PDE5 inhibition.

Answer (Q18, Application). (a) NO is unusual because it is a small, membrane-permeant gas synthesized on demand by NOS; it diffuses directly into neighboring cells without a receptor or transporter and has a very short half-life, so its range is set by diffusion and decay. (b) NO activates soluble guanylate cyclase \rightarrow cGMP \rightarrow PKG \rightarrow smooth muscle relaxation; sildenafil inhibits PDE5, which normally degrades cGMP, so cGMP accumulates only where NO is being made, potentiating relaxation. (c) Without PDE5 inhibition, PDE5 rapidly hydrolyses cGMP to 5'-GMP, terminating the signal and ending relaxation. See section 8. 19. Notch signaling requires direct cell-cell contact (juxtacrine). When Notch receptor (on receiving cell) binds Delta ligand (on sending cell), γ -secretase cleaves the Notch intracellular domain (NICD), which enters the nucleus. Explain: (a) why this signaling cannot be mediated by a diffusible messenger; (b) the role of Notch in lateral inhibition during development.

Answer (Q19, Application). (a) Notch signaling cannot use a diffusible messenger because the ligand (Delta/Jagged) is membrane-bound on the sending cell and signaling depends on mechanical force from ligand endocytosis, which exposes Notch to ADAM and γ -secretase cleavage — this only occurs when the two cells are in direct contact. (b) In lateral inhibition, a cell expressing more Delta activates Notch in its neighbors; Notch signaling suppresses Delta in those neighbors, so one cell adopts the primary fate while adjacent cells are forced to the alternative fate, generating fine-grained 'salt-and-pepper' patterning during development. See section 8. 20. TGF- β receptors (type I and type II serine/threonine kinase receptors) signal via SMAD proteins. Explain: (a) how receptor dimerization activates SMAD2/3 phosphorylation; (b) how SMAD4 forms a complex with phospho-SMAD2/3; (c) how this complex regulates target gene transcription in the context of tumor suppression vs EMT (epithelial-mesenchymal transition).

Answer (Q20, Application). (a) Ligand binding brings type II and type I TGF- β receptors together; the constitutively active type II receptor transphosphorylates and activates the type I receptor, which then phosphorylates receptor-SMADs (SMAD2/3). (b) Phospho-SMAD2/3 binds the co-SMAD SMAD4, forming a heteromeric complex that translocates to the nucleus. (c) The SMAD complex binds DNA with cofactors to regulate transcription; in normal epithelium it acts as a tumor suppressor (induces p21, cytostasis), but with cooperating oncogenic signals the same complex drives an EMT program (Snail/Slug), promoting invasion — outcome is context-dependent. See section 8.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the concept of “signal integration”: a cell simultaneously receives growth factor (MAPK activation), anchorage signals (integrin-FAK signaling), and survival signals (insulin \rightarrow PI3K-Akt). How does the cell integrate these three pathways to make a proliferation vs death decision? Name at least one molecular node where the three signals converge.

Answer (Q21, Synthesis). The cell integrates the three inputs at convergent nodes rather than treating them independently. Growth factor \rightarrow MAPK drives cyclin D1; survival (insulin \rightarrow PI3K-Akt) inactivates pro-apoptotic BAD and activates mTORC1; anchorage (integrin-FAK) is also required for full PI3K/mTORC1 activation. A key convergence node is mTORC1, which requires both growth-factor (PI3K/Akt) and integrin signals, providing an anchorage checkpoint: a cell receiving the combined growth, survival, and anchorage inputs proliferates, while loss of anchorage or survival input tips the balance toward apoptosis (anoikis). The decision reflects the integrated balance, and removing the integrin input would change the conclusion. See section 8. 22. Design a CRISPR screen to identify novel negative regulators of the EGFR-MAPK pathway in non-small-cell lung cancer cells. Describe the library design, the cellular readout, and how you would validate the top hits as therapeutically relevant targets.

Answer (Q22, Synthesis). Hypothesis: knocking out a true negative regulator increases EGFR-MAPK output and growth. Design a genome-wide CRISPR knockout library (e.g., about 4 sgRNAs/gene) transduced at low MOI into NSCLC cells; controls are non-targeting sgRNAs and known regulators (NF1, DUSP6, Sprouty). Readout: an ERK-activity transcriptional reporter (FACS sort high-ERK cells) or proliferation/dropout under EGFR-inhibitor selection, comparing sgRNA abundance vs the unsorted population. Replicate the screen; validate top hits with individual knockouts measuring phospho-ERK by Western blot, and test therapeutic relevance by checking whether re-expressing the gene or pairing its loss with a MEK inhibitor restores drug sensitivity. A hit whose loss does not raise phospho-ERK falsifies it as a negative regulator. See section 8. 23. Receptor endocytosis and downregulation reduce cell sensitivity to a signal. However, some endosomal signaling (e.g., from endosome-localized EGFR) is qualitatively different from plasma membrane signaling. Evaluate the concept of “spatial encoding” of signal quality by receptor location. What specific downstream effectors are activated preferentially from endosomal vs surface receptors?

Answer (Q23, Synthesis). Spatial encoding means a receptor’s signaling output depends on its location, not just its ligand. Surface EGFR strongly engages RAS-MAPK and PLC- γ for proliferative/immediate responses, whereas EGFR that has been internalised into endosomes preferentially sustains PI3K-Akt survival signaling and continues ERK signaling from the endosome via β -arrestin scaffolds, producing a qualitatively different,

prolonged output. Thus endocytosis is not merely ‘off’: it relocates the receptor to a compartment with different available effectors, so the same ligand produces compartment-specific signaling and downregulation simultaneously. See section 8. 24. Intracellular Ca^{2+} oscillations are widely used for signal encoding. Evaluate how the frequency and amplitude of Ca^{2+} oscillations can encode different cellular responses (NF- κ B vs NFAT activation). What molecular mechanism (IP_3 R sensitivity to Ca^{2+} and inhibition by Ca^{2+}) generates oscillations?

Answer (Q24, Synthesis). Ca^{2+} oscillations encode information in frequency and amplitude rather than a static level: low-frequency/transient spikes preferentially activate NF- κ B, whereas sustained or high-frequency oscillations are needed to keep the Ca^{2+} -dependent phosphatase calcineurin active long enough to dephosphorylate NFAT and drive its nuclear retention. The oscillations themselves arise because the IP_3 receptor is biphasically regulated by Ca^{2+} — modest cytosolic Ca^{2+} increases its open probability (Ca^{2+} -induced Ca^{2+} release) but high local Ca^{2+} inhibits it; this positive-then-negative feedback, plus SERCA re-uptake, produces repetitive spikes. Whether this ‘decoding’ interpretation holds can be tested by clamping Ca^{2+} at fixed frequencies and measuring NF- κ B vs NFAT activation. See section 8. 25. Synaptic signaling relies on glutamate receptor subtypes (AMPA, NMDA, mGluR) with vastly different ion conductances, Ca^{2+} permeabilities, and kinetics. Evaluate how the combination of fast ionotropic (AMPA) and slow modulatory (NMDA, mGluR) signaling enables both rapid synaptic transmission and long-term plasticity at the same synapse.

Answer (Q25, Synthesis). AMPA receptors are fast ionotropic channels (sub-millisecond Na^+/K^+ flux) that mediate rapid, moment-to-moment excitatory transmission. NMDA receptors are slower coincidence detectors: they conduct Ca^{2+} only when glutamate binds AND the membrane is already depolarized (removing the Mg^{2+} block), so Ca^{2+} entry occurs only with paired pre/post activity, triggering CaMKII and LTP. mGluRs are slow modulatory GPCRs that adjust synaptic gain over seconds. Co-locating fast (AMPA) and slow (NMDA/mGluR) systems lets one synapse both transmit signals instantly and use the Ca^{2+} -gated NMDA pathway to write long-term, activity-dependent plasticity. See section 8. 26. Drug resistance in targeted therapy often results from mutations that reactivate downstream signaling. In BRAF^{V600E} melanoma treated with vemurafenib (BRAF inhibitor), resistance arises via: (a) RAS mutation bypassing BRAF; (b) MEK1 mutation making it insensitive; (c) RAF1 dimerization activating MEK. Evaluate why combination therapy (BRAF + MEK inhibition) reduces resistance emergence.

Answer (Q26, Synthesis). Vemurafenib inhibits the BRAF V600E kinase, shutting MEK→ERK. Resistance reactivates ERK by routes that bypass drug-bound BRAF: (a) a RAS mutation drives signaling through CRAF independent of BRAF; (b) a MEK1 mutation makes MEK constitutively active downstream of BRAF; (c) RAF1(CRAF) dimerization can paradoxically transactivate and phosphorylate MEK. Each restores ERK output despite BRAF blockade. Combining a BRAF inhibitor with a MEK inhibitor (trametinib) blocks the pathway at two sequential nodes, so a single bypass mutation no longer reactivates ERK; the cell needs two coincident resistance events, which is far less probable, yielding more durable responses. See section 8. 27. The PI3K-Akt-mTOR pathway is a master regulator of cell growth and metabolism. Evaluate the consequences of complete mTOR inhibition in cancer vs healthy cells: why do rapalogs (mTORC1 inhibitors) produce cytostatic rather than cytotoxic effects in most cancers, and what feedback mechanisms restore Akt activity?

Answer (Q27, Synthesis). mTORC1 inhibitors (rapalogs) block protein synthesis and cell growth but do not directly trigger death, so most cancer cells arrest (cytostatic) rather than die (cytotoxic) — surviving cells can resume growth when the drug is withdrawn. Moreover mTORC1 normally drives a negative feedback (via S6K) that suppresses IRS-1/PI3K; relieving this feedback with rapalogs paradoxically reactivates PI3K→Akt, restoring survival signaling and blunting efficacy. This is why rapalogs are often combined with PI3K/Akt or upstream RTK inhibitors to prevent feedback-driven Akt rescue. See section 8. 28. Feedback loops in signaling networks can generate bistability (switch-like most-or-none responses) or oscillations (e.g., NF- κ B oscillations). Evaluate the mathematical conditions (using a two-state model) under which positive feedback creates bistability vs oscillations. Give one biological example of each.

Answer (Q28, Synthesis). In a two-state activation model, pure positive feedback with sufficient cooperativity (nonlinearity) creates two stable steady states — bistability — giving an all-or-none switch with hysteresis; the ERK→SOS positive-feedback loop produces such switch-like, irreversible ERK activation (and the p53→PUMA ‘point of no return’ in apoptosis). Oscillations require positive feedback combined with delayed negative feedback: NF- κ B activation induces I κ B, which re-inhibits NF- κ B after a time delay, producing repetitive nuclear NF- κ B pulses. So bistability needs strong fast positive feedback alone; oscillation needs that positive feedback plus a slower opposing negative loop. See section 8. 29. Exosomes (30–150 nm extracellular vesicles) carry signaling molecules (proteins, miRNAs, lipids) between cells over long distances. Evaluate the evidence that exosomes constitute a bona fide signaling mechanism distinct from classical paracrine signaling, and propose experimental criteria to distinguish “exosomal” from conventional secreted-protein-mediated communication.

Answer (Q29, Synthesis). Exosomes can transfer proteins, miRNAs, and lipids that change recipient-cell behavior, which argues they are a bona fide signaling mechanism distinct from soluble paracrine factors because the cargo is membrane-encapsulated, can be delivered over long distances, and includes nucleic acids that classical secreted proteins cannot carry. To distinguish exosomal from conventional secreted-protein communication: deplete or block exosome biogenesis/release (e.g., Rab27a or nMase2 knockdown) and test loss of effect; purify exosomes by density/size and show the isolated vesicles reproduce the response; and demonstrate cargo transfer (labeled miRNA/protein appearing in recipients). A bona fide

exosomal mechanism is supported if the response survives in the vesicle fraction but is lost when vesicle release is blocked. See section 8. 30. Critically evaluate the “oncogene addiction” hypothesis: cancer cells become “addicted” to a single dominant oncogene signal (e.g., BCR-ABL in CML), making targeted inhibition highly effective. Under what conditions does addiction arise, and why do multiple oncogenic mutations (e.g., in pancreatic cancer) prevent effective single-agent targeted therapy?

Answer (Q30, Synthesis). Oncogene addiction is the observation that some tumors depend on one dominant oncogenic signal (e.g., BCR-ABL in CML), so inhibiting that node (imatinib) collapses the survival/proliferation network and is highly effective. Addiction arises when a single driver mutation rewires the cell so that downstream survival and growth signaling are funnelled through that one node, making the cell acutely sensitive to its loss (synthetic dependence). When a tumor carries multiple independent oncogenic mutations (e.g., KRAS plus others in pancreatic cancer), redundant parallel inputs sustain signaling even if one node is blocked, so single-agent targeted therapy fails; the evidence for addiction is strongest in genetically simple, single-driver cancers and weakest in multi-mutation tumors. See section 8.

Questions — Bioenergetics and Cellular Respiration

Instructor Use and Coverage Notes

- Coverage target: Calculate an energy yield or redox consequence and connect it to cellular work.
- Model/data emphasis: Delta G, ATP yield, and electron-carrier accounting.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis.
- Misconception probe: ATP is not stored energy in a vague sense; it is a coupling currency with defined reaction chemistry.
- Transfer product: Transfer energy accounting to exercise, fermentation, hypoxia, and mitochondrial disease.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 9 of the textbook — review that chapter before attempting the exercises below.

1. Define free energy (G). What does a negative ΔG indicate about a reaction?

Answer (Q1, Recall). Free energy (G) is the Gibbs free energy, the portion of a system’s energy available to do useful work at constant temperature and pressure. A negative ΔG (exergonic) indicates a spontaneous reaction that releases free energy; a positive ΔG (endergonic) requires an energy input. Cells couple endergonic reactions (e.g. biosynthesis) to highly exergonic ones such as ATP hydrolysis to drive them forward. See section 9. 2. Write the overall equation for aerobic cellular respiration.

Answer (Q2, Recall). Aerobic respiration: $C_6H_{12}O_6 + 6 O_2 \rightarrow 6 CO_2 + 6 H_2O$, with $\Delta G^{\circ} \approx -2,870 \text{ kJ/mol}$. Glucose is fully oxidised to CO₂, O₂ is the terminal electron acceptor reduced to water, and the released free energy is captured as about 30–32 ATP per glucose. See section 9. 3. What is ATP? What bonds are broken during ATP hydrolysis, and why is this energy release large?

Answer (Q3, Recall). ATP (adenosine triphosphate) is the cell’s energy-coupling currency: an adenosine linked to three phosphates by two phosphoanhydride bonds. Hydrolysis of the terminal phosphoanhydride bond ($ATP \rightarrow ADP + P_i$) has a large negative ΔG ($\approx -30 \text{ kJ/mol}$ standard, ≈ -50 to -54 kJ/mol in the cell). The release is large because the products are stabilized by relief of charge repulsion, resonance stabilization, and favorable solvation, not because the bond itself is unusually strong. See section 9. 4. Name the four stages of aerobic respiration and state where each occurs in the eukaryotic cell.

Answer (Q4, Recall). The four stages are: (1) glycolysis — cytoplasm; (2) pyruvate decarboxylation (PDC) — mitochondrial matrix; (3) the citric acid (Krebs/TCA) cycle — mitochondrial matrix; (4) the electron transport chain and oxidative phosphorylation — inner mitochondrial membrane. See section 9. 5. How many ATP are produced by substrate-level phosphorylation in glycolysis?

Answer (Q5, Recall). Glycolysis produces 4 ATP by substrate-level phosphorylation but consumes 2 ATP in the investment phase, for a net of 2 ATP per glucose by substrate-level phosphorylation (steps 7 and 10, phosphoglycerate kinase and pyruvate kinase). It also yields 2 net NADH. See section 9. 6. What is the purpose of the preparatory steps (pyruvate decarboxylation) before the Krebs cycle?

Answer (Q6, Recall). Pyruvate decarboxylation links glycolysis to the TCA cycle. The pyruvate dehydrogenase complex oxidatively decarboxylates each pyruvate (3C), releasing one CO₂, reducing one NAD⁺ to NADH, and attaching the remaining 2-carbon acetyl group to coenzyme A to form acetyl-CoA. This produces 2 NADH and 2 CO₂ per glucose and feeds acetyl-CoA into the cycle. See section 9. 7. What is the electron transport chain? Name the four major protein complexes.

Answer (Q7, Recall). The electron transport chain is a series of redox carriers in the inner mitochondrial membrane that pass electrons from NADH and FADH₂ to O₂, using the released energy to pump protons and build the proton-motive force. The four major complexes are Complex I (NADH dehydrogenase), Complex II (succinate dehydrogenase), Complex III (cytochrome bc₁, the Q cycle), and Complex IV (cytochrome c oxidase). See section 9. 8. What is the chemiosmotic theory? Who proposed it and when?

Answer (Q8, Recall). The chemiosmotic theory states that electron transport pumps protons across the inner mitochondrial membrane, creating an electrochemical proton gradient (proton-motive force) whose energy drives ATP synthesis by ATP synthase. It was proposed by Peter Mitchell in 1961 and earned him the 1978 Nobel Prize in Chemistry. See section 9. 9. What is fermentation? Name two types and the products of each.

Answer (Q9, Recall). Fermentation regenerates NAD⁺ from NADH so that glycolysis can continue without O₂; it does not itself make ATP. Lactic acid fermentation (muscle, erythrocytes) converts pyruvate to lactate; alcoholic fermentation (yeast) converts pyruvate to ethanol + CO₂. Both yield only 2 ATP per glucose, from glycolysis alone. See section 9. 10. What is the difference between substrate-level phosphorylation and oxidative phosphorylation?

Answer (Q10, Recall). In substrate-level phosphorylation a high-energy phosphate is transferred directly from a substrate to ADP by an enzyme (glycolysis steps 7 and 10, and the TCA GTP step); it is fast, O₂-independent, and yields little ATP. In oxidative phosphorylation, ATP synthase uses the proton-motive force generated by the electron transport chain; it requires O₂ and supplies about 28 of the about 32 ATP per glucose. See section 9.

Questions 11–20: Application and Analysis

11. Calculate the theoretical maximum ATP yield from one glucose molecule in aerobic respiration. How does the actual yield (about 30 ATP) differ from the textbook maximum (about 38), and why?

Answer (Q11, Application). Theoretical yield: 2 (glycolysis SLP) + 2 (TCA GTP) + 10 NADH × 2.5 + 2 FADH₂ × 1.5 ≈ 32 ATP using modern P/O ratios (the classic ‘38’ assumed 3 ATP/NADH and 2 ATP/FADH₂). The actual about 30 is lower because the malate-aspartate shuttle vs glycerol-3-phosphate shuttle changes the value of cytosolic NADH (2.5 vs 1.5 ATP each), and because proton leak and the cost of importing Pi/ADP siphon off part of the proton-motive force. See section 9. 12. In anaerobic fermentation, yeast converts pyruvate to ethanol + CO₂. Explain why this regeneration of NAD⁺ is essential for continued glycolysis, even though no ATP is produced in the process.

Answer (Q12, Application). Glycolysis nets 2 ATP but reduces 2 NAD⁺ to NADH at the GAPDH step. Cytosolic NAD⁺ is present in only catalytic amounts, so if NADH is not reoxidised, GAPDH stalls and glycolysis (and its 2 ATP) halts. Converting pyruvate to ethanol + CO₂ reoxidises NADH back to NAD⁺, sustaining flux through glycolysis even though the fermentation step itself makes no ATP. See section 9. 13. Cyanide (CN⁻) blocks Complex IV (cytochrome c oxidase). Predict the consequences for: (a) proton gradient; (b) NADH/NAD⁺ ratio; (c) ATP production; (d) O₂ consumption; (e) lactic acid production.

Answer (Q13, Application). Cyanide blocks Complex IV, so electrons cannot reach O₂. (a) Proton pumping stops, so the proton gradient collapses; (b) carriers stay reduced, so NADH/NAD⁺ rises sharply; (c) oxidative phosphorylation ATP production stops; (d) O₂ consumption falls to near zero; (e) cells switch to fermentation to regenerate NAD⁺, so lactic acid production rises. The result is a lethal histotoxic hypoxia. See section 9. 14. Uncoupling proteins (UCPs) such as thermogenin in brown adipose tissue dissipate the proton gradient as heat rather than driving ATP synthesis. Explain the physiological role of this process and calculate: if 50% of the proton gradient is uncoupled, what happens to O₂ consumption vs ATP output?

Answer (Q14, Application). Uncoupling proteins (e.g. thermogenin/UCP1 in brown adipose tissue) let protons re-enter the matrix bypassing ATP synthase, so the gradient’s energy is released as heat — important for non-shivering thermogenesis in neonates and cold-adapted mammals. Because the gradient is continually dissipated, electron transport speeds up: O₂ consumption rises while ATP output falls. With 50% of the gradient uncoupled, roughly half the proton flux makes heat instead of ATP, so ATP yield per O₂ drops by about half while total O₂ consumption increases. See section 9. 15. Glycolysis includes an irreversible phosphofructokinase-1 (PFK-1) step. PFK-1 is allosterically activated by AMP, ADP, and F-2,6-BP, and inhibited by ATP and citrate. Explain how this regulation matches glycolytic rate to cellular energy status.

Answer (Q15, Application). PFK-1 catalyses the committed, irreversible step of glycolysis. When energy is low, AMP and ADP rise and F-2,6-BP increases, allosterically activating PFK-1 so glycolysis speeds up to make ATP. When energy is plentiful, ATP and citrate accumulate and inhibit PFK-1, slowing glycolysis. This makes glycolytic flux track cellular energy charge moment to moment. See section 9. 16. Brown adipose tissue (BAT) is thermogenic. Compare the metabolic activity of BAT vs white adipose tissue (WAT): what substrate do they preferentially oxidise, how do they regulate UCP1 expression (adrenergic → cAMP → PKA → lipolysis → FA activation of UCP1), and what clinical interest does BAT activation generate?

Answer (Q16, Application). Brown adipose tissue oxidises fatty acids primarily to drive UCP1-mediated heat production; white adipose tissue stores triacylglycerol and oxidises little itself. In BAT, cold/adrenergic signaling → β-adrenergic receptor → cAMP → PKA → lipolysis → free fatty acids that both fuel and directly activate UCP1, uncoupling respiration to make heat. Clinically, activating or recruiting BAT is of interest for combating obesity and type 2 diabetes by increasing energy expenditure. See section 9. 17. The proton-motive force (pmf) has two components: electrical (ΔΨ ≈ −140 mV) and chemical (ΔpH ≈ 1 unit = −59 mV at 37°C; note sign convention for force driving H⁺ into the matrix). Calculate the total pmf in mV and the Gibbs energy per mole of protons entering the matrix (ΔG = FΔΨ + 2.303RT·ΔpH).

Answer (Q17, Application). Total pmf = ΔΨ + (−59 mV per ΔpH unit at 37°C) ≈ −140 mV + (−59 mV) ≈ −200 mV in magnitude. The Gibbs energy per mole of protons is ΔG = FΔΨ + 2.303 RT ΔpH ≈ 96,485 C/mol × 0.200 V ≈ 19–20 kJ/mol of protons entering the matrix — the per-proton energy budget that funds ATP synthesis. See section 9. 18. The malate-aspartate shuttle transfers NADH electrons from the cytoplasm into the mitochondrial matrix. Why is this shuttle needed, and why does a cell using the glycerol-3-phosphate shuttle instead produce slightly less ATP? (Hint: which NADH-equivalent is delivered to which complex?)

Answer (Q18, Application). Cytosolic NADH cannot cross the inner mitochondrial membrane, so its electrons must be shuttled in. The malate-

aspartate shuttle (liver, heart, kidney) regenerates matrix NADH, which enters at Complex I and yields about 2.5 ATP per electron pair. The glycerol-3-phosphate shuttle (skeletal muscle, brain) delivers electrons to ubiquinone via an FAD-linked enzyme, bypassing Complex I, so it yields only about 1.5 ATP per pair — hence about 30 ATP/glucose instead of about 32. See section 9. 19. Cancer cells preferentially use aerobic glycolysis (Warburg effect) even when oxygen is available. Propose three mechanistic explanations for why rapidly proliferating cells would benefit from this apparently inefficient strategy.

Answer (Q19, Application). Three rationales: (1) speed — glycolytic ATP is produced far faster than by oxidative phosphorylation, matching the high demand of proliferation; (2) biosynthesis — diverting glucose carbon supplies precursors (G6P → ribose for nucleotides via the pentose phosphate pathway, 3-PG → serine, pyruvate → amino acids); (3) redox/NADPH and microenvironment — supports antioxidant defense and adapts to hypoxic, poorly vascularised tumor regions, while secreted lactate acidifies the milieu and favors invasion. See section 9. 20. Chloramphenicol inhibits bacterial 50S ribosomes and mitochondrial ribosomes. Explain why chloramphenicol can cause myelosuppression (bone marrow failure) after prolonged use, and why it is still used clinically when other antibiotics fail.

Answer (Q20, Application). Mitochondria descend from bacteria and use bacteria-like 70S ribosomes, so chloramphenicol — which inhibits the 50S subunit of bacterial and mitochondrial ribosomes — also blocks mitochondrial protein synthesis. In rapidly dividing bone marrow this impairs synthesis of ETC subunits, causing dose-dependent reversible myelosuppression (and rarely idiosyncratic aplasia). It is still reserved for severe infections (e.g. typhoid, meningitis, rickettsiae) when safer antibiotics fail, because its broad efficacy can be life-saving. See section 9.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the ATP synthase as a molecular motor. Describe the rotary mechanism (F_0 rotation driven by H^+ flux → F_1 conformational change → alternating binding-change mechanism). Calculate the torque generated if F_0 rotates at 100 rpm with a step size of 120° per ATP.

Answer (Q21, Synthesis). ATP synthase is a rotary motor: proton flux through the membrane-embedded F_0 c-ring drives rotation of the central γ stalk, which cycles the three F_1 β catalytic sites through loose, tight, and open states (Boyer's binding-change mechanism), synthesizing and releasing ATP. With about 3.67 H^+ per ATP and a 120° rotation per ATP, three ATP are made per full 360° turn; at 100 rpm that is about 5 ATP/s per enzyme. The torque equals the work per ATP ($\Delta G \approx 50\text{--}60\text{ kJ/mol} \approx \text{about } 80\text{--}100\text{ pN}\cdot\text{nm}$) divided by the $2\pi/3$ rad step, giving roughly 40–50 pN·nm. See section 9. 22. Evaluate the efficiency of oxidative phosphorylation: how close is the actual ATP/O ratio to the theoretical maximum, and what factors cause inefficiency (proton leak, incomplete coupling)? What impact does membrane composition (cardiolipin content) have on coupling efficiency?

Answer (Q22, Synthesis). The measured P/O ratios (about 2.5 ATP/NADH, about 1.5 ATP/FADH₂) fall short of idealised maxima because of intrinsic proton leak, pump slip, and the H^+ cost of importing P_i and ADP and exporting ATP. Cardiolipin, the inner-membrane signature phospholipid, binds and stabilizes the respiratory supercomplexes and ATP synthase and limits proton leak, so adequate cardiolipin content (and its remodeling, e.g. tafazzin in Barth syndrome) raises coupling efficiency; depletion lowers the effective ATP/O ratio. See section 9. 23. Design an experiment to test whether a newly discovered mitochondrially targeted compound acts as an uncoupler, a chain blocker, or an ATP synthase inhibitor. What measurements (O_2 consumption rate, membrane potential, ATP levels, pH) would you take, and in what order?

Answer (Q23, Synthesis). Hypothesis: the compound is an uncoupler, a chain blocker, or an ATP synthase inhibitor. Using isolated mitochondria, measure O_2 consumption rate, membrane potential, and ATP. Add substrate then ADP (State 3); add the compound. An uncoupler raises O_2 consumption while collapsing membrane potential and ATP. A chain blocker lowers O_2 consumption and membrane potential. An ATP synthase inhibitor lowers O_2 consumption and ATP but maintains or raises membrane potential, and adding an uncoupler afterward restores respiration — the decisive control distinguishing it from a chain blocker. Replicate across independent preparations. See section 9. 24. Cells can switch between aerobic respiration, fermentation, and fatty acid oxidation. Design a metabolic flux experiment using ^{13}C -labeled glucose and isotope mass spectrometry (metabolomics) to map which pathways are active under normoxia, hypoxia, and caloric restriction. What isotopomer patterns would distinguish glycolytic from TCA-derived carbon?

Answer (Q24, Synthesis). Feed cells uniformly ^{13}C -glucose and measure metabolite isotopomers by mass spectrometry under normoxia, hypoxia, and caloric restriction. Lactate/alanine carrying the full glycolytic ^{13}C label with little label in TCA intermediates indicates fermentative/Warburg flux (favored in hypoxia); progressive ^{13}C enrichment of citrate, α -ketoglutarate, succinate, and malate indicates pyruvate → TCA oxidation. Dilution of TCA labeling by unlabelled acetyl-CoA reveals fatty acid oxidation, prominent under caloric restriction. Distinct mass-isotopomer distributions thus separate glycolytic from TCA-derived carbon. See section 9. 25. The pentose phosphate pathway (PPP) branches from glycolysis at G6P and produces NADPH and ribose-5-phosphate. Evaluate the relative importance of PPP in: (a) red blood cells (where NADPH protects against oxidative damage via glutathione); (b) rapidly proliferating cancer cells (where ribose is needed for nucleotide synthesis). Design a therapeutic strategy targeting the PPP specifically in cancer cells.

Answer (Q25, Synthesis). The PPP oxidative branch converts G6P to ribulose-5-phosphate, generating NADPH and ribose-5-phosphate. (a) In red

blood cells NADPH keeps glutathione reduced to detoxify peroxides; without it (e.g. G6PD deficiency) oxidative hemolysis occurs. (b) In proliferating cancer cells the PPP supplies ribose-5-phosphate for nucleotide synthesis and NADPH for lipid synthesis and redox balance. A cancer-selective strategy is to inhibit G6PD or transketolase (or block NADPH regeneration), raising oxidative stress and limiting nucleotide supply in tumor cells, which are more PPP-dependent than most normal tissue. See section 9. 26. Mitochondria-derived reactive oxygen species (ROS) cause oxidative stress. Evaluate the paradox that low ROS function in redox signaling (activating NF- κ B, Nrf2, and HIF-1 α) while high ROS cause macromolecular damage. What antioxidant systems exist in mitochondria (SOD2, thioredoxin, peroxiredoxin), and how might targeted mitochondrial antioxidants (MitoQ, SS-31) prevent disease?

Answer (Q26, Synthesis). ROS arise mainly from electron leak at Complexes I and III. At low levels they act as second messengers, reversibly oxidising thiols to activate redox-sensitive pathways (NF- κ B, Nrf2, HIF-1 α); at high levels they oxidise lipids, proteins, and mtDNA — a dose-dependent, hormetic relationship rather than a contradiction. Mitochondrial defenses include MnSOD (SOD2), the thioredoxin/peroxiredoxin system, and glutathione peroxidase. Matrix-targeted antioxidants such as MitoQ and SS-31 (elamipretide) concentrate where ROS are generated and may limit oxidative damage in ischemia-reperfusion and neurodegeneration without blunting physiological signaling. See section 9. 27. Metabolic reprogramming in hypoxia (HIF-1 α pathway) switches cells from oxidative phosphorylation to anaerobic glycolysis. Evaluate the molecular logic: why would a cell transcriptionally upregulate glycolytic enzymes AND simultaneously downregulate Complex IV (via COX4-2 subunit switch) AND activate BNIP3-mediated mitophagy (selective mitochondrial degradation) in response to O₂ lack?

Answer (Q27, Synthesis). Low O₂ stabilizes HIF-1 α , which coordinately reprograms metabolism away from O₂-dependent ATP. It upregulates glycolytic enzymes and lactate dehydrogenase to sustain ATP without O₂; it switches Complex IV to the COX4-2 isoform that operates more efficiently at low O₂; and it induces BNIP3, triggering mitophagy to prune mitochondria, lowering O₂ demand and ROS output. Together these shift the cell to glycolytic ATP while protecting it from ROS damage during hypoxia. See section 9. 28. The ketone bodies (β -hydroxybutyrate, acetoacetate) produced during fasting and ketogenic diets are increasingly recognized as signaling molecules (not just fuel). Evaluate the evidence that β -hydroxybutyrate inhibits histone deacetylases (HDACs), thereby acting as an epigenetic regulator. What genes are induced, and how might this explain the neuroprotective and anti-inflammatory properties attributed to ketogenic diets?

Answer (Q28, Synthesis). During fasting and ketogenic diets the liver converts surplus fatty-acid-derived acetyl-CoA into β -hydroxybutyrate and acetoacetate, exported as fuel for brain, heart, and muscle. β -hydroxybutyrate is also an endogenous class-I HDAC inhibitor: inhibiting HDACs raises histone acetylation and induces genes such as FOXO3 and MT2 that strengthen antioxidant defenses. That antioxidant program plus suppression of inflammation (e.g. the NLRP3 inflammasome) are proposed mechanisms for the neuroprotective and anti-inflammatory effects of ketogenic states; the evidence is suggestive but still partly correlative. See section 9. 29. Thermodynamic coupling in oxidative phosphorylation can be described by non-equilibrium thermodynamics. Evaluate: when the ATP/ADP ratio is very high, does flow of H⁺ through ATP synthase reverse (ATP \rightarrow ADP + Pi, using pmf to rotate in reverse)? Under what physiological conditions does this reverse mode actually occur, and what is its role in maintaining mitochondrial membrane potential when Complex I/III activity is inhibited?

Answer (Q29, Synthesis). ATP synthase is reversible. When the proton-motive force falls but ATP/ADP stays high, the enzyme can run backward, hydrolysing ATP and pumping protons outward to defend the membrane potential. This reverse mode occurs physiologically in ischemia/hypoxia or when Complex I or III is inhibited, preserving $\Delta\Psi$ for protein/ion import and apoptotic gatekeeping at the cost of consuming ATP — a protective but expensive state usually limited by the inhibitor protein IF1. See section 9. 30. Critically evaluate the “two-hit” model of mitochondrial disease: patients with heteroplasmic mtDNA mutations are often asymptomatic until a critical threshold (often about 80% mutated mtDNA) is exceeded. What cellular mechanisms (quality control, complementation in fused networks) maintain function below the threshold? At what threshold does bioenergetic failure occur, and how does tissue-specific metabolism (brain vs muscle vs liver) determine which tissue is most sensitive?

Answer (Q30, Synthesis). Heteroplasmic cells tolerate mutant mtDNA because wild-type mitochondria and mtDNA-encoded subunits complement defective ones within the fused network, and quality-control fission/mitophagy removes the worst organelles — keeping bioenergetics adequate until mutant load passes a tissue-specific threshold (often about 70–90%, classically about 80%). Above threshold, oxidative phosphorylation fails and symptoms emerge. High-demand oxidative tissues (brain, then heart and skeletal muscle) cross the bioenergetic failure point first, whereas glycolytically flexible liver tolerates higher mutant loads, explaining the encephalo-myopathic presentation of many mtDNA diseases. See section 9.

Questions — Photosynthesis

Instructor Use and Coverage Notes

- Coverage target: Compute carbon-fixation requirements and explain a limiting factor.
- Model/data emphasis: Photon, ATP/NADPH, and Calvin-cycle stoichiometry.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis.
- Misconception probe: Plants do not eat sunlight; they use light energy to reduce carbon using electrons and enzymes.
- Transfer product: Transfer photosynthetic constraints to crops, algae, climate, or ecosystem productivity.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 10 of the textbook — review that chapter before attempting the exercises below.

1. Write the overall equation for photosynthesis. Which reactant provides O₂?

Answer (Q1, Recall). Overall: 6 CO₂ + 6 H₂O + light → C₆H₁₂O₆ + 6 O₂ (ΔG ≈ +2,870 kJ/mol, an endergonic, light-driven reaction). The evolved O₂ comes entirely from water, not CO₂ — water is split by the oxygen-evolving complex of Photosystem II to supply electrons, protons, and O₂. See section 10. 2. Locate photosynthesis: in which organelle and in which specific membrane compartment do the light reactions occur?

Answer (Q2, Recall). Photosynthesis occurs in the chloroplast (in plants and algae). The light reactions occur in the thylakoid membrane (with proton accumulation in the thylakoid lumen), while the Calvin cycle takes place in the surrounding stroma. See section 10. 3. What are photosystems I and II? What is the primary electron donor in each?

Answer (Q3, Recall). Photosystems are pigment–protein reaction-center complexes in the thylakoid membrane. Photosystem II (P680) uses water as its primary electron donor (oxidising it via the oxygen-evolving complex to release O₂). Photosystem I (P700) receives electrons from the cytochrome b6f chain via plastocyanin, and its excited reaction center donates electrons ultimately to NADP⁺. See section 10. 4. Define the Z-scheme. Trace the path of electrons from water to NADP⁺.

Answer (Q4, Recall). The Z-scheme is the energetic ‘zig-zag’ diagram of non-cyclic electron flow through two photosystems in series. Path: H₂O → (oxygen-evolving complex of PSII) → P680* → pheophytin → plastoquinone (QA, QB) → cytochrome b6f → plastocyanin → P700* (PSI) → ferredoxin → ferredoxin-NADP⁺ reductase → NADP⁺ + H⁺ → NADPH. Two photons (one per photosystem) are absorbed per electron. See section 10. 5. What are the products of the light reactions passed to the Calvin cycle?

Answer (Q5, Recall). The light reactions supply ATP and NADPH (plus reduced ferredoxin transiently) to the Calvin cycle in the stroma; O₂ is released as a by-product and is not used by the cycle. ATP provides chemical energy and NADPH provides reducing power for CO₂ fixation. See section 10. 6. Name the three stages of the Calvin cycle (also called the C₃ cycle or light-independent reactions).

Answer (Q6, Recall). The three stages of the Calvin cycle are: (1) carboxylation — RuBisCO fixes CO₂ onto ribulose-1,5-bisphosphate (RuBP) to form two 3-phosphoglycerate; (2) reduction — 3-PGA is phosphorylated (ATP) and reduced (NADPH) to glyceraldehyde-3-phosphate (G3P); (3) regeneration — most G3P is used (with ATP) to regenerate RuBP. See section 10. 7. What is RuBisCO? What reaction does it catalyse and what is its substrate?

Answer (Q7, Recall). RuBisCO (ribulose-1,5-bisphosphate carboxylase/oxygenase) is the Calvin-cycle enzyme that catalyses carboxylation: it adds CO₂ to its substrate ribulose-1,5-bisphosphate (RuBP), producing two molecules of 3-phosphoglycerate. It also has an oxygenase side-activity (using O₂ instead of CO₂) that initiates photorespiration. See section 10. 8. Distinguish C₃, C₄, and CAM plants. Give one example species of each.

Answer (Q8, Recall). C₃ plants fix CO₂ directly via RuBisCO to 3-PGA (e.g. wheat/rice). C₄ plants first fix CO₂ with PEP carboxylase in mesophyll cells to a 4-carbon acid, then release CO₂ around RuBisCO in bundle-sheath cells (e.g. maize). CAM plants fix CO₂ at night into malate and release it to RuBisCO by day (e.g. pineapple or a cactus) — C₄ and CAM are CO₂-concentrating mechanisms that suppress photorespiration, with CAM giving the highest water-use efficiency. See section 10. 9. What is photorespiration? Under what conditions is it maximized?

Answer (Q9, Recall). Photorespiration begins when RuBisCO’s oxygenase activity adds O₂ (instead of CO₂) to RuBP, making 2-phosphoglycolate that must be salvaged through the C₂ pathway across chloroplast, peroxisome, and mitochondrion, releasing CO₂ and consuming ATP with no sugar gain. It is maximized under high temperature, high light, and low CO₂/high O₂ (e.g. closed stomata in hot, dry conditions), where the oxygenase reaction is favored. See section 10. 10. What is the wavelength absorbed by chlorophyll a and chlorophyll b?

Answer (Q10, Recall). Chlorophyll a absorbs maximally at roughly 430 nm (blue) and 662–680 nm (red). Chlorophyll b absorbs maximally at roughly 453 nm (blue) and 642 nm (red); it is an accessory pigment that broadens the harvested spectrum and funnels energy to chlorophyll a. Both reflect green light, giving plants their color. See section 10.

Questions 11–20: Application and Analysis

11. DCMU (herbicide, kills plants) blocks the electron acceptor site of Photosystem II. Predict its effects on: (a) O₂ evolution; (b) NADPH production; (c) ATP (photophosphorylation); (d) the Calvin cycle.

Answer (Q11, Application). DCMU blocks the QB plastoquinone-binding site of PSII, stopping electron flow out of PSII. (a) O₂ evolution stops (water splitting halts without electron acceptor turnover). (b) NADPH production stops (no electrons reach PSI/NADP⁺ via linear flow). (c) Linear photophosphorylation collapses because the proton gradient from PSII/b₆f is lost (only limited cyclic ATP around PSI may persist). (d) The Calvin cycle stops once ATP and NADPH are exhausted — the plant cannot fix carbon and dies. See section 10. 12. Non-cyclic photophosphorylation produces both ATP and NADPH. Cyclic photophosphorylation produces primarily ATP. Explain the mechanism of cyclic flow (electron recirculates through Fd → PQ → Cyt b₆f → PSI) and when a cell uses cyclic vs non-cyclic flow.

Answer (Q12, Application). In cyclic flow, PSI-excited electrons pass from ferredoxin back to the plastoquinone pool/cytochrome b₆f complex and return to P700, pumping protons and making ATP but no NADPH and no O₂. Cells use cyclic flow when ATP demand exceeds NADPH demand — the linear Z-scheme yields an ATP:NADPH ratio (about 9 ATP : 6 NADPH per 3 CO₂) below the about 3:2 the Calvin cycle requires, so cyclic flow tops up ATP, and it is also up-regulated under stress (high light, low CO₂) to balance the energy budget and support photoprotection. See section 10. 13. A student growing *Arabidopsis thaliana* increases light intensity 10-fold. Initially photosynthetic rate rises, then plateaus. Explain the two-phase response: which reaction limits at low light (light reactions) and which limits at high light (Calvin cycle enzyme capacity)?

Answer (Q13, Application). At low light the rate is light-limited: the light reactions cannot supply ATP/NADPH fast enough, so photosynthesis rises roughly linearly with intensity. As intensity increases the system becomes light-saturated: the rate plateaus because the Calvin cycle's enzymatic capacity (RuBisCO turnover, RuBP regeneration) and CO₂ supply become limiting, not photon capture. Adding CO₂ or more RuBisCO would raise the plateau; adding light would not — the predicted, testable signature of a Calvin-cycle (carbon/enzyme) limitation. See section 10. 14. C₄ plants (e.g., maize) separate initial CO₂ fixation (HCO₃⁻ → oxaloacetate, in mesophyll) from RuBisCO (in bundle sheath). Explain: (a) how this concentrates CO₂ around RuBisCO; (b) why it reduces photorespiration; (c) why C₄ plants outcompete C₃ plants in hot, sunny conditions.

Answer (Q14, Application). (a) In C₄ plants PEP carboxylase fixes HCO₃⁻ to oxaloacetate → malate in mesophyll cells; malate moves to bundle-sheath cells and is decarboxylated, releasing CO₂ right at RuBisCO (about 10× above ambient). (b) High local CO₂ outcompetes O₂ at RuBisCO's active site, so the oxygenase reaction and photorespiration are nearly eliminated. (c) In hot, sunny, dry conditions C₃ plants lose CO₂ to high photorespiration and must keep stomata more open; C₄ plants maintain high carboxylation with smaller stomatal opening, so they have higher water-use efficiency and outcompete C₃ plants there. See section 10. 15. The quantum yield of O₂ production is about 1 O₂ per 8 photons absorbed (theoretical: 1 O₂ per 8 photons absorbed). Why is this the minimum, and how does the Z-scheme energetically justify why 4 photons per PSII and 4 per PSI are needed to produce 1 O₂ and 2 NADPH?

Answer (Q15, Application). Producing one O₂ requires removing 4 electrons from 2 H₂O. In the Z-scheme each electron must be excited twice — once at PSII and once at PSI — so 4 photons at PSII + 4 photons at PSI = 8 photons minimum per O₂ (and per 2 NADPH). This is the theoretical minimum because each photosystem performs one charge separation per photon, and the energy of a single photon is insufficient to span the full about 1.1 V from water to NADP⁺; the two-photon (two-step) boost is energetically required. Real quantum yields are slightly worse (about 9–10 photons per O₂). See section 10. 16. Photorespiration occurs when RuBisCO oxygenates RuBP (instead of carboxylating it), producing phosphoglycolate, which must be recycled through the glycolate pathway. Calculate: if 25% of RuBisCO reactions are oxygenation rather than carboxylation, what fraction of carbon fixed is immediately lost? How does this affect net carbon gain?

Answer (Q16, Application). RuBisCO oxygenation makes one 2-phosphoglycolate (2C); salvage through the C₂ pathway recovers carbon but releases about 1 CO₂ per 2 glycolate processed, so roughly one quarter of the carbon entering photorespiration is lost. If 25% of RuBisCO turnovers are oxygenations, net carbon gain falls substantially — on the order of a about 20–30% reduction in net C₃ photosynthesis at 25°C — because fixed carbon is re-released as CO₂ and ATP/NADPH are consumed without sugar production. See section 10. 17. Antenna complexes (LHCI, LHCII) harvest photons and funnel excitation energy to reaction centers by resonance energy transfer (Förster transfer). Explain: (a) why antenna complexes increase efficiency; (b) why there is a risk of photodamage (singlet O₂ production) at high light; (c) what non-photochemical quenching (NPQ) does to protect the reaction centers.

Answer (Q17, Application). (a) Antenna complexes (LHCI/LHCII) hold many pigments that absorb photons over a broad spectrum and funnel the excitation by Förster resonance/exciton transfer to the reaction center at about 95% efficiency, so each reaction center is fed far faster than it could collect light alone. (b) At high light, excitation arrives faster than photochemistry can use it; long-lived triplet chlorophyll forms and transfers energy

to O₂, generating damaging singlet oxygen. (c) Non-photochemical quenching (NPQ) — driven by lumen acidification, the xanthophyll/zeaxanthin cycle and PsbS — safely dissipates excess excitation as heat, protecting the reaction centers from photodamage. See section 10. 18. Rubisco activase unfolds the tight inhibitory conformation of RuBisCO when CO₂ is absent. Explain: (a) why RuBisCO requires activation before catalysis; (b) how activase uses ATP hydrolysis to open the active site; (c) why rubisco activase is itself heat-sensitive and limits photosynthesis at high temperatures.

Answer (Q18, Application). (a) RuBisCO requires activation because a non-substrate CO₂ carbamylates an active-site lysine and recruits Mg²⁺ to form the catalytically competent site; tight-binding inhibitory sugar phosphates (e.g. RuBP, CA1P) also block uncarbamylated enzyme. (b) RuBisCO activase, an AAA+ ATPase, uses ATP hydrolysis to remodel RuBisCO and physically remove the inhibitory sugar phosphates, allowing carbamylation and catalysis. (c) Activase is thermolabile and denatures/aggregates at elevated temperature, so at high temperatures RuBisCO stays inhibited — making activase a key limit on photosynthesis under heat stress. See section 10. 19. CAM (Crassulacean acid metabolism) plants open stomata primarily at night. Trace: (a) nocturnal CO₂ fixation into malate (by PEPC); (b) daytime malate decarboxylation to CO₂; (c) CO₂ fixation by RuBisCO; (d) the advantage in arid environments. Compare water-use efficiency (WUE) of CAM vs C₃ plants.

Answer (Q19, Application). (a) At night, stomata open in the cool, humid dark; PEP carboxylase fixes CO₂ into oxaloacetate → malate, stored as malic acid in the vacuole (lumen pH drops about 7→4). (b) By day stomata close and malate is decarboxylated, releasing CO₂ internally. (c) RuBisCO fixes that concentrated CO₂ via the normal Calvin cycle behind closed stomata. (d) Opening stomata only at night drastically cuts transpirational water loss, so CAM plants achieve very high water-use efficiency (roughly 3–5× that of C₃ plants), an advantage in arid environments. See section 10. 20. The chloroplast ATP synthase (CF₁F₀) is structurally similar to the mitochondrial ATP synthase. Compare: the direction of proton gradient (lumen to stroma vs IMS to matrix); whether CF₁F₀ can run in reverse (hydrolyse ATP to pump H⁺); and the regulatory role of the thiol-regulated γ-subunit in the dark vs light.

Answer (Q20, Application). Chloroplast CF₁F₀ and mitochondrial F₁F₀ share the rotary catalytic mechanism. Proton-gradient direction differs: in chloroplasts protons accumulate in the thylakoid lumen and flow out to the stroma to make ATP, whereas in mitochondria protons flow from the intermembrane space into the matrix. CF₁F₀ can in principle run in reverse (ATP hydrolysis pumping H⁺), but the chloroplast enzyme is held off in the dark by a thiol-regulated γ-subunit: in the light, reduced thioredoxin (and the proton gradient) activates it for ATP synthesis; in the dark the oxidised γ-subunit inhibits it to prevent wasteful ATP hydrolysis. See section 10.

Questions 21–30: Synthesis and Evaluation

- Evaluate the artificial leaf as a technology for solar fuel production: splitting water to produce H₂ photochemically. What catalysts mimic the Mn cluster of the oxygen-evolving complex (OEC)? What are the current efficiency limits, and how do they compare to photosynthetic efficiency (about 3% vs photovoltaic about 25%)?

Answer (Q21, Synthesis). An ‘artificial leaf’ uses light-driven catalysts to split water into O₂ and H₂ (or reduce CO₂). The oxygen-evolving Mn₄CaO₅ cluster of PSII is mimicked by earth-abundant water-oxidation catalysts such as cobalt-phosphate (Co-Pi) and manganese/nickel oxides, as well as IrO₂; H₂ is generated at coupled photocathodes. Current integrated solar-to-fuel efficiencies are typically a few to about 10%, exceeding the about 1–3% net efficiency of crop photosynthesis but below about 25% silicon photovoltaics. The judgment that artificial leaves can scale depends on contestable evidence — catalyst durability, cost, and system-level efficiency — and would change if cheap, stable catalysts achieved high efficiency at scale. See section 10. 22. Rising CO₂ atmospheric concentrations (currently about 420 ppm) should theoretically increase C₃ photosynthesis (CO₂ fertilization effect) but FACE (Free Air CO₂ Enrichment) experiments show attenuated responses. Evaluate three mechanisms of “photosynthetic downregulation” under elevated CO₂ and assess the net impact on crop yields.

Answer (Q22, Synthesis). FACE experiments show smaller-than-predicted C₃ gains under elevated CO₂ because of photosynthetic downregulation: (1) acclimation — sustained sugar accumulation represses RuBisCO/photosynthetic gene expression and lowers RuBisCO content; (2) sink limitation — if growth/storage capacity does not increase, end-product feedback (Pi limitation) caps the rate; (3) co-limitation by nitrogen and water — extra CO₂ cannot be used without proportional N for RuBisCO and adequate water/nutrients. Net crop-yield effects are real but modest (often well below the theoretical CO₂-fertilization expectation) and are further offset by heat and drought, so the simple fertilization prediction should not be treated as settled. See section 10. 23. RuBisCO is notoriously inefficient (k_{cat} about 3 s⁻¹, compared to >1,000 s⁻¹ for most enzymes). Evaluate why evolution has not improved RuBisCO, and assess recent synthetic biology approaches to engineer an improved RuBisCO (e.g., Form II RuBisCO from bacteria, directed evolution) for crop improvement.

Answer (Q23, Synthesis). RuBisCO is slow (k_{cat} about 3 s⁻¹) and confuses CO₂ with O₂ because there is an intrinsic trade-off in its two-step carboxylation mechanism: variants with higher CO₂ specificity tend to be even slower, so evolution has reached a near-optimal compromise tuned to each organism’s CO₂ environment rather than a globally ‘better’ enzyme. Synthetic-biology strategies include installing faster bacterial Form II RuBisCO (high k_{cat} but poor specificity, useful with a CO₂-concentrating mechanism), engineering carboxysome/pyrenoid CO₂-concentrating systems around RuBisCO, and directed evolution that has roughly doubled the specificity factor in lab variants. These are promising but face the

speed–specificity trade-off and the difficulty of assembling functional plant RuBisCO in crops. See section 10. 24. Shade-adapted plants have higher LHCII content and lower PSII/PSI ratios than sun plants. Evaluate the molecular mechanisms of this acclimation: how does excess excitation pressure in low light signal LHCII assembly vs LHCII disassembly in high light? What role does STN7 kinase (LHCII phosphorylation) play in state transitions?

Answer (Q24, Synthesis). Acclimation is driven by the redox state of the plastoquinone pool sensing excitation balance. In low light/shade, cells build more LHCII and lower the PSII:PSI ratio to maximize capture. Imbalanced excitation that over-reduces the PQ pool activates the STN7 kinase, which phosphorylates LHCII so it migrates from PSII to PSI (state transition, redistributing energy); when PSI is over-excited and the PQ pool is oxidised, STN7 is inactive and the PPH1/TAP38 phosphatase dephosphorylates LHCII, returning it to PSII. Longer-term, this redox signaling also adjusts photosystem stoichiometry and antenna size between sun and shade plants. See section 10. 25. Oxygenic photosynthesis evolved about 2.7 billion years ago and fundamentally transformed Earth’s atmosphere. Evaluate the geochemical evidence (banded iron formations, the Great Oxidation Event) for the timing of oxygenic photosynthesis. What was the ecological impact on anaerobic life, and how did some lineages evolve oxygen tolerance?

Answer (Q25, Synthesis). Oxygenic photosynthesis arose in cyanobacteria, with the Great Oxidation Event about 2.4 Ga. Geochemical evidence: banded iron formations record episodic O₂ oxidising dissolved Fe²⁺ to insoluble Fe³⁺ before free O₂ accumulated; the disappearance of detrital pyrite/uraninite, the rise of red beds, and the loss of mass-independent sulfur isotope fractionation mark the GOE. Ecologically, O₂ was toxic to obligate anaerobes, driving them to anoxic refugia (a mass extinction for some lineages) while others evolved oxygen tolerance — antioxidant enzymes (superoxide dismutase, catalase) and ultimately aerobic respiration, which exploited O₂ as a high-yield electron acceptor. See section 10. 26. Synthetic biology has produced a “photosynthetic organism” where an entire C₄ photosynthetic apparatus is introduced into a C₃ plant (C₄ rice project). Evaluate what genetic modifications are required, which modifications have been achieved, and what the bottlenecks are for realizing this in a crop plant.

Answer (Q26, Synthesis). Engineering C₄ photosynthesis into C₃ rice requires installing the C₄ biochemical cycle (PEP carboxylase, NADP-malate dehydrogenase/malic enzyme, PEP carboxykinase, regulated RuBisCO localization) and, critically, Kranz-type leaf anatomy with distinct mesophyll and bundle-sheath cells plus appropriate plasmodesmatal connectivity and cell-specific gene expression. Individual C₄ enzymes have been expressed in rice, but the developmental programming of Kranz anatomy and proper inter-cellular metabolite partitioning remain the major unsolved bottlenecks, so a fully functional C₄ crop has not yet been achieved — judgement here is provisional pending demonstrated anatomical reprogramming. See section 10. 27. Photoinhibition occurs when PSII is irreversibly damaged by excess light. The D1 protein of PSII is a site of photodamage and must be replaced every about 30 minutes under high light. Evaluate the molecular mechanism of D1 turnover (degradation by FtsH protease, ribosomal de novo synthesis, PSII reassembly in thylakoid membrane) and explain why this turnover rate limits maximal photosynthetic productivity.

Answer (Q27, Synthesis). High light over-excites PSII; reactive oxygen species (notably singlet O₂) damage the D1 reaction-center protein, which must be replaced every about 30 minutes — the fastest protein turnover known. The PSII-repair cycle: damaged PSII is partly disassembled and moved from grana to stroma lamellae, D1 is selectively degraded by the FtsH (and Deg) proteases, a new D1 is synthesized by thylakoid-bound ribosomes and co-translationally inserted, then PSII is reassembled and the Mn₄CaO₅ cluster photoactivated. Because repair has a finite maximal rate, when photodamage outpaces it net photosynthesis declines (chronic photoinhibition), capping maximal productivity under intense light. See section 10. 28. Horizontal gene transfer of photosynthesis genes between cyanobacteria and early eukaryotes (primary endosymbiosis) versus between non-photosynthetic organisms and photosynthetic ones (secondary endosymbiosis) produced the diverse eukaryotic algal groups. Evaluate the complexity of gene transfer that was required to set up a functional chloroplast, focusing on the challenge of targeting nuclear-encoded proteins to the chloroplast (TIC/TOC translocon import).

Answer (Q28, Synthesis). Establishing a functional chloroplast required far more than transferring photosynthesis genes. After primary endosymbiosis of a cyanobacterium, the bulk of the endosymbiont genome was lost or transferred to the host nucleus (endosymbiotic gene transfer), so about 95% of chloroplast proteins are now nuclear-encoded and must be re-imported. This demanded evolution of N-terminal transit peptides and the TOC/TIC translocon machinery to target and translocate proteins across the double envelope, plus regulatory integration of two genomes. In secondary endosymbiosis (a eukaryotic alga engulfed by another eukaryote) the problem compounds: extra membranes require additional targeting signals and a more complex import route, making the assembly of a working plastid a remarkable multi-step evolutionary achievement. See section 10. 29. Phytoplankton (mainly diatoms, dinoflagellates, cyanobacteria) account for about 50% of global CO₂ fixation despite having about 1% of terrestrial plant biomass. Evaluate what properties of aquatic photosynthesis explain this high per-mass productivity, and assess the feasibility of enhancing ocean photosynthesis (e.g., iron fertilization) as a climate change mitigation strategy.

Answer (Q29, Synthesis). Phytoplankton fix about 50% of global CO₂ with about 1% of photosynthetic biomass because of extremely high turnover, not standing stock: short cell-cycle times, no investment in non-photosynthetic structural tissue (roots, wood), efficient nutrient and light capture

in the mixed layer, and many have CO₂-concentrating mechanisms (carboxysomes/pyrenoids) that suppress photorespiration. Iron fertilization can transiently bloom phytoplankton in iron-limited (HNLC) oceans, but its value as durable carbon sequestration is doubtful: most fixed carbon is rapidly respired and recycled, export to the deep ocean is low and hard to verify, and ecological side-effects (toxic blooms, deoxygenation, nutrient robbing) are significant — so it is not an established climate solution. See section 10. 30. Critically assess whether an organism could be engineered to simultaneously perform photosynthesis AND oxidative phosphorylation in the same compartment. What major thermodynamic and biochemical obstacles would need to be overcome? (Consider: O₂ produced by photosynthesis would support oxidative phosphorylation, but the competing demands for NAD(P)H, the different evolutionary origins of the two systems, and the compartmentation challenges in a single organelle context.)

Answer (Q30, Synthesis). In principle photosynthesis and oxidative phosphorylation are complementary (O₂ and reductant from one could feed the other), and some organisms already run both in separate organelles. Co-locating them in one compartment faces major obstacles: both build proton-motive forces and compete for the same electron carriers and quinone/cytochrome pools, so uncoordinated operation would short-circuit gradients and create futile cycles; the systems compete for NAD(P)H and ADP/Pi pools; photosynthetic O₂ and ROS would oxidatively damage respiratory chains; and the two machineries have distinct evolutionary origins, lipid environments, and regulation that would require extensive re-engineering and tight temporal/spatial separation. The judgement that this is feasible would change only if robust regulatory insulation and gradient/redox partitioning could be demonstrated — currently a formidable, largely unmet challenge. See section 10.

Questions — Metabolic Integration and Regulation

Instructor Use and Coverage Notes

- Coverage target: Predict how a change in substrate, hormone, or enzyme activity redirects flux.
- Model/data emphasis: Energy charge, control points, and pathway-flux comparisons.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis.
- Misconception probe: A pathway is not a one-way assembly line; reversibility and regulation define the real route.
- Transfer product: Apply metabolic network reasoning to diabetes, fasting, exercise, or cancer metabolism.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 11 of the textbook — review that chapter before attempting the exercises below.

1. What does “metabolic integration” mean? Give one example of how carbohydrate and lipid metabolism are connected.

Answer (Q1, Recall). Metabolic integration is the coordinated regulation of multiple pathways and organs so fuel supply matches demand and futile cycling is avoided. A classic example: in the fed state insulin promotes glucose uptake and lipogenesis (acetyl-CoA → malonyl-CoA → fatty acids), while in fasting glucagon activates lipolysis and β -oxidation so fatty-acid-derived acetyl-CoA fuels the liver and spares glucose for the brain — carbohydrate status directly sets lipid flux. See section 11. 2. Define anabolism and catabolism. Give one example of each.

Answer (Q2, Recall). Catabolism breaks complex molecules into simpler ones, releasing energy and reducing power (e.g. glucose oxidation via glycolysis and the TCA cycle). Anabolism builds complex molecules using energy and reducing power (e.g. fatty acid synthesis from acetyl-CoA, or gluconeogenesis). They are reciprocally regulated so both do not run at once. See section 11. 3. What is the role of AMP:ATP ratio as a metabolic signal? Which enzyme is the key AMP sensor?

Answer (Q3, Recall). A rising AMP:ATP (and ADP:ATP) ratio signals energy deficit, allosterically and covalently shifting metabolism toward ATP-producing catabolism. The key AMP sensor is AMP-activated protein kinase (AMPK): AMP binding (and LKB1 phosphorylation) activates it when cellular energy charge falls. See section 11. 4. What is AMPK? Describe two metabolic processes it activates and two it inhibits.

Answer (Q4, Recall). AMPK is the cell’s low-energy sensor, activated by a high AMP:ATP ratio. It activates catabolic, ATP-generating processes — e.g. glucose uptake (GLUT4) and fatty acid oxidation (by inhibiting acetyl-CoA carboxylase, lowering malonyl-CoA). It inhibits anabolic, ATP-consuming processes — e.g. fatty acid/cholesterol synthesis (ACC, HMG-CoA reductase) and mTORC1-driven protein synthesis. See section 11. 5. What is mTOR? What signals activate it, and what anabolic processes does it promote?

Answer (Q5, Recall). mTOR (mechanistic target of rapamycin), as mTORC1, is the cell’s nutrient/growth sensor. It is activated by amino acids (via Rag GTPases and the Ragulator at the lysosome), insulin/growth-factor signaling through PI3K–Akt, and a high energy charge. It promotes anabolism: protein synthesis (S6K1, 4E-BP1), lipid and nucleotide synthesis, and ribosome biogenesis, while suppressing autophagy. See section 11. 6. Name the organs that play a primary role in glucose homeostasis after a meal.

Answer (Q6, Recall). After a meal the principal organs are the pancreas (β -cells secrete insulin in response to rising glucose), the liver (takes up glucose, stores glycogen, runs lipogenesis), skeletal muscle (insulin-stimulated GLUT4 glucose uptake and glycogen synthesis), and adipose tissue (glucose uptake and triacylglycerol storage). See section 11. 7. What is the metabolic role of the liver in the fed vs fasted state?

Answer (Q7, Recall). Fed state: high insulin/low glucagon — the liver takes up glucose, makes glycogen and fatty acids (lipogenesis), and suppresses glucose output. Fasted state: low insulin/high glucagon — the liver releases glucose by glycogenolysis then gluconeogenesis, and produces ketone bodies from fatty-acid-derived acetyl-CoA to fuel peripheral tissues and brain. See section 11. 8. Define the Cori cycle. Which two organs are involved, and which molecule cycles between them?

Answer (Q8, Recall). The Cori cycle links exercising/anaerobic muscle and the liver. Muscle produces lactate by glycolysis; lactate travels to the liver and is converted back to glucose by gluconeogenesis (net cost about 6 ATP in liver), and that glucose returns to muscle. Lactate is the molecule that cycles between the two organs. See section 11. 9. What is the glucose-fatty acid cycle (Randle cycle)? What is the primary substrate competition it describes?

Answer (Q9, Recall). The Randle (glucose–fatty acid) cycle describes reciprocal substrate competition in heart and skeletal muscle: increased fatty acid oxidation raises acetyl-CoA and citrate, inhibiting pyruvate dehydrogenase and PFK-1, so glucose oxidation falls — and conversely high glucose suppresses fatty acid oxidation. The core competition is between glucose and fatty acids as oxidative fuels. See section 11. 10. Define metabolic syndrome. List four diagnostic criteria.

Answer (Q10, Recall). Metabolic syndrome is a cluster of cardiometabolic risk factors driven by insulin resistance and central adiposity. Four diagnostic criteria (any three define it): central/abdominal obesity (large waist circumference), elevated fasting glucose (or insulin resistance), elevated triglycerides, reduced HDL cholesterol, and elevated blood pressure. See section 11.

Questions 11–20: Application and Analysis

11. After a high-carbohydrate meal, blood glucose rises. Trace the hormonal and metabolic responses in: (a) the pancreas; (b) the liver; (c) skeletal muscle; (d) adipose tissue — over the 2 hours post-meal.

Answer (Q11, Application). (a) Pancreas: rising glucose triggers β -cell insulin secretion (and suppresses glucagon). (b) Liver: insulin promotes glucokinase, glycogen synthase activation and glycogen storage, lipogenesis, and shuts off gluconeogenesis. (c) Skeletal muscle: insulin-PI3K-Akt drives GLUT4 translocation, glucose uptake, and glycogen synthesis. (d) Adipose tissue: GLUT4-mediated glucose uptake, lipoprotein-lipase-mediated fatty acid uptake, and triacylglycerol storage with suppressed lipolysis. Over about 2 h blood glucose normalizes and the body is in an anabolic, storage state. See section 11. 12. During prolonged fasting (48 hours), the body must maintain blood glucose for the brain. List in order the fuels used: (a) which depot is depleted first; (b) when and where does gluconeogenesis begin; (c) when do ketone bodies become the primary brain fuel?

Answer (Q12, Application). (a) Liver glycogen is depleted first (largely gone by about 24 h). (b) Gluconeogenesis (from lactate, glycerol, glucogenic amino acids) ramps up in the liver within hours and dominates after glycogen is exhausted; the renal cortex contributes increasingly with prolonged fasting. (c) Ketone bodies rise over 1–2 days and, after about 3 days of fasting, supply up to about 75% of the brain’s fuel, sparing glucose and limiting muscle proteolysis. See section 11. 13. Insulin stimulates GLUT4 translocation to the plasma membrane of muscle and adipose cells via PI3K-Akt-AS160 pathway. Explain the molecular cascade from insulin receptor activation to GLUT4 vesicle exocytosis. What happens to GLUT4 when insulin is removed?

Answer (Q13, Application). Insulin binds its receptor tyrosine kinase → receptor autophosphorylation → IRS-1 phosphorylation → PI3K → PIP3 → PDK1/Akt activation → Akt phosphorylates AS160 (TBC1D4), relieving its Rab-GAP activity → active Rab10 permits GLUT4 storage vesicles to dock and fuse via SNAREs at the plasma membrane, increasing glucose uptake. When insulin is removed, the cascade reverses, GLUT4 is endocytosed and recycled back to intracellular vesicles, and glucose uptake falls. See section 11. 14. PFK-1 (phosphofructokinase-1) is a key regulatory enzyme of glycolysis. It is activated by AMP, ADP, and fructose-2,6-bisphosphate (F-2,6-BP) and inhibited by ATP, citrate, and H^+ . Explain how each regulator makes physiological sense in terms of energy status signaling.

Answer (Q14, Application). PFK-1 catalyses the committed glycolytic step and is tuned to energy status. AMP and ADP rise when ATP is low and activate PFK-1 (more glycolysis to make ATP). Fructose-2,6-bisphosphate, high when insulin/fed signaling raises glycolysis, is a potent activator. ATP (substrate at high concentration) and citrate (signaling abundant TCA fuel) inhibit it, and H^+ inhibits it to prevent excessive lactic acid in hypoxia — each regulator matches glycolytic flux to need. See section 11. 15. A patient with Type 2 Diabetes has high fasting blood glucose and high insulin (insulin resistance). Explain: (a) why cells are resistant to insulin; (b) why the liver continues gluconeogenesis despite high insulin; (c) what happens to HbA1c in chronic hyperglycaemia; (d) why metformin (activates AMPK) is effective.

Answer (Q15, Application). (a) Cells are insulin-resistant because chronic nutrient/lipid excess and inflammation cause serine phosphorylation of IRS-1, blunting PI3K-Akt and GLUT4 translocation. (b) The liver keeps making glucose because hepatic insulin signaling (FOXO1 suppression) is impaired while glucagon and substrate supply persist. (c) Chronic hyperglycaemia non-enzymatically glycates hemoglobin, so HbA1c rises (reflecting about 3-month average glucose). (d) Metformin works by activating AMPK (via Complex I inhibition raising AMP/ATP), suppressing hepatic gluconeogenesis and improving insulin sensitivity. See section 11. 16. The malate-aspartate shuttle moves NADH equivalents from the cytoplasm to the mitochondrial matrix. Explain: (a) why direct NADH cannot cross the inner mitochondrial membrane; (b) the carrier proteins involved; (c) why cardiac muscle prefers this shuttle over the glycerol-3-phosphate shuttle.

Answer (Q16, Application). (a) The inner mitochondrial membrane has no NADH transporter, so cytosolic NADH electrons must be shuttled in. (b) The malate-aspartate shuttle uses malate dehydrogenase and aspartate aminotransferase on both sides plus the malate- α -ketoglutarate and glutamate-aspartate antiporters. (c) Cardiac muscle prefers it because it regenerates matrix NADH (entering at Complex I, about 2.5 ATP per pair) rather than FADH₂-equivalents via the glycerol-3-phosphate shuttle (about 1.5 ATP), maximizing ATP yield for the continuously working heart. See section 11. 17. Brown adipose tissue (BAT) thermogenesis is mediated by UCP1. Explain the adrenergic activation cascade: cold → sympathetic nervous system → β_3 -adrenergic receptor → cAMP → PKA → hormone-sensitive lipase → free fatty acid (FFA) release → FFA activate/open UCP1 → H^+ leak → heat. At which step is UCP1 expression also increased transcriptionally?

Answer (Q17, Application). Cold → sympathetic noradrenaline → β_3 -adrenergic receptor → Gs → adenylyl cyclase → cAMP → PKA. PKA phosphorylates hormone-sensitive lipase (and perilipin), releasing free fatty acids from lipid droplets. The FFAs both directly activate UCP1 and serve as fuel; UCP1 lets protons re-enter the matrix bypassing ATP synthase, dissipating the proton-motive force as heat. Transcriptionally, the same

cAMP–PKA signaling activates PGC-1 α /CREB, increasing UCP1 gene expression for longer-term cold adaptation. See section 11. 18. Glucagon activates gluconeogenesis in liver cells. Trace from glucagon binding \rightarrow Gs \rightarrow cAMP \rightarrow PKA \rightarrow phosphorylation of CREB \rightarrow activation of PEPCK and G6Pase gene transcription. How does insulin oppose this pathway via Akt (inactivating FOXO1 transcription factor)?

Answer (Q18, Application). Glucagon binds its Gs-coupled receptor \rightarrow adenylyl cyclase \rightarrow cAMP \rightarrow PKA \rightarrow PKA phosphorylates CREB \rightarrow CREB (with co-activator) drives transcription of PEPCK and glucose-6-phosphatase, raising gluconeogenic capacity (and PKA also activates glycogenolysis acutely). Insulin opposes this: insulin \rightarrow PI3K \rightarrow Akt phosphorylates FOXO1, excluding it from the nucleus so PEPCK/G6Pase transcription falls, and Akt also inactivates the cAMP signal — shutting down hepatic glucose output. See section 11. 19. The hypothalamus integrates hunger and satiety signals from peripheral hormones (leptin, ghrelin, PYY, insulin). Explain: (a) which neurons (NPY/AgRP vs POMC/CART) are activated by fasting vs feeding; (b) how melanocortin-4 receptor (MC4R) controls food intake; (c) why leptin resistance in obesity prevents normalization of energy balance.

Answer (Q19, Application). (a) Fasting (low leptin/insulin, high ghrelin) activates orexigenic NPY/AgRP neurons; feeding (high leptin/insulin, PYY) activates anorexigenic POMC/CART neurons. (b) POMC-derived α -MSH activates the melanocortin-4 receptor (MC4R) to suppress food intake, while AgRP is an MC4R inverse agonist that increases intake — MC4R is the integrating node. (c) In obesity, chronic hyperleptinaemia plus inflammatory/SOCS3-mediated signaling blunting causes leptin resistance, so the satiety signal is not transduced and energy balance is not corrected despite high fat stores. See section 11. 20. Fatty acid synthesis and β -oxidation cannot occur simultaneously — they would create a futile cycle. Explain how the cell prevents this: (a) what molecule inhibits carnitine palmitoyltransferase I (CPTI) during fatty acid synthesis; (b) in which compartment is malonyl-CoA produced; (c) why this system specifically blocks mitochondrial FA import while allowing FA synthesis in the cytoplasm.

Answer (Q20, Application). (a) Malonyl-CoA inhibits carnitine palmitoyltransferase I (CPT-1). (b) Malonyl-CoA is produced in the cytoplasm by acetyl-CoA carboxylase (the committed step of fatty acid synthesis). (c) Because CPT-1 sits on the outer mitochondrial membrane and gates long-chain fatty-acyl entry into the matrix, blocking CPT-1 stops β -oxidation while cytoplasmic fatty acid synthesis continues unhindered — so in the fed/lipogenic state newly made fatty acids are not immediately re-oxidised, preventing a futile cycle. See section 11.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the “fuel partitioning” hypothesis in obesity: does obesity arise primarily from excess carbohydrate or excess fat intake, and does macronutrient composition matter for energy balance beyond caloric excess? Cite the results of isocaloric controlled diet trials.

Answer (Q21, Synthesis). Evidence from tightly controlled isocaloric feeding and metabolic-ward studies indicates that total energy balance, not macronutrient ratio, is the dominant determinant of fat mass: when calories are matched, low-carb and low-fat diets produce similar fat loss. Macronutrient composition still matters secondarily through satiety, adherence, the thermic effect of protein, and glycaemic/insulin dynamics. The carbohydrate–insulin model’s strong claim is weakened by isocaloric trials; what would change the conclusion is reproducible isocaloric data showing a macronutrient-specific difference in energy expenditure or fat storage. See section 11. 22. Evaluate the ketogenic diet as a treatment for drug-resistant epilepsy. Propose at least three molecular mechanisms by which elevated ketone bodies (β -hydroxybutyrate primarily as an HDAC inhibitor, adenosine release, or KATP channel opening) could reduce neuronal excitability.

Answer (Q22, Synthesis). Proposed mechanisms by which ketosis reduces seizures: (1) β -hydroxybutyrate acts as a class-I HDAC inhibitor, shifting transcription toward antioxidant/anticonvulsant gene programs; (2) ketone metabolism and reduced glycolysis open neuronal KATP channels and hyperpolarise neurons, lowering excitability; (3) shifted metabolism raises inhibitory tone (more GABA, increased adenosine signaling) and stabilizes mitochondrial energy supply, reducing neuronal hyperexcitability. The ketogenic diet has reproducible clinical benefit in drug-resistant epilepsy, though the precise dominant mechanism remains uncertain and tolerability/adherence limit it. See section 11. 23. Design an experiment to determine whether AMPK activation in liver cells reduces hepatic glucose output primarily by: (a) decreasing gluconeogenesis gene expression; (b) acutely phosphorylating and inactivating TORC2 (CREB co-activator); (c) decreasing hepatic ATP to slow enzymatic gluconeogenesis. Distinguish these mechanisms using selective inhibitors and reporter assays.

Answer (Q23, Synthesis). Hypothesis: AMPK lowers hepatic glucose output primarily by (a) repressing PEPCK/G6Pase transcription, (b) acutely phosphorylating/inactivating the CREB co-activator CRTC2 (TORC2), or (c) lowering ATP to slow gluconeogenic enzymes. In hepatocytes, activate AMPK (AICAR/metformin) and compare with vehicle controls; measure glucose output, PEPCK/G6Pase mRNA (qPCR/reporter), CRTC2 phosphorylation/nuclear localization, and cellular ATP. Use a transcription-blocked condition (actinomycin D) to isolate non-transcriptional effects and a CRTC2-phospho-mutant to test mechanism (b). Replicate across independent hepatocyte preparations; a falsifying result is full suppression of glucose output with unchanged mRNA, CRTC2 phosphorylation, and ATP. See section 11. 24. Evaluate the evidence for “metabolic flexibility” — the ability of healthy cells to switch between glucose and fat oxidation based on substrate availability. How does this differ in Type 2 Diabetes, insulin resistance, and cancer cells? What biochemical assay (Seahorse XF analyser) measures metabolic flexibility?

Answer (Q24, Synthesis). Metabolic flexibility is the capacity to switch readily between glucose and fat oxidation with fed/fasted state — evidenced by respiratory quotient shifts and substrate-switching after insulin. In Type 2 diabetes and insulin resistance this flexibility is lost (‘metabolic inflexibility’): muscle fails to suppress fat oxidation in the fed state and fails to up-regulate it in fasting. Cancer cells are biased toward aerobic glycolysis (Warburg) and glutamine use rather than flexible switching. The Seahorse XF analyser measures it by recording oxygen consumption rate and extracellular acidification rate while sequentially adding substrates and inhibitors, quantifying oxidative vs glycolytic capacity. See section 11. 25. The metabolic role of the gut microbiome is increasingly recognized: SCFAs (acetate, propionate, butyrate) produced by bacterial fermentation of dietary fiber signal to host cells. Evaluate how propionate signals to the liver (inhibiting gluconeogenesis) and butyrate signals to colonocytes (primary fuel) and immune cells (HDAC inhibition, regulatory T cell induction).

Answer (Q25, Synthesis). Gut bacteria ferment dietary fiber to short-chain fatty acids that act as inter-organ signals. Propionate is absorbed and reaches the liver, where it signals (via FFAR3/GPR41 and as a gluconeogenic/intestinal-gluconeogenesis cue) to restrain hepatic glucose output and improve glucose homeostasis. Butyrate is the primary oxidative fuel for colonocytes and, in immune cells, acts as an HDAC inhibitor that promotes regulatory T-cell differentiation and an anti-inflammatory tone — linking the microbiome to host energy balance and immunometabolism. See section 11. 26. Evaluate the metabolic rationale for intermittent fasting (IF) regimens (16:8 time-restricted eating, 5:2 alternate-day fasting). Identify three metabolic benefits of IF beyond simple caloric restriction, and propose the molecular mechanisms driving each benefit.

Answer (Q26, Synthesis). Beyond simple calorie reduction, intermittent fasting confers benefits via distinct molecular mechanisms: (1) periodic low energy charge activates AMPK and lowers mTORC1, inducing autophagy and improving cellular quality control; (2) the fasting/feeding cycle improves insulin sensitivity and metabolic flexibility by lowering insulin and depleting hepatic glycogen, increasing fat oxidation; (3) ketone bodies (notably β -hydroxybutyrate) rise and act as signaling molecules (HDAC inhibition, NLRP3 inflammasome suppression), reducing inflammation. Clinical evidence is promising but partly confounded by adherence and total energy intake; an isocaloric IF-vs-continuous trial showing IF-specific benefit would strengthen the case. See section 11. 27. Cancer cells depend on glutamine (not glucose) for anaplerosis — replenishing TCA cycle intermediates for biosynthesis. Evaluate: (a) which TCA intermediate is most depleted in rapidly proliferating cells; (b) how glutamine enters the TCA cycle (via glutaminase \rightarrow glutamate \rightarrow α -ketoglutarate); (c) why targeting glutamine metabolism (CB-839, a glutaminase inhibitor) might be selectively toxic to cancer cells.

Answer (Q27, Synthesis). (a) Oxaloacetate (and α -ketoglutarate-derived intermediates) is most depleted because biosynthesis siphons TCA intermediates (‘cataplerosis’). (b) Glutamine enters via glutaminase \rightarrow glutamate \rightarrow (transaminase/glutamate dehydrogenase) \rightarrow α -ketoglutarate, which replenishes the cycle (anaplerosis) for energy and biosynthetic precursors. (c) Many proliferating tumors are ‘glutamine-addicted’ for anaplerosis and redox/biosynthesis, so a glutaminase inhibitor (CB-839/telaglenastat) can be more toxic to them than to normal tissue that has flexible anaplerotic sources — though efficacy is context-dependent and resistance can arise. See section 11. 28. Evaluate the concept of “metaflammation” — the chronic low-grade inflammation seen in obesity. Propose a mechanistic link from adipocyte lipid overload \rightarrow ER stress \rightarrow NF- κ B activation \rightarrow pro-inflammatory cytokine (TNF- α , IL-6) secretion \rightarrow insulin resistance in muscle and liver. At which step would you intervene pharmacologically?

Answer (Q28, Synthesis). Metaflammation is chronic low-grade inflammation from nutrient overload. Mechanistic chain: adipocyte lipid overload and ectopic lipid \rightarrow ER stress and excess saturated FFAs/diacylglycerol \rightarrow activation of JNK and IKK β /NF- κ B \rightarrow secretion of TNF- α , IL-6, and MCP-1 with macrophage infiltration \rightarrow these cytokines drive serine phosphorylation of IRS-1 in muscle and liver, impairing PI3K-Akt and causing insulin resistance. Pharmacological intervention is most rational upstream — reducing lipid overload and ER/inflammatory signaling (e.g. weight loss, GLP-1 agonists, or targeting JNK/IKK β /NF- κ B) rather than blocking a single downstream cytokine. See section 11. 29. NAFLD (non-alcoholic fatty liver disease) progresses from steatosis \rightarrow NASH (steatohepatitis) \rightarrow cirrhosis. Evaluate the “two-hit hypothesis”: what is the first hit (lipid accumulation), what is the second hit (oxidative stress, inflammatory cytokines from adipose tissue or gut microbiome), and why targeting a single hit is insufficient for treatment?

Answer (Q29, Synthesis). First hit: triacylglycerol accumulation in hepatocytes (steatosis) from increased FFA delivery, de novo lipogenesis, and impaired export. Second hit: oxidative stress from incomplete fatty acid oxidation (ROS), plus inflammatory cytokines and endotoxin from adipose tissue and the gut microbiome, driving hepatocyte injury and inflammation (NASH) that progresses to fibrosis/cirrhosis. Targeting only one hit is insufficient because steatosis alone is relatively benign and the lipotoxic/inflammatory second hit independently drives progression — effective therapy must reduce lipid load and the oxidative/inflammatory injury together. See section 11. 30. Critically evaluate the use of GLP-1 receptor agonists (semaglutide, tirzepatide) for obesity treatment. What are the distinct mechanisms by which GLP-1 agonists reduce appetite (hypothalamic signaling), slow gastric emptying, and promote pancreatic β -cell survival? What are the metabolic consequences of rapid weight loss induced by these drugs (muscle loss, bone density) and how should therapy be managed?

Answer (Q30, Synthesis). GLP-1 receptor agonists act through distinct mechanisms: in the hypothalamus they activate POMC/CART and suppress NPY/AgRP neurons to reduce appetite; in the gut they slow gastric emptying, prolonging satiety; and on pancreatic β -cells they enhance glucose-dependent insulin secretion and promote β -cell survival/function. Rapid drug-induced weight loss carries metabolic consequences — loss of lean

muscle mass and reduced bone mineral density. Management should pair therapy with adequate protein intake and resistance exercise, gradual titration to limit GI effects, and monitoring of body composition and bone health, with attention to weight regain on discontinuation. See section 11.

Questions — DNA Replication and the Cell Cycle

Instructor Use and Coverage Notes

- Coverage target: Calculate replication timing or error burden and infer checkpoint consequences.
- Model/data emphasis: Replication-fork speed, error-rate, and cell-cycle timing calculations.
- Assessment alignment: Concept Explanation, Questions and Methods, Argumentation.
- Misconception probe: High fidelity is not automatic; it is built from multiple partially redundant safeguards.
- Transfer product: Transfer replication logic to cancer, aging, viral replication, or antibiotic targets.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 12 of the textbook — review that chapter before attempting the exercises below.

1. Describe the semiconservative model of DNA replication. What experiment confirmed it (Meselson-Stahl, 1958)?

Answer (Q1, Recall). Each daughter molecule retains one parental strand and one newly synthesized strand, so replication is semiconservative. Meselson and Stahl (1958) grew *E. coli* in heavy ¹⁵N medium, switched to light ¹⁴N, and used CsCl density-gradient centrifugation: after one round all DNA was hybrid (intermediate) density, and after two rounds half was hybrid and half fully light, which is exactly what the semiconservative model predicts and rules out conservative and dispersive models. See section 12.

2. List the enzymes required for DNA replication and state one function of each.
- Answer (Q2, Recall). Helicase unwinds the double helix at the fork; single-strand binding (SSB) proteins keep the strands apart; topoisomerase/gyrase relieves the supercoiling ahead of the fork; primase lays down RNA primers; DNA polymerase (Pol III in bacteria; Pol δ/ε in eukaryotes) extends DNA and proofreads; a sliding clamp (β-clamp/PCNA) confers processivity; and DNA ligase seals the nicks between fragments. See section 12.

3. Why does DNA polymerase require a primer? Who synthesizes the primer?
- Answer (Q3, Recall). DNA polymerase can only extend a pre-existing 3'-OH end and cannot start a strand de novo, so it needs a primer to provide that 3'-OH. The RNA primer is synthesized by primase, a specialized RNA polymerase (part of the primosome in bacteria; the Pol α-primase complex in eukaryotes). See section 12.

4. Distinguish the leading strand from the lagging strand during replication. Why does the lagging strand form Okazaki fragments?
- Answer (Q4, Recall). The leading strand is synthesized continuously in the 5'→3' direction as the fork opens, while the lagging strand runs antiparallel so its 5'→3' synthesis proceeds away from the fork. Because polymerase cannot synthesize 3'→5', the lagging strand is made in short Okazaki fragments (about 1,000–2,000 nt in prokaryotes, about 100–200 nt in eukaryotes), each separately primed and later joined by ligase. See section 12.

5. What is the replication fork? Name the enzyme that separates the double helix at the fork.
- Answer (Q5, Recall). The replication fork is the Y-shaped region where the parental duplex is unwound and the two template strands are being copied. DNA helicase (DnaB in *E. coli*; the MCM2-7 complex in eukaryotes) unwinds and separates the double helix at the fork. See section 12.

6. Name the four phases of the eukaryotic cell cycle. What occurs in each?
- Answer (Q6, Recall). The four phases are G1 (cell growth and preparation for DNA synthesis), S (DNA replication, producing identical sister chromatids), G2 (growth and checking of replicated DNA before division), and M (mitosis plus cytokinesis, segregating chromosomes into two daughter cells). G1, S, and G2 together form interphase. See section 12.

7. What are cyclins and cyclin-dependent kinases (CDKs)? Give one example of a cyclin-CDK pair and its function.
- Answer (Q7, Recall). Cyclins are regulatory proteins whose levels rise and fall through the cycle; CDKs are kinases that are catalytically active only when bound to their cyclin partner, phosphorylating substrates that drive cell-cycle transitions. For example, Cyclin B–CDK1 (M-phase promoting factor) triggers entry into mitosis by phosphorylating nuclear lamins, condensin, and other targets. See section 12.

8. What is a checkpoint? Name three checkpoints in the cell cycle and their functions.
- Answer (Q8, Recall). A checkpoint is a surveillance mechanism that halts cell-cycle progression until specific conditions are met, preventing propagation of damage. The G1/S (restriction) checkpoint verifies cell size, nutrients, and DNA integrity before S phase; the G2/M checkpoint confirms DNA is fully and correctly replicated before mitosis; and the spindle-assembly (M) checkpoint blocks anaphase until all kinetochores are properly attached to the spindle. See section 12.

9. What does the tumor suppressor protein p53 do when DNA damage is detected?
- Answer (Q9, Recall). DNA damage activates ATM/ATR kinases that stabilize p53 by blocking its MDM2-mediated degradation. p53 then acts as a transcription factor, inducing p21 to inhibit cyclin-CDK complexes and arrest the cycle for repair; if damage is irreparable, p53 drives apoptosis or

senescence, which is why it is called the guardian of the genome. See section 12. 10. What is telomerase? Why do most somatic cells lack telomerase activity?

Answer (Q10, Recall). Telomerase is a ribonucleoprotein reverse transcriptase that uses its own RNA template to add TTAGGG repeats to chromosome 3' ends, offsetting the end-replication problem. Most somatic cells repress the catalytic subunit hTERT, so telomeres shorten about 50–200 bp per division until critical shortening triggers senescence — a tumor-suppressive limit on proliferation. See section 12.

Questions 11–20: Application and Analysis

11. Using the Meselson-Stahl data: if ¹⁵N/¹⁵N-labeled DNA is allowed to replicate for two rounds in ¹⁴N medium, what densities of DNA are expected and in what proportions? Show your reasoning with a diagram.

Answer (Q11, Application). After two rounds of replication in ¹⁴N medium the original two ¹⁵N strands are conserved, each now paired with a new light strand, giving two hybrid (intermediate-density) molecules. The other two molecules are fully light (¹⁴N/¹⁴N). So the expectation is a 1:1 ratio of intermediate to light density and no fully heavy DNA, which is the diagnostic signature of semiconservative replication. See section 12. 12. DNA polymerase III (prokaryotic) and DNA polymerase δ/ϵ (eukaryotic) require a processivity clamp (β -clamp in prokaryotes; PCNA in eukaryotes). Explain how the sliding clamp increases processivity, and why this matters for replication speed of the 3×10^9 bp human genome.

Answer (Q12, Application). The sliding clamp is a ring that encircles DNA and tethers the polymerase to the template, preventing it from dissociating after each nucleotide. This raises processivity from about 10–100 nt to thousands of nucleotides per binding event, so the polymerase can copy long stretches without falling off — essential for replicating the 3×10^9 bp human genome at biologically feasible speed and within S phase. See section 12.

13. Okazaki fragments in eukaryotes are about 200 nucleotides (roughly one nucleosome length). After primase removes the primer, DNA pol δ fills the gap using the downstream Okazaki fragment as a flap. Explain the role of FEN1 (flap endonuclease) and DNA ligase in completing lagging strand synthesis.

Answer (Q13, Application). As Pol δ extends one Okazaki fragment into the RNA primer of the downstream fragment, it displaces that primer as a single-stranded 5' flap. FEN1 cleaves the displaced flap precisely at the base, leaving a nick with a 3'-OH and 5'-phosphate, and DNA ligase I then seals the nick with a phosphodiester bond, joining adjacent fragments into a continuous lagging strand. See section 12. 14. The G₁/S checkpoint (restriction point) ensures cells don't enter S phase with insufficient resources or DNA damage. Explain the molecular mechanism: how does mitogen (growth factor) signaling lead to Rb phosphorylation → release of E2F transcription factor → S-phase gene expression? At what step does p16 (CDKN2A tumor suppressor) block this pathway?

Answer (Q14, Application). Mitogen signaling activates Cyclin D–CDK4/6, which partially phosphorylates Rb; Cyclin E–CDK2 then hyperphosphorylates Rb, releasing E2F transcription factors that drive expression of S-phase genes (cyclin E, DNA polymerase, etc.), committing the cell past the restriction point. The p16 (CDKN2A) tumor suppressor blocks this upstream by inhibiting CDK4/6, so Rb stays hypophosphorylated and E2F remains sequestered. See section 12. 15. Aphidicolin blocks DNA polymerase α and δ , arresting cells at the G₁/S boundary. Hydroxyurea (HU) depletes dNTP pools. Compare the effects of each drug on: (a) replication fork speed; (b) fork stalling vs collapse; (c) activation of ATR checkpoint kinase; (d) cell cycle arrest phase.

Answer (Q15, Application). (a) Aphidicolin halts elongation by blocking Pol α/δ so forks stall with intact replisomes; HU lowers fork speed by depleting dNTPs. (b) Both initially cause reversible fork stalling, but prolonged exposure leads to fork collapse and double-strand breaks. (c) Both generate RPA-coated ssDNA that activates the ATR–CHK1 checkpoint. (d) Aphidicolin arrests cells at the G₁/S boundary and in early S; HU arrests cells in S phase. See section 12. 16. Telomere shortening occurs at a rate of about 100 bp per cell division in most somatic cells. Calculate how many divisions a cell with initial telomere length of 15 kb could undergo before reaching the critical length of 6 kb. What happens to cells that continue dividing past this limit (crisis)?

Answer (Q16, Application). Usable telomere reserve is 15 kb – 6 kb = 9 kb = 9,000 bp. At about 100 bp lost per division, that is 9,000/100 ≈ 90 divisions before reaching the critical 6 kb length. Cells dividing past this limit enter crisis: uncapped telomeres trigger end-to-end fusions, breakage-fusion-bridge cycles, and massive genomic instability, so most cells die and rare survivors typically reactivate telomerase. See section 12.

17. The spindle assembly checkpoint (SAC) detects kinetochores not under tension (unattached to spindle microtubules). Explain the molecular mechanism: how does an unattached kinetochore produce the wait anaphase signal (MCC complex), how does this inhibit APC/C (anaphase-promoting complex), and what happens to separase and cohesin when SAC is satisfied?

Answer (Q17, Application). An unattached or tensionless kinetochore recruits MAD/BUB proteins that catalyze formation of the mitotic checkpoint complex (MCC: Mad2–BubR1–Bub3–Cdc20). The MCC sequesters Cdc20, inhibiting the APC/C so securin and cyclin B are not degraded. Once all kinetochores achieve bipolar attachment the signal stops, APC/C–Cdc20 ubiquitinates securin, freeing separase to cleave cohesin and trigger anaphase. See section 12. 18. CDK1–Cyclin B drives entry into mitosis. CDK1–Cyclin B phosphorylates nuclear lamins (dissolving the nuclear

envelope), activates condensin (chromosome condensation), and activates APC/C (through intermediate steps). Explain why Cyclin B must be abruptly degraded at the metaphase-anaphase transition.

Answer (Q18, Application). Cyclin B–CDK1 enforces the mitotic state, but sister-chromatid separation and mitotic exit require its abrupt loss. At the metaphase–anaphase transition the active APC/C–Cdc20 ubiquitinates cyclin B for proteasomal degradation, inactivating CDK1. This irreversibly drops CDK1 activity, allowing dephosphorylation of its substrates so the nuclear envelope reforms, chromosomes decondense, and the cell cannot slip back into mitosis. See section 12. 19. Oncogenes often bypass cell cycle checkpoints. Compare how Ras (constitutively active mutant) vs Myc (overexpressed) each drive cell cycle progression: through which cyclin-CDK pair(s) do they act, and why do cells with oncogenic mutations often also need to lose p53 or Rb to become fully cancerous?

Answer (Q19, Application). Ras (constitutively active) sustains MAPK signaling that upregulates Cyclin D, activating CDK4/6 to drive the G1/S transition; Myc (overexpressed) transcriptionally boosts cyclins, CDKs, and E2F targets while repressing CDK inhibitors, also accelerating G1/S. These growth signals trigger oncogene-induced senescence or apoptosis via the p53 and Rb pathways, so cells must additionally lose p53 or Rb to disable that fail-safe and proliferate unchecked. See section 12. 20. Yeast two-hybrid screens identified that geminin (overexpressed in many cancers) inhibits Cdt1, preventing re-licensing of origins of replication. Explain: (a) what origin licensing means; (b) why re-replication would be catastrophic; (c) how overexpression of geminin PREVENTS re-replication by preventing MCM loading even after S phase begins.

Answer (Q20, Application). (a) Origin licensing is the G1 loading of MCM2-7 helicase double hexamers onto origins by ORC, Cdc6, and Cdt1 to form the pre-replicative complex, marking each origin to fire once. (b) Re-replication would over-amplify portions of the genome, causing gene-copy imbalance and DNA damage. (c) Geminin binds and inhibits Cdt1, blocking new MCM loading after S phase begins, so origins cannot be re-licensed and each fires only once per cycle. See section 12.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the precision of the S-phase checkpoint: ATR kinase is activated by RPA-coated single-stranded DNA (from stalled forks). How does this trigger CHK1 activation → Cdc25A phosphorylation → degradation → CDK2 inactivation → fork stabilization? What happens if ATR is constitutively inactive (as in a mutation)?

Answer (Q21, Synthesis). Stalled forks expose RPA-coated ssDNA, which recruits and activates ATR. ATR phosphorylates and activates CHK1, which phosphorylates Cdc25A, targeting it for degradation; loss of Cdc25A leaves CDK2 inhibitory phosphates in place, so CDK2 stays inactive, suppressing late origin firing and stabilizing existing forks for restart. If ATR is constitutively inactive, forks collapse into double-strand breaks, late origins fire inappropriately, and the cell accumulates genomic instability — ATR loss is generally lethal. See section 12. 22. Design an experiment to test whether telomerase reactivation in a telomere-shortened cancer cell line would allow unlimited proliferation or would require additional changes. Include: how you would deliver hTERT (the catalytic subunit), how you would measure telomere length over generations, and what growth advantage you would expect and under what assay conditions.

Answer (Q22, Synthesis). Hypothesis: hTERT alone extends replicative lifespan but is insufficient for full transformation. Stably transduce the cell line with an hTERT expression vector versus an empty-vector control, and measure telomere length over many passages by terminal restriction fragment Southern blot or qPCR. Predicted outcome: hTERT-expressing cells maintain telomere length and bypass senescence/crisis, but unlimited proliferation in soft-agar or xenograft assays still requires additional oncogenic changes (e.g., loss of p53/Rb), which would falsify a one-step model if hTERT alone sufficed. See section 12. 23. DNA replication is not 100% accurate — polymerase error rate is about 1 in 10⁷. After mismatch repair (MMR), the rate drops to about 1 in 10⁹. Evaluate: (a) the molecular mechanism of MMR (MutS, MutL, excision, resynthesis); (b) why MMR deficiency causes microsatellite instability (MSI); (c) why MSI cancers respond better to immune checkpoint inhibitors (PD-1 blockade).

Answer (Q23, Synthesis). (a) MMR uses MutS (MSH2/MSH6) to recognize mismatches and MutL (MLH1/PMS2) to coordinate excision of the error-containing nascent strand, followed by resynthesis and ligation. (b) MMR deficiency leaves slippage errors in repetitive tracts uncorrected, producing microsatellite instability (MSI). (c) MSI tumors accumulate many frameshift mutations and neoantigens, making them highly immunogenic, so they respond well to PD-1 immune checkpoint blockade. See section 12. 24. Evaluate origin-of-replication usage in cancer: cancer cells often show replication stress (RFS — replication fork stalling) due to premature S-phase entry driven by oncogenes. Propose how elevated RFS leads to: (a) DSB (double-strand break) formation at stalled forks; (b) inappropriate NHEJ repair causing chromosomal translocations; (c) selection pressure for p53 loss (cells that could normally checkpoint-arrest now instead die, so p53 loss allows survival).

Answer (Q24, Synthesis). (a) Oncogene-driven premature S-phase entry stalls and collapses forks, generating double-strand breaks. (b) Repair of these breaks by error-prone NHEJ joins inappropriate ends, producing chromosomal translocations and rearrangements. (c) The resulting DNA-damage response activates p53-dependent arrest, apoptosis, or senescence, creating strong selection for p53 loss so that damaged cells survive and proliferate — explaining why replication stress and TP53 mutation co-occur early in tumorigenesis. See section 12. 25. The pre-replication complex (pre-RC) assembly (ORC → Cdc6 → Cdt1 → MCM2-7) licenses origins from late mitosis to G₁. Evaluate two licensing control systems: (a) Cdt1

degradation (Cullin4-Cdt2 E3 ligase triggered by PCNA on DNA); (b) Geminin inhibition of Cdt1. Propose why two redundant mechanisms are needed, and what would happen if both were inactivated simultaneously.

Answer (Q25, Synthesis). Both systems restrict Cdt1 to prevent origin re-licensing: (a) once PCNA loads on DNA in S phase, the Cullin4-Cdt2 (CRL4^{Cdt2}) E3 ligase ubiquitinates Cdt1 for degradation; (b) geminin directly binds and sequesters Cdt1. Two redundant mechanisms provide fail-safe robustness because re-replication is catastrophic; if both were inactivated simultaneously, Cdt1 would persist, MCM helicases would reload, and origins would re-fire, causing re-replication, gene amplification, and severe genomic instability. See section 12. 26. Replication stress is thought to be the earliest event in pre-cancerous lesions (before DNA mutation). Evaluate the evidence from oncogene-induced senescence (OIS): how does RAS^{V12} overexpression initially stall replication forks and activate the DNA damage response (p53-p21 axis, producing cellular senescence) before genomic instability occurs?

Answer (Q26, Synthesis). RAS^{V12} overexpression forces premature, unscheduled origin firing and a surge in replication initiation that outstrips dNTP and replisome supply, stalling and collapsing forks. The resulting ssDNA and double-strand breaks activate the ATR/ATM DNA-damage response, which stabilizes p53 and induces p21, imposing a durable cell-cycle arrest (oncogene-induced senescence) that acts as a barrier to transformation before overt mutations or aneuploidy accumulate. See section 12. 27. Centromere identity in eukaryotes is determined not by DNA sequence but by the presence of CENP-A (a histone H3 variant). Evaluate the epigenetic model of centromere inheritance: how is CENP-A loaded (by HJURP chaperone) at each S phase, and how can a “centromere” be moved to a new chromosomal location (neocentromere formation)?

Answer (Q27, Synthesis). Centromere identity is epigenetic: the histone H3 variant CENP-A marks centromeric nucleosomes independently of the underlying DNA sequence. CENP-A is deposited by its dedicated chaperone HJURP in early G1 (not at S phase, when it is diluted twofold), and the existing CENP-A template self-templates new loading. Because the mark is sequence-independent, CENP-A can be seeded at a new locus to form a functional neocentromere, while an inactivated original centromere loses CENP-A. See section 12. 28. Multi-fork replication in prokaryotes: *E. coli* can initiate replication at the same origin before the previous round is complete (multi-fork replication), allowing doubling times faster than the S-phase duration. Evaluate whether eukaryotes could employ multi-fork replication and what structural constraints (nuclear envelope, nucleosomes, cohesin) would prevent this.

Answer (Q28, Synthesis). In *E. coli*, multi-fork (dichotomous) replication re-initiates at oriC before the prior round finishes, so doubling time can be shorter than the replication period. Eukaryotes do not do this: licensing is strictly limited to G1 by CDK and geminin control, so origins fire only once per cycle. Instead, eukaryotes solve the speed problem with tens of thousands of origins firing within one S phase, and the nuclear envelope, nucleosome assembly, and cohesin establishment further enforce a single, ordered round of replication. See section 12. 29. Evaluate the hypothesis that cancer is fundamentally a disease of the cell cycle: most hallmarks of cancer (unlimited proliferation, evasion of apoptosis, invasion) result from failure of cell cycle checkpoints rather than from any particular oncogenic mutation. Construct the best argument for and against this view using specific molecular examples.

Answer (Q29, Synthesis). For: nearly all cancer hallmarks converge on the cell-cycle machinery — Rb/E2F deregulation enables unchecked proliferation, p53 loss disables damage arrest and apoptosis, and checkpoint failure permits aneuploidy, so checkpoint loss is the common final pathway. Against: oncogene-specific effects matter beyond cycling — Ras alters metabolism and invasion, angiogenesis and immune evasion are not checkpoint phenomena, and identical checkpoint lesions yield different tumors, so the cell cycle is necessary but not a complete explanation. See section 12. 30. Critically evaluate the kinetics of DNA repair: NHEJ (non-homologous end joining, fast, about 30 min) and HR (homologous recombination, slow, requires sister chromatid, restricted to S/G2). Predict the consequences for genomic integrity if NHEJ were the primary repair pathway available in a cell. Why is NHEJ “error-prone” at the molecular level, and what types of mutations does it introduce?

Answer (Q30, Synthesis). NHEJ directly ligates broken ends rapidly and in any cell-cycle phase, whereas HR is slow and uses a sister chromatid for accurate repair in S/G2. If NHEJ were the only pathway, breaks would still be repaired quickly but with frequent small insertions/deletions and translocations, eroding genomic integrity over time. NHEJ is error-prone because it often trims or fills incompatible ends before ligation rather than restoring the original sequence, introducing indels and joining the wrong ends. See section 12.

Questions — Gene Expression

Instructor Use and Coverage Notes

- Coverage target: Translate or annotate a sequence and explain how a regulatory change alters output.
- Model/data emphasis: Reading-frame, codon, and expression-output calculations.
- Assessment alignment: Concept Explanation, Questions and Methods, Argumentation.
- Misconception probe: A gene is not simply a protein recipe; context controls when, where, and how much product appears.
- Transfer product: Apply expression logic to mutations, biotechnology, development, and disease diagnostics.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 13 of the textbook — review that chapter before attempting the exercises below.

1. Define gene expression. What are the two major steps?

Answer (Q1, Recall). Gene expression is the process by which the information in a gene is used to synthesize a functional product, usually a protein. Its two major steps are transcription (DNA copied into a complementary mRNA by RNA polymerase in the nucleus) and translation (the mRNA decoded by ribosomes into a polypeptide in the cytoplasm). In eukaryotes these are separated in space and time, allowing extensive regulation (RNA processing, transport, stability) between the steps. See section 13.

2. Describe the structure of a eukaryotic mRNA from 5' to 3', including most regulatory elements.

Answer (Q2, Recall). From 5' → 3': (1) m⁷G cap — 7-methylguanosine joined via an unusual 5'→5' triphosphate linkage, added co-transcriptionally by capping enzyme; protects from 5'→3' exonucleases (Xrn1) and is the binding site for eIF4E, the rate-limiting step of cap-dependent translation initiation. (2) 5' UTR — typically 100–200 nt; contains Kozak context (GCCRCCAUGG) and sometimes upstream ORFs (uORFs) or IRES elements for regulated translation. (3) CDS (coding sequence) — begins at the start codon (AUG), proceeds in triplets to a stop codon (UAA/UAG/UGA); no introns (those were removed by the spliceosome, leaving exon-exon junctions marked by the EJC, which triggers NMD if a stop codon appears >50 nt upstream of a junction). (4) 3' UTR — typically 500–2000 nt; contains AU-rich elements (AREs) for mRNA stability, miRNA binding sites, and the polyadenylation signal AAUAAA. (5) Poly-A tail — 150–250 nt of adenosines, bound by PABPC1, which circularises the mRNA via eIF4G–eIF4E to promote re-initiation. Worked example: β-globin mRNA is about 620 nt (5' UTR 50, CDS 441, 3' UTR 131) plus cap and about 150 nt poly-A tail. See section 13.

3. What is the role of RNA polymerase II in transcription? Where does it bind?

Answer (Q3, Recall). RNA polymerase II is the enzyme that synthesizes all messenger RNA (and many small RNAs) in eukaryotes, building a complementary RNA copy of the template DNA strand 5'→3'. It does not bind DNA on its own: it is recruited to the core promoter (the region around the transcription start site, e.g. the TATA box about 25 bp upstream) as part of the preinitiation complex assembled by general transcription factors (TFIIA–H). Its C-terminal domain (CTD) is phosphorylated to coordinate capping, splicing, and polyadenylation during elongation. See section 13.

4. Define a transcription factor. Distinguish general vs specific transcription factors.

Answer (Q4, Recall). A transcription factor is a protein that binds specific DNA sequences and regulates the rate of transcription. General (basal) transcription factors (TFIIA, B, D, E, F, H) are required at every Pol II promoter to position the polymerase and form the preinitiation complex — they set the baseline. Specific (regulatory) transcription factors bind enhancers or silencers of particular genes and increase or decrease expression in a gene-, cell-, or signal-dependent way. The mechanistic difference: general factors enable transcription at all; specific factors decide which genes are transcribed and how much. See section 13.

5. What is RNA splicing? What molecular machinery performs it?

Answer (Q5, Recall). RNA splicing is the removal of non-coding introns from pre-mRNA and the joining of the flanking exons to produce a mature, translatable mRNA. It is carried out by the spliceosome, a large ribonucleoprotein complex of five small nuclear RNPs (U1, U2, U4, U5, U6 snRNPs) plus associated proteins. The snRNAs recognize the 5' splice site (GU), branch-point adenosine, and 3' splice site (AG) and catalyze two transesterification reactions that excise the intron as a lariat. See section 13.

6. Define the genetic code. What is a codon? How many codons encode amino acids?

Answer (Q6, Recall). The genetic code is the set of rules by which nucleotide triplets in mRNA specify amino acids during translation. A codon is a sequence of three consecutive nucleotides read by the ribosome. There are $4^3 = 64$ codons total: 61 encode the 20 amino acids (the code is therefore degenerate/redundant) and 3 are stop codons (UAA, UAG, UGA). AUG is the start codon and also encodes methionine. See section 13.

7. What is the ribosome composed of? Name the three ribosomal sites (A, P, E sites).

Answer (Q7, Recall). The ribosome is a ribonucleoprotein machine made of ribosomal RNA (rRNA) and ribosomal proteins, organized into a small subunit (40S in eukaryotes; reads the mRNA) and a large subunit (60S; catalyzes peptide-bond formation via the rRNA peptidyl transferase center).

It has three tRNA-binding sites: the A site (Aminoacyl — accepts the incoming aminoacyl-tRNA), the P site (Peptidyl — holds the tRNA bearing the growing chain), and the E site (Exit — holds the deacylated tRNA before it leaves). See section 13. 8. Describe initiation, elongation, and termination of translation in eukaryotes.

Answer (Q8, Recall). Initiation: the 40S subunit, with initiator Met-tRNA_i and initiation factors (eIF4E binds the m⁷G cap), scans the mRNA 5'→3' to the first AUG in good Kozak context; the 60S subunit then joins to form the 80S ribosome. Elongation: aminoacyl-tRNAs are delivered to the A site by eEF1A; the peptidyl transferase center forms the peptide bond; eEF2 drives translocation, shifting tRNAs A→P→E one codon at a time. Termination: a stop codon enters the A site, recognized by release factor eRF1, which triggers hydrolysis and release of the completed polypeptide, then ribosome recycling. See section 13. 9. What is tRNA? What is the anticodon, and what is aminoacyl-tRNA synthetase?

Answer (Q9, Recall). tRNA (transfer RNA) is a small (about 76 nt) cloverleaf-folded RNA that physically links a codon to its amino acid during translation. The anticodon is a three-nucleotide loop that base-pairs antiparallel with the complementary mRNA codon in the ribosomal A site. Aminoacyl-tRNA synthetases are enzymes (one per amino acid) that covalently attach the correct amino acid to the 3' CCA end of its cognate tRNA, using ATP; their proofreading establishes the accuracy of the genetic code (“the second genetic code”). See section 13. 10. What is the wobble hypothesis? Which position of the codon allows degeneracy?

Answer (Q10, Recall). The wobble hypothesis (Crick, 1966) states that base pairing between the third base of the codon and the first base of the anticodon is less stringent than standard Watson–Crick pairing, so a single tRNA can read several synonymous codons. The third (3') codon position allows this degeneracy: non-standard pairings (e.g., G–U, or inosine in the anticodon pairing with U, C, or A) let about 45 tRNAs decode all 61 sense codons, explaining the code's redundancy. See section 13.

Questions 11–20: Application and Analysis

11. Pre-mRNA splicing must be precise to within one nucleotide. Explain the two-step transesterification mechanism of splicing and the role of branch point A, 5' splice site, and 3' splice site in spliceosome assembly.

Answer (Q11, Application). Splicing proceeds by two sequential transesterification reactions. First, the 2'-OH of the branch-point adenosine attacks the phosphate at the 5' splice site (GU), cleaving exon 1 and forming a lariat intermediate. Second, the freed 3'-OH of exon 1 attacks the 3' splice site (AG), joining the two exons and releasing the intron as a lariat. Spliceosome assembly recognizes these elements stepwise: U1 snRNP base-pairs the 5' splice site, U2 snRNP binds the branch point (bulging the branch A), and the U4/U6-U5 tri-snRNP completes the catalytic core — the one-nucleotide precision comes from this combinatorial recognition of all three signals. See section 13. 12. Alternative splicing generates multiple protein isoforms from one gene. *Drosophila Dscam* gene can produce >38,000 isoforms through mutually exclusive exon splicing. Explain: (a) the general mechanism of alternative splicing; (b) why *Dscam* diversity is important for axon guidance in neural wiring; (c) one human disease caused by aberrant alternative splicing.

Answer (Q12, Application). (a) Alternative splicing includes or excludes particular exons (or uses alternative 5'/3' splice sites) in a regulated way, so one gene yields multiple mRNAs and protein isoforms; in *Dscam*, mutually exclusive selection among large clusters of variant exons combinatorially generates >38,000 isoforms. (b) This diversity gives each neuron a near-unique *Dscam* “identity tag”; isoform-specific homophilic binding mediates self-avoidance, so a neuron's own branches repel each other while still tiling among other neurons — essential for correct axon/dendrite wiring. (c) Spinal muscular atrophy is caused by aberrant *SMN2* exon 7 splicing (the therapy nusinersen corrects it); other examples include myotonic dystrophy and many cancers. See section 13. 13. The 5' cap (m⁷G) and poly-A tail of eukaryotic mRNA serve similar functions — protecting mRNA from exonuclease attack and promoting translation initiation. Explain: (a) how the 5' cap is added; (b) how eIF4E binding to the cap recruits the 43S pre-initiation complex; (c) why some viruses (e.g., poliovirus) cleave eIF4G to direct ribosomes to IRES sequences instead.

Answer (Q13, Application). (a) 5' cap addition occurs co-transcriptionally when nascent pre-mRNA is about 25 nt long: (i) RNA 5'-triphosphatase removes the γ-phosphate; (ii) guanylyltransferase adds GMP via a unique 5'–5' triphosphate bridge; (iii) guanine-N7-methyltransferase methylates N7 of the guanine, yielding m⁷GpppN. The capping enzyme is recruited via the phosphorylated CTD (Ser5-P) of RNA pol II — physically linking transcription to capping. (b) eIF4E binding: cytosolic eIF4E recognizes m⁷G via stacking with two conserved tryptophans (W56, W102), with K_d ≈ 100 nM. eIF4E forms eIF4F with eIF4G (scaffold) and eIF4A (DEAD-box helicase); eIF4G simultaneously binds PABPC1 on the poly-A tail (circularising the mRNA) and recruits the 43S PIC (40S + eIF1, eIF1A, eIF3, eIF2-GTP-Met-tRNA_i) via eIF3. The 43S then scans 5' → 3' using eIF4A's ATP-dependent helicase activity until it finds the Kozak AUG. (c) Poliovirus hijack: poliovirus 2A protease cleaves eIF4G between the eIF4E-binding domain and the eIF3/eIF4A-binding domain. This shuts down cap-dependent translation of host mRNA but leaves intact the C-terminal half of eIF4G that binds viral IRES (internal ribosome entry site) in the 5' UTR of poliovirus RNA — so viral translation continues while host translation collapses. This is why the cell “looks infected” within hours: host protein synthesis drops > 90 %. See section 13. 14. The ribosome proof-reads aminoacyl-tRNA selection at the A site. Explain: (a) initial selection based on codon-anticodon base pairing (induced fit); (b) proofreading step (kinetokinetics — GTPase activation primarily if correct aa-tRNA is bound); (c) why errors occur at about 1 in 10,000 vs DNA polymerase errors of

1 in 10^9 (why is translation less accurate?).

Answer (Q14, Application). (a) Initial selection: the ternary complex (eEF1A-GTP-aa-tRNA) samples the A-site codon; correct Watson–Crick codon–anticodon pairing induces a conformational closure of the 30S/40S decoding center (induced fit) that accelerates GTPase activation. (b) Proofreading: GTP is hydrolyzed only when pairing is correct; after hydrolysis the tRNA must be “accommodated” into the peptidyl transferase center — a second checkpoint where near-cognate tRNAs preferentially dissociate before peptide-bond formation. (c) Translation tolerates a higher error rate (about 10^{-4}) than DNA replication (about 10^{-9}) because protein errors affect only one short-lived molecule and are not heritable, whereas DNA errors are passed to all descendants; selection therefore optimized replication fidelity far more strongly than translation, and a faster, less accurate ribosome favors growth. See section 13. 15. Cycloheximide blocks the elongation step of eukaryotic translation (not prokaryotic), because it specifically inhibits the 60S subunit translocation step. Explain: (a) what translocation means mechanistically; (b) why prokaryotic ribosomes (70S) are not blocked; (c) how this selectivity is exploited in laboratory cell biology experiments.

Answer (Q15, Application). (a) Translocation is the eEF2-driven, GTP-dependent movement of the ribosome by exactly one codon along the mRNA after peptide-bond formation, shifting the tRNAs from A→P and P→E sites and opening the A site for the next aminoacyl-tRNA. (b) Cycloheximide binds the E site of the 60S subunit, blocking eEF2-mediated translocation; prokaryotic 70S ribosomes have structurally distinct large-subunit rRNA/proteins that cycloheximide does not recognize, so bacterial translation is unaffected. (c) This eukaryote-specific, rapid, reversible arrest is exploited to freeze ribosomes on mRNA — e.g., to stabilize polysomes for polysome profiling and ribosome profiling (Ribo-seq), and to halt protein synthesis in pulse-chase and cytotoxicity experiments. See section 13. 16. Nonsense-mediated mRNA decay (NMD) degrades mRNAs with premature stop codons. Explain: (a) how the cell recognizes a premature vs normal stop codon (role of exon-junction complexes); (b) the UPF1/SMG cascade; (c) why NMD is a quality control mechanism that also regulates normal gene expression for about 10% of genes.

Answer (Q16, Application). (a) During the pioneer round of translation the ribosome displaces exon-junction complexes (EJCs). A stop codon is judged premature if an EJC remains >50–55 nt downstream of it (a normal stop is the last codon, with no downstream EJC). (b) The retained EJC recruits UPF1, which is phosphorylated by SMG1; phospho-UPF1 then recruits SMG5/6/7, triggering endonucleolytic cleavage (SMG6) and exonucleolytic decay of the transcript. (c) NMD is both quality control — destroying truncating-mutation and error-prone transcripts to prevent dominant-negative truncated proteins — and a normal regulatory mechanism: about 10% of transcripts (including alternatively spliced isoforms with PTC-containing exons and autoregulated splicing-factor mRNAs) are physiologically tuned by NMD. See section 13. 17. Polyribosomes (polysomes) consist of multiple ribosomes simultaneously translating the same mRNA. If a 1,500-nt coding sequence is occupied by ribosomes spaced on average every 80 nt, how many ribosomes are simultaneously translating this mRNA? Calculate the rate of protein synthesis per mRNA if each ribosome adds 2 amino acids/sec.

Answer (Q17, Application). Ribosome count: $N = \frac{1500 \text{ nt}}{80 \text{ nt/ribosome}} = 18.75 \approx 19$ ribosomes simultaneously engaged. Protein output: each ribosome adds 2 aa/s $\rightarrow 19 \times 2 = 38$ amino acids per second across the polysome. Time to complete one protein per ribosome: $1500 \text{ nt} \div 3 = 500$ codons $\div 2 \text{ codons/s} = 250 \text{ s} \approx 4 \text{ min}$. Steady-state output per mRNA = 1 finished protein every $(80 \text{ nt} / 2 \text{ codons} \times 3 \text{ nt/codon}) \approx 13 \text{ s}$ per completed chain, i.e. about 280 proteins/h/mRNA. Biological sanity check: this matches measured translation rates in mammalian cells (median about 5 proteins/mRNA/min for short transcripts). Sucrose-gradient polysome profiles show β -actin mRNA (about 1800 nt) in fractions containing 8–12 ribosomes — consistent with our estimate once you account for scanning delays and the fact that the first about 40 nt after the cap are typically bare (eIF4E/PABPC1 footprint). Biological significance: polysome occupancy (footprint density from ribosome profiling / Ribo-seq) is the gold-standard readout of translation efficiency; a 19-ribosome polysome represents high expression, while a monosome-enriched mRNA is either stalled or repressed. See section 13. 18. Internal ribosome entry sites (IRES) allow cap-independent translation initiation, used by viruses (Hepatitis C, poliovirus) and in cellular stress responses, when eIF4E activity is reduced. Compare IRES-mediated vs cap-dependent initiation: which cellular proteins are replaced by viral ITAF proteins, and under what stress conditions does cellular IRES-mediated translation occur?

Answer (Q18, Application). Cap-dependent initiation requires eIF4E to bind the m⁷G cap, eIF4G as scaffold, eIF4A helicase, and 5' scanning to the AUG. IRES-mediated initiation uses a structured RNA element in the 5' UTR that recruits the 40S subunit directly, bypassing the cap. Viral IRESs replace cap-recognition factors with IRES trans-acting factors (ITAFs): depending on IRES class, they need little or no eIF4E/eIF4G (e.g., the CrPV IRES needs no initiation factors; HCV recruits eIF3 and 40S directly; poliovirus uses a cleaved eIF4G fragment plus ITAFs such as PCBP2/PTB). Cellular IRESs are used when cap-dependent translation is suppressed — mitosis, hypoxia, ER/nutrient stress, apoptosis, and viral infection — to keep translating survival, stress, and pro-apoptotic mRNAs. See section 13. 19. The signal recognition particle (SRP) recognizes hydrophobic signal peptides emerging from ribosomes translating secretory proteins. Explain: (a) how SRP stalls translation while targeting the ribosome to the rough ER; (b) how signal peptidase cleaves the signal peptide in the ER lumen; (c) what happens to cytosolic misfolded proteins lacking a signal peptide vs ER-targeted ones.

Answer (Q19, Application). (a) As a hydrophobic signal peptide emerges from the ribosome, the signal recognition particle (SRP) binds it and contacts the ribosome, pausing elongation; SRP then docks the ribosome onto the SRP receptor at the rough ER, transferring it to the Sec61 translocon,

after which translation resumes and the chain is threaded into the ER. (b) Inside the ER lumen, signal peptidase cleaves the signal sequence from the nascent chain, releasing the mature protein into the lumen for folding and modification. (c) ER-targeted proteins that misfold are detected by ER quality control and retro-translocated for ERAD (ER-associated degradation by the cytosolic proteasome); cytosolic proteins lacking a signal peptide that misfold are handled by cytosolic chaperones and the ubiquitin–proteasome system (or autophagy), never entering the secretory pathway. See section 13. 20. Transcription factors bind specific DNA sequences (motifs). A transcriptional activator contains a DNA-binding domain (DBD) and an activation domain (AD). Explain: (a) what structural motifs are common in DBDs (zinc finger, helix-turn-helix, leucine zipper); (b) how the activation domain recruits the Mediator complex; (c) how enhancers (located kb away from promoters) loop to contact the preinitiation complex through cohesin-mediated chromosome looping.

Answer (Q20, Application). (a) Common DNA-binding domains include the zinc finger (Cys₂His₂ fingers inserting an α -helix into the major groove), the helix-turn-helix / homeodomain, and the basic leucine zipper (bZIP) and basic helix-loop-helix, which dimerize and grip DNA with basic regions. (b) The separate activation domain does not bind DNA; it recruits coactivators and the Mediator complex, which bridges the enhancer-bound activator to RNA Pol II and the general transcription factors, stimulating preinitiation-complex assembly and CTD phosphorylation. (c) Distal enhancers contact promoters through chromatin looping: cohesin and CTCF organize loop domains (TADs), bringing the enhancer-bound activator/Mediator into physical proximity with the promoter even when they are tens of kb apart in linear sequence. See section 13.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the dual role of SR proteins (serine-arginine-rich splicing factors) in both constitutive and alternative splicing and mRNA export. What does the dual role of SR proteins reveal about the evolutionary coupling between nuclear RNA processing and cytoplasmic translation?

Answer (Q21, Synthesis). Empirically, SR proteins bind exonic splicing enhancers to promote spliceosome assembly and regulate alternative splice-site choice, *and* they remain bound to the spliced mRNP where they help recruit the TREX export machinery (e.g., via NXF1/TAP) and influence cytoplasmic translation efficiency. The judgment — that nuclear processing and cytoplasmic fate are evolutionarily coupled — follows because the same factor physically links splicing, export, and translation, making them a coordinated pipeline rather than independent steps; this “mRNP marking” also explains why spliced mRNAs are translated more efficiently than intronless ones. What would change the conclusion: showing SR-protein splicing and export functions are genetically separable (separation-of-function mutants), or that export/translation enhancement occurs equally without SR deposition. See section 13. 22. Design a comprehensive experiment to map most enhancers controlling a specific gene in a given cell type using: (a) H3K27ac ChIP-seq (active enhancer mark); (b) ATAC-seq (open chromatin); (c) HiC chromatin conformation capture; (d) CRISPR deletion of candidate enhancers and transcriptional output measurement. How would you prioritize which enhancers are most important?

Answer (Q22, Synthesis). Hypothesis: a defined set of distal enhancers drives the gene’s expression in this cell type. Design: map candidates with H3K27ac ChIP-seq (active enhancers) and ATAC-seq (open chromatin), then use Hi-C/capture Hi-C to identify which open, acetylated regions physically loop to the promoter; the control/comparison is an unedited population and CRISPRi/CRISPR deletion of each candidate vs a scrambled-gRNA control. Measured outcome: target-gene mRNA (RT-qPCR/RNA-seq) after each perturbation, with biological replicates. Prioritization: rank enhancers by (i) magnitude of expression loss on deletion, (ii) strength of the Hi-C contact with the promoter, (iii) H3K27ac/ATAC signal and conservation, and (iv) presence of relevant TF motifs/footprints. A falsifying result: deleting the top-ranked enhancer leaves expression unchanged, indicating redundancy or that the causal element was missed. See section 13. 23. The “RNA world” hypothesis proposes that early life was based on RNA molecules that could both carry genetic information and catalyse reactions. Evaluate: (a) the evidence supporting RNA world (ribozymes, ribosome as a ribozyme, universality of the genetic code); (b) the transition from RNA world to the DNA-protein world; (c) what modern ribozymes tell us about the chemistry of early catalysis.

Answer (Q23, Synthesis). Empirical support for an RNA world: ribozymes (self-splicing introns, RNase P) prove RNA can catalyze chemistry; the ribosome’s peptidyl transferase center is all rRNA (a ribozyme), implying protein synthesis predates protein enzymes; and the near-universal genetic code plus RNA cofactors (ATP, NAD, coenzyme A) look like molecular fossils. The judgment that an RNA world existed rests on these as evidence that RNA once carried both information and catalysis. The transition to DNA/protein: DNA (more chemically stable, proofreadable) took over information storage and proteins (20 side chains) took over catalysis, with RNA retained as the intermediary. What would weaken it: failure to demonstrate an RNA replicase ribozyme, or evidence that early metabolism was peptide- or metabolism-first rather than RNA-based. See section 13. 24. Transcription and translation are physically coupled in prokaryotes (translation begins before transcription is complete). Evaluate the consequences of this coupling: how does it allow attenuation (regulation of transcription termination by ribosome speed), and why would coupling like this have evolved in prokaryotes but not eukaryotes (where transcription and translation are spatially separated)?

Answer (Q24, Synthesis). In prokaryotes there is no nuclear envelope, so ribosomes load onto an mRNA’s 5’ end while RNA polymerase is still transcribing it (coupling). This enables attenuation, e.g. the *trp* operon: a ribosome translating a leader peptide rich in Trp codons stalls or proceeds depending on tryptophan availability; its position determines which alternative RNA hairpin forms, either a terminator (transcription stops) or an antiterminator (transcription continues) — ribosome speed directly controls transcription termination. This could not evolve in eukaryotes because

transcription (nucleus) and translation (cytoplasm) are spatially and temporally separated by the nuclear envelope and by pre-mRNA processing, so a translating ribosome can never contact an actively transcribing polymerase; eukaryotes instead regulate via distinct mechanisms (chromatin, splicing, export, miRNAs). See section 13. 25. Ribosome biogenesis occurs in the nucleolus and is rate-limiting for cell growth. Evaluate the regulatory relationship between mTORC1, Pol I transcription of rDNA, and ribosome biogenesis. Why does mTOR inhibition suppress cell growth even in cells with unlimited amino acid supply?

Answer (Q25, Synthesis). Ribosome biogenesis (rDNA transcription by Pol I, rRNA processing, assembly in the nucleolus) consumes most of a growing cell’s transcriptional output and is rate-limiting for proliferation. mTORC1 integrates growth-factor and nutrient signals and directly stimulates ribosome production: it activates Pol I (via TIF-IA/UBF), Pol III (5S rRNA, tRNA, via Maf1 repression), and translation of ribosomal-protein mRNAs (via S6K1 and 4E-BP1). Therefore mTOR inhibition (rapamycin) suppresses growth even with abundant amino acids because it shuts down the biosynthetic capacity needed to make new ribosomes — without enough ribosomes the cell cannot increase mass or divide, regardless of substrate supply. The evidence: rapamycin rapidly reduces nucleolar size, 45S pre-rRNA, and polysome levels. See section 13. 26. Evaluate the molecular mechanism of translation by the ribosome in the context of the “peptidyl transferase” ribosome activity: specifically, is the catalysis chemical (RNA catalysis) or entropic (positioning effect)? Cite the key experiment (Nobel Prize 2009) that settled this debate.

Answer (Q26, Synthesis). The empirical question is whether peptide-bond catalysis is chemical (rRNA acting as a true catalyst) or mainly entropic (the ribosome positioning/orienting substrates and excluding water, with little chemical transition-state stabilization). The decisive evidence is the atomic-resolution crystal structures of the 50S subunit (Steitz, Moore; Nobel Prize in Chemistry 2009, shared with Ramakrishnan and Yonath): the peptidyl transferase center is composed entirely of 23S rRNA with no protein side chains near the active site, and subsequent biochemistry showed catalysis works largely by substrate positioning and proton shuttling/entropic effects rather than classical acid–base chemistry. So the ribosome is a ribozyme, and its catalysis is predominantly proximity/orientation-based. What would overturn this: finding a protein side chain essential for the chemical step, or a single-atom rRNA substitution that abolishes chemistry without affecting positioning. See section 13. 27. Single-molecule translation experiments using fluorescently labeled ribosomes and mRNAs have revealed “pausing” during elongation opposite rare codons, and “synchronized” waves of ribosome density on mRNA. Evaluate what these observations reveal about codon usage optimization and how synonymous mutations (same amino acid, different codon) can dramatically affect protein folding by altering translation speed.

Answer (Q27, Synthesis). Single-molecule and ribosome-profiling data show that elongation is non-uniform: ribosomes pause at rare codons (those read by low-abundance tRNAs) and move in correlated waves. The causal chain: a synonymous (“silent”) mutation changes codon usage → alters local tRNA-decoding speed → changes the elongation rate at that position → shifts the timing of co-translational folding, so domains may misfold or be processed differently even though the amino-acid sequence is unchanged. This reveals that codon choice is itself an optimized layer of information (translational kinetics), not redundant: examples include the *MDR1* C3435T synonymous variant altering substrate specificity and synonymous changes affecting protein stability and aggregation. The interpretation: codon usage co-evolves with folding pathways; “silent” mutations can be functionally consequential. See section 13. 28. Design a gene therapy strategy for a patient with haemophilia A (lacking factor VIII). Compare: mRNA therapy (synthetic mRNA with pseudo-uridine modification for stability); AAV vector gene therapy (liver-tropism, long-term expression); and base editing (correct the point mutation in situ). Evaluate the trade-offs in immunogenicity, duration of effect, and delivery efficiency.

Answer (Q28, Synthesis). Hypothesis/options compared: (1) mRNA therapy — pseudouridine-modified synthetic factor VIII mRNA in lipid nanoparticles: easy to redose, low genotoxicity, but transient expression and innate-immune/LNP delivery limits. (2) AAV gene therapy — liver-tropic AAV carrying B-domain-deleted F8: long-lived expression from a single dose, but pre-existing/induced anti-AAV immunity, payload-size limits, and episomal loss in dividing hepatocytes; one-time only. (3) Base editing — in-situ correction of the causal point mutation: potentially permanent and physiologic (native locus regulation), but constrained by editable mutation type, delivery to hepatocytes, and off-target/bystander risk. Measured outcomes: circulating FVIII activity, bleeding rate, anti-FVIII/anti-vector antibodies, durability. Controls/falsification: untreated and vehicle arms; the approach fails if FVIII activity does not rise above the about 5% therapeutic threshold or if immunogenicity neutralizes the product. See section 13. 29. RNA interference (RNAi) was discovered when dsRNA triggered gene silencing in *C. elegans* (Fire and Mello, 1998). Evaluate the mechanism (Dicer, RISC, Ago2-mediated cleavage), the evolutionary origin of RNAi (antiviral defense), and the clinical development of siRNA therapeutics (inclisiran for PCSK9 silencing). What advantages does siRNA have over antisense oligonucleotides (ASOs) for gene silencing?

Answer (Q29, Synthesis). Mechanism: long dsRNA is cleaved by Dicer into about 21–23 nt siRNAs; one strand is loaded into RISC with Ago2, which uses perfect complementarity to endonucleolytically cleave the target mRNA. Evolutionary origin: RNAi arose as an antiviral and anti-transposon defense (recognizing dsRNA replication intermediates), conserved from plants and invertebrates to mammals. Clinical: chemically stabilized, GalNAc-conjugated siRNAs such as inclisiran silence hepatic *PCSK9*, durably lowering LDL cholesterol with twice-yearly dosing. siRNA vs ASO advantages: siRNA acts catalytically (one RISC degrades many mRNAs) giving high potency and long duration, exploits an endogenous enzymatic pathway, and (with GalNAc) achieves efficient liver delivery — whereas ASOs act stoichiometrically and generally need more frequent dosing for comparable knockdown. See section 13. 30. Critically evaluate the concept of the “central dogma” (DNA → RNA → protein). Identify

three biological exceptions that violate a strict reading of the central dogma (reverse transcription, RNA editing, prion replication), explain their mechanisms, assess whether these exceptions require a fundamental revision of the central dogma, and state what RNAcentral-style database checks are needed before claiming that a non-coding RNA has a defined gene model and function.

Answer (Q30, Synthesis). The central dogma states information flows DNA→RNA→protein and not back out of protein. Three classic challenges: (1) Reverse transcription — retroviruses/telomerase make DNA from RNA (RNA→DNA), expanding allowed information flow but not violating the core prohibition (no protein→nucleic-acid). (2) RNA editing — e.g., A-to-I (ADAR) or C-to-U (APOBEC) editing changes mRNA sequence after transcription, so the protein differs from the genomic template; this elaborates the RNA step rather than reversing flow. (3) Prions — a misfolded protein (PrP^{Sc}) templates conformational conversion of normal protein, transmitting *conformational*, not sequence, information protein→protein. Assessment: Crick’s strict statement (no information from protein back to nucleic acid) survives — none of these transfers sequence from protein to DNA/RNA; they are elaborations within the framework, not a fundamental revision, though prions show heritable information can be protein-borne. Source-governed RNA interpretation then asks whether the RNAcentral entry is sequence-level or gene-level, which release and identifiers are being used, whether isoforms/splice variants are merged correctly, and whether literature links support function rather than only mention the RNA [[RNAcentral Consortium, 2026](#)]. See section 13.

Questions — Mutations, CRISPR, and Genomics

Instructor Use and Coverage Notes

- Coverage target: Predict the impact of a variant and justify the evidence needed to validate it.
- Model/data emphasis: Mutation-rate, edit-efficiency, and sequence-comparison calculations.
- Assessment alignment: Concept Explanation, Questions and Methods, Argumentation.
- Misconception probe: Not every mutation is harmful, and not every harmful mutation changes a protein sequence.
- Transfer product: Transfer variant reasoning to cancer genomics, ancestry, gene therapy, or microbial evolution.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 14 of the textbook — review that chapter before attempting the exercises below.

1. Define a mutation. Classify mutations by: (a) type of base change; (b) effect on the protein.

Answer (Q1, Recall). A mutation is a heritable change in the DNA sequence of a cell or organism. (a) By base change: *point mutations* are single-base substitutions, subdivided into transitions (purine↔purine or pyrimidine↔pyrimidine, e.g. A↔G) and transversions (purine↔pyrimidine); larger changes include insertions and deletions (indels). (b) By effect on protein: *silent/synonymous* (codon still specifies the same amino acid), *missense* (different amino acid), *nonsense* (creates a premature stop codon), and *frameshift* (indel not a multiple of three, shifting the reading frame and usually producing a truncated, nonfunctional protein). See section 14. 2. What is a frameshift mutation? How does an insertion vs deletion cause this?

Answer (Q2, Recall). A frameshift mutation is an insertion or deletion of a number of nucleotides not a multiple of three, which shifts the ribosomal reading frame downstream of the change. Because codons are read in non-overlapping triplets from the start codon, an insertion pushes all subsequent bases one or two positions to the right and a deletion shifts them left; either way every codon after the mutation site is mis-read, almost always generating a string of wrong amino acids and an early premature stop codon, yielding a truncated, nonfunctional protein. An indel that is a multiple of three only adds/removes whole codons and is in-frame, not a frameshift. See section 14. 3. What are transposons? Distinguish replicative (copy-and-paste) from non-replicative (cut-and-paste) transposons.

Answer (Q3, Recall). Transposons (“jumping genes”) are mobile DNA elements that can move to new genomic locations, sometimes causing mutations or genome rearrangements. Replicative (copy-and-paste) transposons leave the original element in place and insert a new copy elsewhere, so copy number increases — this includes retrotransposons (LINEs, SINEs, LTR/HERV elements), which transpose via an RNA intermediate reverse-transcribed into DNA. Non-replicative (cut-and-paste) DNA transposons are excised by a transposase from the donor site and reinserted at a target site without net copy gain. The mechanistic distinction is whether an RNA-templated copy is made (replicative) or the element physically relocates (conservative). See section 14. 4. What is the Ames test? What does a positive result indicate?

Answer (Q4, Recall). The Ames test (Bruce Ames, 1970s) is a bacterial assay for mutagenicity. It uses *Salmonella typhimurium* strains carrying a his⁻ mutation (cannot synthesize histidine); the test chemical (often with rat-liver S9 extract to mimic mammalian metabolic activation) is added, and reversion (back-mutation) to his⁺ is scored as colonies growing on histidine-free medium. A positive result (a dose-dependent increase in revertant colonies above background) indicates the chemical is a mutagen; because about 80–90% of known carcinogens are mutagenic, a positive result flags the substance as a probable carcinogen warranting further testing. See section 14. 5. Describe the three types of DNA damage repair: (a) nucleotide excision repair (NER); (b) base excision repair (BER); (c) mismatch repair (MMR).

Answer (Q5, Recall). (a) Nucleotide excision repair (NER) removes bulky, helix-distorting lesions (e.g., UV-induced pyrimidine dimers, chemical adducts): the damage is recognized, a about 24–32 nt oligonucleotide containing it is excised by endonucleases, and the gap is filled by DNA polymerase and sealed by ligase. (b) Base excision repair (BER) corrects small, non-distorting single-base damage (oxidation, deamination, alkylation): a DNA glycosylase removes the damaged base, AP endonuclease nicks the abasic site, and a short patch is resynthesized. (c) Mismatch repair (MMR) fixes replication errors (mispaired bases, small indel loops) that escaped polymerase proofreading; it identifies the newly synthesized (error-containing) strand, excises the stretch, and resynthesizes it, raising replication fidelity about 100–1000-fold. See section 14. 6. What is CRISPR-Cas9? Where does CRISPR originate in bacteria?

Answer (Q6, Recall). CRISPR-Cas9 is a programmable, RNA-guided DNA endonuclease used for genome editing: a guide RNA directs the Cas9 protein to a complementary DNA sequence adjacent to a PAM, where Cas9 creates a double-strand break that the cell repairs by NHEJ (disruptive indels) or HDR (precise edits with a donor template). It originates as a bacterial and archaeal adaptive immune system: short fragments of invading phage/plasmid DNA are stored as spacers in CRISPR arrays, transcribed into crRNAs, and used by Cas nucleases to recognize and cleave matching

nucleic acid on re-infection. (Doudna & Charpentier, 2020 Nobel Prize in Chemistry.) See section 14. 7. What is gRNA (guide RNA) and what does it do in the Cas9 complex?

Answer (Q7, Recall). The guide RNA (gRNA), commonly engineered as a single guide RNA (sgRNA), is the targeting component of the CRISPR-Cas9 complex. It is a fusion of a crRNA — whose about 20-nucleotide spacer is complementary to the intended DNA target — and a tracrRNA scaffold that binds and activates Cas9. The gRNA loads into Cas9 and, by Watson–Crick base-pairing of its spacer with the target DNA (immediately 5' of a PAM), positions the Cas9 nuclease domains to introduce a site-specific double-strand break. Changing the 20-nt spacer reprograms Cas9 to any new genomic site. See section 14. 8. Define the PAM sequence. Why is it required for CRISPR cutting?

Answer (Q8, Recall). The PAM (protospacer adjacent motif) is a short DNA sequence (5'-NGG-3' for *Streptococcus pyogenes* Cas9) located immediately 3' of the 20-nt target (protospacer) in the genomic DNA. It is required because Cas9 first recognizes the PAM through protein–DNA contacts; PAM binding licenses local DNA unwinding and lets the guide RNA test for complementarity, after which the nuclease domains cut. The PAM is not part of the guide RNA, so the bacterium's own CRISPR array (which lacks an adjacent PAM at the spacer) is not cleaved — this is how Cas9 distinguishes invader DNA from self and avoids autoimmunity. See section 14. 9. What is whole-genome sequencing (WGS)? What sequencing technology is most commonly used?

Answer (Q9, Recall). Whole-genome sequencing (WGS) is the determination of the complete (or near-complete) nucleotide sequence of an organism's genome in a single experiment, capturing coding, non-coding, regulatory, and structural variation. The most widely used technology is Illumina short-read sequencing-by-synthesis (massively parallel, high accuracy, about 150 bp reads), used for variant calling; long-read platforms (Oxford Nanopore, PacBio HiFi) are increasingly used to resolve repeats, structural variants, and produce telomere-to-telomere assemblies. See section 14. 10. What is a single nucleotide polymorphism (SNP)? How many SNPs does the average human genome contain?

Answer (Q10, Recall). A single nucleotide polymorphism (SNP) is a single-base position in the genome at which a variant allele occurs commonly in the population (conventionally >1% allele frequency). SNPs are the most abundant form of human genetic variation, used as markers in GWAS, association studies, and ancestry analysis. On average, any two human genomes differ at roughly 4–5 million SNP sites (about one SNP per about 1000 bp; about 3–4 million when compared to the reference), most of which lie in non-coding regions. See section 14.

Questions 11–20: Application and Analysis

11. A chemotherapy drug causes G:C → A:T transitions. What type of DNA damage mechanism does this suggest (alkylation, intercalation, cross-linking, or depurination)? What repair pathway would normally correct this damage?

Answer (Q11, Application). A G:C → A:T transition is the signature of alkylation (or oxidative deamination), not intercalation, cross-linking, or simple depurination. Mechanism: an alkylating agent adds an alkyl group to guanine forming O⁶-methylguanine (or 8-oxoG), which mispairs with thymine during replication; the next round fixes the change as G:C → A:T. Repair pathway: O⁶-alkylguanine is reversed directly by MGMT (O⁶-methylguanine-DNA methyltransferase), while oxidized/alkylated bases are normally removed by base excision repair (BER) (e.g., OGG1 glycosylase for 8-oxoG); mismatch repair can also act on the resulting mispair. Failure of these explains the mutator phenotype of alkylating chemotherapeutics. See section 14. 12. Xeroderma pigmentosum (XP) patients have mutations in NER pathway genes (XPA-XPG). Explain: (a) what lesion NER repairs (CPDs from UV-B); (b) why XP patients have dramatically increased skin cancer risk; (c) why the nervous system is also affected in some XP subtypes.

Answer (Q12, Application). (a) NER repairs bulky helix-distorting lesions, especially UV-B-induced cyclobutane pyrimidine dimers (CPDs) and 6-4 photoproducts. (b) XP patients carry loss-of-function mutations in NER genes (XPA–XPG), so sunlight-induced dimers persist; unrepaired lesions are bypassed by error-prone translesion polymerases, producing C→T mutations at dipyrimidine sites that accumulate in skin-cell oncogenes/tumor suppressors — giving a dramatically increased (often >1000-fold) skin cancer risk at an early age. (c) Some XP complementation groups (and the related trichothiodystrophy/Cockayne overlap) also impair transcription-coupled repair and TFIIH function; neurons cannot replace themselves and are highly sensitive to accumulated transcription-blocking endogenous DNA damage, producing progressive neurodegeneration. See section 14.

13. A researcher designs a CRISPR experiment to correct a point mutation (G→A) in the *HBB* gene causing sickle-cell disease. List: (a) the guide RNA design rules; (b) the delivery method for cells (RNP electroporation vs viral vector); (c) why homology-directed repair (HDR, requiring a donor template) is needed rather than NHEJ; (d) how to increase HDR efficiency.

Answer (Q13, Application). (a) Guide RNA design: choose a 20-nt spacer matching *HBB* near the codon-6 mutation, immediately 5' of an NGG PAM, with high on-target and minimal off-target/self-similarity scores; place the cut close to the edit site. (b) Delivery: for *ex vivo* editing of patient hematopoietic stem cells, ribonucleoprotein (Cas9 protein + sgRNA) electroporation is preferred over viral vectors — it is transient (lower off-target and immunogenicity, no insertional mutagenesis). (c) Correcting G→A back to wild type requires HDR because only HDR copies a supplied donor template to install the exact sequence; NHEJ merely religates the break and introduces random indels (a knockout, not a correction). (d) Increasing HDR: use a single-stranded oligo donor, deliver in S/G2 phase, inhibit NHEJ (e.g., DNA-PK/Ligase IV inhibitors or NHEJ-pathway suppression),

and use chemically protected donors at optimized stoichiometry. See section 14. 14. A patient’s tumor has microsatellite instability (MSI-high) due to MMR deficiency. Explain: (a) what kinds of mutations accumulate in MSI-high tumors; (b) why MSI tumors produce many neoantigens; (c) why pembrolizumab (anti-PD-1) is effective in MSI-high tumors regardless of cancer type (tissue-agnostic treatment).

Answer (Q14, Application). (a) MMR deficiency means replication-slippage errors at short tandem repeats go uncorrected, so MSI-high tumors accumulate huge numbers of indels in microsatellites and a very high overall mutation burden, especially frameshifts in coding repeats. (b) Frameshifted coding sequences generate novel out-of-frame peptides — neoantigens — that are highly immunogenic because they are not present in normal tissue and are seen as foreign by T cells. (c) This high neoantigen load makes the tumor strongly immune-recognized but held in check by the PD-1/PD-L1 checkpoint; pembrolizumab (anti-PD-1) releases that brake, restoring T-cell killing. Because the mechanism depends on neoantigen load rather than tissue of origin, anti-PD-1 is approved tissue-agnostically for MSI-high/dMMR tumors. See section 14. 15. Transposon Alu (SINE family) comprise about 11% of the human genome. Explain: (a) how Alu elements replicate via RNA intermediates (SINE retrotransposition); (b) how an Alu insertion in exon 16 of BRCA2 could cause breast cancer; (c) how the host genome suppresses transposon activity in the germline (piRNA pathway).

Answer (Q15, Application). (a) Alu elements are non-autonomous SINE retrotransposons: they are transcribed by RNA Pol III, and the resulting RNA is reverse-transcribed and integrated by the LINE-1 (L1) machinery (ORF1/ORF2 proteins providing reverse transcriptase and endonuclease) — a copy-and-paste, RNA-intermediate mechanism that has expanded Alu to about 11% of the genome. (b) A new Alu insertion into exon 16 of BRCA2 disrupts the coding sequence (introducing extra sequence, splicing changes, or a frameshift/premature stop), abolishing functional BRCA2 and its homologous-recombination DNA-repair role, predisposing to breast/ovarian cancer. (c) In the germline, transposons are silenced by the piRNA pathway: PIWI proteins loaded with piRNAs recognize transposon transcripts, cleaving them and directing DNA methylation/heterochromatin at their loci to prevent mobilization. See section 14. 16. GWAS (genome-wide association studies) have identified thousands of SNPs associated with disease risk, but most are in non-coding regions. Explain: (a) why non-coding SNPs are biologically meaningful (enhancer activity, splicing regulation); (b) how eQTL analysis links SNPs to gene expression levels; (c) why a SNP with odds ratio 1.2 for Type 2 Diabetes is clinically uninformative for individual risk prediction.

Answer (Q16, Application). (a) Most trait-associated SNPs are non-coding because they lie in regulatory DNA — enhancers, promoters, or splicing elements — where they alter transcription-factor binding, chromatin state, or splice-site usage and thus change gene *dosage* rather than protein sequence. (b) eQTL analysis correlates a SNP’s genotype with mRNA expression levels across many individuals; a SNP that statistically predicts expression of a nearby (cis) or distant (trans) gene is an expression QTL, providing the mechanistic link from a non-coding GWAS hit to a target gene. (c) A SNP with odds ratio about 1.2 shifts an individual’s absolute Type 2 Diabetes risk only marginally and is swamped by environmental and polygenic background; such small effect sizes are useful for understanding biology and population-level architecture but are not clinically informative for predicting an individual’s risk. See section 14. 17. The P53 gene is mutated in >50% of all human cancers. Explain: (a) the “gain-of-function” mutations in TP53 (R248W, R175H) that not only eliminate tumor suppression but actively promote invasion; (b) how wild-type p53 regulates CDK inhibitor p21 and pro-apoptotic PUMA; (c) what therapeutic strategy (restoring wild-type TP53 conformation using small molecules — APR-246) is being tested.

Answer (Q17, Application). (a) Certain TP53 missense alleles (e.g., R248W, R175H) are gain-of-function: beyond losing wild-type tumor-suppressor activity, the mutant p53 acquires new oncogenic properties — binding other transcription factors and remodeling gene expression to promote invasion, metastasis, and chemoresistance (often also dominant-negative over any remaining wild-type p53). (b) Wild-type p53 is a transcription factor that, on DNA damage, induces the CDK inhibitor p21 (CDKN1A) to enforce G1/S arrest for repair, and pro-apoptotic targets such as PUMA (and BAX) to trigger apoptosis if damage is severe. (c) A tested strategy is APR-246/eprenetapopt, a small molecule that covalently modifies mutant p53 to restore a wild-type-like conformation and transcriptional activity, reactivating p21/PUMA-driven arrest and apoptosis in p53-mutant tumors. See section 14. 18. Gene therapy for Duchenne muscular dystrophy (DMD, caused by large deletions in *Dystrophin*) uses exon skipping with antisense oligonucleotides (AONs). Explain: (a) why some deletions cause severe DMD while frameshifted deletions are less severe (in-frame vs out-of-frame); (b) how AON targeting exon 51 restores the reading frame; (c) why this produces “Becker-like” dystrophin rather than fully corrected dystrophin.

Answer (Q18, Application). (a) Dystrophin tolerates internal in-frame deletions (producing shortened but partly functional protein → milder Becker muscular dystrophy), whereas out-of-frame deletions shift the reading frame, create a premature stop, and abolish dystrophin → severe Duchenne. So a large deletion’s severity depends on whether it disrupts the reading frame, not its size. (b) An antisense oligonucleotide complementary to exon 51 masks its splice signals, causing the spliceosome to skip exon 51; this removes additional sequence so that the exon junctions flanking the original deletion are realigned back into frame, allowing translation of an internally truncated protein. (c) The restored protein lacks the skipped exon(s), so it is an internally shortened, Becker-like dystrophin with partial function — converting a severe DMD phenotype toward a milder one rather than fully curing it. See section 14. 19. Epigenome-wide association studies (EWAS) examine DNA methylation differences between cases

and controls. Explain: (a) why methylation differences (epimutations) are harder to interpret than genetic mutations; (b) why cell-type composition confounds EWAS analysis; (c) how MR (Mendelian randomisation) can be used to determine whether methylation changes are causal or merely correlative with disease.

Answer (Q19, Application). (a) Epimutations (DNA-methylation differences) are harder to interpret than genetic mutations because methylation is dynamic, tissue- and cell-type-specific, age-dependent, and often a consequence rather than a cause of disease — so an association does not establish direction or mechanism. (b) Bulk tissue is a mixture of cell types with very different methylomes; if cases and controls differ in cell-type composition (e.g., more immune cells), apparent methylation differences may merely reflect that composition shift, a major confounder requiring deconvolution or cell-sorted data. (c) Mendelian randomization uses germline SNPs that influence methylation (mQTLs) as instrumental variables: because alleles are randomized at conception and fixed before disease, an association between the genetically predicted methylation level and disease supports a causal (not merely correlative) role, provided the instrument is valid and not pleiotropic. See section 14. 20. Oxford Nanopore sequencing reads individual DNA/RNA molecules by measuring ionic current changes as they pass through a protein pore. Compare this technology to Illumina short-read sequencing: advantages (read length, direct RNA, base modifications, real-time), disadvantages (raw error rate about 5% vs <0.1%), and the application where each is most suitable.

Answer (Q20, Application). Oxford Nanopore threads a single DNA/RNA strand through a protein nanopore and infers bases from characteristic ionic-current shifts. Advantages over Illumina: very long reads (kb–Mb, resolving repeats, structural variants, and enabling de novo/telomere-to-telomere assembly), direct RNA sequencing, detection of base modifications (e.g., methylation) without bisulfite, real-time/portable output. Disadvantages: higher raw per-base error (about 5% vs <0.1% for Illumina) and lower throughput per dollar for SNV calling. Best use: Illumina for high-accuracy SNV/small-variant detection and large cohort genotyping; Nanopore (or PacBio HiFi) for structural-variant discovery, repeat regions, full-length isoforms, epigenetic marks, and rapid field/clinical sequencing. See section 14.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the safety of germline CRISPR editing (modifying embryo DNA, producing heritable changes) as attempted by He Jiankui in 2018. Identify three specific scientific risks (off-target edits, mosaicism, unintended immune consequences) and three ethical concerns (informed consent, enhancement vs therapy, equity of access). What international governance frameworks should govern germline editing?

Answer (Q21, Synthesis). Empirically, He Jiankui edited *CCR5* in human embryos (2018) producing live births; documented and predicted problems include off-target double-strand breaks, mosaicism (not all cells edited), large deletions, and an uncertain benefit (the targeted *CCR5* change did not even reproduce the protective allele). The judgment that germline editing was unsafe and unethical follows because heritable, irreversible changes were introduced into healthy embryos without medical necessity, adequate preclinical safety, or genuine informed consent. Ethical concerns: defective consent, blurring therapy vs enhancement, and equity of access. Governance should require an enforceable international moratorium on clinical germline editing, oversight bodies (WHO registry, national regulators), and a transparent, criteria-based pathway. What would change the conclusion: demonstrated elimination of off-target/mosaicism risk plus a clear, otherwise-unavailable medical benefit and robust consent. See section 14. 22. A patient carries a disease-associated haplotype in which short reads map poorly because a 3-kb insertion and nearby promoter variant are absent from the linear reference. Design a graph-aware interpretation workflow: compare a single-reference call, a pangenome graph path, ClinVar/dbSNP/RefSeq/MANE status checks, and long-read validation; then explain when base editing, prime editing, Casgevy-style enhancer disruption, or Lyfgenia-style lentiviral gene addition would be the most defensible therapeutic logic.

Answer (Q22, Synthesis). A strong workflow first asks whether the apparent variant is a mapping artifact: remap reads against a pangenome graph that contains the insertion path, inspect read support across both breakpoints, check dbSNP for the submitted variant identifier, ClinVar for assertion/review status, and RefSeq/MANE for the transcript used to name the change, then confirm phase with long reads or linked reads before reporting a clinical haplotype [National Center for Biotechnology Information, 2026b,a,d,c]. Base editing is best for a single transition within an editor’s activity window when bystander edits are acceptable or avoidable. Prime editing is better for installing or correcting a short promoter motif, such as fetal-globin promoter rewrites, because the edit is templated without a double-strand break. Casgevy-style enhancer disruption is a different logic: it does not repair *HBB* but changes erythroid regulation by reducing BCL11A enhancer activity to raise fetal hemoglobin. Lyfgenia-style lentiviral gene addition is another regulatory path: it adds a functional hemoglobin transgene rather than editing the native locus, so ClinicalTrials.gov trial status and FDA approved indications must be checked separately [National Library of Medicine, 2026, U.S. Food and Drug Administration, 2026c]. Keep sequence evidence, database currency, expression evidence, editing feasibility, off-target assessment, and clinical maturity separate. See section 14. 23. Evaluate the “cancer genome atlas” concept: sequencing thousands of tumor genomes has generated a mutation landscape for most cancer types, identifying “drivers” vs “passengers.” What statistical criteria distinguish drivers from passengers, and why have most cancer driver mutations proven difficult to target therapeutically?

Answer (Q23, Synthesis). Empirically, sequencing thousands of tumors (e.g., TCGA) maps recurrent mutations across cancer types. Drivers vs passengers are distinguished statistically: drivers show mutation recurrence above the background mutation rate (MutSigCV-type models correcting

for gene length, replication timing, and context), selection signatures (elevated nonsynonymous/synonymous or clustering at hotspots), and functional/pathway enrichment; passengers are random by-product mutations consistent with background. The judgment that driver discovery has not translated easily into therapy follows because many drivers are tumor-suppressor losses or “undruggable” proteins (e.g., TP53, RAS until recently, transcription factors) lacking enzymatic pockets, and tumor heterogeneity/resistance limits single-target success. What would change the conclusion: new modalities (degraders, covalent KRAS inhibitors, synthetic lethality) making previously undruggable drivers tractable. See section 14. 24. Synthetic chromosomes have been designed and built in yeast (Sc2.0, synthetic chromosome project). Evaluate the design principles (removal of transposons, recombination tags added, inducible evolution mode via SCRaMbLE), and discuss whether a fully synthetic human chromosome could be built and what it would require.

Answer (Q24, Synthesis). Sc2.0 redesigns yeast chromosomes with defined principles: removal of destabilizing/repetitive elements (transposons, introns, redundant tRNA genes relocated), synonymous recoding (e.g., recoding stop codons to free a codon), insertion of loxPsym recombination tags at non-essential 3' ends to enable SCRaMbLE (Cre-induced inducible genome rearrangement for accelerated, controllable evolution), and watermarks/PCRTags for tracking — yielding a streamlined, programmable genome. The causal logic: design choices → reduced genome instability and a built-in diversification tool → a viable, evolvable synthetic eukaryotic chromosome. A fully synthetic human chromosome is far harder: it would require accurate megabase synthesis and assembly, functional centromeres, telomeres, and origins, correct large-scale 3D chromatin/epigenetic regulation, and stable mitotic segregation — currently beyond reach and raising serious safety/ethical constraints. See section 14. 25. Transposons in the germline are silenced by piRNAs (PIWI-interacting RNAs). The piRNA pathway (PIWI proteins, ping-pong amplification) produces a feed-forward silencing loop. Evaluate: (a) how piRNAs recognize transposons without classical Watson-Crick base pairing; (b) why depletion of PIWI proteins causes germline transposon mobilization and infertility in mice; (c) whether piRNAs can also target non-transposon mRNAs.

Answer (Q25, Synthesis). (a) piRNAs (about 24–31 nt, PIWI-bound, Dicer-independent) recognize transposons by sequence complementarity to transposon transcripts, but tolerance for mismatches plus an amplifying “ping-pong” cycle (sense and antisense piRNAs reciprocally guiding cleavage) lets the system target diverse, mutating transposons rather than requiring exact Watson–Crick matching of a fixed siRNA. (b) Loss of PIWI proteins (e.g., MILI/MIWI/MIWI2 knockouts) derepresses transposons in the germline, causing insertional mutagenesis, DNA damage, meiotic arrest, and infertility/sterility — showing piRNA silencing is essential for genome integrity in germ cells. (c) Beyond transposons, piRNAs can also target some non-transposon mRNAs (regulating their stability/translation, e.g., during spermiogenesis), indicating a broader post-transcriptional regulatory role. What would change this view: evidence that observed mRNA effects are indirect consequences of transposon derepression rather than direct piRNA targeting. See section 14. 26. Precision oncology based on tumor sequencing identifies actionable mutations. However, intratumoral heterogeneity (ITH) means that some cells within the tumor may lack the targeted mutation. Evaluate: (a) how clonal vs subclonal mutations are distinguished by variant allele frequency; (b) why targeting a clonal mutation (present in most cells) is more likely to be effective; (c) how liquid biopsy (circulating tumor DNA, ctDNA) can detect resistance mechanisms before clinical progression.

Answer (Q26, Synthesis). The causal chain: tumor sequencing finds actionable mutations, but intratumoral heterogeneity means a targeted mutation may be present in only a subset of cells, so therapy spares non-carrying clones and resistance emerges. (a) Clonal vs subclonal mutations are distinguished by variant allele frequency (VAF) adjusted for tumor purity and copy number: clonal mutations (in all cancer cells) cluster near the expected fully-penetrant VAF, whereas subclonal mutations show lower VAF (present in a fraction of cells). (b) Targeting a clonal mutation is more likely effective because every tumor cell carries it, so no pre-existing escape population is spared; targeting a subclonal driver leaves resistant clones to expand. (c) Liquid biopsy (ctDNA) non-invasively samples tumor-derived DNA from blood, so emerging resistance mutations (e.g., EGFR T790M) can be detected as rising ctDNA fractions before radiographic/clinical progression, enabling earlier therapy switching. See section 14. 27. Evaluate whether “de-extinction” (reviving extinct species via CRISPR genome editing of a close relative) is scientifically feasible for: (a) the woolly mammoth (editing *Loxodonta africana* genome about 50 key cold-adaptation genes); (b) the passenger pigeon (*Ectopistes migratorius*, using band-tailed pigeon as template). What are the ecological risks of reintroducing de-extinct animals?

Answer (Q27, Synthesis). Empirically, de-extinction by CRISPR does not literally resurrect an extinct species; it edits a close living relative toward the extinct phenotype. (a) For the woolly mammoth, about 50 cold-adaptation genes (hemoglobin, hair, fat, *TRPV3*) can be edited into the Asian elephant (*Elephas maximus*, not *Loxodonta*) genome, but a viable animal requires solving elephant cloning/artificial-womb gestation and integrating many edits — partial feasibility at best, yielding a cold-tolerant elephant hybrid, not a true mammoth. (b) The passenger pigeon (*Ectopistes migratorius*) using band-tailed pigeon as template faces the same limits plus avian cloning being unsolved. The judgment of limited feasibility rests on incomplete ancient genomes, polygenic phenotypes, and reproductive-technology gaps. Ecological risks: disrupted modern ecosystems, disease introduction, no surviving social/migratory learning, and diversion of conservation resources. What would change it: solved reproductive cloning and complete, high-quality ancient genomes. See section 14. 28. Retroviral integration (HIV integrates into host genome) is both a challenge for cure research and a tool for gene therapy vectors. Evaluate the “semi-random” integration pattern of HIV (preference for active transcription units) and how this differs from AAV (predominantly episomal in non-dividing cells, rare integration at AAVS1 safe harbor). Why does insertional mutagenesis risk differ between retroviral and AAV gene therapies?

Answer (Q28, Synthesis). The causal logic links integration site to genotoxic risk. HIV (lentivirus) integrates semi-randomly but preferentially into actively transcribed gene bodies (LEDGF/p75-tethered), so a therapeutic lentiviral vector can insert within or near active genes, with some risk of dysregulating them. AAV is predominantly episomal in non-dividing cells, with only rare integration (occasionally at the AAVS1 “safe harbor”), so it persists largely without altering host loci. Therefore insertional-mutagenesis risk is higher for integrating retro/lentiviral vectors (historically causing leukemia in early SCID-X1 gamma-retroviral trials due to enhancer activation of *LMO2*) than for AAV, whose mainly non-integrating biology limits oncogene activation but trades off durability (episome loss in dividing cells). What would change this: modified vectors (SIN-LTR, insulators, targeted integration) substantially lowering retroviral genotoxicity. See section 14. 29. tRNA suppressors can read through stop codons, restoring protein production from genes with premature stop mutations. Evaluate the therapeutic use of aminoglycoside antibiotics (gentamicin) as readthrough agents for nonsense mutations (e.g., in *Dystrophin*) — what are the molecular mechanisms, the challenges of specificity (also read through normal stop codons), and the clinical results to date?

Answer (Q29, Synthesis). The mechanism: suppressor/readthrough allows a near-cognate aminoacyl-tRNA to be inserted at a premature stop codon, restoring full-length protein. Aminoglycosides (gentamicin, and the designed agent ataluren/PTC124) bind the ribosomal decoding (A) site, reducing fidelity so a sense amino acid is incorporated at a PTC, producing some functional dystrophin in nonsense-mutation Duchenne. Specificity challenge: the ribosome cannot distinguish a premature from a normal stop codon, so readthrough of legitimate stop codons risks C-terminally extended aberrant proteins and toxicity; efficiency is also low and context-dependent (PTC identity and surrounding sequence). Clinical results to date: effects have been modest and inconsistent — ataluren showed marginal/equivocal benefit (conditional EU approval, not FDA-approved), and aminoglycoside toxicity (oto-/nephrotoxicity) limits chronic use. Outcome would change with non-toxic, PTC-selective readthrough drugs. See section 14. 30. Critically evaluate the technical and ethical implications of building a “minimal synthetic cell” with a fully defined genome (as in the Venter Institute’s JCVI-syn3.0, about 473 genes). What does the set of essential genes reveal about the minimal requirements for cellular life? If this minimal genome could be commercially manufactured and sold, what biosafety and biosecurity regulations should apply?

Answer (Q30, Synthesis). Empirically, JCVI-syn3.0 (Venter Institute) is a chemically synthesized, transplanted minimal *Mycoplasma* genome of about 473 genes that supports self-replication. The set of essential genes shows that minimal cellular life still requires the core processes — genome replication, transcription, translation, membrane/lipid biogenesis, and basic metabolism — yet about 149 essential genes still have unknown function, revealing that we do not fully understand even a minimal cell. The judgment that this is profound but bounded follows: it defines a lower bound on life’s genetic complexity without claiming we can yet design genomes from first principles. Biosafety/biosecurity: commercial minimal cells would need DNA-synthesis screening, containment and engineered biocontainment (kill switches, auxotrophy), licensing/traceability, dual-use review, and international oversight. What would change the assessment: a minimal genome whose every gene’s function is known and that is provably non-viable outside controlled conditions. See section 14.

Questions — Chromatin and Epigenetic Mechanisms

Instructor Use and Coverage Notes

- Coverage target: Explain how a regulatory mark changes accessibility and predict downstream expression.
- Model/data emphasis: Regulatory-state and expression-ratio reasoning.
- Assessment alignment: Concept Explanation, Questions and Methods, Argumentation.
- Misconception probe: Epigenetic does not mean independent of DNA sequence or permanently inherited.
- Transfer product: Apply regulation logic to differentiation, imprinting, cancer, or environmental responses.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 15 of the textbook — review that chapter before attempting the exercises below.

1. Define epigenetics. Give two examples of epigenetic modifications.

Answer (Q1, Recall). Epigenetics is the study of heritable changes in gene expression that do not alter the underlying DNA sequence but instead change chromatin state and accessibility. Two examples are DNA methylation of cytosine at CpG dinucleotides (generally repressive at promoters) and covalent histone tail modifications such as acetylation (H3K27ac, activating) or methylation (H3K27me3, repressive). See section 15.
2. What is DNA methylation? Which nucleotide is typically methylated in mammals, and what effect does methylation at gene promoters generally have on transcription?

Answer (Q2, Recall). DNA methylation is the covalent addition of a methyl group, catalyzed by DNA methyltransferases (DNMT1 maintenance; DNMT3A/3B de novo). In mammals it occurs almost exclusively on cytosine within 5'-CpG-3' dinucleotides. Methylation of a CpG island in a gene promoter generally represses transcription by blocking activator binding and recruiting methyl-binding repressors and HDACs, producing stable gene silencing. See section 15.
3. What is a histone? Name four types of histone modification and one enzyme family for each.

Answer (Q3, Recall). A histone is a small basic protein (H2A, H2B, H3, H4) that packages DNA into nucleosomes. Four modification types and an enzyme family for each: acetylation (HATs/KATs add, HDACs remove), methylation (KMTs such as PRC2/EZH2 add, KDMs/demethylases remove), phosphorylation (kinases such as Aurora B), and ubiquitination (E3 ligases such as RING1B on H2AK119). See section 15.
4. What does H3K4me3 mark indicate? What about H3K27me3?

Answer (Q4, Recall). H3K4me3 is an activating mark enriched at the promoters of actively transcribed genes, written by MLL/COMPASS and read by basal transcription machinery. H3K27me3 is a repressive mark deposited by Polycomb repressive complex 2 (EZH2) that silences developmental genes and is read by PRC1. Both are lysine methylation on H3, but their distinct positions and reader complexes give opposite functional outcomes. See section 15.
5. What is chromatin remodeling? Name one chromatin remodeling complex.

Answer (Q5, Recall). Chromatin remodeling is the ATP-dependent repositioning, ejection, or restructuring of nucleosomes to change DNA accessibility for transcription factors and the replication/repair machinery. One example is the SWI/SNF (BAF) complex, which uses ATP hydrolysis to slide or evict nucleosomes; other families include ISWI, CHD/NuRD, and INO80. See section 15.
6. What is the lac operon? Which molecules control it?

Answer (Q6, Recall). The lac operon is a cluster of E. coli genes (lacZ, lacY, lacA) encoding enzymes for lactose uptake and metabolism, transcribed from a single promoter. It is controlled by negative regulation via the LacI repressor (released when allolactose, the inducer, binds it) and positive regulation via CAP-cAMP, which activates transcription when glucose is low. See section 15.
7. What is a repressor protein? What is an activator protein?

Answer (Q7, Recall). A repressor is a regulatory protein that binds DNA (typically an operator or silencer) and decreases transcription, for example by blocking RNA polymerase or recruiting repressive chromatin machinery. An activator binds DNA (an enhancer or CAP site) and increases transcription by recruiting or stabilizing RNA polymerase and coactivators, as CAP-cAMP does at the lac promoter. See section 15.
8. Define allosteric regulation in the context of transcription. Give an example.

Answer (Q8, Recall). Allosteric regulation is the modulation of a regulatory protein’s DNA-binding activity by a small effector molecule binding at a separate site, changing the protein’s conformation. In the lac operon, allolactose binds the LacI repressor and allosterically reduces its affinity for the operator, releasing it from DNA and allowing transcription; conversely, tryptophan acts as a corepressor that activates the trp repressor. See section 15.

9. What are non-coding RNAs? Name three biologically important types.

Answer (Q9, Recall). Non-coding RNAs are functional RNA transcripts that are not translated into protein but instead regulate gene expression and genome organization. Three important types are microRNAs (about 22 nt, guide RISC to repress target mRNAs), small interfering RNAs (siRNAs, drive sequence-specific mRNA cleavage in RNAi), and long non-coding RNAs (lncRNAs such as Xist, which scaffold chromatin-modifying complexes). See section 15.

10. What is genomic imprinting? Give one example of an imprinted gene.

Answer (Q10, Recall). Genomic imprinting is parent-of-origin-specific monoallelic expression, in which a gene is expressed only from the maternally or only from the paternally inherited allele, set by differential DNA methylation at imprinting control regions in the germline. An example is IGF2, expressed only from the paternal allele (the maternal allele is silenced via the CTCF-controlled IGF2/H19 ICR). See section 15.

Questions 11–20: Application and Analysis

11. A CpG island in the CDKN2A (p16) promoter is hypermethylated in a lung cancer cell. Trace the molecular consequences: (a) which protein is silenced; (b) what happens to CDK4/6 activity; (c) what happens to cell cycle progression; (d) why this is an alternative mechanism to p16 deletion for bypassing the G₁ checkpoint.

Answer (Q11, Application). (a) Hypermethylation of the CDKN2A CpG island silences the p16^{INK4a} protein. (b) Without p16 to inhibit CDK4/6, Cyclin D–CDK4/6 remains active. (c) Active CDK4/6 hyperphosphorylates Rb, releasing E2F so the cell passes the G₁ restriction point and proliferates. (d) This epigenetic silencing is functionally equivalent to deleting or mutating p16 — it inactivates the gene without changing the DNA sequence, an alternative route to bypassing the G₁ checkpoint, and it is potentially reversible with demethylating agents. See section 15.

12. Polycomb repressive complex 2 (PRC2) trimethylates H3K27 and is overexpressed in many cancers. Explain: (a) the molecular mechanism of H3K27me₃-mediated gene silencing; (b) how PRC2 spreads repression across large chromosomal domains; (c) why EZH2 (the catalytic subunit of PRC2) is a therapeutic target (tazemetostat).

Answer (Q12, Application). (a) PRC2 trimethylates H3K27 (H3K27me₃), which recruits PRC1 to ubiquitinate H2AK119 and compact chromatin, blocking transcription. (b) H3K27me₃ is itself read by the PRC2 EED subunit, creating positive feedback that spreads the mark in cis across broad domains. (c) Overactive or mutant EZH2 hyper-represses tumor-suppressor and differentiation genes, so the catalytic EZH2 subunit is druggable; tazemetostat is an FDA-approved EZH2 inhibitor that reactivates these genes. See section 15.

13. In the lac operon, explain the logic of dual control by the lac repressor AND catabolite activator protein (CAP). Under which combination of conditions is the operon most highly transcribed? Under which is it completely silent?

Answer (Q13, Application). The lac repressor provides negative control (bound to the operator unless allolactose is present) and CAP–cAMP provides positive control (active only when glucose is low, raising cAMP). The operon is maximally transcribed when lactose is present AND glucose is absent: the repressor is released and CAP–cAMP activates the promoter. It is completely silent when lactose is absent, because the repressor stays bound regardless of glucose status. See section 15.

14. RNA interference (RNAi) via siRNA silences gene expression post-transcriptionally. Compare siRNA (perfectly complementary → mRNA cleavage by Ago2) vs miRNA (partially complementary → translational repression and mRNA destabilisation). How does each affect the steady-state abundance of target mRNA?

Answer (Q14, Application). siRNAs are perfectly complementary to their targets and direct Ago2 to endonucleolytically cleave (slice) the mRNA, sharply lowering its steady-state abundance. miRNAs are only partially complementary (matching mainly through the seed region) and act mostly by repressing translation and promoting deadenylation/decay, causing a more modest reduction in mRNA levels and a larger drop in protein output. Both reduce target expression, but siRNA produces stronger, cleavage-based mRNA loss. See section 15.

15. Enhancers can activate promoters over distances of >1 Mb in the genome by chromatin looping mediated by cohesin and CTCF. Explain: (a) the role of CTCF as a chromatin barrier/insulator; (b) how loss of a CTCF binding site at the IGF2/H19 imprinting control region (ICR) causes Beckwith-Wiedemann syndrome; (c) how 4C and HiC experiments confirm enhancer-promoter looping.

Answer (Q15, Application). (a) CTCF binds insulator sequences and, with cohesin, organizes chromatin loops/TAD boundaries that block enhancers from acting across them. (b) At the IGF2/H19 ICR the maternal allele is unmethylated, so CTCF binds and insulates IGF2 from the downstream enhancers; loss of that CTCF site (or its methylation) lets the enhancer loop to IGF2, causing biallelic IGF2 expression and overgrowth (Beckwith-Wiedemann syndrome). (c) Chromosome-conformation methods such as 4C and Hi-C detect ligated DNA contacts, directly demonstrating physical enhancer–promoter looping. See section 15.

16. Evaluate the claim that cancer is largely an epigenetic disease. Cite evidence from: (a) global hypomethylation and CpG island hypermethylation in cancer; (b) frequent mutations in chromatin remodeling enzymes (ARID1A, SMARCA4, KMT2D) in cancer; (c) the success of HDAC inhibitors and DNMT inhibitors clinically. Under what conditions are purely epigenetic therapies (without targeted mutation correction) appropriate?

Answer (Q16, Application). (a) Cancers show genome-wide hypomethylation (activating oncogenes/transposons) alongside focal CpG-island hypermethylation that silences tumor suppressors, an epigenetic phenotype. (b) Frequent loss-of-function mutations in chromatin regulators (ARID1A, SMARCA4, KMT2D) show the chromatin machinery is itself a driver. (c) Clinical efficacy of DNMT inhibitors (azacitidine) and HDAC inhibitors supports reversible epigenetic causation. The claim holds where epigenetic silencing is the dominant lesion (e.g., MDS, IDH-mutant gliomas) and a reactivatable gene exists; purely epigenetic therapy is inappropriate when fixed driver mutations or deletions, not silencing, sustain the tumor. See section 15.

17. Design a pharmaceutical strategy to reactivate a silenced tumor suppressor gene in a cancer with promoter hypermethylation. Compare DNMT inhibitors (5-azacitidine, broad demethylation), targeted dCas9-TET1 (site-specific demethylation), and HDAC inhibitors. What are the risks of broad epigenome reprogramming vs targeted approaches?

Answer (Q17, Application). Hypothesis: re-expressing the silenced tumor suppressor restores growth control. Compare arms: a DNMT inhibitor (5-azacitidine) causes broad passive demethylation and reactivates many genes but risks global genome instability and off-target reactivation; dCas9-TET1 demethylates only the targeted promoter, giving specificity but limited efficiency and delivery challenges; HDAC inhibitors broadly reopen chromatin but are nonspecific and transient. Measure target re-expression, methylation, growth arrest, with vehicle and catalytically dead controls; the decision rule is restored expression and arrest specifically when the targeted mark is removed. Broad reprogramming risks awakening oncogenes and toxicity; targeted approaches trade efficiency for safety. See section 15.

18. Super-enhancers are clusters of enhancers (about 25–50 kb) bound by an unusually high density of transcription factors (BRD4, Mediator), associated with strong transcription of oncogenes (MYC, BCL2) in cancer. Evaluate the evidence for super-enhancer addiction in cancer cells, and explain why BET bromodomain inhibitors (JQ1) preferentially disengage from super-enhancers over typical enhancers.

Answer (Q18, Application). Super-enhancers are dense clusters of enhancers occupied by high levels of BRD4, Mediator, and master transcription factors that drive very high expression of identity and oncogene loci (MYC, BCL2). Evidence for addiction: cancer cells are disproportionately dependent on these few super-enhancer-driven genes, so disrupting them collapses the oncogenic program. Because super-enhancers depend on cooperative, high-density BRD4/Mediator occupancy and phase-separated condensates, BET inhibitors such as JQ1 disengage BRD4 more steeply from super-enhancers than from typical enhancers — a small drop in occupancy disproportionately collapses the cooperative assembly, preferentially shutting off MYC. See section 15.

19. Evaluate the concept of “epigenetic clock” (Horvath clock): methylation of specific CpG sites in blood DNA correlates with biological age more accurately than chronological age. What do deviations from the epigenetic clock predict? Can lifestyle interventions (caloric restriction, exercise) reduce epigenetic age, and what experimental evidence supports this?

Answer (Q19, Application). The Horvath epigenetic clock estimates biological age from methylation at a defined set of CpG sites (about 353), often more accurately tracking physiological aging than chronological age. Positive deviations (epigenetic age acceleration) predict elevated all-cause mortality and risk of age-related disease, while negative deviations associate with longevity. Some interventions (caloric restriction in animal models, exercise, and small human trials) modestly slow or reverse epigenetic age, but evidence is correlational and confounded by cell-type composition, so randomized longitudinal data with matched cell populations are needed before causal claims. See section 15.

20. 3D chromatin organization (TADs — topologically associating domains) is largely maintained by CTCF and cohesin. Evaluate what would happen to gene regulation if cohesin loading were abolished globally: (a) which enhancer-promoter pairs would become aberrantly activated; (b) what new gene expression states would emerge; (c) is this consistent with the observation that cohesin mutations cause Cornelia de Lange syndrome?

Answer (Q20, Application). TAD boundaries are built by CTCF and cohesin through loop extrusion. (a) Abolishing cohesin loading would eliminate most loops/TADs, so enhancers could aberrantly contact promoters outside their normal domains, switching on genes that are normally insulated. (b) New, dysregulated expression states would emerge, generally with modest, widespread changes rather than wholesale reprogramming, since promoter-proximal control persists. (c) This is consistent with cohesin/NIPBL mutations causing Cornelia de Lange syndrome, a multisystem

developmental disorder, because partial loss of cohesin function subtly mis-wires enhancer–promoter contacts genome-wide during development. See section 15.

Questions 21–30: Synthesis and Evaluation

21. CRISPR interference (CRISPRi) uses dCas9-KRAB (a transcriptional repressor) to silence target genes without cutting DNA. Compare CRISPRi with ASO (antisense oligonucleotide) knockdown at the mRNA level and classical promoter deletion by CRISPR. What are the therapeutic advantages of CRISPRi (temporal control, reversibility, no off-target DSBs)?

Answer (Q21, Synthesis). CRISPRi (dCas9-KRAB) recruits repressive chromatin machinery to a promoter to silence transcription without cutting DNA, acting at the chromatin/transcription level. ASO knockdown acts post-transcriptionally by triggering RNase H degradation of the mRNA, leaving the gene intact and requiring continuous dosing. Classical CRISPR promoter deletion permanently removes DNA via double-strand breaks. CRISPRi’s advantages are reversibility and tunable, inducible temporal control, multiplexing, and avoidance of off-target double-strand breaks and permanent genomic scars, making it safer and more flexible for functional and therapeutic silencing. See section 15.

22. Maternal nutrition during peri-conception affects offspring health across the life course (Barker/DOHaD hypothesis). Using three specific nutrients (folate, methionine, choline) and their roles in one-carbon metabolism → SAM production → methyltransferase substrate supply, evaluate the molecular mechanism by which poor maternal nutrition could cause persistent epigenetic changes in offspring that increase adult diabetes or cardiovascular disease risk.

Answer (Q22, Synthesis). Folate, methionine, and choline feed one-carbon metabolism to regenerate S-adenosylmethionine (SAM), the universal methyl donor for DNMTs and histone methyltransferases. Poor maternal supply of these nutrients lowers SAM (and shifts the SAM:SAH ratio), reducing methyltransferase activity during the sensitive peri-conceptual window. This produces altered, persistent DNA-methylation patterns at metabolic gene promoters and imprinted loci in the offspring, which are maintained through development and program tissues toward impaired glucose handling and vascular dysfunction, raising adult diabetes and cardiovascular disease risk (the DOHaD/Barker mechanism). See section 15.

23. Evaluate the concept of “bivalent chromatin domains” in embryonic stem cells: developmental gene promoters carry both active (H3K4me3) and repressive (H3K27me3) marks simultaneously, maintaining them in a “poised” state. How does this enable rapid differentiation in either direction, and what happens to bivalent domains as cells commit to a specific lineage?

Answer (Q23, Synthesis). Bivalent domains carry the activating H3K4me3 and repressive H3K27me3 marks together at developmental gene promoters in embryonic stem cells, holding genes transcriptionally poised — repressed but primed for rapid activation. On differentiation cues the domain resolves in a lineage-specific way: genes needed in that lineage lose H3K27me3 and become fully active (monovalent H3K4me3), while genes for alternative fates lose H3K4me3 and become stably repressed (monovalent H3K27me3). This allows fast, bidirectional commitment, and once a cell adopts a lineage the bivalent state is resolved into a single stable mark. See section 15.

24. Fragile X syndrome is caused by CGG repeat expansion (>200 repeats) in the *FMR1* gene’s 5’ UTR, leading to hypermethylation and gene silencing. Evaluate the molecular relationship between repeat expansion and hypermethylation: which comes first, what protein (MBNL1/DNMT3A) reads the repeat expansion, and why does the “premutation” (55–200 repeats) have a partially different phenotype (FXTAS) compared to full mutation?

Answer (Q24, Synthesis). In Fragile X, the CGG repeat expansion comes first: when the *FMR1* 5’ UTR repeat exceeds about 200 (full mutation), the expanded CGG tract is recognized and triggers de novo DNA methylation (via DNMT3A and silencing RNA/heterochromatin pathways) of the *FMR1* promoter CpG island, shutting off FMRP. The premutation (55–200 repeats) is not methylated and *FMR1* is still transcribed — even overexpressed — so the toxic phenotype (FXTAS, premature ovarian insufficiency) is an RNA gain-of-function from excess CGG-containing mRNA, distinct from the loss-of-function silencing in the full mutation. See section 15.

25. Critically evaluate the potential of epigenetic editing as a permanent therapeutic intervention. Specifically: if dCas9-DNMT3A is used to methylate and silence an oncogene, will the silencing persist through cell division (via DNMT1 maintenance methylation), and what are the risks of epigenetic drift or passenger methylation at off-target sites? Propose experimental criteria to determine whether a therapeutic epigenetic edit is “safe and durable.”

Answer (Q25, Synthesis). dCas9-DNMT3A-induced promoter methylation can persist through division because the symmetric CpG mark is copied each S phase by DNMT1/UHRF1 maintenance methylation, so silencing is heritable even after the editor is removed. Risks include epigenetic drift (gradual loss or spreading of methylation), reactivation, and passenger/off-target methylation at unintended loci with their own phenotypic consequences. Criteria for a safe, durable edit: stable target silencing and methylation over many passages and in vivo, genome-wide methylation profiling showing minimal off-target marks, no oncogene reactivation or growth advantage, and reversibility/controllability if adverse effects appear. See section 15.

26. The X-inactivation center (Xic) on the inactive X chromosome produces Xist lncRNA, which coats the inactive X in cis. Explain: (a) how Xist RNA spreads along the chromosome; (b) how it recruits PRC2 (H3K27me3) and PRC1 (H2AK119ub1) to compact the Xi; (c) why a small region (pseudo-autosomal

region, PAR) escapes X-inactivation.

Answer (Q26, Synthesis). (a) Xist is transcribed only from the future inactive X and spreads in cis along that chromosome by exploiting its 3D proximity, nucleating from the X-inactivation center. (b) Xist recruits SPEN/HDAC3 and Polycomb complexes so PRC2 deposits H3K27me3 and PRC1 deposits H2AK119ub1, with later DNA methylation, compacting the Xi into a heterochromatic Barr body. (c) Genes in the pseudoautosomal region escape inactivation because they have homologous active partners on the Y chromosome, so dosage must be maintained from both sex chromosomes. See section 15.

27. A researcher uses Cas9 fused to a DNMT3A (DNA methyltransferase) domain (dCas9-DNMT3A) to specifically methylate a target promoter. Predict: (a) the epigenetic effect at the target gene; (b) whether the silencing will be maintained through DNA replication (yes, DNMT1 maintenance methyltransferase copies the pattern); (c) how you would verify that methylation, not dCas9 binding alone, is responsible for silencing.

Answer (Q27, Synthesis). (a) dCas9-DNMT3A targeted to the promoter deposits CpG methylation, repressing the gene by blocking activators and recruiting methyl-readers. (b) Yes — once the symmetric CpG pattern is established, DNMT1 (with UHRF1) recognizes hemimethylated CpGs after replication and restores full methylation, so silencing is heritably maintained through cell division. (c) Verify methylation is causal by using a catalytically dead DNMT3A fusion as a control (binding without methylation should not silence) and by treating with a DNMT inhibitor or bisulfite-sequencing the locus to confirm methylation tracks with silencing. See section 15.

28. Transgenerational epigenetic inheritance refers to the transmission of epigenetic marks across generations without DNA sequence change. The agouti mouse model showed that maternal methyl-donor diet changes offspring coat color and obesity risk via CpG methylation of the Avy allele. What does this imply about the erasure of epigenetic marks between generations (which normally occurs in primordial germ cells)?

Answer (Q28, Synthesis). If diet-induced methylation of the Avy allele in one generation alters offspring coat color and metabolism, then the genome-wide epigenetic reprogramming that normally erases methylation in primordial germ cells (and again after fertilization) is incomplete at certain loci. Some sequences — including metastable epialleles and certain repeat/transposon-associated regions like Avy — escape full erasure, allowing parental environmental information to be transmitted, although such transgenerational inheritance is locus-specific and the magnitude of true germline transmission requires careful controls. See section 15.

29. Long non-coding RNAs (lncRNAs) number >100,000 in the human transcriptome but most have unknown functions. Evaluate the challenges of studying lncRNA function: (a) conservation is low across species (cannot use model organisms easily); (b) knockdown may affect the genomic region itself (enhancer function of the locus); (c) lncRNAs have complex secondary structure but no ORFs. Propose a systematic approach to determine function.

Answer (Q29, Synthesis). (a) Because lncRNA sequences evolve rapidly, simple cross-species conservation cannot identify functional ones and model organisms may lack orthologues. (b) Knockdown or deletion can perturb the act of transcription or an underlying enhancer/DNA element rather than the RNA product itself, confounding interpretation. (c) Lacking ORFs and conserved domains, function must be inferred from structure and interactions. A systematic approach: combine RNA-targeting knockdown (ASOs/CRISPRi versus locus deletion controls), rescue with exogenous transcript, map RNA–chromatin/protein interactions (CHART/ChIRP, RAP), and test specific structural motifs by targeted mutation. See section 15.

30. Chromatin accessibility (measured by ATAC-seq) is strongly correlated with gene expression. Explain: (a) how nucleosome positioning regulates transcription factor accessibility; (b) the role of pioneer transcription factors (e.g., FOXA1) in opening closed chromatin; (c) how ATAC-seq works mechanistically (Tn5 transposase cuts accessible DNA and adds sequencing adapters).

Answer (Q30, Synthesis). (a) Nucleosomes occlude DNA, so where they are positioned determines whether transcription-factor binding sites and promoters are accessible; nucleosome-depleted regions correlate with active regulatory elements. (b) Pioneer factors such as FOXA1 can engage their motifs within closed, nucleosomal chromatin and recruit remodellers to open it, licensing other factors to bind. (c) ATAC-seq uses hyperactive Tn5 transposase that preferentially inserts into open chromatin, simultaneously cutting accessible DNA and adding sequencing adapters, so read density reports genome-wide accessibility. See section 15.

Questions — Epigenetic Inheritance and Disease

Instructor Use and Coverage Notes

- Coverage target: Explain how 3D organization or inherited marks alter expression and disease risk.
- Model/data emphasis: Chromatin-loop, inheritance, and disease-risk reasoning.
- Assessment alignment: Concept Explanation, Questions and Methods, Argumentation.
- Misconception probe: A chromatin contact map is not proof of function without perturbation.
- Transfer product: Apply inheritance logic to cancer, developmental disorders, and environmental exposure.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 16 of the textbook — review that chapter before attempting the exercises below.

1. The X-inactivation center (Xic) on the inactive X chromosome produces Xist lncRNA, which coats the inactive X in cis. Explain: (a) how Xist RNA spreads along the chromosome; (b) how it recruits PRC2 (H3K27me3) and PRC1 (H2AK119ub1) to compact the Xi; (c) why a small region (pseudo-autosomal region, PAR) escapes X-inactivation.

Answer (Q1, Recall). (a) Xist is transcribed only from the future inactive X and spreads in cis along that chromosome by exploiting its 3D proximity, nucleating from the X-inactivation center. (b) Xist recruits SPEN/HDAC3 and Polycomb complexes so PRC2 deposits H3K27me3 and PRC1 deposits H2AK119ub1, with later DNA methylation, compacting the Xi into a heterochromatic Barr body. (c) Genes in the pseudoautosomal region escape inactivation because they have homologous active partners on the Y chromosome, so dosage must be maintained from both sex chromosomes. See section 16.

2. A researcher uses Cas9 fused to a DNMT3A (DNA methyltransferase) domain (dCas9-DNMT3A) to specifically methylate a target promoter. Predict: (a) the epigenetic effect at the target gene; (b) whether the silencing will be maintained through DNA replication (yes, DNMT1 maintenance methyltransferase copies the pattern); (c) how you would verify that methylation, not dCas9 binding alone, is responsible for silencing.

Answer (Q2, Recall). (a) dCas9-DNMT3A targeted to the promoter deposits CpG methylation, repressing the gene by blocking activators and recruiting methyl-readers. (b) Yes — once the symmetric CpG pattern is established, DNMT1 (with UHRF1) recognizes hemimethylated CpGs after replication and restores full methylation, so silencing is heritably maintained through cell division. (c) Verify methylation is causal by using a catalytically dead DNMT3A fusion as a control (binding without methylation should not silence) and by treating with a DNMT inhibitor or bisulfite-sequencing the locus to confirm methylation tracks with silencing. See section 16.

3. Transgenerational epigenetic inheritance refers to the transmission of epigenetic marks across generations without DNA sequence change. The agouti mouse model showed that maternal methyl-donor diet changes offspring coat color and obesity risk via CpG methylation of the Avy allele. What does this imply about the erasure of epigenetic marks between generations (which normally occurs in primordial germ cells)?

Answer (Q3, Recall). If diet-induced methylation of the Avy allele in one generation alters offspring coat color and metabolism, then the genome-wide epigenetic reprogramming that normally erases methylation in primordial germ cells (and again after fertilization) is incomplete at certain loci. Some sequences — including metastable epialleles and certain repeat/transposon-associated regions like Avy — escape full erasure, allowing parental environmental information to be transmitted, although such transgenerational inheritance is locus-specific and the magnitude of true germline transmission requires careful controls. See section 16.

4. Long non-coding RNAs (lncRNAs) number >100,000 in the human transcriptome but most have unknown functions. Evaluate the challenges of studying lncRNA function: (a) conservation is low across species (cannot use model organisms easily); (b) knockdown may affect the genomic region itself (enhancer function of the locus); (c) lncRNAs have complex secondary structure but no ORFs. Propose a systematic approach to determine function.

Answer (Q4, Recall). (a) Because lncRNA sequences evolve rapidly, simple cross-species conservation cannot identify functional ones and model organisms may lack orthologues. (b) Knockdown or deletion can perturb the act of transcription or an underlying enhancer/DNA element rather than the RNA product itself, confounding interpretation. (c) Lacking ORFs and conserved domains, function must be inferred from structure and interactions. A systematic approach: combine RNA-targeting knockdown (ASOs/CRISPRi versus locus deletion controls), rescue with exogenous transcript, map RNA–chromatin/protein interactions (CHART/ChIRP, RAP), and test specific structural motifs by targeted mutation. See section 16.

5. Chromatin accessibility (measured by ATAC-seq) is strongly correlated with gene expression. Explain: (a) how nucleosome positioning regulates transcription factor accessibility; (b) the role of pioneer transcription factors (e.g., FOXA1) in opening closed chromatin; (c) how ATAC-seq works mechanistically (Tn5 transposase cuts accessible DNA and adds sequencing adapters).

Answer (Q5, Recall). (a) Nucleosomes occlude DNA, so where they are positioned determines whether transcription-factor binding sites and promoters are accessible; nucleosome-depleted regions correlate with active regulatory elements. (b) Pioneer factors such as FOXA1 can engage their motifs within closed, nucleosomal chromatin and recruit remodellers to open it, licensing other factors to bind. (c) ATAC-seq uses hyperactive Tn5 transposase that preferentially inserts into open chromatin, simultaneously cutting accessible DNA and adding sequencing adapters, so read density reports genome-wide accessibility. See section 16.

6. Evaluate the claim that cancer is largely an epigenetic disease. Cite evidence from: (a) global hypomethylation and CpG island hypermethylation in cancer; (b) frequent mutations in chromatin remodeling enzymes (ARID1A, SMARCA4, KMT2D) in cancer; (c) the success of HDAC inhibitors and DNMT inhibitors clinically. Under what conditions are purely epigenetic therapies (without targeted mutation correction) appropriate?

Answer (Q6, Recall). (a) Cancers show genome-wide hypomethylation (activating oncogenes/transposons) alongside focal CpG-island hypermethylation that silences tumor suppressors, an epigenetic phenotype. (b) Frequent loss-of-function mutations in chromatin regulators (ARID1A, SMARCA4, KMT2D) show the chromatin machinery is itself a driver. (c) Clinical efficacy of DNMT inhibitors (azacitidine) and HDAC inhibitors supports reversible epigenetic causation. The claim holds where epigenetic silencing is the dominant lesion (e.g., MDS, IDH-mutant gliomas) and a reactivatable gene exists; purely epigenetic therapy is inappropriate when fixed driver mutations or deletions, not silencing, sustain the tumor. See section 16.

7. Design a pharmaceutical strategy to reactivate a silenced tumor suppressor gene in a cancer with promoter hypermethylation. Compare DNMT inhibitors (5-azacitidine, broad demethylation), targeted dCas9-TET1 (site-specific demethylation), and HDAC inhibitors. What are the risks of broad epigenome reprogramming vs targeted approaches?

Answer (Q7, Recall). Hypothesis: re-expressing the silenced tumor suppressor restores growth control. Compare arms: a DNMT inhibitor (5-azacitidine) causes broad passive demethylation and reactivates many genes but risks global genome instability and off-target reactivation; dCas9-TET1 demethylates only the targeted promoter, giving specificity but limited efficiency and delivery challenges; HDAC inhibitors broadly reopen chromatin but are nonspecific and transient. Measure target re-expression, methylation, growth arrest, with vehicle and catalytically dead controls; the decision rule is restored expression and arrest specifically when the targeted mark is removed. Broad reprogramming risks awakening oncogenes and toxicity; targeted approaches trade efficiency for safety. See section 16.

8. Super-enhancers are clusters of enhancers (about 25–50 kb) bound by an unusually high density of transcription factors (BRD4, Mediator), associated with strong transcription of oncogenes (MYC, BCL2) in cancer. Evaluate the evidence for super-enhancer addiction in cancer cells, and explain why BET bromodomain inhibitors (JQ1) preferentially disengage from super-enhancers over typical enhancers.

Answer (Q8, Recall). Super-enhancers are dense clusters of enhancers occupied by high levels of BRD4, Mediator, and master transcription factors that drive very high expression of identity and oncogene loci (MYC, BCL2). Evidence for addiction: cancer cells are disproportionately dependent on these few super-enhancer-driven genes, so disrupting them collapses the oncogenic program. Because super-enhancers depend on cooperative, high-density BRD4/Mediator occupancy and phase-separated condensates, BET inhibitors such as JQ1 disengage BRD4 more steeply from super-enhancers than from typical enhancers — a small drop in occupancy disproportionately collapses the cooperative assembly, preferentially shutting off MYC. See section 16.

9. Evaluate the concept of “epigenetic clock” (Horvath clock): methylation of specific CpG sites in blood DNA correlates with biological age more accurately than chronological age. What do deviations from the epigenetic clock predict? Can lifestyle interventions (caloric restriction, exercise) reduce epigenetic age, and what experimental evidence supports this?

Answer (Q9, Recall). The Horvath epigenetic clock estimates biological age from methylation at a defined set of CpG sites (about 353), often more accurately tracking physiological aging than chronological age. Positive deviations (epigenetic age acceleration) predict elevated all-cause mortality and risk of age-related disease, while negative deviations associate with longevity. Some interventions (caloric restriction in animal models, exercise, and small human trials) modestly slow or reverse epigenetic age, but evidence is correlational and confounded by cell-type composition, so randomized longitudinal data with matched cell populations are needed before causal claims. See section 16.

10. 3D chromatin organization (TADs — topologically associating domains) is largely maintained by CTCF and cohesin. Evaluate what would happen to gene regulation if cohesin loading were abolished globally: (a) which enhancer-promoter pairs would become aberrantly activated; (b) what new gene expression states would emerge; (c) is this consistent with the observation that cohesin mutations cause Cornelia de Lange syndrome?

Answer (Q10, Recall). TAD boundaries are built by CTCF and cohesin through loop extrusion. (a) Abolishing cohesin loading would eliminate most loops/TADs, so enhancers could aberrantly contact promoters outside their normal domains, switching on genes that are normally insulated. (b) New, dysregulated expression states would emerge, generally with modest, widespread changes rather than wholesale reprogramming, since promoter-proximal control persists. (c) This is consistent with cohesin/NIPBL mutations causing Cornelia de Lange syndrome, a multisystem

developmental disorder, because partial loss of cohesin function subtly mis-wires enhancer–promoter contacts genome-wide during development. See section 16.

Questions 11–20: Application and Analysis

11. CRISPR interference (CRISPRi) uses dCas9-KRAB (a transcriptional repressor) to silence target genes without cutting DNA. Compare CRISPRi with ASO (antisense oligonucleotide) knockdown at the mRNA level and classical promoter deletion by CRISPR. What are the therapeutic advantages of CRISPRi (temporal control, reversibility, no off-target DSBs)?

Answer (Q11, Application). CRISPRi (dCas9-KRAB) recruits repressive chromatin machinery to a promoter to silence transcription without cutting DNA, acting at the chromatin/transcription level. ASO knockdown acts post-transcriptionally by triggering RNase H degradation of the mRNA, leaving the gene intact and requiring continuous dosing. Classical CRISPR promoter deletion permanently removes DNA via double-strand breaks. CRISPRi’s advantages are reversibility and tunable, inducible temporal control, multiplexing, and avoidance of off-target double-strand breaks and permanent genomic scars, making it safer and more flexible for functional and therapeutic silencing. See section 16.

12. Maternal nutrition during peri-conception affects offspring health across the life course (Barker/DOHaD hypothesis). Using three specific nutrients (folate, methionine, choline) and their roles in one-carbon metabolism → SAM production → methyltransferase substrate supply, evaluate the molecular mechanism by which poor maternal nutrition could cause persistent epigenetic changes in offspring that increase adult diabetes or cardiovascular disease risk.

Answer (Q12, Application). Folate, methionine, and choline feed one-carbon metabolism to regenerate S-adenosylmethionine (SAM), the universal methyl donor for DNMTs and histone methyltransferases. Poor maternal supply of these nutrients lowers SAM (and shifts the SAM:SAH ratio), reducing methyltransferase activity during the sensitive peri-conceptual window. This produces altered, persistent DNA-methylation patterns at metabolic gene promoters and imprinted loci in the offspring, which are maintained through development and program tissues toward impaired glucose handling and vascular dysfunction, raising adult diabetes and cardiovascular disease risk (the DOHaD/Barker mechanism). See section 16.

13. Evaluate the concept of “bivalent chromatin domains” in embryonic stem cells: developmental gene promoters carry both active (H3K4me3) and repressive (H3K27me3) marks simultaneously, maintaining them in a “poised” state. How does this enable rapid differentiation in either direction, and what happens to bivalent domains as cells commit to a specific lineage?

Answer (Q13, Application). Bivalent domains carry the activating H3K4me3 and repressive H3K27me3 marks together at developmental gene promoters in embryonic stem cells, holding genes transcriptionally poised — repressed but primed for rapid activation. On differentiation cues the domain resolves in a lineage-specific way: genes needed in that lineage lose H3K27me3 and become fully active (monovalent H3K4me3), while genes for alternative fates lose H3K4me3 and become stably repressed (monovalent H3K27me3). This allows fast, bidirectional commitment, and once a cell adopts a lineage the bivalent state is resolved into a single stable mark. See section 16.

14. Fragile X syndrome is caused by CGG repeat expansion (>200 repeats) in the *FMR1* gene’s 5’ UTR, leading to hypermethylation and gene silencing. Evaluate the molecular relationship between repeat expansion and hypermethylation: which comes first, what protein (MBNL1/DNMT3A) reads the repeat expansion, and why does the “premutation” (55–200 repeats) have a partially different phenotype (FXTAS) compared to full mutation?

Answer (Q14, Application). In Fragile X, the CGG repeat expansion comes first: when the *FMR1* 5’ UTR repeat exceeds about 200 (full mutation), the expanded CGG tract is recognized and triggers de novo DNA methylation (via DNMT3A and silencing RNA/heterochromatin pathways) of the *FMR1* promoter CpG island, shutting off FMRP. The premutation (55–200 repeats) is not methylated and *FMR1* is still transcribed — even overexpressed — so the toxic phenotype (FXTAS, premature ovarian insufficiency) is an RNA gain-of-function from excess CGG-containing mRNA, distinct from the loss-of-function silencing in the full mutation. See section 16.

15. Critically evaluate the potential of epigenetic editing as a permanent therapeutic intervention. Specifically: if dCas9-DNMT3A is used to methylate and silence an oncogene, will the silencing persist through cell division (via DNMT1 maintenance methylation), and what are the risks of epigenetic drift or passenger methylation at off-target sites? Propose experimental criteria to determine whether a therapeutic epigenetic edit is “safe and durable.”

Answer (Q15, Application). dCas9-DNMT3A-induced promoter methylation can persist through division because the symmetric CpG mark is copied each S phase by DNMT1/UHRF1 maintenance methylation, so silencing is heritable even after the editor is removed. Risks include epigenetic drift (gradual loss or spreading of methylation), reactivation, and passenger/off-target methylation at unintended loci with their own phenotypic consequences. Criteria for a safe, durable edit: stable target silencing and methylation over many passages and in vivo, genome-wide methylation profiling showing minimal off-target marks, no oncogene reactivation or growth advantage, and reversibility/controllability if adverse effects appear. See section 16.

16. Define epigenetics. Give two examples of epigenetic modifications.

- Answer (Q16, Application). Epigenetics is the study of heritable changes in gene expression that do not alter the underlying DNA sequence but instead change chromatin state and accessibility. Two examples are DNA methylation of cytosine at CpG dinucleotides (generally repressive at promoters) and covalent histone tail modifications such as acetylation (H3K27ac, activating) or methylation (H3K27me3, repressive). See section 16.
17. What is DNA methylation? Which nucleotide is typically methylated in mammals, and what effect does methylation at gene promoters generally have on transcription?

Answer (Q17, Application). DNA methylation is the covalent addition of a methyl group, catalyzed by DNA methyltransferases (DNMT1 maintenance; DNMT3A/3B de novo). In mammals it occurs almost exclusively on cytosine within 5'-CpG-3' dinucleotides. Methylation of a CpG island in a gene promoter generally represses transcription by blocking activator binding and recruiting methyl-binding repressors and HDACs, producing stable gene silencing. See section 16.

18. What is a histone? Name four types of histone modification and one enzyme family for each.

Answer (Q18, Application). A histone is a small basic protein (H2A, H2B, H3, H4) that packages DNA into nucleosomes. Four modification types and an enzyme family for each: acetylation (HATs/KATs add, HDACs remove), methylation (KMTs such as PRC2/EZH2 add, KDMs/demethylases remove), phosphorylation (kinases such as Aurora B), and ubiquitination (E3 ligases such as RING1B on H2AK119). See section 16.

19. What does H3K4me3 mark indicate? What about H3K27me3?

Answer (Q19, Application). H3K4me3 is an activating mark enriched at the promoters of actively transcribed genes, written by MLL/COMPASS and read by basal transcription machinery. H3K27me3 is a repressive mark deposited by Polycomb repressive complex 2 (EZH2) that silences developmental genes and is read by PRC1. Both are lysine methylation on H3, but their distinct positions and reader complexes give opposite functional outcomes. See section 16.

20. What is chromatin remodeling? Name one chromatin remodeling complex.

Answer (Q20, Application). Chromatin remodeling is the ATP-dependent repositioning, ejection, or restructuring of nucleosomes to change DNA accessibility for transcription factors and the replication/repair machinery. One example is the SWI/SNF (BAF) complex, which uses ATP hydrolysis to slide or evict nucleosomes; other families include ISWI, CHD/NuRD, and INO80. See section 16.

Questions 21–30: Synthesis and Evaluation

21. What is the lac operon? Which molecules control it?

Answer (Q21, Synthesis). The lac operon is a cluster of *E. coli* genes (*lacZ*, *lacY*, *lacA*) encoding enzymes for lactose uptake and metabolism, transcribed from a single promoter. It is controlled by negative regulation via the LacI repressor (released when allolactose, the inducer, binds it) and positive regulation via CAP–cAMP, which activates transcription when glucose is low. See section 16.

22. What is a repressor protein? What is an activator protein?

Answer (Q22, Synthesis). A repressor is a regulatory protein that binds DNA (typically an operator or silencer) and decreases transcription, for example by blocking RNA polymerase or recruiting repressive chromatin machinery. An activator binds DNA (an enhancer or CAP site) and increases transcription by recruiting or stabilizing RNA polymerase and coactivators, as CAP–cAMP does at the lac promoter. See section 16.

23. Define allosteric regulation in the context of transcription. Give an example.

Answer (Q23, Synthesis). Allosteric regulation is the modulation of a regulatory protein's DNA-binding activity by a small effector molecule binding at a separate site, changing the protein's conformation. In the lac operon, allolactose binds the LacI repressor and allosterically reduces its affinity for the operator, releasing it from DNA and allowing transcription; conversely, tryptophan acts as a corepressor that activates the trp repressor. See section 16.

24. What are non-coding RNAs? Name three biologically important types.

Answer (Q24, Synthesis). Non-coding RNAs are functional RNA transcripts that are not translated into protein but instead regulate gene expression and genome organization. Three important types are microRNAs (about 22 nt, guide RISC to repress target mRNAs), small interfering RNAs (siRNAs, drive sequence-specific mRNA cleavage in RNAi), and long non-coding RNAs (lncRNAs such as Xist, which scaffold chromatin-modifying complexes). See section 16.

25. What is genomic imprinting? Give one example of an imprinted gene.

Answer (Q25, Synthesis). Genomic imprinting is parent-of-origin-specific monoallelic expression, in which a gene is expressed only from the maternally or only from the paternally inherited allele, set by differential DNA methylation at imprinting control regions in the germline. An example is IGF2, expressed only from the paternal allele (the maternal allele is silenced via the CTCF-controlled IGF2/H19 ICR). See section 16.

26. A CpG island in the CDKN2A (p16) promoter is hypermethylated in a lung cancer cell. Trace the molecular consequences: (a) which protein is silenced; (b) what happens to CDK4/6 activity; (c) what happens to cell cycle progression; (d) why this is an alternative mechanism to p16 deletion for bypassing the G₁ checkpoint.

Answer (Q26, Synthesis). (a) Hypermethylation of the CDKN2A CpG island silences the p16^{INK4a} protein. (b) Without p16 to inhibit CDK4/6, Cyclin D–CDK4/6 remains active. (c) Active CDK4/6 hyperphosphorylates Rb, releasing E2F so the cell passes the G₁ restriction point and proliferates. (d) This epigenetic silencing is functionally equivalent to deleting or mutating p16 — it inactivates the gene without changing the DNA sequence, an alternative route to bypassing the G₁ checkpoint, and it is potentially reversible with demethylating agents. See section 16.

27. Polycomb repressive complex 2 (PRC2) trimethylates H3K27 and is overexpressed in many cancers. Explain: (a) the molecular mechanism of H3K27me₃-mediated gene silencing; (b) how PRC2 spreads repression across large chromosomal domains; (c) why EZH2 (the catalytic subunit of PRC2) is a therapeutic target (tazemetostat).

Answer (Q27, Synthesis). (a) PRC2 trimethylates H3K27 (H3K27me₃), which recruits PRC1 to ubiquitinate H2AK119 and compact chromatin, blocking transcription. (b) H3K27me₃ is itself read by the PRC2 EED subunit, creating positive feedback that spreads the mark in cis across broad domains. (c) Overactive or mutant EZH2 hyper-represses tumor-suppressor and differentiation genes, so the catalytic EZH2 subunit is druggable; tazemetostat is an FDA-approved EZH2 inhibitor that reactivates these genes. See section 16.

28. In the lac operon, explain the logic of dual control by the lac repressor AND catabolite activator protein (CAP). Under which combination of conditions is the operon most highly transcribed? Under which is it completely silent?

Answer (Q28, Synthesis). The lac repressor provides negative control (bound to the operator unless allolactose is present) and CAP–cAMP provides positive control (active only when glucose is low, raising cAMP). The operon is maximally transcribed when lactose is present AND glucose is absent: the repressor is released and CAP–cAMP activates the promoter. It is completely silent when lactose is absent, because the repressor stays bound regardless of glucose status. See section 16.

29. RNA interference (RNAi) via siRNA silences gene expression post-transcriptionally. Compare siRNA (perfectly complementary → mRNA cleavage by Ago2) vs miRNA (partially complementary → translational repression and mRNA destabilisation). How does each affect the steady-state abundance of target mRNA?

Answer (Q29, Synthesis). siRNAs are perfectly complementary to their targets and direct Ago2 to endonucleolytically cleave (slice) the mRNA, sharply lowering its steady-state abundance. miRNAs are only partially complementary (matching mainly through the seed region) and act mostly by repressing translation and promoting deadenylation/decay, causing a more modest reduction in mRNA levels and a larger drop in protein output. Both reduce target expression, but siRNA produces stronger, cleavage-based mRNA loss. See section 16.

30. Enhancers can activate promoters over distances of >1 Mb in the genome by chromatin looping mediated by cohesin and CTCF. Explain: (a) the role of CTCF as a chromatin barrier/insulator; (b) how loss of a CTCF binding site at the IGF2/H19 imprinting control region (ICR) causes Beckwith-Wiedemann syndrome; (c) how 4C and HiC experiments confirm enhancer-promoter looping.

Answer (Q30, Synthesis). (a) CTCF binds insulator sequences and, with cohesin, organizes chromatin loops/TAD boundaries that block enhancers from acting across them. (b) At the IGF2/H19 ICR the maternal allele is unmethylated, so CTCF binds and insulates IGF2 from the downstream enhancers; loss of that CTCF site (or its methylation) lets the enhancer loop to IGF2, causing biallelic IGF2 expression and overgrowth (Beckwith-Wiedemann syndrome). (c) Chromosome-conformation methods such as 4C and Hi-C detect ligated DNA contacts, directly demonstrating physical enhancer–promoter looping. See section 16.

Questions — Mendelian Principles and Probability

Instructor Use and Coverage Notes

- Coverage target: Compute a genetic probability or chi-square result and explain the biological assumption.
- Model/data emphasis: Punnett, binomial, and chi-square calculations.
- Assessment alignment: Statistical Tests and Data Analysis, Representing and Describing Data.
- Misconception probe: Dominant does not mean common, stronger, or better.
- Transfer product: Transfer Mendelian probability to model organisms and introductory human genetics.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 17 of the textbook — review that chapter before attempting the exercises below.

1. State Mendel’s two laws. Give the biological basis for each in terms of meiosis.

Answer (Q1, Recall). Law of segregation: the two alleles of a gene separate during gamete formation so each gamete carries only one allele; mechanistically this is the separation of homologous chromosomes (and their alleles) at meiosis I anaphase. Law of independent assortment: alleles of different genes segregate independently, because non-homologous chromosome pairs orient randomly at the metaphase I plate. Independent assortment holds only for genes on different chromosomes (or far apart on the same one). See section 17.

2. Define allele, locus, genotype, and phenotype.

Answer (Q2, Recall). An allele is one of the alternative DNA sequence variants of a gene. A locus is the fixed physical position of that gene on a chromosome. A genotype is the pair of alleles an individual carries at a locus (e.g. Aa), while the phenotype is the observable trait that genotype produces in a given environment. See section 17.

3. What is a Punnett square? Draw and solve: $Aa \times Aa$.

Answer (Q3, Recall). A Punnett square is a table that lists the possible gametes from each parent and combines them to predict offspring genotypes under Mendelian segregation. For $Aa \times Aa$, each parent produces gametes A and a . The four equally likely cells are AA , Aa , Aa , and aa , giving a genotype ratio of $1\ AA : 2\ Aa : 1\ aa$. With complete dominance, the phenotype ratio is 3 dominant : 1 recessive. This prediction assumes independent gamete formation, equal fertilization probability, and no viability difference among the genotypes; see section 17.

4. What are the expected phenotype ratios for a monohybrid cross between two heterozygotes?

Answer (Q4, Recall). A monohybrid cross between two heterozygotes ($Aa \times Aa$) yields a 3:1 phenotype ratio (3 dominant : 1 recessive) and a 1:2:1 genotype ratio ($1\ AA : 2\ Aa : 1\ aa$). This assumes complete dominance and that every genotype reliably expresses its expected phenotype. See section 17.

5. What are the expected phenotype ratios for a dihybrid cross between two double heterozygotes?

Answer (Q5, Recall). A dihybrid cross between two double heterozygotes ($AaBb \times AaBb$) yields the classic 9:3:3:1 phenotype ratio — $9\ A_B_ : 3\ A_bb : 3\ aaB_ : 1\ aabb$. This is the product of two independent 3:1 monohybrid ratios and requires the two genes to assort independently and act independently on the phenotype. See section 17.

6. Define codominance. Give the human blood type system as an example.

Answer (Q6, Recall). Codominance is an allelic relationship in which both alleles in a heterozygote are fully and simultaneously expressed, so neither masks the other. The human ABO system illustrates this: an $I^A I^B$ individual is blood type AB, expressing both the A and B surface antigens, rather than an intermediate or single antigen. See section 17.

7. What is incomplete dominance? Give one example and show the F_1 and F_2 ratios.

Answer (Q7, Recall). Incomplete dominance occurs when the heterozygote shows an intermediate phenotype because one functional allele produces insufficient product for the full dominant effect. In snapdragons, red ($C^R C^R$) \times white ($C^W C^W$) gives an all-pink F_1 ($C^R C^W$); selfing the F_1 gives an F_2 of 1 red : 2 pink : 1 white — the genotype ratio is visible directly because each genotype has its own phenotype. See section 17.

8. What is a testcross? For what is it used?

Answer (Q8, Recall). A testcross mates an individual showing the dominant phenotype to a homozygous recessive individual ($A? \times aa$). It reveals the unknown genotype: an all-dominant offspring set indicates AA , whereas a roughly 1:1 dominant:recessive split indicates Aa . See section 17.

9. What is epistasis? Give one example where two loci interact to modify phenotype.

Answer (Q9, Recall). Epistasis is a gene interaction in which the genotype at one locus masks or modifies the phenotypic expression of a second, independent locus. In Labrador retrievers, ee at the extension locus is recessive epistatic to the B (black/chocolate) locus: any ee dog is yellow regardless of its B genotype, collapsing the dihybrid F_2 to 9 black : 3 chocolate : 4 yellow. See section 17.

10. What is pleiotropy? Give one example of a single gene that affects multiple traits.

Answer (Q10, Recall). Pleiotropy is the phenomenon in which a single gene affects multiple, seemingly unrelated phenotypic traits. Sick-cell disease (a single β -globin mutation) is a classic example: it causes anemia, pain crises, organ damage, splenic dysfunction, and stroke risk, while also conferring malaria resistance in heterozygotes. See section 17.

Questions 11–20: Application and Analysis

11. A black cat (BB) is crossed with a white cat (bb). What is the F_1 phenotype? What is the F_2 ratio if F_1 cats are interbred? If black is incompletely dominant, what is the F_1 phenotype?

Answer (Q11, Application). With complete dominance, $BB \times bb$ gives an all-black F_1 (Bb). Interbreeding the F_1 ($Bb \times Bb$) gives an F_2 of 3 black : 1 white. If black is instead *incompletely* dominant, the F_1 heterozygotes (Bb) show an intermediate (gray) phenotype, and the F_2 would be 1 black : 2 gray : 1 white. See section 17.

12. A chi-square analysis of 580 pea seeds (450 round:130 wrinkled) gives $\chi^2 = 2.6$ (critical value 3.84, $p = 0.05$). Should the null hypothesis of 3:1 ratio be rejected? What does this conclusion mean biologically?

Answer (Q12, Application). $\chi^2_{\text{calc}} = 2.6 < \chi^2_{\text{crit}} = 3.84$ ($df = 1$, $\alpha = 0.05$), so we fail to reject the null hypothesis: the observed 450:130 split is statistically consistent with the expected 3:1 ratio (expected 435 round : 145 wrinkled). Biologically, this supports single-gene Mendelian inheritance with complete dominance; the deviation is attributable to chance sampling, not a different genetic mechanism. The test never *proves* 3:1 — it only fails to reject it. See section 17.

13. Two true-breeding strains of wheat produce red and white kernels. The cross produces medium-red F_1 , and F_2 shows a continuous range of colors with frequencies approximately 1:4:6:4:1. This is consistent with two genes each contributing an additive unit of color. What mode of inheritance does this illustrate?

Answer (Q13, Application). This is polygenic (quantitative) inheritance with additive alleles. Two genes each contributing one additive unit of pigment produce 5 phenotypic classes in F_2 with frequencies 1:4:6:4:1 (the binomial expansion of dose 0–4 across 4 alleles), with the medium-red F_1 intermediate between the parental extremes. Environmental variation further blurs the classes into a continuous distribution. See section 17.

14. A woman is phenotypically normal but her father had phenylketonuria (PKU, autosomal recessive). What is the probability that she is a carrier? If she marries a known carrier, what is the probability their first child will have PKU?

Answer (Q14, Application). Her father is aa , so the woman necessarily inherited one a allele; being unaffected she is Aa — she is a carrier with probability 1 (= 100%). Crossed with a known carrier ($Aa \times Aa$), each child has a $\frac{1}{4}$ probability of PKU (aa). Combined chance the first child is affected = $1 \times \frac{1}{4} = \frac{1}{4}$. See section 17.

15. In coat color genetics of Labrador retrievers: B is dominant for black pigment; b is recessive (brown/chocolate). E is dominant for coat expression; ee gives yellow regardless of B/b. Set up the dihybrid cross $BbEe \times BbEe$ and calculate the expected ratio of black:chocolate:yellow.

Answer (Q15, Application). $BbEe \times BbEe$ gives the standard 9 $B_E_$: 3 B_ee : 3 $bbE_$: 1 $bbee$. Because ee is epistatic (yellow regardless of B), the two ee classes merge: 9 $B_E_$ = black, 3 $bbE_$ = chocolate, and 3 B_ee + 1 $bbee$ = 4 yellow. Expected ratio = 9 black : 3 chocolate : 4 yellow. See section 17.

16. Evaluate the concept of “genetic heterogeneity”: the same phenotype (e.g., congenital deafness) can result from mutations in any of >100 different genes, each segregating in different families. How does genetic heterogeneity complicate: (a) pedigree analysis; (b) population frequency estimates; (c) the development of a comprehensive gene therapy?

Answer (Q16, Application). Genetic heterogeneity means one phenotype maps to many independent loci. (a) Pedigree analysis: different families may show different inheritance modes (AD, AR, X-linked, mitochondrial), so pooling pedigrees obscures the pattern and a single family’s mode

cannot generalize. (b) Population frequency: the overall trait frequency is the sum over many rare loci, so a single allele-frequency or Hardy–Weinberg estimate is invalid; per-locus data are required. (c) Gene therapy: no single corrective construct works for all patients — therapy must be allele/gene-specific, raising cost and complexity. The decisive test is locus mapping/sequencing per family. See section 17.

17. Design a genetic screen in *C. elegans* to identify most genes involved in a specific pathway (e.g., vulva development). Describe the EMS (ethyl methanesulfonate) mutagenesis strategy, the phenotypic screen, and how you would determine whether two mutations affect the same gene (complementation test) or the same pathway (epistasis test).

Answer (Q17, Application). Hypothesis: specific genes are required for vulval development. Mutagenesis: treat worms with EMS to induce random point mutations; screen F_2 for the vulvaless or multivulva phenotype (with isogenic untreated controls). Same gene vs. same pathway: a complementation test crosses two recessive mutants — mutant F_1 = allelic (same gene), wild-type F_1 = different genes. An epistasis test then orders genes in a pathway: in a double mutant, the phenotype of the downstream/epistatic gene prevails, revealing pathway order. Replication across independent alleles and a defined scoring rule guard against false positives. See section 17.

18. Quantitative traits (height, intelligence, blood pressure) are determined by many genes plus environment. Evaluate the methodology of heritability estimation from twin studies: what does $h^2 = 0.8$ actually mean, and why does high heritability NOT mean that environmental interventions are ineffective? Use PKU as a concrete counter-example.

Answer (Q18, Application). $h^2 = 0.8$ means 80% of the *phenotypic variance in that population, in its current environments* is attributable to genetic variance — it is a population-and-environment-specific variance ratio, not a statement about any individual or about modifiability. High heritability does not imply environmental interventions fail, because heritability only partitions the variance present, not the trait’s response to a *new* environment. PKU is the counter-example: it is highly heritable (single-gene), yet a low-phenylalanine diet — an environmental change outside the studied range — almost entirely prevents the intellectual disability. See section 17.

19. Evaluate Mendel’s choice of pea traits: several of the seven traits happened to be either not linked or on different chromosomes. If two of Mendel’s traits had been tightly linked (say, flower color and pod color on the same chromosome), how would the F_2 data have deviated from the 9:3:3:1 ratio, and would Mendel still have discovered independent assortment?

Answer (Q19, Application). If two traits were tightly linked, their alleles would not assort independently: parental allele combinations would be over-represented and recombinant types rare, so the F_2 would deviate sharply from 9:3:3:1 toward an excess of parental phenotypes (the deviation scaling with map distance / recombination frequency). Mendel could still have discovered segregation and independent assortment from his *other* unlinked traits, but the linked pair alone would have masked independent assortment — historically fortunate that his seven analyzed traits behaved independently. See section 17.

20. Inbreeding increases homozygosity and can reveal recessive deleterious alleles. Calculate the inbreeding coefficient (F) for offspring of a first-cousin mating, and predict the increase in: (a) homozygosity for a rare allele ($q = 0.01$); (b) probability of autosomal recessive disease compared to random mating. Why do many societies have legal or cultural prohibitions against close-relative marriages?

Answer (Q20, Application). For first cousins, the inbreeding coefficient is $F = 1/16 = 0.0625$. (a) The probability of homozygosity for a rare allele rises to approximately $q^2 + F \cdot q(1-q)$; for $q = 0.01$ this is $\approx 0.0001 + 0.0625 \cdot (0.0099) \approx 0.00072$, roughly 7× the random-mating value of $q^2 = 0.0001$. (b) Autosomal-recessive disease risk is likewise inflated by the $F \cdot q(1-q)$ term, the relative increase being largest for the rarest alleles. Societies restrict close-kin marriage chiefly because this elevated homozygosity sharply raises the burden of recessive disease in offspring. See section 17.

Questions 21–30: Synthesis and Evaluation

21. Anticipation (increasing severity across generations) occurs in trinucleotide repeat disorders (Huntington’s disease, myotonic dystrophy). Explain the molecular mechanism by which repeats expand between generations (slippage during DNA replication) and why larger repeats cause earlier onset and greater severity. Why is repeat expansion more common through the paternal germline in HD but the maternal germline in DM1?

Answer (Q21, Synthesis). Trinucleotide repeats (e.g. CAG in *HTT*, CTG in *DMPK*) expand through replication/repair slippage: the nascent strand mispairs on the repetitive template, forming hairpin loops that add repeat units, and longer tracts are more unstable, so they tend to grow each generation (anticipation). Larger repeats produce more toxic gene product (or RNA) earlier, giving earlier onset and greater severity. Expansion bias is germline-specific: large CAG expansions are favored in spermatogenesis (paternal bias in Huntington’s), whereas the CTG repeat expands preferentially in the maternal germline in myotonic dystrophy type 1, reflecting differences in replication/repair dynamics in the two gametogenic lineages. See section 17.

22. Evaluate the concept of “genomic imprinting conflict” (kinship theory): paternally imprinted genes (expressed primarily from paternal allele) are generally growth-promoting (*IGF2*), while maternally imprinted genes (expressed primarily from maternal allele) are generally growth-restraining (*H19*). Evaluate

the evolutionary logic that predicts this based on parent-offspring conflict theory. What happens when this balance is disrupted (Silver-Russell syndrome vs Beckwith-Wiedemann syndrome)?

Answer (Q22, Synthesis). Kinship (parent-of-origin conflict) theory predicts that paternally expressed genes favor extracting more maternal resources for the offspring (growth-promoting, e.g. *IGF2*), while maternally expressed genes restrain offspring demand to conserve resources for the mother's other (possibly different-father) offspring (growth-restraining, e.g. *H19*) — the asymmetry arises only when females mate with multiple males. Disrupting the balance shifts growth: loss of paternal *IGF2* expression underlies the growth-restricted Silver–Russell syndrome, whereas excess *IGF2* / loss of maternal restraint underlies the overgrowth Beckwith–Wiedemann syndrome. The theory is testable via the predicted directionality of imprinted-gene effects on growth. See section 17.

23. Multifactorial diseases (Type 1 Diabetes, schizophrenia) have both genetic and environmental contributions. Evaluate the strengths and limitations of GWAS and polygenic risk scores: (a) minimum detectable effect size at genome-wide significance ($p < 5 \times 10^{-8}$); (b) the “missing heritability” problem; (c) why PRS transferability across ancestries is a scientific and equity concern; (d) what consent and privacy information belongs in a clinical PRS report.

Answer (Q23, Synthesis). (a) GWAS detects variants whose effect is large enough that, given allele frequency and sample size, association reaches $p < 5 \times 10^{-8}$; common variants of small effect need very large cohorts and rare large-effect variants are missed. (b) The missing heritability problem: significant common variants typically explain a modest fraction of trait heritability, far below twin-study estimates, due to many sub-threshold variants, rare variants, gene–gene/gene–environment effects, and inflated twin estimates. (c) A PRS trained mainly in one ancestry can lose calibration and discrimination in another because linkage disequilibrium, allele frequency, environment, and health-system context differ; deployment without validation can therefore worsen health disparities. (d) A clinical report should state the discovery cohort, target population, calibration method, confidence interval, action threshold, data-retention plan, secondary-use policy, reidentification risk, and family implications. See section 17.

24. Phenocopies are environmentally caused conditions that resemble genetic conditions. Thalidomide-induced limb malformations in 1950s–60s phenocopied the autosomal recessive condition phocomelia. Evaluate: (a) how phenocopies complicate pedigree analysis; (b) how you would distinguish a phenocopy from a genetic condition in a clinical or research context; (c) the ethical implications of confusing genetic and environmental causation for public health policy.

Answer (Q24, Synthesis). A phenocopy is an environmentally induced phenotype mimicking a genetic disorder. (a) It complicates pedigrees by appearing as sporadic or non-Mendelian cases (no consistent transmission, possible shared environmental exposure rather than shared genotype). (b) Distinguish it by molecular testing (absence of the causative mutation), a documented environmental exposure (e.g. thalidomide timing), discordance in monozygotic twins, and lack of recurrence risk consistent with Mendelian ratios. (c) Misattributing an environmental cause to genetics — or vice versa — misdirects public-health policy: it can stigmatize families, divert resources from removing a preventable exposure, and delay protective regulation. See section 17.

25. Critically evaluate Mendel’s pea experiments, considering: (a) sample sizes (he used thousands of plants, giving high statistical power); (b) evidence that Mendel may have “improved” his data (Weldon’s 1902 re-analysis and Ronald Fisher’s 1936 statistical critique suggesting perfect ratios are too good to be true); (c) whether Mendel’s results are reproducible, and what this debate reveals about the role of confirmation bias in science.

Answer (Q25, Synthesis). (a) Mendel’s large samples (thousands of plants) gave high statistical power, making his ratios reliable estimates. (b) Fisher’s 1936 analysis (anticipated by Weldon, 1902) showed the aggregate fit to expected ratios is *too good* — the pooled χ^2 is improbably small — suggesting unconscious bias in classification or selective reporting, though no fraud is established. (c) Mendel’s core conclusions are robustly reproducible in modern crosses, so the laws stand; the debate illustrates that even correct conclusions can be reached via data that show confirmation bias, underscoring the need for pre-specified analysis and blinded scoring rather than discarding the findings. See section 17.

26. ABO blood type shows codominance (A and B antigens) and simple recessive (O, no antigen). A man of unknown blood type has a type O child with a type A woman (confirmed genotype $I^A i$). What is the man’s blood type? What are most possible blood types of this union’s children?

Answer (Q26, Synthesis). The type O child is ii , so it received an i from each parent. The type A mother is $I^A i$, contributing i ; the father must therefore also carry an i allele and be capable of producing a type O child — his blood type can be A ($I^A i$), B ($I^B i$), or O (ii), but not AB. For an $I^A i \times i i$ (e.g. type O father) union, children are $\frac{1}{2}$ type A ($I^A i$) : $\frac{1}{2}$ type O (ii); the full set across his possible genotypes is type A, B, AB, or O depending on his second allele. See section 17.

27. Maternal effect genes in *Drosophila* (e.g., *bicoid*) determine the embryo’s polarity based on the maternal genotype, not the embryo’s genotype. Explain how this violates the simple Mendelian expectation that offspring phenotype reflects offspring genotype. What does this tell us about developmental genetics?

Answer (Q27, Synthesis). With maternal-effect genes such as *bicoid*, the mother’s genotype, acting through mRNA/protein she deposits in the oocyte, fixes the embryo’s phenotype regardless of the embryo’s own genotype — so a genotypically mutant embryo from a heterozygous mother develops normally, and phenotypes lag one generation behind genotypes. This violates the Mendelian expectation that an offspring’s phenotype reflects its

- own genotype, and shows that early development is governed by maternally supplied cytoplasmic determinants, not just zygotic transcription. See section 17.
28. Haemophilia A is X-linked recessive. A carrier woman ($X^H X^h$) has children with a normal man ($X^H Y$). What are the expected phenotype ratios for daughters? For sons? What is the probability that the first four children include at least two affected sons (use binomial distribution)?
- Answer (Q28, Synthesis). Punnett square for $X^H X^h \times X^H Y$: gametes from mother $\{X^H, X^h\}$, from father $\{X^H, Y\}$. Offspring: $X^H X^H$, $X^H X^h$, $X^H Y$, $X^h Y$ — each with prob $1/4$. Daughters (inherit paternal X^H): $1/2$ homozygous unaffected ($X^H X^H$), $1/2$ carrier ($X^H X^h$); phenotype ratio $1:0$ (all phenotypically normal, since daughters always receive X^H from father). Sons (inherit paternal Y , maternal X): $1/2$ unaffected ($X^H Y$), $1/2$ affected ($X^h Y$); phenotype ratio $1:1$. Binomial probability of ≥ 2 affected sons among first 4 children: this conflates two coin flips per child — $P(\text{son}) = 1/2$ and $P(\text{affected} \mid \text{son}) = 1/2$, so $P(\text{affected son per child}) = p = 1/4$. With $n = 4$, $k \geq 2$: $P(k = 0) = \binom{4}{0}(0.25)^0(0.75)^4 = 0.3164$; $P(k = 1) = \binom{4}{1}(0.25)^1(0.75)^3 = 0.4219$; therefore $P(k \geq 2) = 1 - 0.3164 - 0.4219 = 0.2617 \approx 26\%$. Genetic counselling implication: about 1 in 4 such pedigrees will present with 2+ affected boys in the first 4 children — a common source of “unlucky” kindreds in pedigree analysis and a reason recurrence-risk counselling uses binomials, not single-child probabilities. See section 17.
29. Set up and interpret the F_2 results of a dihybrid cross ($AaBb \times AaBb$) if the two genes show complementary epistasis ($A-B-$ = one phenotype; $A-bb$, $aaB-$, $aabb$ = albino). What is the expected ratio? What does this imply about the biochemical pathway?
- Answer (Q29, Synthesis). $AaBb \times AaBb$ gives $9 A_B_ : 3 A_bb : 3 aaB_ : 1 aabb$. With complementary (duplicate-recessive) epistasis, only $A_B_$ shows the pigmented phenotype; the other three classes are albino, giving a $9:7$ ratio (9 colored : 7 albino). This implies both gene products are required, non-redundant enzymes in the same linear biosynthetic pathway — a block at either step (aa or bb) halts product formation. See section 17.
30. Three pea plants of unknown genotype most produce round seeds. Two plants crossed to a wrinkled plant (rr) produce: plant A = most round; plant B = 50% round:50% wrinkled; plant C = 75% round:25% wrinkled. Determine the genotype of each plant and explain the crosses.
- Answer (Q30, Synthesis). Each plant is testcrossed to rr . Plant A = all round \rightarrow no wrinkled offspring \rightarrow homozygous RR . Plant B = 1:1 round:wrinkled \rightarrow segregation expected from $Rr \times rr \rightarrow Rr$. Plant C = 3:1 (75% round) \rightarrow this ratio cannot come from a single testcross to rr unless C is Rr selfed/crossed to another Rr ; given a true testcross the 3:1 indicates additional round parents — most parsimoniously C is Rr with the 3:1 reflecting an $Rr \times Rr$ component. The informative testcross diagnostics are A = RR (no recessives) and B = Rr (1:1). See section 17.

Questions — Mendelian Extensions and Human Genetics

Instructor Use and Coverage Notes

- Coverage target: Use pedigree or extension evidence to justify an inheritance diagnosis.
- Model/data emphasis: Pedigree, epistasis, and multi-locus probability calculations.
- Assessment alignment: Statistical Tests and Data Analysis, Representing and Describing Data.
- Misconception probe: A single-gene model is a starting hypothesis, not the default for every trait.
- Transfer product: Transfer extension reasoning to counseling, GWAS interpretation, and breeding.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 18 of the textbook — review that chapter before attempting the exercises below.

1. ABO blood type shows codominance (A and B antigens) and simple recessive (O, no antigen). A man of unknown blood type has a type O child with a type A woman (confirmed genotype IA*i*). What is the man’s blood type? What are most possible blood types of this union’s children?

Answer (Q1, Recall). The type O child is *ii*, so it received an *i* from each parent. The type A mother is I^A*i*, contributing *i*; the father must therefore also carry an *i* allele and be capable of producing a type O child — his blood type can be A (I^A*i*), B (I^B*i*), or O (*ii*), but not AB. For an I^A*i* × *i* *i* (e.g. type O father) union, children are ½ type A (I^A*i*) : ½ type O (*ii*); the full set across his possible genotypes is type A, B, AB, or O depending on his second allele. See section 18.

2. Maternal effect genes in *Drosophila* (e.g., *bicoid*) determine the embryo’s polarity based on the maternal genotype, not the embryo’s genotype. Explain how this violates the simple Mendelian expectation that offspring phenotype reflects offspring genotype. What does this tell us about developmental genetics?

Answer (Q2, Recall). With maternal-effect genes such as *bicoid*, the mother’s genotype, acting through mRNA/protein she deposits in the oocyte, fixes the embryo’s phenotype regardless of the embryo’s own genotype — so a genotypically mutant embryo from a heterozygous mother develops normally, and phenotypes lag one generation behind genotypes. This violates the Mendelian expectation that an offspring’s phenotype reflects its own genotype, and shows that early development is governed by maternally supplied cytoplasmic determinants, not just zygotic transcription. See section 18.

3. Haemophilia A is X-linked recessive. A carrier woman (X^HX^h) has children with a normal man (X^HY). What are the expected phenotype ratios for daughters? For sons? What is the probability that the first four children include at least two affected sons (use binomial distribution)?

Answer (Q3, Recall). Punnett square for X^HX^h × X^HY: gametes from mother {X^H, X^h}, from father {X^H, Y}. Offspring: X^HX^H, X^HX^h, X^HY, X^hY — each with prob 1/4. Daughters (inherit paternal X^H): 1/2 homozygous unaffected (X^HX^H), 1/2 carrier (X^HX^h); phenotype ratio 1:0 (all phenotypically normal, since daughters always receive X^H from father). Sons (inherit paternal Y, maternal X): 1/2 unaffected (X^HY), 1/2 affected (X^hY); phenotype ratio 1:1. Binomial probability of ≥ 2 affected sons among first 4 children: this conflates two coin flips per child — P(son) = 1/2 and P(affected | son) = 1/2, so P(affected son per child) = *p* = 1/4. With *n* = 4, *k* ≥ 2: $P(k = 0) = \binom{4}{0}(0.25)^0(0.75)^4 = 0.3164$; $P(k = 1) = \binom{4}{1}(0.25)^1(0.75)^3 = 0.4219$; therefore $P(k \geq 2) = 1 - 0.3164 - 0.4219 = 0.2617 \approx 26\%$. Genetic counselling implication: about 1 in 4 such pedigrees will present with 2+ affected boys in the first 4 children — a common source of “unlucky” kindreds in pedigree analysis and a reason recurrence-risk counselling uses binomials, not single-child probabilities. See section 18.

4. Set up and interpret the F₂ results of a dihybrid cross (AaBb × AaBb) if the two genes show complementary epistasis (A-B- = one phenotype; A-bb, aaB-, aabb = albino). What is the expected ratio? What does this imply about the biochemical pathway?

Answer (Q4, Recall). *AaBb* × *AaBb* gives 9 A_B_ : 3 A_bb : 3 aaB_ : 1 aabb. With complementary (duplicate-recessive) epistasis, only A_B_ shows the pigmented phenotype; the other three classes are albino, giving a 9:7 ratio (9 colored : 7 albino). This implies both gene products are required, non-redundant enzymes in the same linear biosynthetic pathway — a block at either step (*aa* or *bb*) halts product formation. See section 18.

5. Three pea plants of unknown genotype most produce round seeds. Two plants crossed to a wrinkled plant (*rr*) produce: plant A = most round; plant B = 50% round:50% wrinkled; plant C = 75% round:25% wrinkled. Determine the genotype of each plant and explain the crosses.

Answer (Q5, Recall). Each plant is testcrossed to *rr*. Plant A = all round → no wrinkled offspring → homozygous RR. Plant B = 1:1 round:wrinkled → segregation expected from R*r* × *rr* → R*r*. Plant C = 3:1 (75% round) → this ratio cannot come from a single testcross to *rr* unless C is R*r* selfed/crossed to another R*r*; given a true testcross the 3:1 indicates additional round parents — most parsimoniously C is R*r* with the 3:1 reflecting an R*r* × R*r* component. The informative testcross diagnostics are A = RR (no recessives) and B = R*r* (1:1). See section 18.

- Evaluate the concept of “genetic heterogeneity”: the same phenotype (e.g., congenital deafness) can result from mutations in any of >100 different genes, each segregating in different families. How does genetic heterogeneity complicate: (a) pedigree analysis; (b) population frequency estimates; (c) the development of a comprehensive gene therapy?

Answer (Q6, Recall). Genetic heterogeneity means one phenotype maps to many independent loci. (a) Pedigree analysis: different families may show different inheritance modes (AD, AR, X-linked, mitochondrial), so pooling pedigrees obscures the pattern and a single family’s mode cannot generalize. (b) Population frequency: the overall trait frequency is the sum over many rare loci, so a single allele-frequency or Hardy–Weinberg estimate is invalid; per-locus data are required. (c) Gene therapy: no single corrective construct works for all patients — therapy must be allele/gene-specific, raising cost and complexity. The decisive test is locus mapping/sequencing per family. See section 18.

- Design a genetic screen in *C. elegans* to identify most genes involved in a specific pathway (e.g., vulva development). Describe the EMS (ethyl methanesulfonate) mutagenesis strategy, the phenotypic screen, and how you would determine whether two mutations affect the same gene (complementation test) or the same pathway (epistasis test).

Answer (Q7, Recall). Hypothesis: specific genes are required for vulval development. Mutagenesis: treat worms with EMS to induce random point mutations; screen F₂ for the vulvaless or multivulva phenotype (with isogenic untreated controls). Same gene vs. same pathway: a complementation test crosses two recessive mutants — mutant F₁ = allelic (same gene), wild-type F₁ = different genes. An epistasis test then orders genes in a pathway: in a double mutant, the phenotype of the downstream/epistatic gene prevails, revealing pathway order. Replication across independent alleles and a defined scoring rule guard against false positives. See section 18.

- Quantitative traits (height, intelligence, blood pressure) are determined by many genes plus environment. Evaluate the methodology of heritability estimation from twin studies: what does $h^2 = 0.8$ actually mean, and why does high heritability NOT mean that environmental interventions are ineffective? Use PKU as a concrete counter-example.

Answer (Q8, Recall). $h^2 = 0.8$ means 80% of the *phenotypic variance in that population, in its current environments* is attributable to genetic variance — it is a population-and-environment-specific variance ratio, not a statement about any individual or about modifiability. High heritability does not imply environmental interventions fail, because heritability only partitions the variance present, not the trait’s response to a *new* environment. PKU is the counter-example: it is highly heritable (single-gene), yet a low-phenylalanine diet — an environmental change outside the studied range — almost entirely prevents the intellectual disability. See section 18.

- Evaluate Mendel’s choice of pea traits: several of the seven traits happened to be either not linked or on different chromosomes. If two of Mendel’s traits had been tightly linked (say, flower color and pod color on the same chromosome), how would the F₂ data have deviated from the 9:3:3:1 ratio, and would Mendel still have discovered independent assortment?

Answer (Q9, Recall). If two traits were tightly linked, their alleles would not assort independently: parental allele combinations would be over-represented and recombinant types rare, so the F₂ would deviate sharply from 9:3:3:1 toward an excess of parental phenotypes (the deviation scaling with map distance / recombination frequency). Mendel could still have discovered segregation and independent assortment from his *other* unlinked traits, but the linked pair alone would have masked independent assortment — historically fortunate that his seven analyzed traits behaved independently. See section 18.

- Inbreeding increases homozygosity and can reveal recessive deleterious alleles. Calculate the inbreeding coefficient (F) for offspring of a first-cousin mating, and predict the increase in: (a) homozygosity for a rare allele ($q = 0.01$); (b) probability of autosomal recessive disease compared to random mating. Why do many societies have legal or cultural prohibitions against close-relative marriages?

Answer (Q10, Recall). For first cousins, the inbreeding coefficient is $F = 1/16 = 0.0625$. (a) The probability of homozygosity for a rare allele rises to approximately $q^2 + F \cdot q(1-q)$; for $q = 0.01$ this is $\approx 0.0001 + 0.0625 \cdot (0.0099) \approx 0.00072$, roughly 7× the random-mating value of $q^2 = 0.0001$. (b) Autosomal-recessive disease risk is likewise inflated by the $F \cdot q(1-q)$ term, the relative increase being largest for the rarest alleles. Societies restrict close-kin marriage chiefly because this elevated homozygosity sharply raises the burden of recessive disease in offspring. See section 18.

Questions 11–20: Application and Analysis

- Anticipation (increasing severity across generations) occurs in trinucleotide repeat disorders (Huntington’s disease, myotonic dystrophy). Explain the molecular mechanism by which repeats expand between generations (slippage during DNA replication) and why larger repeats cause earlier onset and greater severity. Why is repeat expansion more common through the paternal germline in HD but the maternal germline in DM1?

Answer (Q11, Application). Trinucleotide repeats (e.g. CAG in *HTT*, CTG in *DMPK*) expand through replication/repair slippage: the nascent strand mispairs on the repetitive template, forming hairpin loops that add repeat units, and longer tracts are more unstable, so they tend to grow each generation (anticipation). Larger repeats produce more toxic gene product (or RNA) earlier, giving earlier onset and greater severity. Expansion bias is germline-specific: large CAG expansions are favored in spermatogenesis (paternal bias in Huntington’s), whereas the CTG repeat expands

- preferentially in the maternal germline in myotonic dystrophy type 1, reflecting differences in replication/repair dynamics in the two gametogenic lineages. See section 18.
12. Evaluate the concept of “genomic imprinting conflict” (kinship theory): paternally imprinted genes (expressed primarily from paternal allele) are generally growth-promoting (*IGF2*), while maternally imprinted genes (expressed primarily from maternal allele) are generally growth-restraining (*H19*). Evaluate the evolutionary logic that predicts this based on parent-offspring conflict theory. What happens when this balance is disrupted (Silver-Russell syndrome vs Beckwith-Wiedemann syndrome)?
- Answer (Q12, Application). Kinship (parent-of-origin conflict) theory predicts that paternally expressed genes favor extracting more maternal resources for the offspring (growth-promoting, e.g. *IGF2*), while maternally expressed genes restrain offspring demand to conserve resources for the mother’s other (possibly different-father) offspring (growth-restraining, e.g. *H19*) — the asymmetry arises only when females mate with multiple males. Disrupting the balance shifts growth: loss of paternal *IGF2* expression underlies the growth-restricted Silver–Russell syndrome, whereas excess *IGF2* / loss of maternal restraint underlies the overgrowth Beckwith–Wiedemann syndrome. The theory is testable via the predicted directionality of imprinted-gene effects on growth. See section 18.
13. Multifactorial diseases (Type 1 Diabetes, schizophrenia) have both genetic and environmental contributions. Evaluate the strengths and limitations of GWAS and polygenic risk scores: (a) minimum detectable effect size at genome-wide significance ($p < 5 \times 10^{-8}$); (b) the “missing heritability” problem; (c) why PRS transferability across ancestries is a scientific and equity concern; (d) what consent and privacy information belongs in a clinical PRS report.
- Answer (Q13, Application). (a) GWAS detects variants whose effect is large enough that, given allele frequency and sample size, association reaches $p < 5 \times 10^{-8}$; common variants of small effect need very large cohorts and rare large-effect variants are missed. (b) The missing heritability problem: significant common variants typically explain a modest fraction of trait heritability, far below twin-study estimates, due to many sub-threshold variants, rare variants, gene–gene/gene–environment effects, and inflated twin estimates. (c) A PRS trained mainly in one ancestry can lose calibration and discrimination in another because linkage disequilibrium, allele frequency, environment, and health-system context differ; deployment without validation can therefore worsen health disparities. (d) A clinical report should state the discovery cohort, target population, calibration method, confidence interval, action threshold, data-retention plan, secondary-use policy, reidentification risk, and family implications. See section 18.
14. Phenocopies are environmentally caused conditions that resemble genetic conditions. Thalidomide-induced limb malformations in 1950s–60s phenocopied the autosomal recessive condition phocomelia. Evaluate: (a) how phenocopies complicate pedigree analysis; (b) how you would distinguish a phenocopy from a genetic condition in a clinical or research context; (c) the ethical implications of confusing genetic and environmental causation for public health policy.
- Answer (Q14, Application). A phenocopy is an environmentally induced phenotype mimicking a genetic disorder. (a) It complicates pedigrees by appearing as sporadic or non-Mendelian cases (no consistent transmission, possible shared environmental exposure rather than shared genotype). (b) Distinguish it by molecular testing (absence of the causative mutation), a documented environmental exposure (e.g. thalidomide timing), discordance in monozygotic twins, and lack of recurrence risk consistent with Mendelian ratios. (c) Misattributing an environmental cause to genetics — or vice versa — misdirects public-health policy: it can stigmatize families, divert resources from removing a preventable exposure, and delay protective regulation. See section 18.
15. Critically evaluate Mendel’s pea experiments, considering: (a) sample sizes (he used thousands of plants, giving high statistical power); (b) evidence that Mendel may have “improved” his data (Weldon’s 1902 re-analysis and Ronald Fisher’s 1936 statistical critique suggesting perfect ratios are too good to be true); (c) whether Mendel’s results are reproducible, and what this debate reveals about the role of confirmation bias in science.
- Answer (Q15, Application). (a) Mendel’s large samples (thousands of plants) gave high statistical power, making his ratios reliable estimates. (b) Fisher’s 1936 analysis (anticipated by Weldon, 1902) showed the aggregate fit to expected ratios is *too good* — the pooled χ^2 is improbably small — suggesting unconscious bias in classification or selective reporting, though no fraud is established. (c) Mendel’s core conclusions are robustly reproducible in modern crosses, so the laws stand; the debate illustrates that even correct conclusions can be reached via data that show confirmation bias, underscoring the need for pre-specified analysis and blinded scoring rather than discarding the findings. See section 18.
16. State Mendel’s two laws. Give the biological basis for each in terms of meiosis.
- Answer (Q16, Application). Law of segregation: the two alleles of a gene separate during gamete formation so each gamete carries only one allele; mechanistically this is the separation of homologous chromosomes (and their alleles) at meiosis I anaphase. Law of independent assortment: alleles of different genes segregate independently, because non-homologous chromosome pairs orient randomly at the metaphase I plate. Independent assortment holds only for genes on different chromosomes (or far apart on the same one). See section 18.
17. Define allele, locus, genotype, and phenotype.

Answer (Q17, Application). An allele is one of the alternative DNA sequence variants of a gene. A locus is the fixed physical position of that gene on a chromosome. A genotype is the pair of alleles an individual carries at a locus (e.g. Aa), while the phenotype is the observable trait that genotype produces in a given environment. See section 18.

18. What is a Punnett square? Draw and solve: $Aa \times Aa$.

Answer (Q18, Application). A Punnett square is a table that lists the possible gametes from each parent and combines them to predict offspring genotypes under Mendelian segregation. For $Aa \times Aa$, each parent produces gametes A and a . The four equally likely cells are AA , Aa , Aa , and aa , giving a genotype ratio of $1 AA : 2 Aa : 1 aa$. With complete dominance, the phenotype ratio is 3 dominant : 1 recessive. This prediction assumes independent gamete formation, equal fertilization probability, and no viability difference among the genotypes; see section 18.

19. What are the expected phenotype ratios for a monohybrid cross between two heterozygotes?

Answer (Q19, Application). A monohybrid cross between two heterozygotes ($Aa \times Aa$) yields a 3:1 phenotype ratio (3 dominant : 1 recessive) and a 1:2:1 genotype ratio ($1 AA : 2 Aa : 1 aa$). This assumes complete dominance and that every genotype reliably expresses its expected phenotype. See section 18.

20. What are the expected phenotype ratios for a dihybrid cross between two double heterozygotes?

Answer (Q20, Application). A dihybrid cross between two double heterozygotes ($AaBb \times AaBb$) yields the classic 9:3:3:1 phenotype ratio — $9 A_B_ : 3 A_bb : 3 aaB_ : 1 aabb$. This is the product of two independent 3:1 monohybrid ratios and requires the two genes to assort independently and act independently on the phenotype. See section 18.

Questions 21–30: Synthesis and Evaluation

21. Define codominance. Give the human blood type system as an example.

Answer (Q21, Synthesis). Codominance is an allelic relationship in which both alleles in a heterozygote are fully and simultaneously expressed, so neither masks the other. The human ABO system illustrates this: an $I^A I^B$ individual is blood type AB, expressing both the A and B surface antigens, rather than an intermediate or single antigen. See section 18.

22. What is incomplete dominance? Give one example and show the F_1 and F_2 ratios.

Answer (Q22, Synthesis). Incomplete dominance occurs when the heterozygote shows an intermediate phenotype because one functional allele produces insufficient product for the full dominant effect. In snapdragons, red ($C^R C^R$) \times white ($C^W C^W$) gives an all-pink F_1 ($C^R C^W$); selfing the F_1 gives an F_2 of 1 red : 2 pink : 1 white — the genotype ratio is visible directly because each genotype has its own phenotype. See section 18.

23. What is a testcross? For what is it used?

Answer (Q23, Synthesis). A testcross mates an individual showing the dominant phenotype to a homozygous recessive individual ($A? \times aa$). It reveals the unknown genotype: an all-dominant offspring set indicates AA , whereas a roughly 1:1 dominant:recessive split indicates Aa . See section 18.

24. What is epistasis? Give one example where two loci interact to modify phenotype.

Answer (Q24, Synthesis). Epistasis is a gene interaction in which the genotype at one locus masks or modifies the phenotypic expression of a second, independent locus. In Labrador retrievers, ee at the extension locus is recessive epistatic to the B (black/chocolate) locus: any ee dog is yellow regardless of its B genotype, collapsing the dihybrid F_2 to 9 black : 3 chocolate : 4 yellow. See section 18.

25. What is pleiotropy? Give one example of a single gene that affects multiple traits.

Answer (Q25, Synthesis). Pleiotropy is the phenomenon in which a single gene affects multiple, seemingly unrelated phenotypic traits. Sick-cell disease (a single β -globin mutation) is a classic example: it causes anemia, pain crises, organ damage, splenic dysfunction, and stroke risk, while also conferring malaria resistance in heterozygotes. See section 18.

26. A black cat (BB) is crossed with a white cat (bb). What is the F_1 phenotype? What is the F_2 ratio if F_1 cats are interbred? If black is incompletely dominant, what is the F_1 phenotype?

Answer (Q26, Synthesis). With complete dominance, $BB \times bb$ gives an all-black F_1 (Bb). Interbreeding the F_1 ($Bb \times Bb$) gives an F_2 of 3 black : 1 white. If black is instead *incompletely* dominant, the F_1 heterozygotes (Bb) show an intermediate (gray) phenotype, and the F_2 would be 1 black : 2 gray : 1 white. See section 18.

27. A chi-square analysis of 580 pea seeds (450 round:130 wrinkled) gives $\chi^2 = 2.6$ (critical value 3.84, $p = 0.05$). Should the null hypothesis of 3:1 ratio be rejected? What does this conclusion mean biologically?

Answer (Q27, Synthesis). $\chi^2_{\text{calc}} = 2.6 < \chi^2_{\text{crit}} = 3.84$ ($df = 1$, $\alpha = 0.05$), so we fail to reject the null hypothesis: the observed 450:130 split is statistically consistent with the expected 3:1 ratio (expected 435 round : 145 wrinkled). Biologically, this supports single-gene Mendelian inheritance with complete dominance; the deviation is attributable to chance sampling, not a different genetic mechanism. The test never *proves* 3:1 — it only fails to reject it. See section 18.

28. Two true-breeding strains of wheat produce red and white kernels. The cross produces medium-red F_1 , and F_2 shows a continuous range of colors with frequencies approximately 1:4:6:4:1. This is consistent with two genes each contributing an additive unit of color. What mode of inheritance does this illustrate?

Answer (Q28, Synthesis). This is polygenic (quantitative) inheritance with additive alleles. Two genes each contributing one additive unit of pigment produce 5 phenotypic classes in F_2 with frequencies 1:4:6:4:1 (the binomial expansion of dose 0–4 across 4 alleles), with the medium-red F_1 intermediate between the parental extremes. Environmental variation further blurs the classes into a continuous distribution. See section 18.

29. A woman is phenotypically normal but her father had phenylketonuria (PKU, autosomal recessive). What is the probability that she is a carrier? If she marries a known carrier, what is the probability their first child will have PKU?

Answer (Q29, Synthesis). Her father is aa , so the woman necessarily inherited one a allele; being unaffected she is Aa — she is a carrier with probability 1 (= 100%). Crossed with a known carrier ($Aa \times Aa$), each child has a $\frac{1}{4}$ probability of PKU (aa). Combined chance the first child is affected = $1 \times \frac{1}{4} = 1/4$. See section 18.

30. In coat color genetics of Labrador retrievers: B is dominant for black pigment; b is recessive (brown/chocolate). E is dominant for coat expression; ee gives yellow regardless of B/b. Set up the dihybrid cross $BbEe \times BbEe$ and calculate the expected ratio of black:chocolate:yellow.

Answer (Q30, Synthesis). $BbEe \times BbEe$ gives the standard 9 B_E_ : 3 B_ee : 3 bbE_ : 1 bbee. Because ee is epistatic (yellow regardless of B), the two ee classes merge: 9 B_E_ = black, 3 bbE_ = chocolate, and 3 B_ee + 1 bbee = 4 yellow. Expected ratio = 9 black : 3 chocolate : 4 yellow. See section 18.

Questions — Chromosomal Inheritance and Linkage

Instructor Use and Coverage Notes

- Coverage target: Use progeny classes to calculate map distances and infer the most likely gene order.
- Model/data emphasis: Recombination frequency and three-point mapping.
- Assessment alignment: Statistical Tests and Data Analysis, Representing and Describing Data.
- Misconception probe: Independent assortment applies to unlinked loci, not to every pair of genes.
- Transfer product: Transfer linkage reasoning to disease mapping, breeding, and genome assemblies.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 19 of the textbook — review that chapter before attempting the exercises below.

1. What is a chromosome? How many chromosomes does a normal human somatic cell contain?

Answer (Q1, Recall). A chromosome is a single, organized DNA–protein structure carrying many genes in linear order, condensed by histones into chromatin. A normal human somatic cell is diploid (2n) with 46 chromosomes — 22 autosomal pairs plus one pair of sex chromosomes (XX or XY). See section 19. 2. Define linkage. Why do linked genes violate Mendel’s law of independent assortment?

Answer (Q2, Recall). Linkage is the tendency of genes located close together on the *same* chromosome to be inherited together. They violate independent assortment because that law applies only to genes on *different* chromosomes (which assort with random metaphase-I orientation); linked alleles travel together on one chromosome unless separated by crossing over, so parental allele combinations are over-represented in the offspring. See section 19. 3. What is a centimorgan (cM)? What recombination frequency corresponds to 1 cM?

Answer (Q3, Recall). A centimorgan (cM) is the unit of genetic map distance. By definition, 1 cM corresponds to a 1% recombination frequency — i.e. a 1% chance that a crossover separates two loci per meiosis. The relation is approximately linear only for short distances ($RF \lesssim 50\%$). See section 19. 4. Describe the process of crossing over. At what stage of meiosis does it occur?

Answer (Q4, Recall). Crossing over is the reciprocal physical exchange of homologous DNA segments between non-sister chromatids of paired homologous chromosomes, producing recombinant chromosomes. It occurs during prophase I of meiosis (pachytene), when homologs are synapsed, and is visible cytologically as chiasmata. See section 19. 5. What is a genetic map? How is it constructed from recombination frequency data?

Answer (Q5, Recall). A genetic (linkage) map orders genes along a chromosome and spaces them by genetic distance. It is built by crossing strains differing at multiple loci, counting recombinant vs parental offspring, and converting recombination frequency to map distance (1% RF = 1 cM); distances between adjacent intervals are summed (with double-crossover correction) to assemble the full map. See section 19. 6. What is X-linked inheritance? Give two examples of X-linked recessive disorders.

Answer (Q6, Recall). X-linked inheritance describes genes on the X chromosome; for X-linked recessive traits, hemizygous males (one X) are affected if they carry the allele, while females must be homozygous to be affected, producing the characteristic male-biased, carrier-mother pedigree. Two classic X-linked recessive disorders are hemophilia A and red–green color blindness (also Duchenne muscular dystrophy). See section 19. 7. Define nondisjunction. What aneuploid conditions result from nondisjunction at meiosis I vs meiosis II?

Answer (Q7, Recall). Nondisjunction is the failure of homologous chromosomes or sister chromatids to separate properly during cell division, producing aneuploid gametes. Meiosis-I nondisjunction (homologs fail to separate) yields gametes with both homologs (one maternal + one paternal), giving trisomies such as Down syndrome (trisomy 21); meiosis-II nondisjunction (sister chromatids fail) yields gametes with two identical copies. Both can produce trisomy or monosomy after fertilization. See section 19. 8. What is trisomy 21? What maternal-age-related risk factor is associated with it?

Answer (Q8, Recall). Trisomy 21 (Down syndrome) is the presence of three copies of chromosome 21, usually from maternal meiosis-I nondisjunction. Its incidence rises sharply with maternal age, because oocytes are arrested in prophase I for decades and age-related loss of sister-chromatid cohesion increases nondisjunction; paternal age has little effect. See section 19. 9. What is a chromosomal translocation? How does the Philadelphia chromosome arise?

Answer (Q9, Recall). A chromosomal translocation is the transfer of a chromosomal segment to a non-homologous chromosome. The Philadelphia chromosome arises from a reciprocal translocation $t(9;22)$ that fuses *BCR* (chr 22) to *ABL1* (chr 9), creating the constitutively active *BCR-ABL1* tyrosine-kinase fusion oncogene that drives chronic myeloid leukemia. See section 19. 10. Compare XX/XY, ZW/ZZ, XO, and haplodiploid sex determination. Why should haplodiploidy be treated as a chromosome mechanism rather than a complete explanation for eusociality?

Answer (Q10, Recall). In XX/XY systems, typical mammalian females are XX and males are XY, with SRY initiating testis development. In ZW/ZZ systems, common in birds and butterflies, females are ZW and males are ZZ. In XO systems, males have one X and no second sex chromosome. In haplodiploidy, common in Hymenoptera, unfertilised haploid eggs develop as males and fertilized diploid eggs develop as females. Haplodiploidy changes relatedness patterns among relatives, so it matters for kin-selection models, but it is not a complete explanation for eusociality because ecology, mating system, colony demography, and phylogenetic history also matter; diploid termites are the key contrast. See section 19.

Questions 11–20: Application and Analysis

11. Three linked genes A, B, C have pairwise recombination frequencies: A–B = 12%, B–C = 7%, A–C = 19%. Does map distance A–C equal A–B + B–C? If not, why, and what genetic phenomenon accounts for the discrepancy?

Answer (Q11, Application). No — A–C (19%) does not equal A–B + B–C (12% + 7% = 19% here, which actually matches closely). When the sum exceeds the directly measured A–C distance, the discrepancy is due to double crossovers between A and C: a double crossover restores the parental arrangement of the outer markers, so those events are not counted as A–C recombinants and the apparent A–C distance is underestimated. Gene order is A–B–C, and additive map distances from short intervals are more accurate than a single long-interval measurement. See section 19. 12. Morgan’s experiments showed that white eye and miniature wing in *Drosophila* are X-linked and linked to each other (recombination frequency about 36%). Explain how these results violate both Mendel’s laws simultaneously, and how recombination still produces some parental and recombinant gamete classes.

Answer (Q12, Application). White eye and miniature wing are both on the X chromosome and physically linked. They violate independent assortment because, being on the same chromosome, their alleles do not assort independently — parental combinations predominate. They also depart from simple autosomal segregation expectations because X-linkage ties inheritance to sex (males hemizygous). Crossing over in the female’s meiosis recombines the two loci about 36% of the time, yielding about 64% parental and about 36% recombinant gametes — recombinants exist but are the minority, the signature of linkage. See section 19. 13. A man with color blindness (X-linked recessive) who has normal vision has a sister who is a confirmed carrier. What is the probability that his daughter will: (a) be a carrier; (b) be color blind; (c) have normal vision? What is the probability any son of his will be color blind?

Answer (Q13, Application). The man is X^cY (color blind), but offspring genotypes depend on the *mother*. His daughters each receive his X^c plus one maternal X; without information on the mother’s genotype, assume she is X^CX^C (non-carrier): then every daughter is X^CX^c — (a) carrier probability = 1, (b) color blind = 0, (c) normal vision = 1. The sister’s carrier status informs the man’s family but not his children. Probability any son is color blind = 0 with a non-carrier mother (sons get the father’s Y and the mother’s X), since sons inherit no X from their father. See section 19. 14. Barr bodies (condensed inactive X chromosomes) are present in cells with >1 X chromosome: 1 Barr body per n+1 X chromosomes. How many Barr bodies would be present in cells from: (a) 46,XX female; (b) 47,XXX female (triple X); (c) 47,XXY male (Klinefelter); (d) 45,X female (Turner)?

Answer (Q14, Application). Barr bodies = (number of X chromosomes) – 1. (a) 46,XX → 1 Barr body (2 X’s). (b) 47,XXX → 2 Barr bodies (3 X’s). (c) 47,XXY (Klinefelter) → 1 Barr body (2 X’s). (d) 45,X (Turner) → 0 Barr bodies (1 X). All X’s beyond one are inactivated to equalize X-linked gene dosage. See section 19. 15. Down syndrome (trisomy 21) risk rises with maternal age. Propose a mechanistic explanation: which proteins hold meiosis I arrested in the human oocyte, how does cohesin decline with age, and how does premature chromatid separation → nondisjunction → trisomy? Name the specific cohesin subunit implicated.

Answer (Q15, Application). Human oocytes arrest in prophase I from fetal life until ovulation, held by sister-chromatid cohesin complexes containing the meiosis-specific kleisin REC8 that keep chiasmata in place. Over decades, cohesin (and the shugoshin-protected centromeric cohesin) is not replenished and gradually degrades; weakened cohesion permits premature separation of homologs or sister chromatids, leading to meiosis-I nondisjunction and aneuploid (trisomy-21) eggs. The implicated subunit is REC8 (meiotic cohesin), explaining the maternal-age effect. See section 19. 16. Robertsonian translocation Down syndrome: a chromosome 21 fuses to chromosome 14. A carrier parent (45 chromosomes, with 14;21 translocation) produces offspring via meiosis. Using a diagram, show the three viable gamete types and predict the proportion of offspring who have translocation Down syndrome, normal karyotype, and carrier status.

Answer (Q16, Application). A balanced rob(14;21) carrier (45 chromosomes) produces six gamete types from 2:2 segregation, but only three give viable conceptuses: (1) normal (*separate* 14 + 21), (2) balanced carrier (the 14;21 fusion only — phenotypically normal), and (3) translocation Down syndrome (the 14;21 fusion *plus* a free 21 → effective trisomy 21). The other classes (monosomy 21, trisomy 14, monosomy 14) are non-viable. Among liveborns the three classes occur in roughly 1 normal : 1 carrier : 1 translocation Down syndrome, though the *observed* recurrence risk (about 10–15% for a female carrier, lower for male) is below the theoretical 1/3 due to selective loss of unbalanced conceptuses. See section 19. 17. The F_{st} (fixation index) of a particular autosomal gene between two human populations is 0.08. Interpret this value: how much of total human genetic variation lies between populations vs within populations? Compare this to the claim that “race explains most human genetic variation.”

Answer (Q17, Application). F_{ST} = 0.08 means only about 8% of the total genetic variation at this locus lies *between* the two populations, while

about 92% lies *within* them — individuals within a population differ from each other far more than the populations differ on average. This is consistent with the canonical human $F_{ST} \approx 0.10\text{--}0.15$ (Lewontin 1972; Rosenberg 2002) and directly refutes the claim that ‘race explains most human genetic variation’: the overwhelming majority of human genetic diversity is shared within all populations. See section 19. 18. Huntington’s disease is autosomal dominant. The causative allele (HTT with >36 CAG repeats) shows near-100% penetrance. If an affected parent (heterozygous, Hh) has five children, what fraction are expected to be affected? Why does penetrance differ from simple Mendelian dominant inheritance in this context?

Answer (Q18, Application). Each child of an Hh (heterozygous) affected parent and an unaffected (hh) partner has a ½ probability of inheriting the dominant disease allele, so on average 2–3 of the 5 children (expected 2.5) are affected. Penetrance for HD with >36 CAG repeats is near-100%, so genotype essentially equals phenotype — but onset is age-dependent and delayed, so carriers are unaffected for decades; this ‘reduced apparent penetrance at a given age’ and anticipation (repeat expansion) distinguish HD from textbook fully-penetrant Mendelian dominance. See section 19. 19. Genomic imprinting: if the paternal allele of IGF2 is expressed and the maternal allele is silenced, predict the phenotype of: (a) a child who inherits a deletion on the paternal chromosome 11 (Beckwith-Wiedemann: overgrowth); (b) a child inheriting a deletion on the maternal chromosome 11 (Silver-Russell: growth restriction). Use the concept of parent-of-origin-specific expression to explain both.

Answer (Q19, Application). Because IGF2 is expressed only from the paternal allele (maternal copy silenced by imprinting): (a) a child with a *paternal* chromosome-11 deletion (or instead double-dose maternal/paternal IGF2 dysregulation) — in Beckwith–Wiedemann, gain of paternal IGF2 expression — has excess IGF2 and overgrowth. (b) a child inheriting the deletion such that the active *paternal* IGF2 is lost (Silver–Russell, e.g. paternal hypomethylation or maternal UPD11) has little/no IGF2 and growth restriction. The asymmetry arises solely because only the paternal allele is transcriptionally active — the parent of origin of the lesion determines the phenotype. See section 19. 20. Inversion heterozygosity in *Drosophila* suppresses recombination in the inverted region because crossing over within an inversion produces unbalanced chromosomes (duplications and deletions), which are lethal. Explain the mechanism and why evolution often preserves inversions if they capture coadapted gene complexes.

Answer (Q20, Application). In an inversion heterozygote, the inverted and normal homologs can only synapse by forming an inversion loop. A crossover *within* the loop produces chromatids with duplications and deletions (paracentric inversions also yield acentric/dicentric chromatids), which are typically inviable, so only non-recombinant gametes survive — recombination in the region is effectively suppressed. Selection therefore favors inversions when they capture a set of co-adapted (epistatically beneficial) alleles, because the inversion locks the favorable haplotype together and shields it from being broken up by recombination (a ‘supergene’). See section 19.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the role of the synaptonemal complex (SC) in meiotic recombination: how does the SC align homologous chromosomes, what components does it consist of, and how does SC disassembly correlate with chiasma formation? What happens when SC formation fails?

Answer (Q21, Synthesis). The synaptonemal complex (SC) is a tripartite proteinaceous zipper — two lateral elements (SYCP2/SYCP3, on each homolog axis) joined by transverse filaments (SYCP1) and a central element — that mediates full synapsis, holding homologs in close, stable register along their lengths during pachytene. SC assembly stabilizes early recombination intermediates and promotes crossover maturation; SC disassembly at diplotene leaves chiasmata (the cytological manifestation of completed crossovers) holding homologs together until anaphase I. When SC formation fails, homolog pairing/crossing over is defective, crossovers drop, and nondisjunction and aneuploidy or meiotic arrest/sterility result — showing recombination is an actively regulated process, not passive. The conclusion would change if crossovers proceeded normally without an SC. See section 19. 22. Comparative genomic hybridization (CGH) and SNP arrays detect copy number variation (CNVs) across the genome. Evaluate the clinical utility of chromosomal microarray (CMA) analysis in: (a) prenatal diagnosis (replacing karyotyping?); (b) diagnosing children with unexplained intellectual disability; (c) identifying germline vs somatic CNVs in cancer. What is the main limitation of CMA vs long-read sequencing for CNV detection?

Answer (Q22, Synthesis). Chromosomal microarray detects sub-microscopic copy-number gains/losses genome-wide. (a) Prenatal: CMA detects clinically relevant CNVs missed by karyotyping and is first-line for fetal anomalies, but it cannot detect balanced rearrangements or low-level mosaicism, so karyotyping/NIPT remain complementary. (b) Unexplained intellectual disability: CMA is the recommended first-tier test, yielding a diagnosis in about 15–20% of cases via pathogenic CNVs. (c) Cancer: comparing tumor vs matched normal DNA distinguishes somatic (tumor-only) from germline CNVs. The main limitation vs long-read sequencing is that CMA detects copy-number imbalance but is blind to balanced/copy-neutral rearrangements, breakpoints, and structural context that long reads resolve directly. See section 19. 23. Design an experiment to map the XIC (X-inactivation center) on the human X chromosome using: (a) X-autosome translocation cell lines; (b) CRISPR deletion of candidate regions; (c) Xist RNA FISH in human iPSC differentiation. What molecular result would confirm the XIC has been correctly identified?

Answer (Q23, Synthesis). Hypothesis: a defined cis-acting region (the XIC) is necessary and sufficient to initiate X inactivation. (a) In X-autosome translocation lines, test whether the autosomal segment becomes inactivated only when physically joined to the candidate region (spreading from

the XIC). (b) Use CRISPR to delete candidate sub-regions and ask which deletion abolishes initiation of silencing (loss-of-function mapping), with control deletions of neighboring DNA. (c) Perform Xist RNA FISH during iPSC differentiation to watch where the silencing ‘cloud’ nucleates. Confirmation: the minimal region whose deletion blocks Xist up-regulation/coating *and* whose presence is sufficient to silence an attached autosome — reproducibly across clones — is the XIC; failure to silence despite an intact candidate region would falsify the call. See section 19. 24. Evaluate the genomic consequences of chromosomal rearrangements that bring proto-oncogenes near active enhancers (“enhancer hijacking”). Give two specific examples (BCL2 and IGH in follicular lymphoma; MYC and IGH in Burkitt lymphoma) and explain why the same translocation in different individuals produces the same cancer phenotype.

Answer (Q24, Synthesis). ‘Enhancer hijacking’ juxtaposes a proto-oncogene with a strong, constitutively active enhancer, driving its overexpression. Follicular lymphoma: t(14;18) places *BCL2* under the immunoglobulin heavy-chain (*IGH*) enhancer → anti-apoptotic BCL2 overexpression. Burkitt lymphoma: t(8;14) places *MYC* under the *IGH* enhancer → constitutive MYC-driven proliferation. The same translocation produces the same cancer phenotype across individuals because the recurrent breakpoint reproducibly creates the same deregulated oncogene–enhancer configuration; the deterministic molecular consequence is what makes these translocations diagnostic. The interpretation would change if the same rearrangement failed to deregulate the oncogene (e.g. inactive enhancer in that lineage). See section 19. 25. The genetic and epigenetic mechanisms of centromere identity are distinct from those of euchromatin. Evaluate: (a) why centromeres require CENP-A (not canonical H3) for proper kinetochore assembly; (b) why centromere sequences are highly repetitive (α -satellite) despite being functionally defined by CENP-A deposition; (c) what would happen to chromosome segregation if CENP-A deposition were globally abolished.

Answer (Q25, Synthesis). (a) Centromere identity is epigenetic, defined by the histone-H3 variant CENP-A, which marks centromeric chromatin and is the assembly platform for the kinetochore (CCAN/KMN network); canonical H3 cannot template kinetochore formation. (b) Centromeric DNA is highly repetitive α -satellite, but sequence alone is neither necessary nor sufficient — neocentromeres can form on non-satellite DNA — so the repeats are a permissive substrate while CENP-A deposition is the actual determinant (sequence persists because it is recombinationally inert, not because it specifies the centromere). (c) Globally abolishing CENP-A deposition would prevent kinetochore assembly, causing failure of spindle attachment, massive missegregation/aneuploidy, mitotic-checkpoint arrest, and cell death. The interpretation would change if a CENP-A-null cell still segregated chromosomes faithfully. See section 19. 26. Position effects in *Drosophila* (position effect variegation, PEV) occur when a gene is relocated near heterochromatin via chromosomal inversion, causing mosaic silencing. Evaluate the molecular basis of heterochromatic silencing spreading (HP1-H3K9me3 loop), what suppresses PEV (loss of heterochromatin factors), and how this relates to genes at the chromosome 16p11.2 deletion locus in autism.

Answer (Q26, Synthesis). In PEV, an inversion places a euchromatic gene next to constitutive heterochromatin, and heterochromatin spreads via a self-propagating loop: H3K9 methyltransferase (Su(var)3-9) deposits H3K9me3, which recruits HP1, which recruits more methyltransferase, extending silencing variably from cell to cell (mosaic expression). Su(var) (suppressor of variegation) mutations that reduce HP1 or H3K9 methylation suppress PEV (more expression), while *E(var)* enhance it — directly demonstrating dose-dependent heterochromatic silencing. By analogy, position and chromatin context modulate the dosage-sensitive genes within the 16p11.2 CNV, helping explain the variable expressivity of its autism/neurodevelopmental phenotypes. See section 19. 27. Evaluate the selective sweep as an evolutionary force producing chromosomal linkage disequilibrium (LD). When a beneficial mutation sweeps to fixation, flanking variants are dragged along (“genetic hitchhiking”), producing extended LD. How is extended LD detected (iHS statistic), and what gene regions in the human genome show evidence of recent selective sweeps?

Answer (Q27, Synthesis). A selective sweep occurs when a beneficial mutation rises rapidly to high frequency; because there is little time for recombination, physically linked neutral variants ‘hitchhike’ to high frequency too, creating a region of extended haplotype homozygosity and strong linkage disequilibrium with reduced diversity around the selected site. It is detected by haplotype-based statistics such as the integrated haplotype score (iHS) (and EHH/XP-EHH), which flag unusually long, common haplotypes. Classic human examples include LCT (lactase persistence), the Duffy/*DARC* locus, *EDAR*, *SLC24A5* pigmentation, and HBB region malaria-resistance variants. The signal would be reattributed if the long haplotype were better explained by demography (a bottleneck) than selection. See section 19. 28. Chromosome conformation capture (3C/4C/HiC) reveals that chromosomes occupy specific territories in the nucleus and that A (active) and B (inactive) compartments are spatially separated. Evaluate how compartment identity is maintained through cell division (given that nuclear organization must be re-established after mitosis), and what proteins mark the A vs B compartment boundaries.

Answer (Q28, Synthesis). Hi-C shows chromosomes occupy distinct territories and partition into active A and inactive B compartments. Compartment identity is largely encoded in the chromatin/epigenetic state of the DNA itself (histone modifications, DNA methylation), so after mitosis it is re-established de novo as marks and architectural factors re-bind rather than being physically inherited — a robust attractor set by the underlying epigenome. A compartments are marked by active chromatin (H3K4me3/H3K27ac, RNA Pol II, open chromatin), and loop/domain boundaries are defined by CTCF and the cohesin complex (loop extrusion); B compartments carry repressive marks (H3K9me3/H3K27me3, HP1, lamina-associated domains anchored by lamin B). Compartmentalization would not be heritable if it could not be reconstructed from the chromatin state

after each division. See section 19. 29. Meiotic drive (non-Mendelian segregation) is a selfish genetic element that biases its own transmission into gametes at >50% frequency. Evaluate the molecular mechanisms of drive (*t*-allele in mice, SD system in *Drosophila*) and the population genetic consequences: under what conditions does a driving allele reach fixation vs form a stable polymorphism? What restricts drive from eliminating the drive-suppressor population?

Answer (Q29, Synthesis). Meiotic drive is a selfish element that biases its own transmission above 50%. In the mouse *t*-haplotype, a complex of distorters poisons all sperm via the *Tcd* loci while the linked responder *Tcr* rescues only *t*-bearing sperm; in *Drosophila* Segregation Distorter (SD), the *Sd* product disrupts chromatin condensation in *Rsp*-sensitive (non-SD) spermatids, so SD sperm preferentially survive. A driving allele tends toward fixation when its transmission advantage outweighs its fitness cost, but reaches a stable polymorphism when homozygotes suffer strong viability/fertility costs (balancing the drive advantage against homozygote lethality/sterility). Drive is restrained from sweeping the suppressor population by deleterious homozygous effects, recombination breaking up the drive complex, and rapid spread of unlinked drive-suppressor (modifier) alleles favored to restore fair segregation. See section 19. 30. Critically evaluate the concept of “chromosomal instability” (CIN) in cancer, where cells gain and lose whole chromosomes or large chromosome arms with each division. Is CIN a cause or consequence of cancer? Evaluate the evidence that CIN generates the aneuploidy needed for tumor evolution vs the evidence that CIN is incompatible with cell viability and is therefore tolerated primarily within a narrow window of “just right” instability.

Answer (Q30, Synthesis). Chromosomal instability (CIN) is an elevated *rate* of whole-chromosome/arm gain and loss per division (distinct from a static aneuploid state). The evidence is two-sided. *Cause-supporting*: CIN generates the ongoing karyotypic diversity (loss of tumor suppressors, gain of oncogene-bearing arms) that fuels Darwinian tumor evolution and drug resistance, and mutations in mitotic-checkpoint/cohesion genes can be early events. *Constraint-supporting*: gross aneuploidy imposes a strong proteostatic and growth burden and excessive missegregation is lethal, so cells tolerate only an intermediate (‘just-right’) instability — too little gives no adaptive variation, too much causes mitotic catastrophe. The reconciling view is that CIN is both consequence and driver, selected within a narrow viable window. The conclusion would change if engineered high-CIN cells reproducibly enhanced tumor fitness without a viability ceiling. See section 19.

Questions — Population Genetics

Instructor Use and Coverage Notes

- Coverage target: Calculate expected frequencies and identify which evolutionary force could explain deviations.
- Model/data emphasis: Hardy-Weinberg and allele-frequency recurrence calculations.
- Assessment alignment: Statistical Tests and Data Analysis, Representing and Describing Data.
- Misconception probe: Hardy-Weinberg is a null model, not a claim that populations do not evolve.
- Transfer product: Apply population-genetic reasoning to screening, conservation, and pathogen evolution.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 20 of the textbook — review that chapter before attempting the exercises below.

1. State the Hardy-Weinberg principle and list the five conditions required for equilibrium.

Answer (Q1, Recall). The Hardy–Weinberg principle states that in a large, randomly mating population free of evolutionary forces, allele and genotype frequencies remain constant from generation to generation, with genotype frequencies given by $p^2 + 2pq + q^2 = 1$. The five conditions are: (1) no natural selection, (2) no mutation, (3) no gene flow (migration), (4) random mating, and (5) infinitely large population (no genetic drift). See section 20. 2. Write the Hardy-Weinberg equations for a two-allele system. What do p , q , p^2 , $2pq$, and q^2 represent?

Answer (Q2, Recall). For two alleles with frequencies p (dominant A) and q (recessive a), the allele equation is $p + q = 1$ and the genotype equation is $p^2 + 2pq + q^2 = 1$. Here p^2 is the frequency of homozygous dominant (AA), $2pq$ the frequency of heterozygotes (Aa), and q^2 the frequency of homozygous recessive (aa) individuals. See section 20. 3. What is allele frequency? What is genotype frequency? How do they relate?

Answer (Q3, Recall). Allele frequency is the proportion of a particular allele among all copies of that gene in a population (ranges 0–1). Genotype frequency is the proportion of individuals having a particular genotype. They relate through Hardy–Weinberg: allele frequencies can be computed from genotype counts (e.g. $p = \text{freq}(AA) + \frac{1}{2}\text{freq}(Aa)$), and under HWE genotype frequencies are predicted as p^2 , $2pq$, q^2 . See section 20. 4. Define genetic drift. Why is it more pronounced in small populations?

Answer (Q4, Recall). Genetic drift is the random change in allele frequencies across generations caused by sampling error in which gametes happen to form the next generation. It is more pronounced in small populations because the variance of allele-frequency change is proportional to $1/(2N_e)$ — with few individuals, chance sampling causes large frequency swings and rapid loss or fixation, whereas large populations average out sampling noise. See section 20. 5. What is the founder effect? Give one human example.

Answer (Q5, Recall). The founder effect is the loss and non-representative sampling of genetic variation that occurs when a new population is established by a small number of founding individuals, so the new gene pool reflects the founders’ alleles, not the source population’s. A classic human example is the Amish (Ellis–van Creveld syndrome) or Afrikaner / French-Canadian populations, where specific rare disease alleles reach unusually high frequency. See section 20. 6. Define gene flow (migration). How does it affect allele frequencies in two populations?

Answer (Q6, Recall). Gene flow (migration) is the transfer of alleles between populations when individuals or gametes move and reproduce. It homogenizes allele frequencies between populations — reducing differentiation (F_{ST}) — so that each generation the recipient population’s frequency moves toward the donor’s by $\Delta p_1 = m(p_2 - p_1)$, where m is the migration rate. See section 20. 7. What is mutation rate? What is the typical per-base-pair mutation rate in humans per generation?

Answer (Q7, Recall). Mutation rate is the probability that a new heritable change arises at a given site per generation. In humans the typical point-mutation rate is approximately 10^{-8} per base pair per generation (giving roughly 70–100 de novo mutations per diploid genome per generation). Mutation is the ultimate source of new alleles but, by itself, changes allele frequencies very slowly. See section 20. 8. Define natural selection. What is the selection coefficient (s)?

Answer (Q8, Recall). Natural selection is the differential survival and reproduction of genotypes due to heritable differences in fitness, systematically changing allele frequencies. The selection coefficient (s) quantifies the relative fitness disadvantage of a genotype: if the favored genotype has fitness $w = 1$, a genotype with fitness $1 - s$ is selected against; s ranges from 0 (no selection) to 1 (lethal/sterile). See section 20. 9. What is heterozygote advantage (overdominance)? Give the sickle-cell anemia example.

Answer (Q9, Recall). Heterozygote advantage (overdominance) occurs when the heterozygote has higher fitness than either homozygote, which maintains both alleles as a stable balanced polymorphism. In sickle-cell anemia, HbA/HbS heterozygotes are protected against severe *Plasmodium*

falciparum malaria while avoiding sickle-cell disease; *HbA/HbA* are malaria-susceptible and *HbS/HbS* have lethal anemia, so the *HbS* allele persists at elevated frequency in malarial regions. See section 20. 10. What is the neutral theory of molecular evolution? Who proposed it?

Answer (Q10, Recall). The neutral theory of molecular evolution holds that the great majority of molecular variation within and between species is selectively neutral and evolves by random genetic drift rather than positive selection, with deleterious mutations removed by purifying selection. It was proposed by Motoo Kimura (1968), with related work by King and Jukes and the nearly-neutral extension by Tomoko Ohta. See section 20.

Questions 11–20: Application and Analysis

11. A population has 500 individuals: 200 AA, 240 Aa, 60 aa. Calculate allele frequencies p and q. Calculate expected HWE genotype frequencies. Use chi-square to test if the population is in HWE.

Answer (Q11, Application). Allele counts: total alleles = $2 \times 500 = 1000$. $A = 2(200) + 240 = 640 \rightarrow p = 0.64$; $a = 2(60) + 240 = 360 \rightarrow q = 0.36$. Expected HWE counts: $AA = p^2 \cdot 500 = 0.4096 \cdot 500 \approx 204.8$, $Aa = 2pq \cdot 500 = 0.4608 \cdot 500 \approx 230.4$, $aa = q^2 \cdot 500 = 0.1296 \cdot 500 \approx 64.8$. $\chi^2 = \sum (O - E)^2 / E = (200 - 204.8)^2 / 204.8 + (240 - 230.4)^2 / 230.4 + (60 - 64.8)^2 / 64.8 \approx 0.112 + 0.400 + 0.356 = 0.87$. With $df = 1$ (3 genotypes – 1 allele estimated – 1), $\chi^2_{crit} = 3.84$ at $\alpha = 0.05$; since $0.87 < 3.84$ we fail to reject HWE — the population is consistent with Hardy–Weinberg equilibrium. See section 20. 12. After a natural disaster reduces a population from 10,000 to 100 individuals, what are the genetic consequences? Calculate how much genetic variation is expected to be lost (as measured by heterozygosity) in one generation: $H_t = H_0(1 - 1/(2N_e))$.

Answer (Q12, Application). Crashing from 10,000 to 100 is a bottleneck: it causes loss of rare alleles, reduced heterozygosity, increased drift and inbreeding, and a non-representative gene pool. Using $H_t = H_0(1 - 1/(2N_e))$ with $N_e = 100$ for one generation: the fraction of heterozygosity retained = $1 - 1/(2 \cdot 100) = 1 - 0.005 = 0.995$, i.e. only about 0.5% of heterozygosity is lost in that single generation. The deeper consequence is the durable loss of allelic diversity and elevated future drift, not the small one-generation H drop. See section 20. 13. In a population of $N_e = 50$ individuals, an allele at frequency $q = 0.2$ is selectively neutral. Calculate the probability it is lost by drift in the first generation (approximate using $1 - q = 0.8$). Over many generations, what is the probability it eventually reaches fixation ($= q_0$)?

Answer (Q13, Application). Under pure drift, a neutral allele’s probability of *eventual fixation equals its current frequency*: $P(\text{fixation}) = q_0 = 0.2$ (and $P(\text{loss}) = 0.8$), independent of N_e . The one-generation probability of immediate loss is small — every one of the $2N_e = 100$ sampled gametes must be the alternative allele, $\approx (1 - q)^{(2N_e)} = 0.8^{100} \approx 2 \times 10^{-10}$ (effectively zero). So loss in a single generation is essentially impossible, but over the long run the allele is fixed with probability 0.2 and lost with probability 0.8. See section 20. 14. Selection against a recessive allele ($s = 1$, lethal; aa dies before reproduction): starting from $q_0 = 0.5$, calculate the allele frequency after 1, 5, and 10 generations using $q_t = q_0 / (1 + t \cdot s \cdot q_0)$. How many generations to reduce q from 0.5 to 0.01?

Answer (Q14, Application). Using $q_t = q_0 / (1 + t \cdot s \cdot q_0)$ with $q_0 = 0.5$, $s = 1$: $t = 1$: $q = 0.5 / (1 + 0.5) = 0.333$; $t = 5$: $q = 0.5 / (1 + 2.5) = 0.143$; $t = 10$: $q = 0.5 / (1 + 5) = 0.0833$. To reach $q = 0.01$: solve $0.01 = 0.5 / (1 + t \cdot 0.5) \rightarrow 1 + 0.5t = 50 \rightarrow t = 98$, so about 98 generations. Note the hallmark of selection against a recessive: progress slows dramatically as q falls, because recessive alleles are increasingly hidden in heterozygotes and shielded from selection. See section 20. 15. Cystic fibrosis has a frequency of 1/2,500 in European populations. Calculate: (a) q (frequency of CF allele); (b) the carrier frequency (2pq); (c) what Hardy–Weinberg assumption must hold for this calculation to be valid; (d) why the CF allele is maintained at relatively high frequency (propose two hypotheses).

Answer (Q15, Application). (a) In Hardy–Weinberg, affected homozygotes occur at frequency $q^2 = 1/2500 = 4 \times 10^{-4}$, so $q = \sqrt{4 \times 10^{-4}} = 0.02$. (b) Carrier (heterozygote) frequency = $2pq$ where $p = 1 - q = 0.98$: $2 \times 0.98 \times 0.02 = 0.0392 \approx 1$ in 25. This is the striking clinical fact about autosomal recessive disease: rare disease (1/2500) \leftrightarrow common carriers (1/25). (c) Valid assumptions: random mating with respect to CF genotype, no selection currently depleting q (acceptable over one generation; see d), no mutation–selection–drift disequilibrium, and a large panmictic population. In pre-treatment populations selection against homozygotes was strong ($s \approx 1$), so q would be declining if the population started away from mutation–selection balance. (d) Two hypotheses for persistence: (i) Heterozygote advantage — CFTR $\Delta F508$ carriers may have reduced chloride secretion into the gut lumen, conferring resistance to cholera / typhoid / tuberculosis diarrhea during historic European epidemics (parallel to sickle-cell/malaria, though less firmly established). (ii) Mutation–selection balance — recurrent CFTR mutation ($\mu \approx 7 \times 10^{-7}$ per allele per generation) with $s \approx 1$ predicts $\hat{q} = \sqrt{\mu/s} \approx 8 \times 10^{-4}$ — much lower than observed, so mutation–selection balance alone cannot account for the 0.02 allele frequency; heterozygote advantage (or historical drift/founder events) must contribute. See section 20. 16. F_{ST} between two populations is 0.15 for an autosomal locus. Interpret this: what fraction of total variation is between vs within populations? Calculate the estimated gene flow (Nm) using the approximation $F_{ST} \approx 1/(1 + 4Nm)$.

Answer (Q16, Application). $F_{ST} = 0.15$ means about 15% of total genetic variation lies *between* the two populations and about 85% lies *within* them — populations are modestly differentiated, with most diversity shared. Using $F_{ST} \approx 1/(1 + 4Nm)$: $0.15 = 1/(1 + 4Nm) \rightarrow 1 + 4Nm = 1/0.15 = 6.667 \rightarrow 4Nm = 5.667 \rightarrow Nm \approx 1.4$ migrants per generation. This illustrates the classic result that even about 1 effective migrant per generation substantially limits differentiation by drift. See section 20. 17. A bottleneck reduces a population to 10 individuals for one generation, then expands.

If initial heterozygosity was 0.6, calculate expected heterozygosity after the bottleneck ($H = H_0(1 - 1/(2N_{\text{bottleneck}}))$). After 10 generations of recovery with large N , how does heterozygosity change?

Answer (Q17, Application). Using $H = H_0(1 - 1/(2N_{\text{bottleneck}}))$ with $H_0 = 0.6$ and $N = 10$: $H = 0.6 \times (1 - 1/20) = 0.6 \times 0.95 = 0.57$ — about a 5% loss of heterozygosity in the single bottleneck generation. After expansion, heterozygosity is not restored quickly: H stays near the reduced level and recovers only slowly (at rate about μ via new mutation, over many thousands of generations with large N), because expansion preserves but does not regenerate the lost allelic diversity. The bottleneck’s genetic signature (reduced heterozygosity, lost rare alleles, elevated LD) is therefore long-lasting. See section 20. 18. The neutral theory predicts that the rate of neutral molecular evolution equals the mutation rate (μ), independent of population size. Explain the logic: if advantageous mutations are rare and deleterious mutations are removed by selection, then substitutions in the fossil record should primarily reflect neutral changes. What types of sequences evolve fastest (synonymous sites) and slowest (amino acid-changing in essential proteins)?

Answer (Q18, Application). If new mutations are mostly neutral, the rate at which they enter the population is $2N \cdot \mu_n$ and each has fixation probability $1/(2N)$, so the substitution rate $= 2N \mu_n \times 1/(2N) = \mu_n$, independent of population size — advantageous mutations are too rare to dominate and deleterious ones are purged by purifying selection, so most fixed substitutions are neutral. Fastest-evolving sequences are those under least constraint: synonymous (silent) sites, pseudogenes, and non-coding spacer DNA; slowest-evolving are functionally critical sites — non-synonymous (amino-acid-changing) positions in essential, conserved proteins (e.g. histones), where most changes are deleterious and removed. See section 20. 19. Balancing selection maintains two or more alleles at a locus above neutral expectations. Name three types of balancing selection and one example of each: (a) heterozygote advantage; (b) frequency-dependent selection; (c) fluctuating selection (spatially or temporally varying). Which type is operative at MHC loci?

Answer (Q19, Application). Three types of balancing selection: (a) Heterozygote advantage (overdominance) — heterozygotes fittest, e.g. *HbS* sickle-cell/malaria. (b) Negative frequency-dependent selection — rare genotypes have higher fitness, e.g. self-incompatibility alleles in plants, or rare-prey/host advantage. (c) Fluctuating (spatially or temporally varying) selection — different alleles favored in different patches or seasons, e.g. *Drosophila* allozymes or banding morphs varying with climate. MHC (HLA) loci are the textbook case, maintained chiefly by heterozygote advantage (broader pathogen recognition) together with negative frequency-dependent selection. See section 20. 20. Sexual selection is a form of natural selection acting on mating success rather than survival. Distinguish intrasexual selection (competition between same-sex individuals) from intersexual selection (mate choice). Give one example of each in animals. How might sexual selection drive the rapid evolution of secondary sexual characteristics even if they reduce survival (Zahavian handicap model)?

Answer (Q20, Application). Sexual selection favors traits that increase mating success even at a survival cost. Intrasexual selection is competition among same-sex individuals for mates — e.g. male red deer (stag) antler combat for harem access. Intersexual selection is mate choice by the other sex — e.g. peahens choosing peacocks with the largest, most symmetric trains. Under the Zahavian handicap principle, a costly ornament can spread because only high-quality individuals can bear the cost and survive, so the handicap is an honest signal of genetic quality; choosy females gain fitter offspring, driving runaway elaboration of the trait despite its survival penalty. See section 20.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the molecular clock hypothesis: if the neutral substitution rate equals μ (the mutation rate), then the number of differences between sequences accumulates linearly with time. What calibrates the molecular clock (fossil dates), how has the clock been used to date the human-chimpanzee split, and what are the sources of rate variation (generation time, effective population size, repair efficiency) that make the clock “sloppy”?

Answer (Q21, Synthesis). The molecular clock follows from neutral theory: since the neutral substitution rate equals μ (independent of N), neutral differences between two lineages accumulate roughly linearly with divergence time. It is calibrated with independently dated fossils (or known biogeographic/geological splits) to convert substitutions into absolute time, and has been used to estimate the human–chimpanzee split at roughly 5–7 million years ago (consistent with the hominin fossil record). The clock is ‘sloppy’ because the rate is not strictly constant: it varies with generation time (per-year rate higher in short-generation species), effective population size and slightly deleterious mutations (Ohta’s nearly-neutral effects), DNA-repair efficiency, metabolic rate, and lineage-specific mutation processes — so calibrated, lineage-specific (relaxed) clocks are required. The conclusion would change if substitution rates were demonstrably constant across all lineages and sequence classes. See section 20. 22. The 1000 Genomes Project revealed that most human genetic variants are rare (minor allele frequency < 1%). Evaluate what the site frequency spectrum (SFS) of human variants tells us about recent population expansion (bottleneck → colonization of new territories → rapid expansion), and how deviations from neutral SFS predictions (Tajima’s D) detect selection.

Answer (Q22, Synthesis). The site frequency spectrum (SFS) — the distribution of variant allele frequencies — is dominated by rare variants (MAF < 1%) in humans. This excess of rare alleles is the genomic signature of recent, rapid population expansion after out-of-Africa bottlenecks: many new mutations have arisen but have had too little time to drift to higher frequency, skewing the SFS toward rare variants relative to a constant-size

neutral expectation. Tajima's D compares two diversity estimators (π vs Watterson's θ): under neutral equilibrium $D \approx 0$; negative D (excess rare variants) indicates a recent sweep *or* population expansion, positive D (excess intermediate-frequency variants) indicates balancing selection *or* a bottleneck. Because demography affects the whole genome while selection acts locally, genome-wide vs locus-specific patterns distinguish selection from demography — that contrast is what would change a selection inference. See section 20. 23. Evaluate the evidence that human populations show significantly different allele frequencies at loci controlling pigmentation (MC1R, SLC24A5, HERC2/OCA2) and that these differences reflect recent local adaptation (UV radiation, vitamin D synthesis) rather than random drift. What evolutionary mechanism drove rapid adaptation at these loci in the past 10,000–20,000 years?

Answer (Q23, Synthesis). Pigmentation loci (*SLC24A5*, *MC1R*, *HERC2/OCA2*, *SLC45A2*) show far higher locus-specific F_{ST} (0.4–0.9) than the genome-wide average (about 0.12) and sit on long, high-frequency haplotypes (extended haplotype homozygosity) — patterns expected from positive directional selection (selective sweeps), not neutral drift, since drift would not single out functionally relevant pigmentation variants for extreme differentiation. The driving mechanism is local adaptation to the UV/latitude gradient: lighter skin at high latitudes improves cutaneous vitamin D synthesis under low UV, while darker skin near the equator protects folate and against UV damage, acting strongly over the last about 10–20 ka as humans colonized higher latitudes. The selection interpretation would be overturned if these loci's differentiation were no greater than neutral genome-wide F_{ST} or lacked sweep haplotype signatures. See section 20. 24. Design an analysis to identify signatures of selection in a genome-wide SNP dataset from 1,000 individuals in two populations. Describe the following statistical tests you would use: Fst outlier analysis, XP-EHH (cross-population extended haplotype homozygosity), and Tajima's D, stating what each detects. What results would indicate recent selective sweeps, and how would you validate a candidate gene using functional data?

Answer (Q24, Synthesis). Hypothesis: specific loci have experienced recent positive selection differing between the two populations. Tests: (1) F_{ST} outlier analysis — loci with F_{ST} far above the genome-wide neutral distribution flag local adaptation/differentiation; (2) XP-EHH — detects a sweep that is near-complete in one population but not the other via cross-population extended haplotype homozygosity; (3) Tajima's D — within-population skew of the SFS (strongly negative near a recent sweep). Recent sweep signature: an extreme F_{ST} outlier *plus* long high-frequency haplotype (XP-EHH) *plus* negative Tajima's D, all converging on the same region (the controls being the genome-wide neutral distributions and the comparison population). Validation: replicate the signal in independent cohorts and provide functional evidence — eQTL/allele-specific expression, reporter assays, CRISPR editing of the candidate variant, and a plausible phenotype/selective agent — to show the variant is causal rather than a hitchhiker or demographic artifact. See section 20. 25. Evaluate “negative frequency-dependent selection” at the ABO blood group locus. Propose why O (producing no antigen) remains at >60% frequency in many human populations despite the disadvantage of lacking most antigens (O individuals cannot receive A, B, or AB blood). What pathogens preferentially target specific blood group antigens, and how does this drive balancing selection?

Answer (Q25, Synthesis). At ABO, negative frequency-dependent selection by pathogens helps maintain the polymorphism: many pathogens mimic or bind specific ABO antigens, so individuals lacking a common antigen (or carrying a rarer type) gain a transient advantage as pathogens adapt to the most common antigens — keeping multiple alleles in the population. The high frequency of O (>60% in many populations) is consistent with O individuals having natural anti-A and anti-B antibodies that confer broad resistance to A/B-mimicking pathogens, offsetting the transfusion limitation (a modern, non-selective constraint). Documented antigen-pathogen links include cholera and norovirus (more severe in type O), severe malaria (worse in type A), and *Helicobacter pylori* / *E. coli* binding blood-group antigens — differing pathogen pressures across environments sustain balancing/frequency-dependent selection. The balancing-selection claim would weaken if ABO frequencies tracked neutral drift/demography rather than pathogen regimes. See section 20. 26. Effective population size (N_e) in humans is estimated at about 10,000–20,000 (from genetic diversity), far smaller than the current census population (about 8 billion). Evaluate three reasons why $N_e \ll N_c$: (a) highly unequal reproductive success; (b) past bottlenecks; (c) sex ratio inequality. How does a small historical N_e affect our genome (e.g., low heterozygosity, linkage disequilibrium)?

Answer (Q26, Synthesis). Effective population size N_e is the size of an idealized population that would lose genetic diversity at the observed rate; human N_e (about 10,000–20,000) is far below census size because N_e is reduced by: (a) highly unequal reproductive success (variance in offspring number lowers N_e below the count of adults), (b) past bottlenecks (a single small generation dominates the long-term harmonic-mean N_e — ‘one bad generation undoes a century’), and (c) unequal sex ratio of breeders ($N_e \approx 4N_mN_f/(N_m+N_f)$), so a skewed breeding sex ratio depresses N_e . A small historical N_e leaves enduring genomic signatures: low overall heterozygosity/nucleotide diversity, extensive long-range linkage disequilibrium and large LD blocks (haplotype structure exploited by GWAS/tag SNPs), and a relatively recent coalescence of human lineages. The interpretation would change if diversity-based N_e matched census size. See section 20. 27. Genetic load is the reduction in population fitness due to deleterious alleles. Evaluate the “mutation load paradox” in humans: each human carries about 70–100 de novo mutations per generation, yet the population continues to grow. How is deleterious load purged by selection (purifying selection), and what analytical framework (fitness decline per mutation, calculated from GWAS) resolves the paradox?

Answer (Q27, Synthesis). Genetic load is the fitness reduction caused by deleterious alleles segregating in a population. The apparent paradox — about 70–100 de novo mutations per person per generation yet a growing population — is resolved because most new mutations are neutral or only weakly deleterious, and purifying (negative) selection continuously removes the harmful ones, often efficiently when their effects combine (synergistic epistasis lets one ‘selective death’ purge several mildly deleterious variants). Quantitatively, equilibrium load depends on the genomic deleterious mutation rate U (load $\approx 1 - e^{-U}$ under multiplicative selection); GWAS/sequencing estimates of the per-mutation fitness decrement and the deleterious mutation rate show the realized mutational load is tolerable given truncation/soft selection and large population growth. The framework would be challenged if observed per-mutation fitness costs implied an unsustainable load. See section 20. 28. Evaluate the role of sexual reproduction vs asexual reproduction in maintaining genetic variation under selection. The Red Queen hypothesis proposes that sexual reproduction is advantageous because it generates novel combinations to keep pace with rapidly evolving parasites. Evaluate: (a) the ecological evidence (host-parasite coevolution in snails, *Potamopyrgus antipodarum*); (b) the genetic evidence (rate of Muller’s ratchet in asexual vs sexual populations); (c) the cost of sex (only about 50% of offspring bear offspring themselves).

Answer (Q28, Synthesis). Sex shuffles alleles into new combinations each generation, generating variation that selection can act on, whereas asexual clones can only spread existing genotypes. (a) Ecological evidence: in the New Zealand snail *Potamopyrgus antipodarum*, sexual lineages persist where parasite (trematode) pressure is high while asexual clones dominate parasite-free habitats — supporting the Red Queen prediction that sex tracks coevolving parasites. (b) Genetic evidence: asexual lineages accumulate deleterious mutations irreversibly via Muller’s ratchet (no recombination to recreate mutation-free genotypes), giving them faster fitness decay and higher extinction rates than recombining sexual lineages. (c) Cost of sex: an asexual female transmits her whole genome to all offspring, whereas a sexual female ‘wastes’ half her output on males (the two-fold cost / cost of males), so the benefits of recombination must exceed this cost to favor sex. The Red Queen interpretation weakens if sexual lineages persisted independently of parasite pressure. See section 20. 29. Population stratification in GWAS occurs when ancestry-related allele frequency differences confound disease-association signals. Evaluate how principal component analysis (PCA) corrects for stratification in GWAS, why failing to correct can generate spurious associations, and why the same caution applies to forensic or outbreak population-inference claims.

Answer (Q29, Synthesis). Population stratification confounds GWAS when cases and controls differ in ancestry: any allele whose frequency varies with ancestry can appear associated with disease even with no causal effect (the classic ‘chopstick gene’ fallacy — a marker tracking East-Asian ancestry spuriously ‘predicting’ chopstick use). Principal component analysis (PCA) on genome-wide genotypes extracts axes that capture ancestry/population structure; including the top PCs as covariates, or using mixed models, adjusts the association test for ancestry and removes systematic frequency differences. Without correction, the genomic inflation factor rises and false-positive associations appear because the test statistic is inflated by structure rather than biology. The same boundary applies outside GWAS: a forensic or outbreak phylogeny can support relatedness, but direction, responsibility, and identity require sampling density, timing, chain-of-custody, and explicit alternative histories. See section 20. 30. Critically evaluate the “mutation-selection-drift” balance framework as a complete explanation for the maintenance of genetic variation in natural populations. Where does this framework work well (e.g., for clearly deleterious alleles), and where does it break down (complex traits with many loci of small effect, phenotypic plasticity, developmental canalization, environmental gene \times environment interactions)? Propose how the modern extended synthesis incorporates concepts beyond classical population genetics.

Answer (Q30, Synthesis). The mutation–selection–drift balance framework works well for clearly deleterious or strongly selected single-locus alleles (e.g. recessive lethals at $q = \sqrt{\mu/s}$, classic balanced polymorphisms like sickle cell) and as a quantitative null for allele-frequency dynamics. It breaks down for highly polygenic complex traits built from thousands of small-effect loci (where per-locus selection is too weak relative to drift and most variation is effectively neutral or under stabilizing selection on the trait, not individual alleles), and it does not naturally accommodate phenotypic plasticity, developmental canalization (cryptic variation buffered until released), gene-by-environment interaction, linked selection/background selection, and epistasis. The extended evolutionary synthesis supplements it with quantitative-genetic and genomic models (infinitesimal/omnigenic architecture, stabilizing selection on traits), developmental bias and plasticity, niche construction, epigenetic inheritance, and explicit linked-selection/demography modeling. The classical framework’s adequacy would be vindicated if complex-trait variation were fully predicted by independent per-locus mutation–selection–drift parameters. See section 20.

Questions — Natural Selection and Adaptation

Instructor Use and Coverage Notes

- Coverage target: Estimate selection strength from data and explain why the result is context dependent.
- Model/data emphasis: Selection coefficient and allele-frequency trajectory calculations.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Evolution is not goal-directed progress; it is local change in populations under constraints.
- Transfer product: Transfer selection reasoning to antibiotics, pesticide resistance, cancer, or climate adaptation.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 21 of the textbook — review that chapter before attempting the exercises below.

1. State Darwin’s mechanism of natural selection in four steps.

Answer (Q1, Recall). Darwin’s mechanism has four steps: (1) individuals vary in heritable traits; (2) more offspring are produced than can survive (overproduction); (3) variants whose traits raise survival and reproduction in the current environment leave more offspring (differential reproductive success); (4) over generations the population’s trait distribution shifts toward the favored variants (descent with modification). See section 21. 2. What is fitness in evolutionary biology? Does it relate to physical strength?

Answer (Q2, Recall). Fitness is an individual’s relative contribution of surviving, reproducing offspring to the next generation — not physical strength. A sterile but long-lived organism has zero fitness; a short-lived prolific one has high fitness. Fitness is always relative to the local environment and the rest of the population. See section 21. 3. Define adaptation. Give one structural, one physiological, and one behavioral example.

Answer (Q3, Recall). An adaptation is a heritable trait shaped by natural selection because it improves fitness in a given environment. Structural: the mammalian eye. Physiological: countercurrent heat exchange in extremities. Behavioral: honeybee waggle-dance recruitment. See section 21. 4. What is directional selection? What is stabilizing selection? Give one example of each.

Answer (Q4, Recall). Directional selection shifts the mean by favoring one extreme (e.g., larger beaks during drought in Galápagos finches). Stabilizing selection favors the intermediate and removes extremes, reducing variance (e.g., human birth weight, where very small and very large neonates have lower survival). See section 21. 5. What is the difference between microevolution and macroevolution?

Answer (Q5, Recall). Microevolution is change in allele frequencies within a population over a few generations (e.g., pesticide resistance). Macroevolution is large-scale change at or above the species level over long timescales (speciation, origin of major clades). They are the same process viewed over different timescales. See section 21. 6. Name four lines of evidence for evolution by natural selection.

Answer (Q6, Recall). Four lines: (1) the fossil record with transitional forms and temporal succession; (2) comparative anatomy (homologous and vestigial structures); (3) molecular/genetic homology (shared genetic code, conserved genes, pseudogenes); (4) biogeography and directly observed selection (e.g., antibiotic resistance). See section 21. 7. What is the fossil record? What is a transitional fossil? Give one example.

Answer (Q7, Recall). The fossil record is the preserved chronological sequence of past organisms in dated strata. A transitional fossil shows a mosaic of ancestral and derived traits linking groups — e.g., *Tiktaalik* (fish-to-tetrapod) or *Archaeopteryx* (dinosaur-to-bird). See section 21. 8. What is homology? Distinguish structural homology from molecular homology.

Answer (Q8, Recall). Homology is similarity due to shared ancestry. Structural homology is corresponding anatomical organization despite different function (the tetrapod forelimb). Molecular homology is shared sequence/gene identity (cytochrome c across eukaryotes), which is harder to mimic by convergence and so gives strong phylogenetic signal. See section 21. 9. What are vestigial structures? Give two examples in humans.

Answer (Q9, Recall). Vestigial structures are reduced, function-diminished remnants of ancestrally functional traits. In humans: the coccyx (reduced tail) and the vermiform appendix (reduced caecum); the palmaris longus muscle and goosebumps are further examples. See section 21. 10. What is convergent evolution? Give one example.

Answer (Q10, Recall). Convergent evolution is the independent evolution of similar traits in unrelated lineages under similar selection (analogy, not homology). Example: the streamlined body and fins of sharks (fish), ichthyosaurs (reptiles), and dolphins (mammals). See section 21.

Questions 11–20: Application and Analysis

11. Rock pocket mice in New Mexico exist on both dark lava and light soil habitats. Mice with dark coats survive better on lava; light mice survive better on soil. Explain: (a) the type of selection (disruptive); (b) the molecular basis of dark coat color (MC1R mutations); (c) what the independent evolution of

dark coats in different geographic populations tells us about convergent evolution.

Answer (Q11, Application). (a) Disruptive selection: two distinct phenotypes (dark and light) have higher fitness than the intermediate, because each matches one microhabitat's substrate. Quantitative measurements (Hoekstra et al. 2004) show a about 40 % survival advantage for matching morphs against raptor predation, translating to selection coefficients $s \approx 0.4$ per generation — extraordinarily strong by evolutionary standards. If dark-coat allele frequency is q in a lava population, the homozygous-dominant-dark genotype has relative fitness 1, homozygous light $1-s$, giving $\Delta q = \frac{sq(1-q)}{1-sq(2-q)}$ — a single adaptive locus can rise from 0.01 to > 0.5 in about 15 generations under $s = 0.4$. (b) Molecular basis: four non-synonymous substitutions in the MC1R (melanocortin-1 receptor) gene produce a constitutively active receptor in dark mice; high cAMP signaling shifts melanocyte output from red/yellow pheomelanin to black eumelanin, darkening the coat without altering pigment biochemistry elsewhere. (c) Convergent evolution: independent populations on Pinacate and Armendaris lava flows evolved dark coats via different molecular paths — at Pinacate the D84E + R109W allele sweeps, at Armendaris a distinct set of MC1R mutations. Parallel phenotypic convergence from non-identical molecular changes is the hallmark of convergent (as opposed to parallel) evolution: natural selection channels diverse mutational inputs toward the same adaptive solution when the selective landscape strongly favors it. See section 21. 12. The industrial melanism of the peppered moth (*Biston betularia*) is a textbook example of directional selection. Calculate: if initial light morph frequency = 0.99 and dark morph = 0.01, and selection coefficient against light morph = 0.33 (on industrial trees), after 50 years (50 generations), predict the approximate frequency of the dark morph using the directional selection equation.

Answer (Q12, Application). Treat the dark morph as favored with selection against light $s = 0.33$. Per generation $p_{\text{dark}}' = p_{\text{dark}} / (p_{\text{dark}} + (1-p_{\text{dark}})(1-s))$. Starting $p_{\text{dark}} = 0.01$ and iterating 50 generations with $s = 0.33$, the dark morph rises essentially to fixation ($\approx 0.98-0.99$) — matching the historical rise of melanic *Biston betularia* near industrial Manchester within about 50 years. See section 21. 13. Sexual selection can drive traits to fixation even when they reduce survival (peacock tail). Use the Zahavian handicap principle to explain: (a) why primarily males with good “condition” can afford to develop large ornaments; (b) how female preference for ornaments evolves (Fisherian runaway vs good genes models); (c) evidence distinguishing the two models.

Answer (Q13, Application). (a) Large ornaments are costly, so only individuals in good condition can grow them without dying — the handicap guarantees signal honesty. (b) Female preference can evolve by Fisherian runaway (preference and ornament alleles become genetically correlated and self-reinforce) or good-genes (ornaments index heritable viability). (c) The models are distinguished by testing whether ornament size predicts offspring viability (good genes) versus only attractiveness (runaway). See section 21. 14. Kin selection allows altruistic behavior to evolve when altruism benefits genetic relatives. Apply Hamilton's rule: altruism evolves when $rB > C$ (r = relatedness, B = benefit, C = cost). A worker honey bee ($r = 0.75$ to full sisters in a simplified haplodiploid case) helps raise 10 additional sisters ($B = 10$) at an opportunity cost of 3 own offspring ($C = 3$). Is helping favored? Then explain why haplodiploidy by itself cannot explain eusociality, using termites as the contrast case.

Answer (Q14, Application). Hamilton's rule is satisfied because $rB = 0.75 \times 10 = 7.5$, and $7.5 > 3$, so helping is favored under the stated assumptions. The threshold benefit is $B > C/r = 3/0.75 = 4$, so raising more than four equivalent full sisters would exceed the cost. The caveat is biological: haplodiploidy raises relatedness in many ants, bees, and wasps, but many haplodiploids are solitary and termites are diploid eusocial insects. Eusociality therefore needs kin structure plus ecology, mating system, nest defense, brood provisioning, and phylogenetic history. See section 21. 15. Selection on quantitative traits can be modeled by the breeder's equation: $R = h^2S$ (R = response to selection, h^2 = heritability, S = selection differential). If height heritability is 0.80 and we select parents who are 5 cm taller than the population mean, predict R . How many generations of selection would be needed to shift mean height by 10 cm?

Answer (Q15, Application). Apply breeder's equation: $R = h^2S$. Given $h^2 = 0.80$, $S = 5 \text{ cm} \rightarrow R = 0.80 \times 5 = 4.0 \text{ cm}$ per generation. To shift the mean by 10 cm: $N = 10/4 = 2.5$ generations (rounded up, 3 generations) under constant selection differential. Key conceptual point: only the additive genetic component of variance ($V_A / V_P = h^2$) responds; the remaining 20 % of variance (dominance, epistasis, environment) cannot be captured by selection. Biological sanity check: human height is about 80 % heritable; a selection differential of 5 cm is achievable in large populations (top about 5 % of the height distribution averages about +5 cm above the mean). Three generations of such directional selection would move the population mean by about 12 cm — which matches the order-of-magnitude of observed secular trends in human stature over a century (modern Dutch males about +20 cm vs 19th-century ancestors), most of which is environmental (nutrition, disease), not genetic — demonstrating why you must separate G from E before invoking the breeder's equation. Long-term cautions: as allele frequencies move toward fixation, V_A collapses and R decays (the “Bulmer effect”) — which is why artificial selection plateaus after 20–50 generations in classical experiments (e.g., Illinois corn protein selection, 100 generations). See section 21. 16. Gould and Lewontin's “spandrel” argument suggests that not most traits are adaptations — some are architectural by-products of other adaptations (spandrels in the context of evolutionary biology). Give two specific biological examples of putative spandrels and evaluate the methodological criteria needed to distinguish a spandrel from an adaptation.

Answer (Q16, Application). Spandrels are non-adaptive by-products of other adaptations. Putative examples: the human chin (a by-product of jaw remodeling) and male nipples (developmental by-product of a shared body plan). Distinguishing a spandrel from an adaptation requires evidence

of current fitness benefit, a history of selection on the trait itself, and a functional design match — not merely a plausible use story. See section 21. 17. Antibiotic resistance evolution offers real-time evidence of natural selection. Describe the Lenski long-term evolution experiment with *E. coli* (>75,000 generations). What phenotypic innovations have evolved, and how does the experiment distinguish “chance” events from adaptive improvement?

Answer (Q17, Application). The Lenski LTEE propagates 12 *E. coli* lineages by daily transfer for >75,000 generations. Adaptive improvement appears as steadily rising relative fitness and cell size; the key innovation is aerobic citrate utilization (Cit⁺) in one lineage. Replaying frozen ancestors shows Cit⁺ required specific potentiating mutations, distinguishing contingent ‘chance’ history from repeatable adaptive gains. See section 21. 18. Coevolution occurs when two species reciprocally affect each other’s evolution. Describe the Red Queen model of host-parasite coevolution: (a) why does the host need to evolve continuously; (b) what does the snail (*Potamopyrgus antipodarum*) – trematode parasite system teach us; (c) what arms race dynamics emerge between plant alkaloids and insect detoxification enzymes?

Answer (Q18, Application). (a) Hosts must evolve continuously because parasites adapt to common host genotypes, so rare host types are favored (negative frequency-dependent selection). (b) The *Potamopyrgus*–trematode system shows sexual lineages persist where parasite pressure is high, supporting the Red Queen explanation for sex. (c) Plant alkaloid diversification and insect detoxification (e.g., cytochrome P450) escalate reciprocally in a coevolutionary arms race. See section 21. 19. Punctuated equilibrium (Gould and Eldredge, 1972) argues that most evolutionary change is concentrated in rapid bursts associated with speciation, not in gradual anagenesis. Evaluate the fossil evidence for and against punctuated equilibrium using the *Cerion* land snail data from the Bahamas and the evolution of horse lineages.

Answer (Q19, Application). Punctuated equilibrium predicts long stasis punctuated by rapid change at speciation. *Cerion* land snails show long morphological stasis with abrupt shifts, supporting it; horse lineages show substantial gradual, branching change, supporting phyletic gradualism in places. The fossil record contains both patterns, so the debate is about relative frequency, not an either/or. See section 21. 20. Biogeography provides evidence for evolution: organisms on islands often resemble those on the nearest mainland but have evolved unique adaptations. Apply the concept of adaptive radiation to Hawaiian honeycreepers (about 50 species from one ancestral finch-like coloniser): which resources were exploited by different lineages, and what ecological opportunity allowed such rapid diversification?

Answer (Q20, Application). Hawaiian honeycreepers radiated from one finch-like coloniser into about 50 species exploiting nectar, seeds, insects, and snails, with bills specialized per resource. Ecological opportunity — vacant niches on isolated young islands with few competitors — plus repeated island formation drove rapid adaptive radiation. See section 21.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the extended evolutionary synthesis (EES) relative to the modern synthesis. Which additional mechanisms does EES incorporate (developmental plasticity, epigenetic inheritance, niche construction, evolvability)? Choose one mechanism and evaluate the evidence that it plays a role comparable in importance to natural selection in at least one biological system.

Answer (Q21, Synthesis). The Extended Evolutionary Synthesis adds developmental plasticity, epigenetic inheritance, niche construction, and evolvability to the gene-frequency core of the Modern Synthesis. Niche construction has strong evidence (e.g., earthworm soil modification altering selection on themselves and descendants), but whether it rivals natural selection in importance is system-dependent and still debated; it modifies the selective environment rather than replacing selection. See section 21. 22. Design an experiment to test the “good genes” hypothesis for female preference in peacocks (*Pavo cristatus*). Describe: the relevant measurements (eyespot count, parasite load, extra-pair offspring survival), statistical analyses needed, and a falsification criterion. What result would confirm vs reject the hypothesis?

Answer (Q22, Synthesis). Measure male eyespot number, parasite/immune load, and survival of (cross-fostered) offspring; analyze with correlation/GLMs relating preference and ornament to offspring viability, controlling for maternal effects. Good-genes is confirmed if offspring of preferred, low-parasite males show higher survival; it is rejected if ornament predicts attractiveness but not offspring viability. See section 21. 23. Evaluate the evolutionary arms race between cuckoos and their hosts (*Cuculus canorus* vs reed warblers). Describe: (a) forgery (egg mimicry); (b) host counter-adaptations (pattern recognition, egg ejection); (c) what would have to happen for the host to “win” and cuckoos to go extinct. What does the coevolutionary balance tell us about the role of Red Queen dynamics in parasite-host coevolution?

Answer (Q23, Synthesis). (a) Cuckoos forge host-egg color/pattern (gens-specific egg mimicry). (b) Hosts counter-adapt by fine pattern discrimination and ejecting odd eggs. (c) For hosts to ‘win’ and cuckoos to go locally extinct, host rejection must approach 100% faster than cuckoos can improve mimicry or switch hosts. The persistent oscillating balance exemplifies Red Queen coevolution — neither side reaches a permanent advantage. See section 21. 24. Molecular convergence (independent evolution of the same molecular change in different lineages) provides the strongest evidence for adaptation at the sequence level. Evaluate three examples: (a) same amino acid substitution in hemoglobin for high-altitude adaptation in birds; (b) convergent microbial drug resistance mutations; (c) convergent VLDLR mutations for flight in birds. What does molecular convergence tell us about the size of genotypic variation space accessible by natural selection?

Answer (Q24, Synthesis). (a) Identical hemoglobin substitutions for high-altitude O₂ affinity in unrelated bird lineages; (b) recurrent *rpoB*/target-site resistance mutations across microbes; (c) convergent VLDLR-pathway changes associated with flight. Repeated independent fixation of the same change shows the accessible adaptive genotype space is small and selection is highly repeatable at the sequence level. See section 21. 25. The “fitness landscape” model represents most possible genotypes as a surface where height corresponds to fitness. Evaluate the limitations of this model for understanding: (a) epistasis (non-additive interactions between loci); (b) adaptive valleys (can evolution cross fitness valleys?); (c) frequency-dependent fitness (landscape changes with allele frequency). Propose an alternative model that addresses these limitations.

Answer (Q25, Synthesis). (a) Additive landscapes ignore epistasis, where a locus’s fitness depends on genotype at others, making the surface rugged. (b) Adaptive valleys require crossing low-fitness genotypes, hard under selection alone (drift, recombination, or environmental change help). (c) Frequency-dependent fitness means the surface is not static. A better model is a dynamic, high-dimensional genotype network (holey/ Gavrilets landscape) where neutral ridges connect peaks. See section 21. 26. Group selection (selection acting on groups rather than individuals) was largely dismissed after Williams (1966), but has been revived as multilevel selection (MLS) theory. Evaluate: (a) the conditions under which group selection overrides individual selection; (b) the evidence from slime mould (*Dictyostelium*) cooperation; (c) whether human cooperation can be explained by MLS or requires cultural group selection.

Answer (Q26, Synthesis). (a) Group selection overrides individual selection when between-group variance and differential group productivity are large relative to within-group selfish advantage and migration is low. (b) *Dictyostelium* fruiting-body cooperation (with cheater conflict) shows multilevel dynamics. (c) Human cooperation is better explained by kin selection, reciprocity, and cultural group selection (norms, punishment) than by simple genetic group selection. See section 21. 27. Evaluate the claim that evolutionary theory is a scientific fact while specific evolutionary narratives (the origin of feathers, the evolution of eukaryotes) are provisional hypotheses. What does “theory” mean in science compared to colloquial usage? How does the misunderstanding of “theory” fuel creationist objections, and what is the appropriate scientific response?

Answer (Q27, Synthesis). In science a ‘theory’ is a well-substantiated explanatory framework (evolution, like gravitation), not a guess. Evolution as a process is a fact and a theory; specific historical narratives (feather origin, eukaryogenesis) are provisional hypotheses tested against evidence. Creationist objections exploit the colloquial ‘just a theory’; the appropriate response is to clarify the scientific meaning and the strength of convergent evidence. See section 21. 28. Evolvability — the capacity to evolve — may itself be a product of natural selection. Evaluate: (a) the evidence that the modular architecture of proteins (protein domains) evolved to enhance evolvability; (b) whether mutation rate itself can be subject to natural selection; (c) the concept of robustness (canalization) and its relationship to evolvability.

Answer (Q28, Synthesis). (a) Modular protein-domain architecture lets domains recombine, plausibly enhancing evolvability, though it may be a by-product of structural constraints. (b) Mutation rate is heritable and selectable — mutator alleles rise in novel/stressful environments and fall once adapted. (c) Robustness (canalization) buffers phenotypes against mutation, accumulating cryptic variation that can fuel future evolvability when released. See section 21. 29. The “major evolutionary transitions” (Szathmáry and Maynard Smith, 1995) describe eight key events in the history of life (e.g., origin of the eukaryotic cell, origin of multicellularity). Evaluate what distinguishes each transition from ordinary speciation, and propose what the next major evolutionary transition might be (e.g., a digital information-based evolving system?).

Answer (Q29, Synthesis). The major transitions (e.g., origin of chromosomes, the eukaryotic cell, multicellularity, eusociality) each change the unit of selection and how information is stored/transmitted — formerly independent replicators become interdependent and reproduce as a whole, unlike ordinary speciation which does not create a new higher-level individual. A plausible next transition is a tightly integrated human–digital information system. See section 21. 30. Critically evaluate whether evolutionary theory can be directly applied to artificial systems (machine learning algorithms, memes, cultural evolution). What structural features must any system have to undergo Darwinian evolution (heritable variation, differential reproduction, competition)? Does cultural evolution satisfy these criteria, and how does it differ from biological evolution in terms of inheritance mechanisms and selection units?

Answer (Q30, Synthesis). Any Darwinian system needs heritable variation, differential reproduction/retention, and competition for limited resources. Cultural evolution satisfies these (ideas vary, are copied with error, and spread differentially) but differs from biology: inheritance can be horizontal and Lamarckian (acquired changes transmitted), selection units are memes/practices, and transmission is high-fidelity-optional and intentional. See section 21.

Questions — Genetic Drift, Gene Flow, and Speciation

Instructor Use and Coverage Notes

- Coverage target: Predict how population size or isolation changes divergence and fixation risk.
- Model/data emphasis: Fixation probability, effective population size, and migration-selection balance.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Random does not mean patternless; stochastic processes have predictable distributions.
- Transfer product: Apply drift reasoning to endangered populations, founder effects, and island radiations.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 22 of the textbook — review that chapter before attempting the exercises below.

1. Define genetic drift. How does it differ from natural selection?

Answer (Q1, Recall). Genetic drift is random change in allele frequencies from sampling error between generations; natural selection is non-random change driven by fitness differences. Drift is strongest in small populations and can fix neutral or even mildly deleterious alleles, whereas selection consistently favors higher-fitness variants regardless of population size. See section 22. 2. What is the founder effect? What is the bottleneck effect? How do they differ?

Answer (Q2, Recall). The founder effect is the loss/skew of variation when a few individuals start a new population; the bottleneck effect is the loss when a population is drastically reduced then recovers. Both are drift, but the founder effect involves colonization by a non-random small sample, while a bottleneck reduces an existing population — both leave reduced heterozygosity. See section 22. 3. Define gene flow. What effect does gene flow have on genetic differentiation between populations?

Answer (Q3, Recall). Gene flow is the movement of alleles between populations via migration/interbreeding. It homogenises allele frequencies, reducing genetic differentiation (lower F_{ST}) and opposing divergence by drift or local selection. See section 22. 4. Define biological species concept (BSC). What is a reproductive isolation barrier?

Answer (Q4, Recall). The Biological Species Concept defines a species as groups of actually or potentially interbreeding natural populations reproductively isolated from other such groups. A reproductive isolation barrier is any heritable trait preventing successful interbreeding or fertile offspring between populations. See section 22. 5. Distinguish pre-zygotic from post-zygotic reproductive isolation barriers. Give two examples of each.

Answer (Q5, Recall). Pre-zygotic barriers act before fertilization: temporal isolation (different breeding seasons) and behavioral isolation (different mating signals). Post-zygotic barriers act after: hybrid inviability (zygote fails to develop) and hybrid sterility (e.g., the mule). They differ in whether they prevent zygote formation or hybrid success. See section 22. 6. What is allopatric speciation? What is sympatric speciation? Give one natural example of each.

Answer (Q6, Recall). Allopatric speciation occurs when a geographic barrier splits populations that then diverge (e.g., Isthmus of Panama snapping shrimp). Sympatric speciation occurs without geographic separation, often via host shift or polyploidy (e.g., apple maggot fly *Rhagoletis*, or polyploid *Tragopogon*). See section 22. 7. What is parapatric speciation? Give one example from plant populations.

Answer (Q7, Recall). Parapatric speciation occurs across a continuous range with a steep environmental gradient and limited gene flow, so divergence proceeds despite contact. Example: grasses (*Anthoxanthum/Agrostis*) diverging on mine-tailing boundaries through soil-metal tolerance and assortative flowering. See section 22. 8. Define peripatric speciation. How does it relate to the founder effect?

Answer (Q8, Recall). Peripatric speciation is allopatric speciation in a small peripheral isolate. It relates to the founder effect because the small founding population carries a non-random allele sample and experiences strong drift, accelerating divergence from the parent population. See section 22. 9. Define F_{ST} (fixation index). What does $F_{ST} = 0$ mean? What does $F_{ST} = 1$ mean?

Answer (Q9, Recall). F_{ST} (fixation index) measures the proportion of total genetic variance due to differences among populations. $F_{ST} = 0$ means populations are genetically identical (panmixia/high gene flow); $F_{ST} = 1$ means populations are completely differentiated (fixed for different alleles, no shared variation). See section 22. 10. What is adaptive radiation? Give one famous example.

Answer (Q10, Recall). Adaptive radiation is rapid diversification of one lineage into many species occupying different ecological niches. Classic example: Darwin’s finches on the Galápagos, diversified in beak form by diet. See section 22.

Questions 11–20: Application and Analysis

11. A population of 1,000 individuals is reduced to 5 for three generations, then recovers to 1,000. Calculate the harmonic mean of the effective population size over the three-generation bottleneck, and use $H_t = H_0(1 - 1/(2N_e))^t$ to estimate the heterozygosity remaining after recovery.

Answer (Q11, Application). Effective size over the bottleneck is the harmonic mean: $N_e = 3 / (1/5 + 1/5 + 1/5) = 5$. Heterozygosity retained $\approx H_0(1 - 1/(2N_e))^t = H_0(1 - 1/10)^3 = H_0(0.9)^3 \approx 0.729 H_0$ — about 27% of heterozygosity is lost over the three-generation bottleneck despite later recovery to 1,000. See section 22. 12. The Amish population (descended from 200 founders in the 1700s) has a 1,000-fold higher frequency of Ellis-van Creveld syndrome (short-limb dwarfism) than the general population. Explain: (a) which mechanism is responsible; (b) whether natural selection for or against the condition is required to explain its frequency; (c) what this implies for genetic counselling in this community.

Answer (Q12, Application). (a) The founder effect (drift), not selection. (b) No selection is required: the high frequency results from a founder carrying the recessive *EVC* allele plus subsequent isolation/endogamy. (c) Genetic counselling should account for the elevated recessive-carrier frequency and offer targeted carrier screening within the community. See section 22. 13. Two sister populations of fish separated 10,000 years ago are now parapatrically distributed along a river system. They differ in color pattern and mating call. When brought together in the lab, they hybridize successfully but hybrids show reduced fertility. Classify: (a) what type of speciation occurred; (b) what type of reproductive isolation is demonstrated; (c) whether they are currently separate species under the BSC.

Answer (Q13, Application). (a) Allopatric/parapatric divergence over 10,000 years. (b) Post-zygotic isolation (reduced hybrid fertility) plus incipient pre-zygotic (call/color) isolation. (c) Under the BSC they are incipient/partial species — reproductive isolation is incomplete (hybrids form but are sub-fertile), so they sit on the speciation continuum rather than being fully separate. See section 22. 14. Calculate the estimated gene flow (Nm = number of migrants per generation) between two populations with $F_{ST} = 0.08$, using $F_{ST} \approx 1/(1 + 4Nm)$. Is this a high or low level of gene flow? What migration rate ($Nm > 1$) is needed to prevent significant divergence?

Answer (Q14, Application). From $F_{ST} \approx 1/(1+4Nm)$: $0.08 = 1/(1+4Nm) \rightarrow 1+4Nm = 12.5 \rightarrow Nm \approx 2.9$ migrants per generation. This is relatively high gene flow; $Nm > 1$ (about one effective migrant per generation) is the classic threshold sufficient to prevent strong divergence by drift, so these populations are only weakly differentiated. See section 22. 15. In cichlid fish adaptive radiation in Lake Victoria, > 500 species evolved in < 15,000 years — an extremely rapid speciation event. Propose: (a) what ecological opportunity promoted rapid radiation; (b) what role mate choice based on color pattern played in sympatric speciation; (c) how light transmission in different lake depths may have driven divergence.

Answer (Q15, Application). (a) Vacant niches and habitat heterogeneity in a young, large lake offered ecological opportunity. (b) Divergent female preference for male nuptial color drove assortative mating and sympatric divergence. (c) Depth-dependent light spectra shifted optimal signaling color, coupling sensory drive to mate choice and accelerating speciation; turbidity collapse reverses it, showing the mechanism’s fragility. See section 22. 16. Ring species provide a spatial illustration of the speciation continuum. The *Larus* gull chain circles the Arctic: populations A interbreed with B, B with C, C with D, D with E, but A and E do not interbreed. Explain: (a) why A and E are or are not separate species under BSC; (b) what this shows about speciation as a gradual, continuous process; (c) how climate change and habitat connectivity changes could affect this ring.

Answer (Q16, Application). (a) Under the BSC A and E are not a single species where they fail to interbreed, yet a continuous chain connects them. (b) This shows speciation is gradual and continuous — reproductive isolation accumulates with genetic distance along the ring. (c) Breaking habitat connectivity (climate change, habitat loss) collapses the chain into discrete isolated species. See section 22. 17. Hybridization between species can produce evolutionary novelty. Allopolyploidy (hybrid + chromosome doubling) has produced many crop species: bread wheat (AABBDD, from three diploid ancestors). Explain: (a) how polyploidy immediately produces reproductive isolation from both ancestors; (b) why polyploid plants are often phenotypically superior (hybrid vigour/heterosis); (c) what the estimated contribution of allopolyploidy to flowering plant diversity is.

Answer (Q17, Application). (a) Allopolyploidy doubles chromosomes so backcrosses to either diploid ancestor yield sterile odd-ploidy hybrids — instantaneous reproductive isolation. (b) Fixed heterozygosity and gene/dosage redundancy give heterosis and buffering. (c) A large fraction of angiosperm diversity (most species have polyploidy in their ancestry; about 15% of speciation events are polyploid) traces to allopolyploidy. See section 22. 18. “Magic traits” are traits that simultaneously cause both ecological divergence (adaptation to different niches) and assortative mating (non-random mating based on the same trait). Give one example of a magic trait and explain why this simplifies the theory of sympatric speciation.

Answer (Q18, Application). A magic trait simultaneously causes ecological divergence and assortative mating. Example: beak size in Darwin’s finches, which determines both diet (natural selection) and song/mate recognition (assortative mating). One trait under divergent selection automatically generates non-random mating, removing the need for separate loci and recombination to align — greatly easing sympatric speciation. See section 22. 19. The biological species concept has been criticised as inapplicable to: (a) asexual organisms; (b) freely hybridizing plant species. Evaluate two alternative species concepts (phylogenetic species concept, ecological species concept) and explain which is most useful for biodiversity conservation.

Answer (Q19, Application). The BSC fails for asexual and freely hybridizing taxa. The Phylogenetic Species Concept (smallest diagnosable monophyletic unit) applies to asexuals and fossils but can oversplit; the Ecological Species Concept (lineage adapted to a distinct niche) captures adaptive divergence. For conservation, the PSC/ESU framework is most useful because it identifies diagnosable, independently evolving units for legal protection. See section 22. 20. Hybrid zones are regions where two distinct populations interbreed. Using the tension zone model: (a) explain why a hybrid zone maintains a stable width; (b) what happens to hybrid fitness at the center of the zone; (c) how hybrid zone data can estimate the selection against hybrids and the rate of gene flow.

Answer (Q20, Application). (a) A tension zone is maintained by a balance between dispersal of parental types into the zone and selection against hybrids, giving a stable cline width independent of the environment. (b) Hybrid fitness is lowest at the zone center. (c) Cline width and shape estimate the selection coefficient against hybrids and dispersal distance, hence effective gene flow across the boundary. See section 22.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the evidence that speciation can occur without geographic separation (sympatric speciation) using the apple maggot fly (*Rhagoletis pomonella*) host-race formation as a case study. What conditions (assortative mating by habitat, additive gene effects, limited gene flow) are required, and what genetic evidence suggests incipient sympatric speciation is occurring?

Answer (Q21, Synthesis). *Rhagoletis* host-race formation supports sympatric speciation: apple vs hawthorn races show habitat-based assortative mating (host fidelity), allochronic isolation (different fruiting times), and additive genetic differences in diapause timing with reduced gene flow. Allele-frequency and diapause clines indicate incipient — not yet complete — sympatric divergence, the strongest empirical case for the process. See section 22. 22. Design a population genomics study to determine whether two morphologically distinct bird populations on isolated islands should be classified as separate species. Describe: the genomic data you would collect (RAD-seq or whole-genome resequencing), the analyses you would perform (F_{ST} , phylogeny, ABBA-BABA test for gene flow), and the threshold values you would use to make the classification decision.

Answer (Q22, Synthesis). Collect whole-genome resequencing (or RAD-seq) from both island populations; compute genome-wide F_{ST} , build a phylogeny, and run ABBA-BABA/D-statistics for gene flow; estimate divergence time and migration. Classify as separate species if F_{ST} is high and uniform, the populations are reciprocally monophyletic, and gene-flow tests show little/no admixture; treat low F_{ST} with ongoing gene flow as one species. See section 22. 23. Evaluate the “glacial refugia” hypothesis for European biodiversity: during Pleistocene glaciations, populations were isolated in southern refugia (Iberia, Italy, Balkans), underwent allopatric evolution, then expanded northward after glaciers retreated. What phylogeographic data would test this hypothesis, and what consequences does secondary contact of previously isolated populations have for hybrid zone formation?

Answer (Q23, Synthesis). Test phylogeographic predictions: southern refugial populations should show higher diversity and older, divergent lineages, with northern populations a subset (signature of post-glacial expansion). mtDNA/genomic phylogeography and demographic modeling test it. Secondary contact of refugial lineages produces hybrid zones whose width and clines reveal the strength of post-contact selection and gene flow. See section 22. 24. Gene drive technology (e.g., CRISPR-based homing drives) can spread a gene (e.g., infertility) through a wild population at rates faster than Mendelian inheritance. Evaluate the ecological risks of releasing a gene drive into a wild mosquito population to suppress malaria transmission: (a) off-target spread to non-target species; (b) irreversibility; (c) international governance challenges (the drive does not respect national borders).

Answer (Q24, Synthesis). (a) Off-target homing or hybridization could spread the drive into related non-target species. (b) Self-propagating drives are effectively irreversible once released. (c) Because organisms cross borders, a unilateral release imposes risk on other nations, demanding international governance, containment (split or daisy-chain drives), and reversal/immunising-drive contingencies before any field release. See section 22. 25. Inbreeding depression (reduced fitness in highly homozygous individuals) limits the viability of small, isolated populations. Evaluate: (a) the mechanisms of inbreeding depression (overdominance vs partial dominance of deleterious recessives); (b) the threshold F_{cr} (critical inbreeding coefficient) below which genetic rescue is needed; (c) policy implications for reintroduction of individuals from genetically distinct populations.

Answer (Q25, Synthesis). (a) Inbreeding depression arises from increased homozygosity exposing deleterious recessives (partial dominance) and loss of overdominant heterozygote advantage. (b) Below a critical inbreeding coefficient (rising F , shrinking N_e), fitness collapses and genetic rescue is warranted. (c) Policy: introduce a few migrants from genetically distinct populations to restore heterozygosity, weighing rescue against outbreeding depression and local adaptation loss. See section 22. 26. The concept of “reproductive character displacement” predicts that the signal used for mate recognition must diverge faster between sympatric sister species than between allopatric ones, to prevent costly hybridization. Evaluate the evidence for reproductive character displacement in: (a) *Ficedula* flycatchers in Scandinavia; (b) cricket frog calling frequencies; (c) *Phlox drummondii* flower color contrast.

Answer (Q26, Synthesis). Reproductive character displacement predicts faster signal divergence in sympatry than allopatry. (a) *Ficedula* flycatcher plumage/song diverges more where sympatric, reducing hybridization. (b) Cricker-frog call frequency shifts in sympatry. (c) *Phlox* flower color

diverges where congeners co-occur. Consistent sympatric exaggeration of the mate-recognition signal supports selection against costly hybridization. See section 22. 27. Evaluate the genomics of speciation: “genomic islands of divergence” are regions of elevated F_{ST} interspersed with regions of low F_{ST} in partially reproductively isolated populations. Interpret these patterns: do islands represent targets of selection, or artifacts of reduced recombination around centromeres? What sequencing/analysis strategy would distinguish selective sweeps from reduced recombination as drivers of F_{ST} peaks?

Answer (Q27, Synthesis). Genomic islands of divergence (high- F_{ST} regions in a low- F_{ST} background) can reflect selection/reproductive-isolation loci OR reduced recombination near centromeres inflating F_{ST} . Distinguish them by mapping recombination rate and absolute divergence (d_{XY}): true selective sweeps/barrier loci show elevated d_{XY} and recent coalescence, whereas low-recombination artifacts show high F_{ST} without elevated d_{XY} . See section 22. 28. Evaluate the concept of the “speciation continuum”: from partially isolated populations (e.g., $F_{ST} = 0.1$) through incipient species (partial reproductive isolation, fertile hybrids) to full species (complete reproductive isolation). At what point on this continuum should conservation efforts classify distinct evolutionary significant units (ESUs) for legal protection?

Answer (Q28, Synthesis). On the speciation continuum, conservation should designate Evolutionarily Significant Units where populations are reciprocally monophyletic at neutral markers and show adaptive/ecological divergence and restricted gene flow — i.e., independently evolving lineages — even before full reproductive isolation, so distinct evolutionary potential is protected without over-splitting clinal variation. See section 22. 29. Mass extinction events (e.g., end-Cretaceous, 66 Mya) dramatically restructured biodiversity. Evaluate: (a) what evolutionary patterns characterize the burst of diversification after mass extinction (adaptive radiation); (b) whether the sixth mass extinction (current human-driven biodiversity crisis) is comparable in rate to previous ones; (c) whether survivors of previous extinctions provide models for predicting which present-day species will persist.

Answer (Q29, Synthesis). (a) Post-extinction recovery shows adaptive radiation as survivors fill emptied niches (e.g., mammalian radiation after the K-Pg). (b) Current background-corrected extinction rates are 100–1000× the fossil baseline, comparable in rate to past mass extinctions though earlier in cumulative magnitude. (c) Previous survivors (generalists, wide ranges, small body size, broad tolerance) predict which present-day taxa are likeliest to persist. See section 22. 30. Critically evaluate the “two-speed genome” concept in fungi (*Zymoseptoria tritici*, wheat pathogen): the genome is divided into “core” (gene-rich, slowly evolving) and “accessory” (transposon-rich, rapidly evolving) chromosomes. How does this architecture accelerate host-pathogen coevolution, and how might it apply to our understanding of evolutionary rate variation in other organisms, including humans (conserved regions vs rapidly evolving regions)?

Answer (Q30, Synthesis). The two-speed genome separates a conserved core (housekeeping, slow) from a transposon-rich accessory compartment (effectors, fast) — compartmentalising rapid host-adaptation while preserving essential function, accelerating coevolution. The same conserved-vs-rapidly-evolving partitioning (e.g., constrained genes vs immune/recognition loci) generalizes to evolutionary-rate heterogeneity across genomes, including humans. See section 22.

Questions — Phylogenetics and the Tree of Life

Instructor Use and Coverage Notes

- Coverage target: Use a tree to infer shared ancestry, character transitions, or divergence time.
- Model/data emphasis: Tree-distance, parsimony, and molecular-clock calculations.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Living species are cousins, not ancestors of one another.
- Transfer product: Transfer tree thinking to pathogens, conservation units, gene families, and development.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 23 of the textbook — review that chapter before attempting the exercises below.

1. What is a phylogenetic tree? What does each node, branch, and tip represent?

Answer (Q1, Recall). A phylogenetic tree depicts evolutionary relationships: tips (terminal taxa) are sampled species/sequences, internal nodes are inferred common ancestors (speciation/divergence events), and branches represent lineages through time (length may encode time or amount of change). See section 23. 2. What is a clade (monophyletic group)? Distinguish monophyletic, paraphyletic, and polyphyletic groups.

Answer (Q2, Recall). A clade (monophyletic group) is an ancestor and all its descendants. Paraphyletic groups include an ancestor and some but not all descendants (e.g., ‘reptiles’ excluding birds); polyphyletic groups unite taxa without their common ancestor (grouping by convergence). See section 23. 3. Define synapomorphy. How does it differ from a plesiomorphy?

Answer (Q3, Recall). A synapomorphy is a shared derived character inherited from the most recent common ancestor of a clade and used to diagnose it. A plesiomorphy is an ancestral character shared more broadly; only synapomorphies (not shared ancestral traits) define clades. See section 23.

4. What is parsimony in phylogenetics? What does the most parsimonious tree minimize?

Answer (Q4, Recall). Parsimony selects the tree requiring the fewest evolutionary changes (character-state transitions) to explain the data, invoking the minimum of independent origins/reversals (homoplasy). See section 23. 5. What is a molecular phylogeny? What type of data is used to construct one?

Answer (Q5, Recall). A molecular phylogeny infers relationships from molecular sequence data — DNA, RNA, or protein sequences (e.g., rRNA genes, mitochondrial genes, or genome-wide markers) — rather than morphology. See section 23. 6. What is a bootstrap value? What does a bootstrap of 90% indicate?

Answer (Q6, Recall). A bootstrap value is the percentage of pseudo-replicate datasets (resampled sites) that recover a given clade. A bootstrap of 90% means the clade is supported in 90% of replicates — strong but not absolute support for that grouping. See section 23. 7. What is an outgroup? How is it used to root a phylogenetic tree?

Answer (Q7, Recall). An outgroup is a taxon known to lie outside the clade of interest. It polarizes characters and roots the tree: the point where the ingroup attaches to the outgroup is the root, defining ancestral vs derived states. See section 23. 8. What is horizontal gene transfer (HGT)? In which domains of life is it most common?

Answer (Q8, Recall). Horizontal (lateral) gene transfer is the transfer of genetic material between organisms other than parent-to-offspring. It is most common among Bacteria and Archaea (and between them), and can make single-gene trees conflict with the organismal tree. See section 23.

9. Define convergent evolution. How can it mislead phylogenetic analysis?

Answer (Q9, Recall). Convergent evolution produces similar character states independently in unrelated lineages (homoplasy). It misleads phylogenetics by making distantly related taxa appear closely related if those convergent characters are scored as homologous. See section 23. 10. What are molecular clocks? How are they calibrated?

Answer (Q10, Recall). Molecular clocks use the roughly constant accumulation of substitutions over time to date divergences. They are calibrated with independent evidence — dated fossils at nodes or known biogeographic/geological events — to convert genetic distance into absolute time. See section 23.

Questions 11–20: Application and Analysis

11. Given the character matrix below (1=present, 0=absent): determine the synapomorphies that define the clade (birds + crocodiles) relative to lizards and snakes, using the parsimony principle.

Taxon	Archosaur skull	Feathers	4-chambered heart	Endothermy
Lizard	0	0	0	0
Crocodile	1	0	1	0
Bird	1	1	1	1

- Answer (Q11, Application). Map each character onto the tree and apply parsimony. Archosaur skull and a four-chambered heart are each present in crocodile and bird but absent in lizard (and snakes), so each is a shared derived character (synapomorphy) uniting birds + crocodiles as the clade Archosauria — one origin is more parsimonious than independent gains in two lineages. Feathers and endothermy are present only in birds, so they are bird-specific (autapomorphies) and do not diagnose the birds + crocodile clade. See section 23.
12. Two competing phylogenies are proposed for the Paleocene mammals: (A) requires 12 evolutionary changes; (B) requires 15 changes. By parsimony, which tree is preferred? Explain what assumption is made when choosing the more parsimonious tree.

Answer (Q12, Application). Tree A requires 12 changes, tree B requires 15; by parsimony tree A is preferred (fewer steps). The assumption is that evolutionary change is relatively rare, so the hypothesis invoking the fewest independent changes (least homoplasy) is the best estimate — an assumption that weakens when rates are high or branches are long. See section 23.

13. Dolphins and ichthyosaurs (extinct reptiles) both have streamlined bodies and fin-like forelimbs. Explain: (a) why a morphological phylogeny based solely on body shape would incorrectly group them; (b) what more reliable character would avoid this error; (c) what type of evolution produced the similarity.

Answer (Q13, Application). (a) Body shape is convergent for aquatic locomotion, so a shape-based tree wrongly groups dolphins with ichthyosaurs. (b) Reliable characters are independent homologies — DNA sequence and skeletal/developmental synapomorphies (mammalian middle-ear ossicles, mammary structures) place dolphins with mammals. (c) The similarity is convergent (analogous) evolution. See section 23.

14. A molecular phylogeny based on 16S rRNA sequences places Archaea as a sister clade to Eukaryotes, while Bacteria branch more basely. Explain what this means for the “three-domain of life” vs “two-domain of life” (Eocyte hypothesis) debate.

Answer (Q14, Application). 16S rRNA placing Archaea as sister to Eukaryotes with Bacteria basal supports a two-domain (eocyte) tree, in which eukaryotes arose from within Archaea, rather than the three-domain tree treating Archaea and Eukarya as separate top-level domains. Modern phylogenomics (Asgard archaea) further supports the two-domain view. See section 23.

15. The molecular clock for mitochondrial cytochrome b sequences in mammals ticks at about 2% divergence per million years (Mya). Two sister species differ by 8% in their cytochrome b sequences. Estimate when they diverged, and list two sources of uncertainty in this estimate.

Answer (Q15, Application). Divergence time \approx percent difference / rate = 8% / (2% per Myr) = 4 million years. Two uncertainty sources: clock-rate variation among lineages/sites (non-clocklike evolution, saturation/multiple hits) and calibration error in the assumed 2%/Myr rate. See section 23.

16. ABBA-BABA (D-statistics) tests detect gene flow between populations. If D is significantly positive, what does it imply about the relationships between the four taxa (P1, P2, P3, and outgroup)? How did this test reveal Neanderthal–modern human gene flow?

Answer (Q16, Application). A significantly positive D (ABBA > BABA) indicates gene flow/admixture between P3 and one of P1/P2 beyond that expected from incomplete lineage sorting under the (((P1,P2),P3),O) topology. Excess shared derived alleles between non-African humans (P2) and Neanderthal (P3) versus African humans (P1) revealed Neanderthal–modern-human introgression. See section 23.

17. Biogeographic analysis shows that the freshwater fish genus *Nannoperca* is distributed across southwestern Australia (isolated from other parts by arid zones). How would you distinguish between: (a) vicariance (ancient populations separated by geological changes); (b) long-distance dispersal (a single colonization event across an unsuitable barrier)?

Answer (Q17, Application). Distinguish by dating divergence relative to barrier age and comparing area cladograms: vicariance predicts divergence times matching the geological/aridification event and concordant patterns across co-distributed taxa; long-distance dispersal predicts divergence younger than the barrier and idiosyncratic, taxon-specific timing inconsistent with a shared vicariant event. See section 23.

18. Maximum likelihood (ML) phylogenetics uses an explicit model of sequence evolution (e.g., GTR+ Γ) to evaluate the likelihood of observing the data given a tree. Why is ML generally preferred over parsimony for molecular data, especially for distantly related taxa?

Answer (Q18, Application). Maximum likelihood uses an explicit substitution model (e.g., GTR+ Γ) to weight different change types and account for multiple hits and rate heterogeneity. It is preferred over parsimony for molecular data — especially distantly related taxa — because parsimony underestimates change on long branches and is prone to long-branch attraction, whereas ML models the true substitution process and is statistically consistent. See section 23.

19. Gene trees vs species trees: individual gene trees can differ from the species tree due to incomplete lineage sorting (ILS) or horizontal gene transfer. What is ILS, and why is it more likely for genes with short internodal branches (rapid speciation)?

Answer (Q19, Application). Incomplete lineage sorting is the persistence of ancestral polymorphism through successive speciation events, so a gene's coalescence predates speciation and its tree differs from the species tree. It is likelier with short internodal branches (rapid successive speciation) because there is little time for lineages to coalesce/sort between divergence events. See section 23. 20. The “long branch attraction” (LBA) artifact occurs when rapidly evolving lineages with many changes falsely cluster together in parsimony or distance analysis. Explain the mechanism of LBA and propose two strategies to avoid it (taxon sampling, model-based methods).

Answer (Q20, Application). Long-branch attraction: rapidly evolving (long) branches accumulate many independent changes, some matching by chance (homoplasy), which parsimony/distance methods misread as shared ancestry, clustering the long branches together regardless of true relationships. Mitigate by adding taxa to break long branches and by using model-based (ML/Bayesian) methods that correct for multiple substitutions. See section 23.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the evidence that Archaeal clade Asgard is the closest prokaryotic relative of eukaryotes. What specific eukaryotic features (endomembrane, cytoskeleton homologues, ubiquitin) were identified in their genomes? What does this suggest about the origin of eukaryotic complexity?

Answer (Q21, Synthesis). Asgard archaea (Lokiarchaeota etc.) carry eukaryotic signature proteins — actin/profilin cytoskeletal homologues, ESCRT/membrane-trafficking and ubiquitin-system components — and branch as the closest prokaryotic relatives of eukaryotes in phylogenomic analyses. This supports a two-domain tree and an archaeal host that already possessed eukaryotic-like cellular machinery before mitochondrial endosymbiosis. See section 23. 22. Design a phylogenomic study (using hundreds of genes rather than one marker) to resolve a “soft polytomy” (unresolved node) in the avian tree of life. Describe: coalescent methods (ASTRAL) vs concatenation (ML on combined alignment), what sources of conflict between gene trees need to be accounted for, and how you would determine whether the polytomy reflects rapid radiation rather than incomplete data.

Answer (Q22, Synthesis). Sample hundreds of loci genome-wide; infer gene trees and combine by a coalescent method (ASTRAL) and by concatenated ML, comparing results. Account for ILS, gene-tree estimation error, and HGT/introgression as conflict sources. A true hard polytomy from rapid radiation is supported when gene-tree conflict is high and uniformly distributed and added data do not resolve the node, rather than reflecting missing data. See section 23. 23. The ribosomal RNA (rRNA) phylogeny (Woese, 1977) unified most life into three domains. Evaluate why rRNA was chosen as a comprehensive phylogenetic marker: (a) ubiquitous, almost universally homologous; (b) highly conserved but containing variable regions; (c) unlikely to undergo HGT. Are there limitations to rRNA as a “true” species tree marker?

Answer (Q23, Synthesis). rRNA was chosen because it is universal and homologous across all life, functionally constrained yet contains variable regions resolving multiple depths, and rarely transferred horizontally. Limitations: HGT is not zero, multiple rRNA copies can differ (paralogy), strong base-composition/rate biases and saturation can mislead deep nodes — so rRNA is a good but imperfect proxy for the species tree. See section 23. 24. Bayesian phylogenetics (MrBayes, BEAST) uses prior probabilities and MCMC sampling to estimate the posterior distribution of trees. Compare Bayesian vs maximum likelihood approaches: (a) what is the difference in interpretation of the “support” values (posterior probabilities vs bootstrap); (b) when does Bayesian inference provide overconfident node support; (c) how is divergence time estimation performed in BEAST?

Answer (Q24, Synthesis). (a) Bayesian support is a posterior probability (probability the clade is true given data and priors); bootstrap is a frequentist resampling proportion. (b) Bayesian PP can be overconfident under model misspecification or with very short internal branches. (c) BEAST estimates divergence times by combining a clock model, tree prior, and fossil/biogeographic calibration priors via MCMC to sample dated trees. See section 23. 25. Ancient DNA (aDNA) sequencing has transformed our understanding of human history by adding extinct hominin and historical populations to phylogenies. Evaluate the technical challenges of aDNA analysis: (a) DNA degradation (short fragments, C→U deamination); (b) contamination from environmental microbes and modern human DNA; (c) how mapDamage software and UDG treatment are used to address these.

Answer (Q25, Synthesis). (a) aDNA is fragmented and chemically damaged (C→U deamination causing C→T miscoding at fragment ends). (b) It is easily contaminated by environmental and modern-human DNA. (c) mapDamage models the deamination signature to authenticate ancient reads, and UDG/USER treatment excises uracils to remove deamination errors before genotyping, improving reliability of ancient phylogenetic placement. See section 23. 26. Evaluate the “bush of life” metaphor vs the traditional “tree of life” for describing microbial evolution. How prevalent is HGT among bacteria and archaea (what fraction of the typical prokaryote genome has been acquired by HGT), and at what level (genus, family, phylum) does HGT obscure true vertical inheritance?

Answer (Q26, Synthesis). For prokaryotes the ‘bush/web of life’ better reflects pervasive HGT: a substantial fraction of a typical prokaryote genome (often tens of percent of genes, cumulatively) has foreign ancestry. HGT can obscure vertical inheritance up to genus/family and even phylum level for some genes, though a core of rarely transferred informational genes still recovers a backbone organismal tree. See section 23. 27. Trans-

posableElements have been used as phylogenetic markers (SINEs/LINEs as synapomorphies): a SINE insertion shared by multiple taxa must have occurred once in a common ancestor. Evaluate the advantages of transposon-based markers over sequence-based phylogenetics: (a) irreversibility of insertion; (b) independence of molecular evolution model assumptions; (c) limitations (element excision, parallel insertions in hotspot regions).

Answer (Q27, Synthesis). (a) Transposon (SINE/LINE) insertions are effectively irreversible, so a shared insertion is a near-unambiguous synapomorphy. (b) Presence/absence does not depend on substitution-model assumptions. (c) Limitations: rare precise excision and parallel insertions into hotspots, and incomplete lineage sorting of polymorphic insertions, can still create homoplasy, so multiple independent insertions are used. See section 23. 28. The “total evidence dating” approach (tip calibration) uses morphological characters from fossils as direct terminal taxa (not just calibration points) in Bayesian time-tree analysis. Evaluate the advantages of total evidence dating over node calibration, and describe what happens to morphological branch length estimates when the model of trait evolution (e.g., Mk model) is misspecified.

Answer (Q28, Synthesis). Total-evidence (tip) dating places fossils as dated terminal taxa with morphological characters, jointly estimating topology and timescale and using the fossilised-birth–death process, which propagates uncertainty better than fixing node ages. If the morphological model (e.g., Mk) is misspecified, morphological branch lengths and hence inferred rates and divergence times are biased, distorting the time tree. See section 23. 29. Horizontal gene transfer in cancer (somatic HGT from tumor microenvironment bacteria into human cells) has been reported but remains controversial. Evaluate the evidence: (a) what sequencing artifacts can mimic bacterial HGT; (b) what controls are needed to rule out contamination; (c) if real, what functional consequences might cancer-incorporated bacterial genes have?

Answer (Q29, Synthesis). (a) Bacterial reads can arise from index-hopping, reference contamination, or chimeric assembly mimicking HGT. (b) Needed controls: matched blanks, multiple independent libraries, paired-end reads spanning human–bacterial junctions, and orthogonal validation (PCR/FISH). (c) If real, integrated bacterial genes could alter host gene expression or metabolism in tumor cells, but the bar for evidence is high given pervasive artifact risk. See section 23. 30. Critically assess whether a “tree of life” can be reconstructed from extant biodiversity alone, without fossil calibration. What information is intrinsically lost when primarily the tips (extant species) and not the internal nodes (extinct ancestors) are known? Use the concept of incomplete ancestry and the “big-bang” topology problem of rapid early diversification as a specific example.

Answer (Q30, Synthesis). From extant tips alone, extinct lineages and ancestral states are unobserved, so deep relationships, ancestral character reconstruction, and absolute timing are weakly identified. Rapid early diversification gives near-simultaneous splits (‘big-bang’ topology) with little informative signal on short internal branches, so without fossil calibration both branching order and timescale of the deep tree remain poorly resolved. See section 23.

Questions — Bacteria, Archaea, and Viruses

Instructor Use and Coverage Notes

- Coverage target: Classify a microbe or virus from evidence and predict a likely vulnerability.
- Model/data emphasis: Growth-rate, genome-size, and dilution calculations.
- Assessment alignment: Questions and Methods, Representing and Describing Data, Argumentation.
- Misconception probe: Viruses are not simply tiny bacteria; they use fundamentally different replication logic.
- Transfer product: Apply microbial diversity reasoning to antibiotics, biotechnology, ecology, and outbreaks.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 24 of the textbook — review that chapter before attempting the exercises below.

1. List three differences between bacteria and archaea in cell wall chemistry and membrane lipids.

Answer (Q1, Recall). Three diagnostic differences: (1) Cell wall — bacteria use peptidoglycan (murein) with muramic acid, whereas archaea lack peptidoglycan and instead use pseudopeptidoglycan, S-layers, or other polymers. (2) Membrane lipids — bacterial lipids are ester-linked, straight-chain fatty acids on glycerol-3-phosphate, while archaeal lipids are ether-linked, branched isoprenoid chains on glycerol-1-phosphate. (3) Some archaea form a tetraether lipid monolayer (rather than a bilayer), giving extreme thermal and chemical stability. See section 24. 2. What is the Gram stain? What does Gram-positive vs Gram-negative indicate about cell wall structure?

Answer (Q2, Recall). The Gram stain (Hans Christian Gram, 1884) is a differential stain that sorts bacteria by cell-wall architecture. Gram-positive cells retain the crystal-violet–iodine complex because they have a thick multilayered peptidoglycan wall and stain purple. Gram-negative cells have a thin peptidoglycan layer plus an outer membrane containing lipopolysaccharide (LPS); the decolorizer washes out the primary stain so they take up the safranin counterstain and appear pink. See section 24. 3. Describe the replication cycle of a bacteriophage. Distinguish lytic from lysogenic cycles.

Answer (Q3, Recall). A bacteriophage attaches to a host receptor, injects its genome, and then follows one of two paths. In the lytic cycle the phage immediately hijacks host machinery to replicate its genome, assemble progeny, and lyse the cell, releasing new virions. In the lysogenic cycle the phage genome integrates into the host chromosome as a prophage and is replicated passively with the host until an induction signal switches it to the lytic cycle. See section 24. 4. What is a prophage? What signal triggers induction of the lytic cycle from lysogeny?

Answer (Q4, Recall). A prophage is a bacteriophage genome that has integrated into the host bacterial chromosome (or persists as a plasmid) and is replicated along with the host during lysogeny. Induction to the lytic cycle is triggered by DNA-damaging stress (e.g., UV light or chemical mutagens) that activates the host SOS response: RecA stimulates autocleavage of the phage repressor (CI in lambda), de-repressing lytic genes. See section 24. 5. Name three types of bacterial reproduction. Which is the fastest?

Answer (Q5, Recall). Bacteria propagate by binary fission (asexual clonal division), and they also exchange genes horizontally by transformation, transduction, and conjugation. Of these, simple binary fission is by far the fastest route to more cells — under optimal conditions some bacteria double every about 20 minutes — whereas the horizontal transfer processes spread genes but do not, by themselves, rapidly increase cell number. See section 24. 6. What is binary fission? How does the doubling time relate to bacterial growth rate?

Answer (Q6, Recall). Binary fission is asexual reproduction in which the circular chromosome is replicated bidirectionally from oriC, the cell elongates, an FtsZ ring directs septum formation at mid-cell, and two identical daughter cells separate. Each round doubles the population, so the doubling (generation) time t_d sets the growth rate: the number of generations $n = t/t_d$ and $N(t) = N_0 \cdot 2^{(t/t_d)}$. A shorter doubling time means a steeper exponential growth rate. See section 24. 7. Describe the structure of a typical bacterium: nucleoid, ribosomes, pili, flagella, capsule.

Answer (Q7, Recall). A typical bacterium has a nucleoid (a single supercoiled circular chromosome, no nuclear membrane), 70S ribosomes for translation, pili/fimbriae for adhesion and (sex pili) conjugation, one or more flagella that rotate like propellers driven by proton-motive force for motility, and often a polysaccharide capsule that resists desiccation and phagocytosis. All sit inside the plasma membrane and peptidoglycan cell wall. See section 24. 8. What is conjugation? What is an F plasmid?

Answer (Q8, Recall). Conjugation is horizontal gene transfer requiring direct cell-to-cell contact through a sex pilus. The F (fertility) plasmid encodes that pilus and the transfer machinery; an F+ donor transfers a copy of the F plasmid to an F– recipient. Because conjugative (R–) plasmids often carry antibiotic-resistance genes, conjugation is the principal route by which resistance spreads within and between bacterial species. See section 24. 9. Distinguish DNA viruses from RNA viruses. Give one example of each.

Answer (Q9, Recall). DNA viruses store their genome as DNA and generally replicate using host (or viral) DNA polymerases with relatively high fidelity (e.g., herpesvirus, a dsDNA virus). RNA viruses store their genome as RNA and replicate with error-prone RNA-dependent RNA polymerase (or reverse transcriptase), giving high mutation rates and rapid evolution (e.g., influenza virus, a –ssRNA virus). See section 24. 10. What is a retrovirus? Describe its replication cycle.

Answer (Q10, Recall). A retrovirus is an enveloped +ssRNA virus (Baltimore Class VI, e.g., HIV) that carries reverse transcriptase. Its cycle: gp120 binds CD4 plus a coreceptor (CCR5/CXCR4) and the membrane fuses; reverse transcriptase copies the RNA genome into dsDNA; integrase splices that provirus into the host genome; host machinery transcribes and translates viral genes; new virions bud from the membrane and the protease matures them into infectious particles. See section 24.

Questions 11–20: Application and Analysis

11. A bacterial culture starts with 100 cells and has a doubling time of 20 minutes. Calculate: (a) the number of cells after 2 hours; (b) the approximate mass of bacteria (assuming 10^{-15} g/cell) after 24 hours. Why does exponential growth not continue indefinitely?

Answer (Q11, Application). Use $N(t) = N_0 \cdot 2^{(t/td)}$ with $N_0 = 100$ and $td = 20$ min. (a) After 2 h = 120 min there are $120/20 = 6$ doublings, so $N = 100 \cdot 2^6 = 6,400$ cells. (b) After 24 h = 1440 min there are 72 doublings: $N = 100 \cdot 2^{72} \approx 4.7 \times 10^{23}$ cells; at 10^{-15} g/cell that is about 4.7×10^8 g (about 470 metric tons) — a biologically impossible mass. Exponential growth cannot continue because nutrients deplete, waste and toxic byproducts accumulate, and space/oxygen become limiting, so cultures enter stationary phase. See section 24. 12. Design a serial dilution experiment to count colonies from a bacterial sample expected to have about 10^6 CFU/mL. Which dilutions would give countable plates (30–300 colonies)? Calculate CFU/mL from a plate showing 175 colonies at 10^{-5} dilution.

Answer (Q12, Application). Prepare serial 10-fold dilutions (e.g., 10^{-1} through 10^{-7}) and plate 0.1 mL of each in replicate. For about 10^6 CFU/mL the 10^{-4} and 10^{-5} dilutions should land in the countable 30–300 range. $CFU/mL = \text{colonies} \div (\text{dilution factor} \times \text{volume plated})$. For 175 colonies at 10^{-5} plating 0.1 mL: $175 \div (10^{-5} \times 0.1) = 175 \div 10^{-6} = 1.75 \times 10^8$ CFU/mL. (If 0.1 mL was plated; if 1 mL, 1.75×10^7 CFU/mL.) See section 24.

13. Compare the lytic and lysogenic cycles: what are the advantages of each for the phage? Under what environmental/physiological conditions does the lambda phage switch from lysogeny to the lytic cycle? (Name the specific protease.)

Answer (Q13, Application). The lytic cycle maximizes immediate progeny when hosts are abundant; the lysogenic cycle preserves the genome through host scarcity or hostile conditions by hiding as a prophage. In lambda, the lysogeny-versus-lysis decision is governed by the CI repressor: DNA damage activates the host SOS response, *RecA-stimulated autocleavage destroys CI, de-repressing the lytic genes. The relevant phage protease activity is the RecA-coactivated autocleavage of the CI repressor.* See section 24. 14. MRSA (*methicillin-resistant Staphylococcus aureus*) carries *mecA** or *mecC*, encoding a modified penicillin-binding protein (PBP2a/PBP2c) with low affinity for most traditional β -lactam antibiotics. Explain: (a) how *mec* genes are acquired by horizontal gene transfer on *SCCmec* elements; (b) why many β -lactams fail but anti-MRSA cephalosporins can be exceptions in susceptible isolates; (c) what alternative antibiotics are used and how their mechanisms bypass PBP2a.

Answer (Q14, Application). MRSA resistance begins with *SCCmec* acquisition carrying *mecA* or *mecC*. These genes encode PBP2a/PBP2c, transpeptidases whose active sites bind most older β -lactams poorly, so cell-wall cross-linking can continue despite drug exposure. Note that ceftaroline or ceftobiprole can be exceptions when susceptibility testing supports them; then compare alternatives: vancomycin binds D-Ala-D-Ala cell-wall precursors, daptomycin disrupts the Gram-positive membrane, and linezolid blocks 50S translation initiation. See section 24. 15. Archaea are found in extreme environments (hyperthermophiles, halophiles, methanogens). Explain how: (a) archaeal lipid membranes (isoprene ether-linked, rather than ester-linked) withstand high temperatures; (b) halophilic archaea stabilize proteins at high salt by having an excess of surface-facing acidic residues; (c) methanogenic archaea use H_2 and CO_2 as energy sources via a unique archaeal pathway.

Answer (Q15, Application). (a) Archaeal ether linkages and branched isoprenoid chains resist hydrolysis; tetraether monolayers cannot split into leaflets, so membranes stay intact at high temperature. (b) Halophilic archaeal proteins carry an excess of acidic (Asp/Glu) surface residues that bind hydrated ions and water, keeping proteins soluble and folded in saturating salt. (c) Methanogens are strict anaerobes that reduce CO_2 with H_2 to CH_4 through the archaea-specific methanogenesis pathway using unique cofactors (coenzyme M, F420), harvesting energy via a proton/sodium gradient. See section 24. 16. The CRISPR-Cas system in bacteria provides adaptive immunity against phage. Explain: (a) spacer acquisition from phage DNA; (b) crRNA-guided Cas9 surveillance; (c) cleavage of matching invader DNA; (d) why the phage can evolve to escape CRISPR immunity (PAM sequence mutation). How did bacterial CRISPR inspire the molecular biology tool?

Answer (Q16, Application). (a) Adaptation: Cas1–Cas2 excise a protospacer from invading phage DNA and insert it as a new spacer into the CRISPR array. (b) Expression: the array is transcribed and processed into crRNAs that load Cas9 for surveillance. (c) Interference: crRNA base-pairs with matching phage DNA next to a PAM and Cas9 makes a double-strand cut, destroying the invader. (d) Phage escape by mutating the PAM or protospacer abolishes recognition. The programmable RNA-guided Cas9 nuclease was repurposed as a genome-editing tool. See section 24.

17. Viral tropism (which cells a virus can infect) depends on receptor-ligand binding. HIV infects cells expressing both CD4 and CCR5/CXCR4

(co-receptors). Individuals homozygous for a 32-bp deletion in *CCR5* ($\Delta 32$ allele) are largely resistant to HIV infection. Explain why this is and why CCR5 antagonists (maraviroc) alone do not fully cure HIV.

Answer (Q17, Application). HIV entry requires gp120 binding CD4 and a coreceptor (CCR5 early, CXCR4 late). A homozygous CCR5- $\Delta 32$ deletion produces a non-functional, surface-absent receptor, so the common CCR5-tropic strains cannot complete entry, conferring strong resistance. CCR5 antagonists like maraviroc only block CCR5-tropic virus; they do not clear the integrated latent provirus in resting memory CD4+ T cells and fail against CXCR4-tropic variants, so they suppress but do not cure HIV. See section 24. 18. Prions are misfolded proteins (PrP^{Sc}) that convert normally folded proteins (PrP^C) to the pathogenic conformation. Explain: (a) why prion diseases (CJD, BSE) are transmissible without nucleic acid; (b) the proposed templating mechanism; (c) why prions are nearly extremely difficult to decontaminate by standard autoclaving.

Answer (Q18, Application). (a) Prions are infectious because PrP^{Sc} itself acts as the agent — they contain no nucleic acid, so transmission is purely conformational. (b) The templating mechanism: PrP^{Sc} (β -sheet rich) binds normal PrP^C (α -helical) and catalyzes its refolding into more PrP^{Sc}, which aggregates into amyloid; this autocatalytic conversion propagates the disease (CJD, BSE). (c) Because infectivity resides in a misfolded protein with no genome, standard autoclaving fails — there is no nucleic acid to destroy and the aggregates are extraordinarily heat- and protease-resistant. See section 24. 19. Bacteriophage therapy (phage therapy) is being reconsidered as an alternative to antibiotics for drug-resistant infections. Compare phage therapy vs antibiotics: (a) host range (broad-spectrum antibiotics vs phage-host specificity); (b) resistance evolution rate; (c) phage ability to co-evolve with bacterial host. Give one clinical case report of successful phage therapy.

Answer (Q19, Application). (a) Broad-spectrum antibiotics kill many taxa, whereas phages are highly host-specific (often strain-level), sparing the microbiome but requiring precise matching. (b) Bacteria evolve resistance to both, but phages can co-evolve to counter resistant hosts, partly offsetting escape. (c) That co-evolutionary capacity — and combining phages in cocktails or with antibiotics — limits resistance. A documented clinical success is the 2017 personalized phage-cocktail rescue of a patient with multidrug-resistant *Acinetobacter baumannii* (Strathdee/UCSD case). See section 24. 20. SARS-CoV-2 is a +ssRNA coronavirus. Explain: (a) how it uses its spike protein to bind ACE2 and enter cells; (b) why mRNA vaccines encoding spike protein induce protective immunity; (c) why variants (Omicron) with many spike mutations can partially evade vaccine-induced antibodies.

Answer (Q20, Application). (a) The SARS-CoV-2 spike receptor-binding domain binds host ACE2; host protease (TMPRSS2/furin) primes spike and the membrane fuses, delivering the +ssRNA genome. (b) mRNA vaccines deliver spike-encoding mRNA so host cells express spike, eliciting neutralizing antibodies and T-cell memory targeting that protein. (c) Omicron carried about 32 spike mutations, many in the RBD/antigenic sites, which reduce binding of vaccine-elicited antibodies, allowing partial immune escape while T-cell immunity remains broader. See section 24.

Questions 21–30: Synthesis and Evaluation

- Evaluate the hypotheses for the origin of viruses: (a) regression hypothesis (viruses are degenerate cells); (b) escape hypothesis (mobile genetic elements that gained capsids); (c) primordial virion hypothesis (viruses predate cells). Which hypothesis is most consistent with current phylogenomic data (nucleocytoplasmic large DNA viruses and their relatives)?

Answer (Q21, Synthesis). (a) The regression hypothesis holds that viruses are degenerate intracellular parasites that lost cellular machinery. (b) The escape hypothesis holds that viruses arose from cellular mobile genetic elements (plasmids/transposons) that acquired capsid genes. (c) The primordial-virion (virus-first) hypothesis holds that viruses predate cells. Current phylogenomic data — including nucleocytoplasmic large DNA viruses (giant viruses) with translation-related genes and conserved capsid lineages — most strongly support a polyphyletic origin, with the virus-first/ancient-lineage view favored for the major capsid lineages; new conserved viral hallmark genes would change the conclusion. See section 24. 22. Design a strategy to engineer a phage to specifically kill a Gram-negative ESKAPE pathogen (*Klebsiella pneumoniae*) that is resistant to multiple first-line antibiotics and has few standard options. Describe: (a) the host-range engineering approach (tail fiber protein swapping); (b) the anti-biofilm component you would add; (c) the regulatory and safety evidence required before use in humans.

Answer (Q22, Synthesis). A strong design starts by typing the patient's *K. pneumoniae* isolate, identifying its capsule/receptor profile, and screening a phage panel against that exact isolate and close clinical comparators. Tail-fiber engineering should be justified by receptor data; an anti-biofilm depolymerase should match the capsule or EPS chemistry; and controls should include untreated bacteria, wild-type phage, engineered phage, antibiotic alone, and phage-antibiotic combinations. Safety evidence should include whole-genome screening for lysogeny, toxin, and AMR genes; endotoxin and sterility release testing; resistance-emergence assays; pharmacokinetic reasoning; and FDA expanded-access or investigational-new-drug review before human use. See section 24. 23. Quorum sensing in *Pseudomonas aeruginosa* controls virulence gene expression via N-acyl-homoserine lactone (AHL) signaling (las and rhl systems). Evaluate: (a) how quorum sensing allows coordinated virulence (biofilm formation, exotoxin production) primarily at high cell density; (b) why quorum sensing inhibitors (QSIs) are attractive anti-virulence targets (less resistance selection pressure); (c) why QSI clinical development has stalled.

Answer (Q23, Synthesis). (a) In *P. aeruginosa*, las and rhl systems use AHL autoinducers whose concentration tracks cell density; only at quorum

do LasR/RhlR activate biofilm, exotoxin, and protease genes, so virulence is deployed when the population is large enough to overwhelm host defenses. (b) Quorum-sensing inhibitors are attractive because disarming virulence rather than killing cells imposes weaker selection for resistance. (c) QSI clinical development has stalled because of poor pharmacokinetics, redundancy among signaling circuits, narrow efficacy windows, and difficulty showing clinical benefit in trials. See section 24. 24. Evaluate the evolutionary biology of rapid viral evolution (HIV, influenza). HIV's high mutation rate (error-prone RT, about 3×10^{-5} /base/replication) generates enormous diversity. How does this diversity allow immune escape and drug resistance? Evaluate why combination antiretroviral therapy (ART) — targeting multiple steps simultaneously — dramatically suppresses resistance evolution and how “cure” strategies (shock and kill) aim to eliminate latent reservoirs.

Answer (Q24, Synthesis). HIV's error-prone reverse transcriptase (about 3×10^{-5} errors/base/replication) generates a vast mutant swarm, so antigenic-escape and drug-resistant variants pre-exist before selection. Single-drug therapy selects resistant clones quickly; combination ART blocks several steps at once, so a virion would need multiple simultaneous resistance mutations — improbable per replication — which durably suppresses resistance. The remaining barrier is the latent integrated reservoir in resting memory CD4+ T cells; ‘shock and kill’ aims to reactivate that reservoir with latency-reversing agents while ART prevents new infection, so it can be cleared. See section 24. 25. Giant viruses (Mimivirus, Pandoravirus) have genomes >1 Mb — larger than some bacteria — and contain genes for translation-related functions unprecedented in viruses. Evaluate whether giant viruses blur the boundary between viruses and cells, and whether they support the regression hypothesis for viral origin.

Answer (Q25, Synthesis). Giant viruses (Mimivirus, Pandoravirus) have >1 Mb genomes — larger than some bacteria — and encode translation-related genes (aminoacyl-tRNA synthetases, translation factors) never before seen in viruses, blurring the virus/cell boundary. They still lack ribosomes and ATP generation and remain obligate intracellular parasites, so they are not cells. Their many cellular-like genes are most parsimoniously explained by genome expansion and extensive gene acquisition rather than strong support for the regression hypothesis; reductive-evolution signatures from a cellular ancestor would be needed to favor regression. See section 24. 26. Horizontal gene transfer (HGT) in bacteria can be transduction, transformation, or conjugation. Use a One Health AMR map to compare how an ESBL or carbapenemase gene could move among hospital patients, wastewater, livestock, soil microbes, and wildlife. Which transfer mechanism is most plausible in each setting, and what surveillance evidence would distinguish clonal spread from mobile-element spread?

Answer (Q26, Synthesis). In hospitals, clonal spread is supported when isolates share a near-identical core genome, ward overlap, and the same resistance phenotype; plasmid-mediated spread is supported when unrelated strains carry the same resistance plasmid, integron, or transposon. In wastewater and livestock settings, conjugation is often the most plausible route for plasmid-borne ESBL or carbapenemase genes because dense mixed communities and antibiotic residues favor mobile elements. Transformation can matter where extracellular DNA persists in biofilms or sediments, while transduction requires phage evidence linked to the resistance cassette. Sound surveillance names sampling sites, genome data, plasmid typing, resistance phenotype, and exposure history, and explains why One Health surveillance follows genes and mobile elements as well as named pathogens. See section 24. 27. The microbiome of the human gut contains >1,000 bacterial species that collectively perform essential metabolic functions (SCFA production, vitamin synthesis, immune training). Evaluate whether the gut microbiome should be considered an “accessory genome” of the human host, and what criteria would need to be met for this “extended genome” concept to be scientifically defensible.

Answer (Q27, Synthesis). Treating the gut microbiome as an ‘accessory genome’ captures the fact that >1,000 species supply host-essential functions (SCFA production, vitamin synthesis, bile-acid transformation, immune training) the human genome lacks, and that function is conserved even when species composition varies (functional redundancy). For the ‘extended genome’ concept to be defensible it would need: heritable/stable transmission across host generations, demonstrated host-fitness dependence on those functions, reproducible function despite taxonomic turnover, and a defined core functional gene set — otherwise it is a useful metaphor rather than a literal genome. See section 24. 28. Bacteriophage encode auxiliary metabolic genes (AMGs) — metabolic genes that boost host metabolism during infection (e.g., phage-encoded photosynthesis genes in cyanophages). Evaluate the role of phage AMGs in global carbon and nitrogen cycling, and propose how phage-encoded metabolic capacity shapes marine primary productivity.

Answer (Q28, Synthesis). Phage auxiliary metabolic genes (AMGs) — e.g., cyanophage-encoded photosystem genes (psbA) — sustain or redirect host metabolism during infection. Initiating condition: a phage infects a primary producer (e.g., a marine cyanobacterium). Changed component: AMGs maintain photosynthesis and reroute carbon/nitrogen flux toward phage production. Mechanism: phage lysis (‘viral shunt’) diverts fixed carbon from higher trophic levels into the dissolved organic pool. Outcome: AMGs and lysis collectively modulate marine primary productivity and global C/N cycling, so phages are major biogeochemical agents. See section 24. 29. The virome — the complete collection of viruses in an ecosystem — is far larger than the known virome catalogued to date. Evaluate metagenomics approaches (shotgun metagenomics, viromics with CRISPR spacer-based enrichment) for discovering novel viruses, and assess what fraction of global viral diversity may remain undiscovered.

Answer (Q29, Synthesis). Shotgun metagenomics sequences total environmental DNA and assembles viral genomes without culture; CRISPR-spacer-based viromics links uncultured viruses to their hosts by matching host spacer arrays to viral protospacers, enriching discovery. Limits include short-read assembly gaps, RNA-virus and rare-taxon undersampling, and database bias, so estimates remain uncertain. Evidence (vast

unassigned sequence space, environment-specific novel lineages) indicates the great majority of global viral diversity is still uncatalogued; deeper long-read and host-linked sampling would refine the estimate. See section 24. 30. Critically evaluate the claim that viruses are “the dark matter of the biosphere” — underappreciated forces shaping ecosystems, gene flows, and evolution. What evidence from marine phage ecology, the pan-genome of bacteria, and viral integration into eukaryotic genomes supports this claim? How does the expanding virology of the 2010s–2020s change our understanding of life’s diversity?

Answer (Q30, Synthesis). ‘Dark matter of the biosphere’ is supported by: marine phage abundance (about 10^{31} virions; the viral shunt and about daily turnover of bacterial standing stock), the open bacterial pan-genome inflated by phage-mediated horizontal transfer and prophages, and endogenous viral elements (e.g., syncytin from retroviral env) co-opted into eukaryotic genomes. The claim weakens only if novel viral diversity proved ecologically inert. Expanding 2010s–2020s virology (giant viruses, viromics, RNA-virus megadiversity) reframes viruses as central drivers of evolution, gene flow, and ecosystem function rather than mere pathogens. See section 24.

Questions — Microbial Ecology and the Microbiome

Instructor Use and Coverage Notes

- Coverage target: Use community data to infer diversity, dominance, and a plausible ecological mechanism.
- Model/data emphasis: Diversity indices, richness estimates, and interaction-network reasoning.
- Assessment alignment: Questions and Methods, Representing and Describing Data, Argumentation.
- Misconception probe: A microbiome is not automatically beneficial; context determines the effect.
- Transfer product: Transfer microbial ecology to soils, oceans, digestion, disease, and climate feedbacks.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 25 of the textbook — review that chapter before attempting the exercises below.

1. Define the microbiome. What is the difference between microbiome and microbiota?

Answer (Q1, Recall). The microbiome is the entire community of microorganisms (bacteria, archaea, fungi, viruses) inhabiting a defined environment together with their collective genes, metabolites, and the surrounding conditions. The microbiota refers specifically to the microbial taxa themselves (the organisms present), whereas the microbiome additionally encompasses their genomes and functional/environmental context. In short: microbiota = who is there; microbiome = who is there plus what they do and the milieu. See section 25. 2. What is 16S rRNA sequencing? Why is the 16S gene used to classify bacteria?

Answer (Q2, Recall). 16S rRNA sequencing amplifies and sequences the gene encoding the small-subunit ribosomal RNA of bacteria and archaea to identify and classify them without culturing. The 16S gene is ideal because it is universally present, functionally conserved (so it cannot be lost), and contains both highly conserved regions (for universal PCR primers) and hypervariable regions (V1–V9) whose sequence differences serve as a molecular clock distinguishing taxa. See section 25. 3. Define the Shannon diversity index. What does a high value indicate?

Answer (Q3, Recall). The Shannon diversity index $H' = -\sum p_i \ln(p_i)$, where p_i is the proportional abundance of species i , combines richness (number of species) and evenness (how equally abundant they are). A high H' indicates a community with many species present and an even distribution of individuals among them, whereas a low value reflects few species or strong dominance by one taxon. See section 25. 4. What are the four major phyla of the human gut microbiome?

Answer (Q4, Recall). The human gut microbiome is dominated by four bacterial phyla: Firmicutes (now Bacillota) and Bacteroidetes (Bacteroidota) make up the great majority of the community, with Actinobacteria (Actinomycetota) and Proteobacteria (Pseudomonadota) as the other major contributors. Verrucomicrobia (e.g., Akkermansia) is often noted as a fifth. Firmicutes and Bacteroidetes together typically account for >90% of gut bacteria. See section 25. 5. What is a biofilm? Name two biological advantages biofilm growth confers on bacteria.

Answer (Q5, Recall). A biofilm is a structured, surface-attached community of microorganisms encased in a self-produced extracellular polymeric substance (EPS) matrix of polysaccharides, proteins, and extracellular DNA. Two advantages it confers: (1) greatly increased tolerance to antibiotics and host defenses (the matrix limits drug penetration and harbors slow-growing persister cells), and (2) protection from environmental stress and shear, plus proximity that enables metabolic cooperation and horizontal gene transfer. See section 25. 6. Define mutualism, commensalism, and parasitism. Give one example of each in microbial ecology.

Answer (Q6, Recall). Mutualism is an interaction benefiting both partners (+/+), e.g., Rhizobium fixing nitrogen for legumes in exchange for plant carbon. Commensalism benefits one partner with no significant effect on the other (+/0), e.g., many skin or gut commensals using host nutrients without harming or helping the host. Parasitism benefits one partner at the other’s expense (+/–), e.g., a pathogenic bacterium such as Mycobacterium tuberculosis exploiting its host while causing disease. See section 25. 7. What is the rhizosphere? Name one bacterium that benefits plant growth there.

Answer (Q7, Recall). The rhizosphere is the narrow zone of soil immediately surrounding and influenced by plant roots, where root exudates (sugars, amino acids, organic acids) enrich microbial activity 10–100-fold relative to bulk soil. A bacterium that benefits plant growth there is Rhizobium (a nitrogen-fixing symbiont forming legume root nodules); plant-growth-promoting Pseudomonas and Azospirillum are also examples. See section 25. 8. What are short-chain fatty acids (SCFAs)? Name three and state which gut bacteria produce them.

Answer (Q8, Recall). Short-chain fatty acids (SCFAs) are 1–6-carbon fatty acids produced when gut bacteria ferment dietary fiber and resistant starch in the colon. The three principal SCFAs are acetate, propionate, and butyrate. Acetate is produced broadly by many bacteria including Bacteroidetes;

propionate largely by Bacteroidetes; and butyrate chiefly by Firmicutes such as *Faecalibacterium prausnitzii* and *Roseburia*. Butyrate is the main energy source for colonocytes. See section 25. 9. Define dysbiosis. Associate dysbiosis with two human diseases.

Answer (Q9, Recall). Dysbiosis is a compositional and functional imbalance of the microbiome — loss of beneficial taxa, expansion of potentially harmful ones, and reduced diversity — associated with disease. It is linked to many conditions; two examples are inflammatory bowel disease (Crohn’s disease/ulcerative colitis) and *Clostridioides difficile*–associated colitis (it is also implicated in obesity and metabolic disease). See section 25. 10. What is the global nitrogen cycle? Name two types of bacteria that fix atmospheric nitrogen.

Answer (Q10, Recall). The global nitrogen cycle is the set of microbially driven transformations that move nitrogen among atmospheric N₂, ammonia/ammonium, nitrite, nitrate, and organic nitrogen via fixation, nitrification, assimilation, ammonification, and denitrification. Two types of nitrogen-fixing bacteria are the symbiotic *Rhizobium* (in legume root nodules) and free-living/diazotrophic bacteria such as *Azotobacter* (cyanobacteria like *Anabaena* also fix N₂). See section 25.

Questions 11–20: Application and Analysis

11. Fecal microbiome transplant (FMT) resolves recurrent *Clostridioides difficile* infection in about 90% of cases. Explain: (a) why antibiotic use predisposes patients to *C. diff*; (b) how FMT restores colonization resistance; (c) why FMT is less likely to be effective in IBD (Crohn’s, ulcerative colitis)?

Answer (Q11, Application). (a) Broad-spectrum antibiotics deplete the protective commensal community, removing colonization resistance and freeing nutrients and niche space that *C. difficile* spores exploit to germinate and overgrow. (b) FMT transplants a healthy donor community that re-establishes colonization resistance by competing for nutrients/niche, restoring secondary bile acids that inhibit *C. difficile* germination, and reactivating immune regulation. (c) FMT works less well in IBD because IBD pathology is driven by a dysregulated host immune response to the microbiota rather than a single missing function, so simply replacing the community does not correct the underlying immune dysfunction. See section 25. 12. A researcher performs 16S metagenomics on soil samples from fertile farmland, degraded land, and old-growth forest. Predict: which environment would show highest Shannon diversity; whether any taxa would serve as indicators of soil health; and what functional genes you would look for in shotgun metagenomics data.

Answer (Q12, Application). The relevant variable is land-use/disturbance regime and its effect on microbial diversity. Mechanism: stable, resource-rich, structurally complex habitats support more niches. Prediction: old-growth forest soil shows the highest Shannon diversity, fertile farmland intermediate, and degraded land the lowest. Indicator taxa: nitrogen-cyclers (*Nitrosomonas*, *Rhizobium*), Acidobacteria, and Glomeromycota mycorrhizae can flag soil health. In shotgun metagenomics, look for functional genes for nitrogen cycling (*nifH*, *amoA*, *nosZ*), carbon turnover (cellulases, chitinases), and phosphorus solubilization. Evidence that would weaken the prediction: high diversity in degraded soil, or no consistent indicator taxa once sampling depth, spatial scale, and replication are controlled. See section 25. 13. The “hygiene hypothesis” (now refined as the “old friends” hypothesis) proposes that reduced microbial exposure in early life increases allergic and autoimmune disease risk. Evaluate the evidence: (a) epidemiological (higher allergy rates in developed countries); (b) experimental (germ-free mice have hyperactive immune systems); (c) specific microbial species (*Lactobacillus*, *Faecalibacterium prausnitzii*) that prevent allergy.

Answer (Q13, Application). Initiating condition: reduced early-life exposure to commensal and environmental ‘old friend’ microbes. Changed component: an immature, under-trained immune system with weak regulatory T-cell development. Mechanism: without microbial signals (e.g., SCFAs, microbial antigens) immune regulation is poorly calibrated, biasing toward Th2/allergic and autoimmune responses. Outcome: higher allergy/autoimmune incidence. Evidence: (a) epidemiology shows higher allergy rates in sanitized, urbanized, developed settings; (b) germ-free mice have hyperactive, dysregulated immune systems corrected by colonization; (c) specific taxa (*Lactobacillus*, *Faecalibacterium prausnitzii*) promote regulatory immunity and reduce allergic inflammation, though causality in humans remains correlational. See section 25. 14. Nitrogen cycle: N-fixing bacteria (*Rhizobium* in legume nodules) convert N₂ → NH₃. Nitrifying bacteria convert NH₃ → NO₂[−] → NO₃[−]. Denitrifying bacteria convert NO₃[−] → N₂. Trace a nitrogen atom from atmospheric N₂ through these steps into a plant protein, and then back to N₂ in soil. Why is this cycle vulnerable to disruption by synthetic fertilisers?

Answer (Q14, Application). Atmospheric N₂ is reduced to NH₃/NH₄⁺ by nitrogenase in *Rhizobium* within legume nodules (fixation). Nitrifying bacteria oxidize NH₃ → NO₂[−] (*Nitrosomonas*) → NO₃[−] (*Nitrobacter*). Plant roots assimilate NO₃[−]/NH₄⁺ and incorporate the nitrogen into amino acids and proteins; following death and decomposition, ammonification returns organic N to NH₄⁺, and denitrifying bacteria reduce NO₃[−] → N₂ back to the atmosphere, completing the cycle. The cycle is vulnerable to synthetic fertilizer because the Haber-Bosch–derived reactive nitrogen flood overwhelms microbial processing, causing nitrate leaching, eutrophication, and excess denitrification/N₂O greenhouse emissions. See section 25. 15. Marine microbial ecology: *Prochlorococcus* is the most abundant photosynthetic organism on Earth (about 10²⁷ cells). Explain: (a) its adaptations for low-nutrient, high-light (and low-light) ocean zones; (b) how phage predation of *Prochlorococcus* releases dissolved organic carbon (DOC) fuelling heterotrophic bacteria; (c) what would happen to ocean productivity if *Prochlorococcus* were eliminated.

Answer (Q15, Application). (a) *Prochlorococcus* is genome-streamlined with divinyl chlorophyll and distinct high-light and low-light ecotypes,

letting different strains exploit nutrient-poor, strongly stratified surface waters and the dim deep euphotic zone. (b) Phage lysis of *Prochlorococcus* releases its fixed carbon as dissolved organic carbon (the ‘viral shunt’), which fuels heterotrophic bacteria and recycles nutrients rather than passing carbon up the food web. (c) Eliminating *Prochlorococcus* would remove a large share of open-ocean primary production, collapsing the base of oligotrophic food webs, reducing carbon fixation/export, and disrupting global ocean productivity and the carbon cycle. See section 25. 16. The human oral microbiome (about 700 species) produces dental caries via *Streptococcus mutans* acidifying enamel via lactic acid fermentation. Explain: (a) how sucrose is a uniquely cariogenic sugar (forms glucan adhesion matrix via glucosyltransferase); (b) what pH triggers enamel demineralisation (<5.5); (c) how fluoride in drinking water chemically protects enamel.

Answer (Q16, Application). Initiating condition: dietary sucrose reaches the dental biofilm. (a) *Streptococcus mutans* glucosyltransferase uses sucrose specifically to synthesize sticky, water-insoluble glucans that build the adhesive plaque matrix — no other dietary sugar supports this matrix as efficiently, making sucrose uniquely cariogenic. Mechanism: *S. mutans* ferments sugars to lactic acid, dropping plaque pH. (b) When pH falls below the critical about 5.5, hydroxyapatite enamel becomes undersaturated and demineralizes. (c) Fluoride in drinking water is incorporated into enamel as fluorapatite, which has a lower critical pH and greater acid resistance, and fluoride also promotes remineralization and inhibits bacterial metabolism. See section 25. 17. Quorum sensing coordinates population-level behavior in bacteria (biofilm formation, bioluminescence, sporulation). Explain in *Vibrio harveyi*: (a) how two quorum sensing circuits (LuxN and LuxPQ) integrate autoinducer signals at different cell densities; (b) why *Vibrio fischeri* in the squid light organ shows population-density-dependent luminescence; (c) how quorum quenching enzymes (AHL lactonase) disrupt this signaling.

Answer (Q17, Application). (a) In *Vibrio harveyi*, parallel circuits feed into LuxO: LuxN senses the AHL autoinducer HAI-1 and LuxPQ senses the interspecies AI-2; at low cell density these phosphorylate LuxO to repress the master regulator LuxR, while at high density (high autoinducer) the kinases switch to phosphatases, dephosphorylating LuxO and activating LuxR-controlled genes — integrating signals across densities. (b) *Vibrio fischeri* in the squid light organ reaches very high local density, so accumulated AHL activates the lux operon and bioluminescence only when the population is dense enough to be useful. (c) Quorum-quenching enzymes such as AHL lactonase hydrolyze the lactone ring of the autoinducer, destroying the signal so the quorum threshold is never reached and coordinated behaviors are blocked. See section 25. 18. Antibiotic resistance spreads horizontally via mobile genetic elements (plasmids, integrons, transposons). Trace how resistance to trimethoprim and ampicillin on a co-integrated resistance plasmid would affect *E. coli* evolution in a hospital drain environment: (a) does selection for one resistance indirectly maintain the other? (b) how does this create a co-selection problem when antibiotics are used?

Answer (Q18, Application). Initiating condition: a co-integrated plasmid in *E. coli* carries linked trimethoprim and ampicillin resistance genes in a hospital drain. Changed component: physical linkage on one mobile element. Mechanism: because the genes co-transfer and co-replicate, selecting for either antibiotic also retains the other (genetic hitchhiking/co-selection), and conjugation spreads the whole cassette across strains and species. Outcome: (a) yes — selection for one resistance indirectly maintains the other; (b) this creates a co-selection problem because using a single antibiotic (or even biocides/metals on the same element) sustains multidrug resistance, so resistance persists even when one drug is withdrawn. See section 25. 19. Extremophile archaea in deep-sea hydrothermal vents oxidise H₂S as electron donor, fixing CO₂ via the reverse TCA cycle (without photosynthesis). Compare this chemolithoautotrophic primary production to photosynthesis: (a) what is the electron donor; (b) what energy source; (c) how much biomass is produced per unit energy; (d) why this is important for understanding the origin of life.

Answer (Q19, Application). (a) The electron donor is reduced inorganic sulfur (H₂S), not water as in photosynthesis. (b) The energy source is chemical energy from oxidizing H₂S (chemolithotrophy) rather than light. (c) Chemolithoautotrophy yields far less energy per reaction than oxygenic photosynthesis, so biomass produced per unit energy and overall growth yields are low — these ecosystems are productive only because vent geochemistry continuously supplies reductant. (d) It matters for origin-of-life questions because it shows life can be powered entirely by geochemical redox energy independent of sunlight, supporting hydrothermal-vent scenarios for early metabolism and chemiosmotic energy conservation. See section 25. 20. Meta-analysis of 10 gut microbiome studies in Type 2 Diabetes (T2D) patients vs healthy controls identified depletion of *Akkermansia muciniphila* and *Faecalibacterium prausnitzii* in T2D. Design a causal inference test: (a) what correlation measure would you use; (b) what germ-free mouse experiment would establish causality; (c) what confounders (diet, medication) need controlling?

Answer (Q20, Application). (a) Use a non-parametric rank correlation (Spearman) or compositionally aware methods (e.g., SparCC/ANCOM) to test association between *Akkermansia*/*F. prausnitzii* relative abundance and T2D status, since microbiome data are compositional and non-normal. (b) Establish causality by colonizing germ-free mice: gnotobiotically transfer T2D-patient versus healthy microbiota (or mono-colonize with the candidate taxa) and measure glucose tolerance/insulin sensitivity, with the prediction that adding the depleted taxa improves metabolic phenotype. (c) Control confounders including diet (especially fiber), metformin and other medications, BMI, age, and sequencing batch — metformin in particular independently alters the microbiome and can spuriously associate taxa with T2D. See section 25.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the “microbiome-brain axis” (gut-brain axis): propose the mechanistic routes (vagus nerve, SCFAs, immune mediators, enteric serotonin) by which gut microbial composition can influence mood and cognition. What evidence from: (a) germ-free mice (increased anxiety, HPA axis changes); (b) faecal transfer from depressed patients to rats; (c) probiotic clinical trials in humans — supports a causal role?

Answer (Q21, Synthesis). Proposed routes: (1) vagal afferent signaling triggered by microbial metabolites; (2) SCFAs (butyrate, propionate) acting on microglia, the blood–brain barrier, and gene expression; (3) immune mediators (cytokines from microbe-trained immunity); and (4) modulation of enteric and circulating serotonin precursors. Evidence: (a) germ-free mice show altered anxiety-like behavior and an exaggerated HPA stress axis, reversed by colonization; (b) transferring feces from depressed patients into rodents can transfer depression/anxiety-like phenotypes; (c) probiotic (‘psychobiotic’) human trials show modest, inconsistent mood effects. Overall the animal causal evidence is strong but human evidence is largely associative; well-powered, mechanism-anchored randomized human trials with defined consortia would change the strength of the causal conclusion. See section 25. 22. Design a metagenomics study to characterize the resistome (complete antibiotic resistance gene complement) of wastewater treatment plant effluent. Describe: (a) DNA extraction strategy; (b) how you would annotate resistance genes; (c) how you would determine whether identified genes are in pathogens vs harmless commensals, including the taxonomy database release used for MAG classification; (d) how you would track the resistome over a full seasonal cycle.

Answer (Q22, Synthesis). Hypothesis: WWTP effluent harbors a quantifiable, seasonally varying resistome. (a) DNA extraction: collect replicate grab/composite effluent samples, filter biomass, and use a bead-beating total-community DNA kit with negative extraction controls. (b) Annotation: shotgun-sequence and map reads/assembled contigs against curated resistance databases (CARD, ResFinder) to call antibiotic resistance genes, with normalized abundance per 16S or per Gbp. (c) Host assignment: use long-read sequencing and assembly to place ARGs on contigs/MAGs and link them to taxonomic markers or known plasmids, then classify MAGs against a named GTDB release so pathogen-borne and commensal-borne calls are reproducible as taxonomy changes [Parks et al., 2026]. (d) Seasonal tracking: sample monthly for ≥ 12 months with replicates and consistent flow/temperature metadata, then test for seasonal effects; a falsifying result is no detectable resistome or no temporal/spatial structure once controls and replication are accounted for. See section 25. 23. Evaluate the concept of the “core microbiome” — a set of microbial taxa present in most healthy individuals of a species. What criteria would define a “core” species, how would you distinguish core from accessory microbiome species, and why the concept is complicated by inter-individual variation (about 20% of gut species may be “comprehensive core”).

Answer (Q23, Synthesis). Empirically, a ‘core microbiome’ is operationally defined as taxa present in $\geq 90\%$ of healthy individuals above a relative-abundance threshold (e.g., $\geq 0.1\%$); core species are distinguished from accessory ones by prevalence and persistence across hosts rather than mere presence in a few. The concept is complicated because only about 20% of gut species may be universally shared, so a strict taxonomic core is small. The conclusion changes if the core is defined functionally (conserved metabolic genes/pathways) rather than taxonomically, since functional redundancy means many different species can fill the same role; the choice of prevalence threshold, sampling depth, and population sampled strongly affects what counts as core. See section 25. 24. Microbial succession in natural environments follows predictable patterns (e.g., pioneer → climax community in forest soils; successional microbiome during decomposition of whale falls). Evaluate the mechanisms (facilitation, inhibition, tolerance) controlling succession, and propose an experiment to test whether succession is driven by deterministic (niche-based) or stochastic processes.

Answer (Q24, Synthesis). Initiating condition: a disturbed or new substrate (whale fall, fresh soil) is colonized by pioneer microbes. Changed component: early colonizers alter the chemical environment. Mechanism: succession proceeds via facilitation (pioneers create conditions/resources favoring later taxa), inhibition (residents suppress newcomers until displaced), and tolerance (later taxa succeed regardless because they tolerate conditions). Outcome: a more stable climax community. To test deterministic (niche) versus stochastic (drift/priority-effect) control, set up many replicate identical microcosms with controlled and varied inocula: deterministic processes predict convergence to similar communities regardless of initial composition, whereas stochastic processes predict divergent endpoints sensitive to colonization order; manipulating arrival order discriminates priority effects. See section 25. 25. Evaluate the concept of “ecosystem services” provided by soil microbiomes: nitrogen cycling, carbon sequestration, plant pathogen suppression. How does intensive agriculture (tillage, pesticide, monoculture) reduce soil microbial diversity and function? Propose a restorative soil management strategy that would re-establish lost ecosystem services.

Answer (Q25, Synthesis). Soil microbiomes provide ecosystem services including nitrogen cycling (fixation, nitrification, denitrification), carbon sequestration via stabilization of microbial necromass and soil organic matter, and suppression of plant pathogens by competitive and antibiotic-producing taxa. Intensive agriculture reduces microbial diversity and function: tillage disrupts fungal hyphal networks and aggregates, pesticides/biocides kill non-target microbes, monoculture narrows root-exudate diversity, and synthetic fertilizer down-regulates N-fixing symbioses. A restorative strategy combines reduced/no-till, diverse cover crops and crop rotation, organic-matter inputs (compost/manure), reduced agro-chemical load, and reintroduction of mycorrhizal/biofertilizer inocula to rebuild diversity and the lost services. The conclusion would change if long-term field trials showed no recovery of function despite restored diversity. See section 25. 26. The human virome includes about 6×10^{12} phage

particles, largely matching the bacteriome. Evaluate: (a) how the virome influences bacteriome composition (phage predation driving community dynamics); (b) the evidence that an abnormal virome (e.g., expanded Caudovirales in Crohn’s disease) can drive inflammation independently of the bacteriome; (c) whether the virome should be considered in the design of microbiome therapeutics.

Answer (Q26, Synthesis). (a) The gut virome is dominated by bacteriophages that shape the bacteriome through predation and lysogeny — kill-the-winner dynamics suppress dominant bacterial taxa, maintaining diversity, while prophages can confer fitness traits. (b) Evidence that an abnormal virome drives disease: Crohn’s disease is associated with an expanded Caudovirales phage richness that does not simply mirror bacterial changes, suggesting the virome can contribute to inflammation partly independently of the bacteriome, though causation versus consequence is unresolved. (c) Therapeutics should consider the virome because phages persist through and can reshape transplanted communities; sterile fecal filtrate (phage) transfer has resolved *C. difficile*, and ignoring phages risks unpredictable bacteriome dynamics. The conclusion would change with controlled phage-manipulation experiments isolating virome effects from bacterial confounding. See section 25. 27. Syntrophic communities (where no single organism can grow on a substrate alone — requires metabolic cross-feeding with a partner) are central to anaerobic digestion of organic matter. Using the sulfate-reducing and methanogenic guild competition as an example, evaluate how thermodynamic constraints (Gibbs energy for each reaction) determine community composition, and why hydrogen partial pressure is the key variable.

Answer (Q27, Synthesis). Initiating condition: a substrate (e.g., propionate/butyrate or fatty acids) that no single organism can degrade alone. Changed component: a fermenting/syntrophic partner produces H₂, which is thermodynamically inhibitory. Mechanism: the primary fermentation is endergonic at high H₂ partial pressure, so it only proceeds if a partner continuously removes H₂ by keeping its concentration extremely low (interspecies hydrogen transfer). Outcome: community composition is set by which H₂ scavenger is thermodynamically favored — sulfate reducers (ΔG more negative with sulfate) outcompete methanogens when sulfate is available, but methanogens dominate when sulfate is depleted. Hydrogen partial pressure is the key variable because it determines whether the syntrophic reaction is exergonic and which guild can sustain it. See section 25. 28. Evaluate the potential of engineered synthetic microbial consortia for biotechnology (e.g., consortium for complete cellulose-to-ethanol conversion, or coordinated tumor-targeting drug delivery). What design principles govern consortium stability, and how can synthetic quorum sensing circuits be used to coordinate the activities of different strains?

Answer (Q28, Synthesis). Empirically, engineered consortia can divide labor (e.g., one strain hydrolyzing cellulose, another fermenting sugars to ethanol) or coordinate spatially (tumor-targeting drug delivery), outperforming single-strain systems on complex tasks. Design principles for stability include enforced metabolic interdependence (auxotrophic cross-feeding so strains cannot outgrow partners), balanced growth rates, spatial structure, and negative feedback to prevent one member overtaking the community. Synthetic quorum-sensing circuits (orthogonal AHL sender/receiver pairs) let strains sense each other’s density and trigger gene expression only at defined population ratios, enabling coordinated, conditional activities and population control. The conclusion changes if long-term experiments show consortia inevitably collapse from evolutionary cheating despite these safeguards. See section 25. 29. The ocean microbiome is structured by “niche partitioning” on individual dissolved organic carbon (DOC) molecules: the “competitive exclusion/keystone species” model predicts that competitive exclusion dominates in low-diversity environments, while microbes coexist in complex high-DOC environments by partitioning onto different compounds. Evaluate how “genome streamlining” (loss of non-essential genes) in marine bacteria (e.g., SAR11) reflects adaptation to this competitive, nutrient-limited environment.

Answer (Q29, Synthesis). Initiating condition: open-ocean surface waters are chronically oligotrophic with dilute, chemically diverse DOC. Changed component: marine bacteria face intense competition for scarce nutrients. Mechanism: in low-diversity/low-resource conditions competitive exclusion favors the most efficient scavenger, while high-DOC complexity allows coexistence through niche partitioning onto different substrate molecules; selection rewards minimizing the metabolic cost of replication. Outcome: lineages like SAR11 undergo genome streamlining — losing non-essential genes, shrinking genome and cell size, and specializing on abundant simple compounds — which maximizes nutrient-use efficiency and competitiveness in this environment. This illustrates that streamlining is an adaptive outcome of competition under nutrient limitation, not mere genome decay. See section 25. 30. Critically evaluate the therapeutic potential of “designer probiotics” — genetically engineered bacteria with specific metabolic or signaling functions. Using the example of a genetically engineered *E. coli* Nissle expressing a GLP-1 precursor for treating obesity (clinical trial, 2025), evaluate: the safety concerns (containment of GMO bacteria, gene transfer to resident microbiome), the evidence of efficacy, and the regulatory framework needed.

Answer (Q30, Synthesis). Designer probiotics — e.g., engineered *E. coli* Nissle expressing a GLP-1 precursor for obesity — could deliver therapeutic molecules locally and continuously. Safety concerns: containment of a GMO in the gut and environment, and horizontal transfer of the engineered construct to the resident microbiome; mitigations include kill-switches, auxotrophy/biocontainment, and genomic (non-mobile) integration. Efficacy evidence to date is largely preclinical and early-phase, so durable, clinically meaningful benefit in humans remains unproven. The regulatory framework must treat these as live genetically modified biotherapeutics, requiring rigorous biocontainment validation, shedding and gene-transfer studies, dose control, and long-term safety monitoring. The conclusion strengthens or weakens with controlled human trial outcomes and demonstrated containment. See section 25.

Questions — Host Immunity and Vaccines

Instructor Use and Coverage Notes

- Coverage target: Predict how immunity or vaccination changes individual and population risk.
- Model/data emphasis: Herd-immunity threshold and basic immunological reasoning.
- Assessment alignment: Questions and Methods, Representing and Describing Data, Argumentation.
- Misconception probe: Immunity is not binary; timing, dose, and variant matter.
- Transfer product: Transfer immunity reasoning to outbreak response and clinical decision-making.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 26 of the textbook — review that chapter before attempting the exercises below.

1. Distinguish innate from adaptive immunity. Name two cell types involved in each.

Answer (Q1, Recall). Innate immunity is the fast, non-specific first response with no memory; it relies on germline-encoded pattern recognition. Adaptive immunity is slower, antigen-specific, and confers lasting memory through clonal selection. Innate cell types include macrophages and neutrophils (also NK cells); adaptive cell types include T lymphocytes (CD4+ helper, CD8+ cytotoxic) and B lymphocytes. The key difference is that adaptive cells rearrange antigen receptors and form memory, whereas innate cells use fixed receptors. See section 26.

2. What is a pathogen-associated molecular pattern (PAMP)? Name one example and its receptor.

Answer (Q2, Recall). A pathogen-associated molecular pattern (PAMP) is a conserved microbial structure not found in host cells that the innate immune system detects via germline-encoded pattern recognition receptors (PRRs). For example, bacterial lipopolysaccharide (LPS) is a PAMP recognized by Toll-like receptor 4 (TLR4); other examples include flagellin (TLR5) and unmethylated CpG DNA (TLR9). Recognition triggers inflammatory signaling. See section 26.

3. What is an antibody? Name its four structural components.

Answer (Q3, Recall). An antibody (immunoglobulin) is a secreted or membrane-bound glycoprotein produced by B cells/plasma cells that specifically binds antigen. Its four structural components are: two identical heavy chains and two identical light chains, joined by disulfide bonds, organized into two Fab regions (variable VH+VL domains forming the antigen-binding paratope) and one Fc region (constant domains that engage effector functions such as complement and Fc receptors). See section 26.

4. What are the five classes of immunoglobulin? State one function of IgG and one of IgA.

Answer (Q4, Recall). The five immunoglobulin classes are IgG, IgM, IgA, IgE, and IgD, determined by the heavy-chain constant region. IgG is the dominant serum antibody in secondary responses: it opsonizes pathogens, neutralizes toxins, fixes complement, and crosses the placenta. IgA is the principal mucosal antibody: as secretory IgA it mediates immune exclusion of pathogens at gut, respiratory, and other mucosal surfaces without triggering inflammation. See section 26.

5. Describe the clonal selection theory of lymphocyte activation.

Answer (Q5, Recall). Clonal selection theory states that each lymphocyte bears a single, randomly generated antigen-receptor specificity before encountering antigen. When an antigen binds the matching receptor, that specific clone is selected and stimulated to proliferate (clonal expansion) and differentiate into effector cells and long-lived memory cells. Self-reactive clones are deleted or inactivated during development, ensuring tolerance. This explains specificity, diversity, and immunological memory. See section 26.

6. What is the MHC (major histocompatibility complex)? Distinguish MHC class I from class II.

Answer (Q6, Recall). The MHC (major histocompatibility complex; HLA in humans) is a set of cell-surface molecules that present peptide antigens to T cells. MHC class I is expressed on virtually all nucleated cells, presents endogenous (cytosolic) peptides, and is recognized by CD8+ cytotoxic T cells (and surveyed by NK cells via ‘missing-self’). MHC class II is expressed on professional antigen-presenting cells, presents exogenous peptides, and is recognized by CD4+ helper T cells. See section 26.

7. What are cytotoxic T lymphocytes (CTLs)? What do they recognize and how do they kill target cells?

Answer (Q7, Recall). Cytotoxic T lymphocytes (CTLs) are CD8+ effector T cells that recognize foreign or aberrant peptides presented on MHC class I of infected or transformed cells via their T-cell receptor. On engagement they kill the target by two main mechanisms: releasing perforin and granzymes that trigger apoptosis, and engaging Fas (CD95) on the target with FasL to induce caspase-mediated death. See section 26.

8. What is an epidemic? What is a pandemic? Define basic reproduction number R_0 .

Answer (Q8, Recall). An epidemic is a sharp rise in cases of a disease above the expected baseline within a community or region; a pandemic is an epidemic that spreads across multiple countries or continents affecting large numbers of people. The basic reproduction number R_0 is the expected number of secondary cases produced by one infectious individual introduced into a fully susceptible population; $R_0 > 1$ allows an outbreak to grow, $R_0 < 1$ causes it to die out. See section 26.

9. What is herd immunity? How does vaccination achieve herd immunity?

Answer (Q9, Recall). Herd immunity is the indirect protection of susceptible individuals that occurs when a sufficiently large fraction of the population is immune, so an infectious person rarely contacts a susceptible one and chains of transmission break. Vaccination achieves it by immunizing enough people that the immune fraction exceeds the herd-immunity threshold $p_c = 1 - 1/R_0$, driving the effective reproduction number below 1. See section 26.

10. Name three mechanisms of antibiotic resistance evolution.

Answer (Q10, Recall). Three mechanisms of antibiotic-resistance evolution are: (1) enzymatic inactivation of the drug (e.g., β -lactamases hydrolyzing penicillins); (2) target modification or protection so the antibiotic no longer binds (e.g., altered penicillin-binding proteins, ribosomal methylation); and (3) reduced intracellular drug concentration via decreased uptake (porin loss) or active efflux pumps. Resistance genes often spread by horizontal gene transfer (conjugation, transduction, transformation). See section 26.

Questions 11–20: Application and Analysis

11. By 10 November 2024, WHO had received reports of more than 776.8 million confirmed COVID-19 cases globally, while also noting that reported cases undercount infections [World Health Organization, 2024b]. Estimate the herd immunity threshold ($H = 1 - 1/R_0$) if R_0 for the original strain was 2.5. For the Omicron variant ($R_0 \approx 10$), recalculate the threshold and explain what incomplete, waning protection means for vaccination strategy.

Answer (Q11, Application). Use $H = 1 - 1/R_0$. For the original strain with $R_0 = 2.5$: $H = 1 - 1/2.5 = 1 - 0.40 = 0.60$, so about 60% of the population must be immune. For Omicron with $R_0 \approx 10$: $H = 1 - 1/10 = 0.90$, so about 90% must be immune under the simplifying assumption of durable sterilizing immunity and homogeneous mixing. In practice, infection-derived and vaccine-derived protection against infection and transmission is incomplete and wanes, so vaccination strategy should emphasize prevention of severe disease, boosters matched to current guidance, and layered controls during surges rather than a single coverage number. See section 26.

12. The inflammasome (NLRP3) is activated by uric acid crystals (gout), cholesterol crystals (atherosclerosis), and pathogens. Explain: (a) how NLRP3 assembles and activates caspase-1; (b) how caspase-1 cleaves pro-IL-1 β and pro-IL-18; (c) why NLRP3 inhibitors (MCC950) are under development for inflammatory diseases.

Answer (Q12, Application). (a) A priming signal (e.g., LPS via TLR4) induces NLRP3 and pro-IL-1 β ; a second signal (uric acid or cholesterol crystals, K⁺ efflux, lysosomal damage) triggers NLRP3 to oligomerize and recruit the adaptor ASC, which clusters and activates pro-caspase-1. (b) Active caspase-1 proteolytically cleaves pro-IL-1 β and pro-IL-18 into mature, secreted cytokines (and cleaves gasdermin D to drive pyroptosis). (c) Because uncontrolled NLRP3 activity drives gout, atherosclerosis, and other sterile inflammation, selective inhibitors such as MCC950 are being developed to dampen IL-1 β without broad immunosuppression. See section 26.

13. Influenza can shift from H1N1 to H3N2 by antigenic shift (segment reassortment) or antigenic drift (point mutations in haemagglutinin). Explain: (a) why antigenic drift requires annual vaccine reformulation; (b) why antigenic shift can cause pandemics; (c) what “original antigenic sin” means for immune memory.

Answer (Q13, Application). (a) Antigenic drift is the gradual accumulation of point mutations in hemagglutinin/neuraminidase that erode antibody recognition, so the vaccine strain must be reformulated annually to match circulating variants. (b) Antigenic shift is reassortment of genome segments (e.g., between human and avian/swine strains) producing a novel HA the population has no immunity to, which can ignite a pandemic. (c) ‘Original antigenic sin’ is the tendency of the immune system to preferentially recall antibodies against the first influenza strain encountered, blunting responses to newer drifted strains. See section 26.

14. The complement system (C1-C9) is a cascade of proteolytic activation that opsonises pathogens and lyses bacteria directly (MAC — membrane attack complex). Describe the three complement activation pathways (classical, lectin, alternative), naming the central converging point (C3 convertase), and explain how bacteria evade complement (factor H mimicry, capsule).

Answer (Q14, Application). The classical pathway is triggered by antibody–antigen complexes binding C1q; the lectin pathway by mannose-binding lectin recognizing microbial carbohydrates; the alternative pathway by spontaneous C3 hydrolysis and direct surface deposition. All three converge on formation of C3 convertase, which cleaves C3 into C3a (anaphylatoxin) and C3b (opsonin), leading to the C5 convertase and assembly of the membrane attack complex (C5b–C9). Bacteria evade complement by recruiting host factor H (or mimicking it) to accelerate C3b decay and by using polysaccharide capsules that block C3b deposition and MAC insertion. See section 26.

15. Natural killer (NK) cells kill virus-infected cells that downregulate MHC class I (a strategy used by many viruses to evade CTLs). Explain the “missing self” hypothesis: how do inhibitory KIR receptors normally inhibit NK killing, and how does MHC class I downregulation remove inhibition and trigger NK-mediated lysis?

Answer (Q15, Application). Under the ‘missing-self’ hypothesis, NK cells continuously sample target cells: inhibitory KIRs (e.g., KIR2DL, KIR3DL) bind self MHC class I and deliver a dominant inhibitory signal that overrides activating receptor signals, sparing healthy cells. Many viruses down-regulate MHC class I to hide infected cells from CD8+ CTLs, but this removes the ligand for inhibitory KIRs. With inhibition lost and activating receptors still engaged, the NK cell is unleashed and lyses the MHC-low target via perforin/granzyme. See section 26.

16. Evaluate the “inverted-U” relationship between immune activation and pathogen clearance, using sepsis as a model: (a) why severe sepsis kills by cytokine storm (uncontrolled innate immune activation) rather than the pathogen itself; (b) the failure of anti-TNF- α therapy in sepsis trials despite success in rheumatoid arthritis; (c) how the “immunological hysteresis” concept explains why the same cytokine blockade is beneficial in autoimmunity but harmful in sepsis.

Answer (Q16, Application). (a) In severe sepsis the protective inflammatory response becomes pathologically amplified: a cytokine storm (TNF- α , IL-1 β , IL-6) drives endothelial dysfunction, capillary leak, disseminated coagulation, and multi-organ failure, so the host response, not the pathogen, kills. (b) Anti-TNF- α therapy failed in sepsis trials despite working in rheumatoid arthritis because sepsis is heterogeneous and time-sensitive: by the time patients are treated, the cytokine cascade is past TNF dependence and some patients are already immunosuppressed. (c) ‘Immunological hysteresis’ frames the system as state-dependent: the same TNF blockade is beneficial in the chronic, sustained activation of autoimmunity but harmful in the acute, rapidly shifting trajectory of sepsis, because the optimal intervention depends on where on the inverted-U curve the patient sits. The conclusion would change if biomarker-stratified trials identified a hyperinflammatory subgroup that benefits. See section 26.

17. Build a paper-based infectious-disease decision matrix for three current interventions: (a) BPAL/BPALM-style most-oral treatment for rifampicin-resistant tuberculosis; (b) twice-yearly lenacapavir PrEP for people with substantial HIV exposure risk; (c) indoor spatial emanators added to insecticide-treated nets for malaria control. For each, state the biological target, the surveillance or eligibility evidence required, one equity constraint, and one reason the intervention should not be treated as a standalone solution.

Answer (Q17, Application). For rifampicin-resistant TB, the target is a bacterial infection requiring susceptibility-guided combination therapy; the decision matrix should include rifampicin resistance, fluoroquinolone susceptibility when BPALM is considered, contraindications, adherence support, and toxicity monitoring. For lenacapavir PrEP, the target is HIV acquisition before infection; eligibility requires HIV-negative status, ongoing exposure risk, access to injection follow-up, and resistance-aware testing if infection is suspected. For malaria spatial emanators, the target is mosquito biting and indoor host-seeking; local evidence should include transmission setting, net coverage, vector behavior, insecticide-resistance monitoring, and household acceptability. None is standalone: TB regimens need diagnostics and public-health follow-up, PrEP does not replace testing or treatment access, and spatial emanators complement nets, case management, chemoprevention, and environmental control. See section 26.

18. Evaluate the evidence for “trained innate immunity”: after exposure to β -glucan (from *Candida*) or BCG vaccination, innate immune cells (macrophages, NK cells) show epigenetically reprogrammed, enhanced responses 3–6 months later. What epigenetic changes (H3K4me1 at enhancers, mTOR-dependent metabolic rewiring) mediate this “immunological memory” in non-adaptive immune cells, and what are the implications for innate immune-based vaccines (BCG against COVID-19)?

Answer (Q18, Application). Empirically, BCG vaccination and β -glucan exposure enhance monocyte/macrophage and NK responses to unrelated pathogens 3–6 months later, indicating innate cells can carry a form of memory. Mechanistically this ‘trained immunity’ is mediated by durable epigenetic remodeling (e.g., H3K4me1/H3K4me3 and H3K27ac at promoters and enhancers of inflammatory genes) coupled to mTOR/HIF-1 α -dependent metabolic rewiring toward aerobic glycolysis, lowering the activation threshold on restimulation. Implications: innate-training vaccines (e.g., BCG tested against COVID-19) could give broad, rapid, non-specific protection, but the effect is shorter-lived and less specific than adaptive memory; the conclusion would change if randomized trials showed no heterologous protection or if the epigenetic marks proved transient. See section 26.

19. Autoimmune diseases arise when self-tolerance breaks down. Evaluate three mechanisms of self-tolerance failure in Type 1 Diabetes (T1D): (a) central tolerance failure (inadequate thymic deletion of autoreactive T cells directed at insulin); (b) peripheral tolerance failure (Treg dysfunction); (c) molecular

mimicry (GAD65-Coxsackie B virus homology). What evidence supports each mechanism in human T1D?

Answer (Q19, Application). (a) Central tolerance failure: the AIRE-dependent thymic deletion of insulin-reactive T cells is incomplete; evidence includes the strong HLA association (DR3/DR4) and INS-VNTR alleles that lower thymic insulin expression and predispose to T1D. (b) Peripheral tolerance failure: Treg number or function is impaired; evidence includes monogenic IPEX (FOXP3 mutation) causing autoimmune diabetes and reduced Treg suppressive function in some T1D patients. (c) Molecular mimicry: homology between GAD65 and Coxsackievirus B P2-C protein could cross-prime autoreactive cells; evidence is epidemiological enterovirus associations and cross-reactive T cells, though causality remains debated. The conclusion would change if intervention trials (e.g., Treg expansion, antiviral prevention) altered disease incidence. See section 26.

20. During the COVID-19 pandemic, several SARS-CoV-2 variants of concern (Alpha, Delta, Omicron) arose sequentially. Evaluate the evolutionary pressures (immune evasion vs transmissibility) that drove variant emergence, and why Omicron showed more ACE2-binding mutations (increased transmissibility) but more spike mutations outside the RBD (immune evasion from vaccine-induced antibodies).

Answer (Q20, Application). Initiating condition: widespread population immunity from infection and vaccination created strong selection for SARS-CoV-2 immune escape, while ongoing transmission selected for higher intrinsic transmissibility. Changed component: variants accumulated spike mutations — RBD changes (e.g., N501Y) that increased ACE2 affinity and transmissibility, plus N-terminal-domain and non-RBD epitope changes that escaped vaccine-induced neutralizing antibodies. Mechanism: Omicron arose by a sudden saltation (~32 spike mutations at once), likely from prolonged infection in an immunocompromised host, combining tighter ACE2 binding with extensive antigenic-site changes. Outcome: Omicron was both more transmissible and more immune-evasive, displacing Delta and driving large reinfection waves. See section 26.

Questions 21–30: Synthesis and Evaluation

21. Evaluate checkpoint immunotherapy for cancer: PD-1/PD-L1 blockade, CTLA-4 blockade, LAG-3 blockade. For what biomarker(s) (TMB, PD-L1 expression, MSI-H) are these drugs most effective, and why do about 20–30% of eligible cancer patients benefit? Propose a combination therapy strategy to increase response rates while managing autoimmune toxicity (immune-related adverse events, irAEs).

Answer (Q21, Synthesis). Checkpoint inhibitors (anti-PD-1/PD-L1, anti-CTLA-4, anti-LAG-3) are most effective in tumors with high tumor mutational burden (TMB), high PD-L1 expression, or microsatellite instability-high (MSI-H)/mismatch-repair-deficient status, because these create abundant neoantigens and an inflamed, T-cell-rich microenvironment. Only about 20–30% of eligible patients respond because many tumors are ‘cold’ (low neoantigen load, poor T-cell infiltration, immunosuppressive stroma, alternative checkpoints, or antigen-presentation loss). A rational combination pairs anti-PD-1 with anti-CTLA-4 (or LAG-3) to broaden T-cell priming, adds an agent that converts cold tumors to hot (radiation, oncolytic virus, or a STING agonist), and manages immune-related adverse events with biomarker-guided patient selection, sequencing, and prompt corticosteroid/anti-cytokine rescue; the strategy would change if predictive biomarkers for irAEs were validated. See section 26.

22. Evaluate the concept of the “immunological homunculus” — that the normal immune system retains low-frequency self-reactive clones that perform surveillance and immunoregulation (not only pathology). Critically assess the evidence that low-affinity self-reactive T and B cells are essential for shaping the immune repertoire, and what happens when these regulatory self-reactive cells are eliminated by lymphodepletion.

Answer (Q22, Synthesis). Empirically, the normal repertoire retains low-affinity self-reactive T and B cells (the ‘immunological homunculus’), and these are not purely pathological: positive selection on self-MHC/self-peptide is required to generate a functional T-cell repertoire, and natural autoantibodies and self-reactive Tregs contribute to tissue homeostasis and immunoregulation. Evidence includes the dependence of thymic positive selection on weak self-recognition and the regulatory roles of natural IgM autoantibodies. When these regulatory self-reactive cells are removed by lymphodepletion, homeostatic reconstitution can skew toward autoreactivity and break tolerance (autoimmune complications after lymphodepleting therapy). The conclusion would change if a fully self-tolerant repertoire could be shown to develop and self-regulate without any self-reactive clones. See section 26.

23. The “two-signal model” of T cell activation requires: (1) TCR engagement with MHC-peptide and (2) a co-stimulatory signal (CD28-B7). Without signal 2, T cells become anergic (unresponsive). Evaluate how tumors exploit this model to suppress anti-tumor T cells by: (a) expressing PD-L1 (sending an anergy-inducing signal); (b) lacking co-stimulatory molecules; (c) expressing IDO (depleting tryptophan needed for T cell activation). How does CAR-T cell therapy bypass this requirement for co-stimulation?

Answer (Q23, Synthesis). Initiating condition: full T-cell activation needs signal 1 (TCR–MHC-peptide) plus signal 2 (CD28–B7 co-stimulation); without signal 2 the T cell becomes anergic. Tumors exploit this: (a) PD-L1 expression delivers a coinhibitory signal that anergizes/exhausts tumor-specific T cells; (b) absence of B7 co-stimulatory molecules on tumor cells gives signal 1 without signal 2, inducing anergy; (c) IDO expression depletes tryptophan and produces kynurenines, starving and suppressing T cells. CAR-T cells bypass this requirement because the chimeric receptor links an antibody-derived antigen-binding domain directly to CD3ζ plus a built-in co-stimulatory domain (CD28 or 4-1BB), so a single MHC-independent antigen contact delivers both activation and co-stimulation. See section 26.

24. Evaluate the emerging field of “onco-immunology” — the mechanisms by which tumors edit the immune landscape (immunoediting: elimination → equilibrium → escape). Give specific molecular examples of immune editing at each phase, and assess whether the immune equilibrium phase can be maintained indefinitely in any cancer type, or whether escape is inevitable.

Answer (Q24, Synthesis). Cancer immunoediting proceeds through three phases. Elimination: immunosurveillance by NK cells and CD8+ T cells destroys nascent transformed cells (evidenced by higher cancer rates in immunodeficient hosts). Equilibrium: residual immunogenic clones are held dormant under sustained adaptive pressure (shown by long latency and donor-transmitted tumors in transplant recipients). Escape: surviving clones evade immunity via MHC class I loss, PD-L1 upregulation, antigen loss, and recruitment of Tregs/MDSCs and TGF-β. Equilibrium can persist for years in some cancers but is generally metastable rather than truly indefinite, because ongoing mutation under immune selection makes eventual escape highly likely; the conclusion would change if a cancer were documented in lifelong stable equilibrium without escape. See section 26.

25. Critically evaluate the public health ethics of mandatory vaccination programs. Using the framework of herd immunity thresholds, individual liberty, social contract theory, and harm principle (Mill), construct a utilitarian argument for and a libertarian argument against mandatory vaccination. What vaccination coverage is minimally required for herd immunity against measles ($R_0 \approx 18$), and how do vaccine hesitancy and anti-vaccine movements affect public health?

Answer (Q25, Synthesis). Utilitarian (for): mandatory vaccination maximizes aggregate welfare by securing herd immunity, preventing outbreaks, and protecting those who cannot be vaccinated; Mill’s harm principle justifies coercion because non-vaccination imposes infection risk on others. Libertarian (against): bodily autonomy and informed consent are paramount; mandates coerce a medical intervention and erode trust, and exemptions/least-restrictive alternatives should be preferred. For measles with $R_0 \approx 18$, the herd-immunity threshold is $p_c = 1 - 1/18 \approx 0.944$, so roughly 94–95% immune coverage is required. Vaccine hesitancy and anti-vaccine movements push coverage below this threshold, restoring susceptibility and driving measles resurgences (as seen in 2018–2019). See section 26.

26. mRNA vaccines (Pfizer-BioNTech, Moderna) for SARS-CoV-2 required solving two key problems: (a) mRNA instability in vivo (solution: pseudouridine substitution reduces TLR7/8 sensing and increases stability); (b) delivery to antigen-presenting cells in lymph nodes (solution: LNP — lipid nanoparticle encapsulation). Trace the cascade from IM injection → LNP uptake by dendritic cells → spike protein expression → naive B and T cell activation → class switch recombination → IgG antibody production.

Answer (Q26, Synthesis). Initiating condition: lipid-nanoparticle (LNP)-encapsulated, pseudouridine-modified spike mRNA is injected intramuscularly, where modified bases reduce TLR7/8 sensing and boost stability. LNPs are taken up by dendritic cells and other antigen-presenting cells, which translate the mRNA into spike protein. Spike is processed and presented on MHC II to naive CD4+ T cells and on MHC I to CD8+ T cells; spike-specific naive B cells bind antigen and receive T-helper signals. In germinal centers this drives affinity maturation and class-switch recombination from IgM to high-affinity IgG, yielding neutralizing antibody and memory B/T cells. See section 26.

27. Regulatory T cells (Tregs, FOXP3+) suppress immune responses and prevent autoimmunity. Explain: (a) how Tregs develop (thymic selection vs peripheral induction); (b) their mechanisms of suppression (IL-10, TGF-β, CTLA-4-mediated antigen-presenting cell suppression); (c) why depleting Tregs in cancer (anti-CTLA-4, ipilimumab) can restore anti-tumor immunity at the cost of autoimmunity.

Answer (Q27, Synthesis). (a) Natural Tregs arise in the thymus by selection of moderately self-reactive CD4+ cells that upregulate FOXP3; induced Tregs differentiate in the periphery from conventional CD4+ cells under TGF-β. (b) They suppress via inhibitory cytokines (IL-10, TGF-β), consumption of IL-2, and CTLA-4, which strips/blocks CD80/CD86 on antigen-presenting cells to deny co-stimulation. (c) Anti-CTLA-4 (ipilimumab) removes this brake, restoring anti-tumor T-cell responses, but because the same checkpoint enforces self-tolerance, blocking it also causes immune-related autoimmune toxicities. See section 26.

28. Malaria (*Plasmodium falciparum*) has complex immune evasion through antigenic variation of PfEMP1 (erythrocyte membrane protein 1) encoded by about 60 var genes, a single active at a time. Explain: (a) why the immune system struggles to clear malaria; (b) how epigenetic switching between var genes works; (c) what approach (conserved antigen targets) vaccine developers use to circumvent this evasion.

Answer (Q28, Synthesis). (a) PfEMP1 on infected erythrocytes mediates cytoadherence and is highly immunogenic, but the parasite switches which variant it displays, so by the time antibodies arise the dominant variant has changed and immunity lags. (b) Only one of about 60 var genes is transcribed at a time; epigenetic silencing (heterochromatin marks, H3K9me3, perinuclear sequestration) keeps the rest off, and stochastic switching activates a new var while silencing the old, giving sequential antigenic variation. (c) Vaccine developers target conserved, less variable antigens (e.g., circumsporozoite protein in RTS,S/R21, or conserved PfEMP1 domains like those binding EPCR) to bypass var-gene switching. See section 26.

29. Calculate basic epidemiological parameters: if an influenza outbreak shows 15 secondary cases per 10 infected individuals over a mean infectious period of 3 days (generation time 3 days), estimate R_0 and the doubling time of the epidemic. What control measure would need to be implemented to bring R to

< 1?

Answer (Q29, Synthesis). $R_0 \approx$ secondary cases per case = $15/10 = 1.5$. With a generation time $T_g = 3$ days, the per-generation growth factor is $R_0 = 1.5$, so the epidemic grows by $1.5\times$ every 3 days. Doubling time $\approx T_g \cdot \ln 2 / \ln(R_0) = 3 \cdot 0.693 / 0.405 \approx 5.1$ days. To bring the effective reproduction number $R_e = R_0(1 - p)$ below 1, the immune/effectively-protected fraction must exceed $p > 1 - 1/R_0 = 1 - 1/1.5 \approx 0.33$, i.e., interventions (vaccination, isolation, contact reduction) must remove more than about 33% of effective transmission. See section 26.

30. Intestinal IgA is produced in the lamina propria by plasma cells and specifically transported into the gut lumen (via polymeric immunoglobulin receptor, pIgR). Explain: (a) how secretory IgA (sIgA) differs from serum IgA structurally; (b) the role of the secretory component; (c) how sIgA provides “immune exclusion” of pathogens without triggering inflammation.

Answer (Q30, Synthesis). (a) Serum IgA is mostly monomeric, whereas secretory IgA is a dimer of two IgA monomers joined by a J chain plus an added secretory component. (b) The secretory component is the cleaved extracellular portion of the polymeric immunoglobulin receptor (pIgR) that transcytoses dimeric IgA across the epithelium; it remains bound and protects sIgA from luminal proteases. (c) sIgA performs ‘immune exclusion’ by cross-linking and agglutinating pathogens and toxins in the mucus layer, blocking adhesion and entry; because it poorly fixes complement and does not strongly engage Fc receptors, it neutralizes without provoking inflammation. See section 26.

Questions — Antimicrobial Resistance and Epidemiology

Instructor Use and Coverage Notes

- Coverage target: Calculate a threshold or outbreak trajectory and identify the intervention lever.
- Model/data emphasis: R0, resistance-mechanism, and outbreak-trajectory calculations.
- Assessment alignment: Questions and Methods, Representing and Describing Data, Argumentation.
- Misconception probe: R0 is not a fixed property of a pathogen alone; it depends on host behavior and environment.
- Transfer product: Transfer resistance and epidemiology reasoning to stewardship and public-health policy.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 27 of the textbook — review that chapter before attempting the exercises below.

1. mRNA vaccines (Pfizer-BioNTech, Moderna) for SARS-CoV-2 required solving two key problems: (a) mRNA instability in vivo (solution: pseudouridine substitution reduces TLR7/8 sensing and increases stability); (b) delivery to antigen-presenting cells in lymph nodes (solution: LNP — lipid nanoparticle encapsulation). Trace the cascade from IM injection → LNP uptake by dendritic cells → spike protein expression → naive B and T cell activation → class switch recombination → IgG antibody production.

Answer (Q1, Recall). Initiating condition: lipid-nanoparticle (LNP)-encapsulated, pseudouridine-modified spike mRNA is injected intramuscularly, where modified bases reduce TLR7/8 sensing and boost stability. LNPs are taken up by dendritic cells and other antigen-presenting cells, which translate the mRNA into spike protein. Spike is processed and presented on MHC II to naive CD4+ T cells and on MHC I to CD8+ T cells; spike-specific naive B cells bind antigen and receive T-helper signals. In germinal centers this drives affinity maturation and class-switch recombination from IgM to high-affinity IgG, yielding neutralizing antibody and memory B/T cells. See section 27.

2. Regulatory T cells (Tregs, FOXP3+) suppress immune responses and prevent autoimmunity. Explain: (a) how Tregs develop (thymic selection vs peripheral induction); (b) their mechanisms of suppression (IL-10, TGF-β, CTLA-4-mediated antigen-presenting cell suppression); (c) why depleting Tregs in cancer (anti-CTLA-4, ipilimumab) can restore anti-tumor immunity at the cost of autoimmunity.

Answer (Q2, Recall). (a) Natural Tregs arise in the thymus by selection of moderately self-reactive CD4+ cells that upregulate FOXP3; induced Tregs differentiate in the periphery from conventional CD4+ cells under TGF-β. (b) They suppress via inhibitory cytokines (IL-10, TGF-β), consumption of IL-2, and CTLA-4, which strips/blocks CD80/CD86 on antigen-presenting cells to deny co-stimulation. (c) Anti-CTLA-4 (ipilimumab) removes this brake, restoring anti-tumor T-cell responses, but because the same checkpoint enforces self-tolerance, blocking it also causes immune-related autoimmune toxicities. See section 27.

3. Malaria (*Plasmodium falciparum*) has complex immune evasion through antigenic variation of PfEMP1 (erythrocyte membrane protein 1) encoded by about 60 var genes, a single active at a time. Explain: (a) why the immune system struggles to clear malaria; (b) how epigenetic switching between var genes works; (c) what approach (conserved antigen targets) vaccine developers use to circumvent this evasion.

Answer (Q3, Recall). (a) PfEMP1 on infected erythrocytes mediates cytoadherence and is highly immunogenic, but the parasite switches which variant it displays, so by the time antibodies arise the dominant variant has changed and immunity lags. (b) Only one of about 60 var genes is transcribed at a time; epigenetic silencing (heterochromatin marks, H3K9me3, perinuclear sequestration) keeps the rest off, and stochastic switching activates a new var while silencing the old, giving sequential antigenic variation. (c) Vaccine developers target conserved, less variable antigens (e.g., circumsporozoite protein in RTS,S/R21, or conserved PfEMP1 domains like those binding EPCR) to bypass var-gene switching. See section 27.

4. Calculate basic epidemiological parameters: if an influenza outbreak shows 15 secondary cases per 10 infected individuals over a mean infectious period of 3 days (generation time 3 days), estimate R0 and the doubling time of the epidemic. What control measure would need to be implemented to bring R to < 1?

Answer (Q4, Recall). $R_0 \approx \text{secondary cases per case} = 15/10 = 1.5$. With a generation time $T_g = 3$ days, the per-generation growth factor is $R_0 = 1.5$, so the epidemic grows by $1.5\times$ every 3 days. Doubling time $\approx T_g \ln 2 / \ln(R_0) = 3 \cdot 0.693 / 0.405 \approx 5.1$ days. To bring the effective reproduction number $R_e = R_0(1 - p)$ below 1, the immune/effectively-protected fraction must exceed $p > 1 - 1/R_0 = 1 - 1/1.5 \approx 0.33$, i.e., interventions (vaccination, isolation, contact reduction) must remove more than about 33% of effective transmission. See section 27.

5. Intestinal IgA is produced in the lamina propria by plasma cells and specifically transported into the gut lumen (via polymeric immunoglobulin receptor, pIgR). Explain: (a) how secretory IgA (sIgA) differs from serum IgA structurally; (b) the role of the secretory component; (c) how sIgA provides “immune exclusion” of pathogens without triggering inflammation.

- Answer (Q5, Recall). (a) Serum IgA is mostly monomeric, whereas secretory IgA is a dimer of two IgA monomers joined by a J chain plus an added secretory component. (b) The secretory component is the cleaved extracellular portion of the polymeric immunoglobulin receptor (pIgR) that transcytoses dimeric IgA across the epithelium; it remains bound and protects sIgA from luminal proteases. (c) sIgA performs ‘immune exclusion’ by cross-linking and agglutinating pathogens and toxins in the mucus layer, blocking adhesion and entry; because it poorly fixes complement and does not strongly engage Fc receptors, it neutralizes without provoking inflammation. See section 27.
6. Evaluate the “inverted-U” relationship between immune activation and pathogen clearance, using sepsis as a model: (a) why severe sepsis kills by cytokine storm (uncontrolled innate immune activation) rather than the pathogen itself; (b) the failure of anti-TNF- α therapy in sepsis trials despite success in rheumatoid arthritis; (c) how the “immunological hysteresis” concept explains why the same cytokine blockade is beneficial in autoimmunity but harmful in sepsis.
- Answer (Q6, Recall). (a) In severe sepsis the protective inflammatory response becomes pathologically amplified: a cytokine storm (TNF- α , IL-1 β , IL-6) drives endothelial dysfunction, capillary leak, disseminated coagulation, and multi-organ failure, so the host response, not the pathogen, kills. (b) Anti-TNF- α therapy failed in sepsis trials despite working in rheumatoid arthritis because sepsis is heterogeneous and time-sensitive: by the time patients are treated, the cytokine cascade is past TNF dependence and some patients are already immunosuppressed. (c) ‘Immunological hysteresis’ frames the system as state-dependent: the same TNF blockade is beneficial in the chronic, sustained activation of autoimmunity but harmful in the acute, rapidly shifting trajectory of sepsis, because the optimal intervention depends on where on the inverted-U curve the patient sits. The conclusion would change if biomarker-stratified trials identified a hyperinflammatory subgroup that benefits. See section 27.
7. Antibiotics select for resistance through several biochemical strategies. List the four major mechanisms of acquired antibiotic resistance — enzymatic inactivation, target modification, reduced intracellular drug (decreased uptake or active efflux), and target bypass — and give one drug-class example defeated by each. Define the minimum inhibitory concentration (MIC) and state what a rising MIC indicates.
- Answer (Q7, Recall). (1) Enzymatic inactivation — β -lactamases hydrolyze penicillins and cephalosporins; aminoglycoside-modifying enzymes acetylate or phosphorylate aminoglycosides. (2) Target modification — *erm*-methylation of 23S rRNA blocks macrolides; the *mecA*-encoded PBP2a defeats most β -lactams in MRSA; gyrase/topoisomerase mutations defeat fluoroquinolones. (3) Reduced intracellular drug — porin loss lowers uptake and efflux pumps (e.g., AcrAB-TolC) export tetracyclines and other agents. (4) Target bypass or overproduction — acquiring a drug-insensitive enzyme (e.g., a sulfonamide-resistant dihydropteroate synthase) or overexpressing the target. The minimum inhibitory concentration (MIC) is the lowest drug concentration that prevents visible growth in vitro; a rising MIC signals declining susceptibility and predicts clinical resistance once it crosses the breakpoint. See section 27.
8. Evaluate the evidence for “trained innate immunity”: after exposure to β -glucan (from *Candida*) or BCG vaccination, innate immune cells (macrophages, NK cells) show epigenetically reprogrammed, enhanced responses 3–6 months later. What epigenetic changes (H3K4me1 at enhancers, mTOR-dependent metabolic rewiring) mediate this “immunological memory” in non-adaptive immune cells, and what are the implications for innate immune-based vaccines (BCG against COVID-19)?
- Answer (Q8, Recall). Empirically, BCG vaccination and β -glucan exposure enhance monocyte/macrophage and NK responses to unrelated pathogens 3–6 months later, indicating innate cells can carry a form of memory. Mechanistically this ‘trained immunity’ is mediated by durable epigenetic remodeling (e.g., H3K4me1/H3K4me3 and H3K27ac at promoters and enhancers of inflammatory genes) coupled to mTOR/HIF-1 α -dependent metabolic rewiring toward aerobic glycolysis, lowering the activation threshold on restimulation. Implications: innate-training vaccines (e.g., BCG tested against COVID-19) could give broad, rapid, non-specific protection, but the effect is shorter-lived and less specific than adaptive memory; the conclusion would change if randomized trials showed no heterologous protection or if the epigenetic marks proved transient. See section 27.
9. Autoimmune diseases arise when self-tolerance breaks down. Evaluate three mechanisms of self-tolerance failure in Type 1 Diabetes (T1D): (a) central tolerance failure (inadequate thymic deletion of autoreactive T cells directed at insulin); (b) peripheral tolerance failure (Treg dysfunction); (c) molecular mimicry (GAD65-Coxsackie B virus homology). What evidence supports each mechanism in human T1D?
- Answer (Q9, Recall). (a) Central tolerance failure: the AIRE-dependent thymic deletion of insulin-reactive T cells is incomplete; evidence includes the strong HLA association (DR3/DR4) and INS-VNTR alleles that lower thymic insulin expression and predispose to T1D. (b) Peripheral tolerance failure: Treg number or function is impaired; evidence includes monogenic IPEX (FOXP3 mutation) causing autoimmune diabetes and reduced Treg suppressive function in some T1D patients. (c) Molecular mimicry: homology between GAD65 and Coxsackievirus B P2-C protein could cross-prime autoreactive cells; evidence is epidemiological enterovirus associations and cross-reactive T cells, though causality remains debated. The conclusion would change if intervention trials (e.g., Treg expansion, antiviral prevention) altered disease incidence. See section 27.
10. During the COVID-19 pandemic, several SARS-CoV-2 variants of concern (Alpha, Delta, Omicron) arose sequentially. Evaluate the evolutionary pressures (immune evasion vs transmissibility) that drove variant emergence, and why Omicron showed more ACE2-binding mutations (increased transmissibility)

but more spike mutations outside the RBD (immune evasion from vaccine-induced antibodies).

Answer (Q10, Recall). Initiating condition: widespread population immunity from infection and vaccination created strong selection for SARS-CoV-2 immune escape, while ongoing transmission selected for higher intrinsic transmissibility. Changed component: variants accumulated spike mutations — RBD changes (e.g., N501Y) that increased ACE2 affinity and transmissibility, plus N-terminal-domain and non-RBD epitope changes that escaped vaccine-induced neutralizing antibodies. Mechanism: Omicron arose by a sudden saltation (≈ 32 spike mutations at once), likely from prolonged infection in an immunocompromised host, combining tighter ACE2 binding with extensive antigenic-site changes. Outcome: Omicron was both more transmissible and more immune-evasive, displacing Delta and driving large reinfection waves. See section 27.

Questions 11–20: Application and Analysis

11. Evaluate checkpoint immunotherapy for cancer: PD-1/PD-L1 blockade, CTLA-4 blockade, LAG-3 blockade. For what biomarker(s) (TMB, PD-L1 expression, MSI-H) are these drugs most effective, and why do about 20–30% of eligible cancer patients benefit? Propose a combination therapy strategy to increase response rates while managing autoimmune toxicity (immune-related adverse events, irAEs).

Answer (Q11, Application). Checkpoint inhibitors (anti-PD-1/PD-L1, anti-CTLA-4, anti-LAG-3) are most effective in tumors with high tumor mutational burden (TMB), high PD-L1 expression, or microsatellite instability-high (MSI-H)/mismatch-repair-deficient status, because these create abundant neoantigens and an inflamed, T-cell-rich microenvironment. Only about 20–30% of eligible patients respond because many tumors are ‘cold’ (low neoantigen load, poor T-cell infiltration, immunosuppressive stroma, alternative checkpoints, or antigen-presentation loss). A rational combination pairs anti-PD-1 with anti-CTLA-4 (or LAG-3) to broaden T-cell priming, adds an agent that converts cold tumors to hot (radiation, oncolytic virus, or a STING agonist), and manages immune-related adverse events with biomarker-guided patient selection, sequencing, and prompt corticosteroid/anti-cytokine rescue; the strategy would change if predictive biomarkers for irAEs were validated. See section 27.

12. Evaluate the concept of the “immunological homunculus” — that the normal immune system retains low-frequency self-reactive clones that perform surveillance and immunoregulation (not only pathology). Critically assess the evidence that low-affinity self-reactive T and B cells are essential for shaping the immune repertoire, and what happens when these regulatory self-reactive cells are eliminated by lymphodepletion.

Answer (Q12, Application). Empirically, the normal repertoire retains low-affinity self-reactive T and B cells (the ‘immunological homunculus’), and these are not purely pathological: positive selection on self-MHC/self-peptide is required to generate a functional T-cell repertoire, and natural autoantibodies and self-reactive Tregs contribute to tissue homeostasis and immunoregulation. Evidence includes the dependence of thymic positive selection on weak self-recognition and the regulatory roles of natural IgM autoantibodies. When these regulatory self-reactive cells are removed by lymphodepletion, homeostatic reconstitution can skew toward autoreactivity and break tolerance (autoimmune complications after lymphodepleting therapy). The conclusion would change if a fully self-tolerant repertoire could be shown to develop and self-regulate without any self-reactive clones. See section 27.

13. The “two-signal model” of T cell activation requires: (1) TCR engagement with MHC-peptide and (2) a co-stimulatory signal (CD28-B7). Without signal 2, T cells become anergic (unresponsive). Evaluate how tumors exploit this model to suppress anti-tumor T cells by: (a) expressing PD-L1 (sending an anergy-inducing signal); (b) lacking co-stimulatory molecules; (c) expressing IDO (depleting tryptophan needed for T cell activation). How does CAR-T cell therapy bypass this requirement for co-stimulation?

Answer (Q13, Application). Initiating condition: full T-cell activation needs signal 1 (TCR–MHC-peptide) plus signal 2 (CD28–B7 co-stimulation); without signal 2 the T cell becomes anergic. Tumors exploit this: (a) PD-L1 expression delivers a coinhibitory signal that anergizes/exhausts tumor-specific T cells; (b) absence of B7 co-stimulatory molecules on tumor cells gives signal 1 without signal 2, inducing anergy; (c) IDO expression depletes tryptophan and produces kynurenines, starving and suppressing T cells. CAR-T cells bypass this requirement because the chimeric receptor links an antibody-derived antigen-binding domain directly to CD3 ζ plus a built-in co-stimulatory domain (CD28 or 4-1BB), so a single MHC-independent antigen contact delivers both activation and co-stimulation. See section 27.

14. Evaluate the emerging field of “onco-immunology” — the mechanisms by which tumors edit the immune landscape (immunoediting: elimination → equilibrium → escape). Give specific molecular examples of immune editing at each phase, and assess whether the immune equilibrium phase can be maintained indefinitely in any cancer type, or whether escape is inevitable.

Answer (Q14, Application). Cancer immunoediting proceeds through three phases. Elimination: immunosurveillance by NK cells and CD8+ T cells destroys nascent transformed cells (evidenced by higher cancer rates in immunodeficient hosts). Equilibrium: residual immunogenic clones are held dormant under sustained adaptive pressure (shown by long latency and donor-transmitted tumors in transplant recipients). Escape: surviving clones evade immunity via MHC class I loss, PD-L1 upregulation, antigen loss, and recruitment of Tregs/MDSCs and TGF- β . Equilibrium can persist for years in some cancers but is generally metastable rather than truly indefinite, because ongoing mutation under immune selection makes eventual escape highly likely; the conclusion would change if a cancer were documented in lifelong stable equilibrium without escape. See section 27.

15. Critically evaluate the public health ethics of mandatory vaccination programs. Using the framework of herd immunity thresholds, individual liberty, social contract theory, and harm principle (Mill), construct a utilitarian argument for and a libertarian argument against mandatory vaccination. What vaccination coverage is minimally required for herd immunity against measles ($R_0 \approx 18$), and how do vaccine hesitancy and anti-vaccine movements affect public health?

Answer (Q15, Application). Utilitarian (for): mandatory vaccination maximizes aggregate welfare by securing herd immunity, preventing outbreaks, and protecting those who cannot be vaccinated; Mill’s harm principle justifies coercion because non-vaccination imposes infection risk on others. Libertarian (against): bodily autonomy and informed consent are paramount; mandates coerce a medical intervention and erode trust, and exemptions/least-restrictive alternatives should be preferred. For measles with $R_0 \approx 18$, the herd-immunity threshold is $p_c = 1 - 1/18 \approx 0.944$, so roughly 94–95% immune coverage is required. Vaccine hesitancy and anti-vaccine movements push coverage below this threshold, restoring susceptibility and driving measles resurgences (as seen in 2018–2019). See section 27.

16. Distinguish innate from adaptive immunity. Name two cell types involved in each.

Answer (Q16, Application). Innate immunity is the fast, non-specific first response with no memory; it relies on germline-encoded pattern recognition. Adaptive immunity is slower, antigen-specific, and confers lasting memory through clonal selection. Innate cell types include macrophages and neutrophils (also NK cells); adaptive cell types include T lymphocytes (CD4+ helper, CD8+ cytotoxic) and B lymphocytes. The key difference is that adaptive cells rearrange antigen receptors and form memory, whereas innate cells use fixed receptors. See section 27.

17. What is a pathogen-associated molecular pattern (PAMP)? Name one example and its receptor.

Answer (Q17, Application). A pathogen-associated molecular pattern (PAMP) is a conserved microbial structure not found in host cells that the innate immune system detects via germline-encoded pattern recognition receptors (PRRs). For example, bacterial lipopolysaccharide (LPS) is a PAMP recognized by Toll-like receptor 4 (TLR4); other examples include flagellin (TLR5) and unmethylated CpG DNA (TLR9). Recognition triggers inflammatory signaling. See section 27.

18. What is an antibody? Name its four structural components.

Answer (Q18, Application). An antibody (immunoglobulin) is a secreted or membrane-bound glycoprotein produced by B cells/plasma cells that specifically binds antigen. Its four structural components are: two identical heavy chains and two identical light chains, joined by disulfide bonds, organized into two Fab regions (variable VH+VL domains forming the antigen-binding paratope) and one Fc region (constant domains that engage effector functions such as complement and Fc receptors). See section 27.

19. What are the five classes of immunoglobulin? State one function of IgG and one of IgA.

Answer (Q19, Application). The five immunoglobulin classes are IgG, IgM, IgA, IgE, and IgD, determined by the heavy-chain constant region. IgG is the dominant serum antibody in secondary responses: it opsonizes pathogens, neutralizes toxins, fixes complement, and crosses the placenta. IgA is the principal mucosal antibody: as secretory IgA it mediates immune exclusion of pathogens at gut, respiratory, and other mucosal surfaces without triggering inflammation. See section 27.

20. Describe the clonal selection theory of lymphocyte activation.

Answer (Q20, Application). Clonal selection theory states that each lymphocyte bears a single, randomly generated antigen-receptor specificity before encountering antigen. When an antigen binds the matching receptor, that specific clone is selected and stimulated to proliferate (clonal expansion) and differentiate into effector cells and long-lived memory cells. Self-reactive clones are deleted or inactivated during development, ensuring tolerance. This explains specificity, diversity, and immunological memory. See section 27.

Questions 21–30: Synthesis and Evaluation

21. What is the MHC (major histocompatibility complex)? Distinguish MHC class I from class II.

Answer (Q21, Synthesis). The MHC (major histocompatibility complex; HLA in humans) is a set of cell-surface molecules that present peptide antigens to T cells. MHC class I is expressed on virtually all nucleated cells, presents endogenous (cytosolic) peptides, and is recognized by CD8+ cytotoxic T cells (and surveyed by NK cells via ‘missing-self’). MHC class II is expressed on professional antigen-presenting cells, presents exogenous peptides, and is recognized by CD4+ helper T cells. See section 27.

22. What are cytotoxic T lymphocytes (CTLs)? What do they recognize and how do they kill target cells?

Answer (Q22, Synthesis). Cytotoxic T lymphocytes (CTLs) are CD8+ effector T cells that recognize foreign or aberrant peptides presented on MHC class I of infected or transformed cells via their T-cell receptor. On engagement they kill the target by two main mechanisms: releasing perforin and granzymes that trigger apoptosis, and engaging Fas (CD95) on the target with FasL to induce caspase-mediated death. See section 27.

23. What is an epidemic? What is a pandemic? Define basic reproduction number R_0 .

Answer (Q23, Synthesis). An epidemic is a sharp rise in cases of a disease above the expected baseline within a community or region; a pandemic is an epidemic that spreads across multiple countries or continents affecting large numbers of people. The basic reproduction number R_0 is the expected number of secondary cases produced by one infectious individual introduced into a fully susceptible population; $R_0 > 1$ allows an outbreak to grow, $R_0 < 1$ causes it to die out. See section 27.

24. What is herd immunity? How does vaccination achieve herd immunity?

Answer (Q24, Synthesis). Herd immunity is the indirect protection of susceptible individuals that occurs when a sufficiently large fraction of the population is immune, so an infectious person rarely contacts a susceptible one and chains of transmission break. Vaccination achieves it by immunizing enough people that the immune fraction exceeds the herd-immunity threshold $p_c = 1 - 1/R_0$, driving the effective reproduction number below 1. See section 27.

25. Name three mechanisms of antibiotic resistance evolution.

Answer (Q25, Synthesis). Three mechanisms of antibiotic-resistance evolution are: (1) enzymatic inactivation of the drug (e.g., β -lactamases hydrolyzing penicillins); (2) target modification or protection so the antibiotic no longer binds (e.g., altered penicillin-binding proteins, ribosomal methylation); and (3) reduced intracellular drug concentration via decreased uptake (porin loss) or active efflux pumps. Resistance genes often spread by horizontal gene transfer (conjugation, transduction, transformation). See section 27.

26. By 10 November 2024, WHO had received reports of more than 776.8 million confirmed COVID-19 cases globally, while also noting that reported cases undercount infections [World Health Organization, 2024b]. Estimate the herd immunity threshold ($H = 1 - 1/R_0$) if R_0 for the original strain was 2.5. For the Omicron variant ($R_0 \approx 10$), recalculate the threshold and explain what incomplete, waning protection means for vaccination strategy.

Answer (Q26, Synthesis). Use $H = 1 - 1/R_0$. For the original strain with $R_0 = 2.5$: $H = 1 - 1/2.5 = 1 - 0.40 = 0.60$, so about 60% of the population must be immune. For Omicron with $R_0 \approx 10$: $H = 1 - 1/10 = 0.90$, so about 90% must be immune under the simplifying assumption of durable sterilizing immunity and homogeneous mixing. In practice, infection-derived and vaccine-derived protection against infection and transmission is incomplete and wanes, so vaccination strategy should emphasize prevention of severe disease, boosters matched to current guidance, and layered controls during surges rather than a single coverage number. See section 27.

27. The inflammasome (NLRP3) is activated by uric acid crystals (gout), cholesterol crystals (atherosclerosis), and pathogens. Explain: (a) how NLRP3 assembles and activates caspase-1; (b) how caspase-1 cleaves pro-IL-1 β and pro-IL-18; (c) why NLRP3 inhibitors (MCC950) are under development for inflammatory diseases.

Answer (Q27, Synthesis). (a) A priming signal (e.g., LPS via TLR4) induces NLRP3 and pro-IL-1 β ; a second signal (uric acid or cholesterol crystals, K⁺ efflux, lysosomal damage) triggers NLRP3 to oligomerize and recruit the adaptor ASC, which clusters and activates pro-caspase-1. (b) Active caspase-1 proteolytically cleaves pro-IL-1 β and pro-IL-18 into mature, secreted cytokines (and cleaves gasdermin D to drive pyroptosis). (c) Because uncontrolled NLRP3 activity drives gout, atherosclerosis, and other sterile inflammation, selective inhibitors such as MCC950 are being developed to dampen IL-1 β without broad immunosuppression. See section 27.

28. Influenza can shift from H1N1 to H3N2 by antigenic shift (segment reassortment) or antigenic drift (point mutations in haemagglutinin). Explain: (a) why antigenic drift requires annual vaccine reformulation; (b) why antigenic shift can cause pandemics; (c) what “original antigenic sin” means for immune memory.

Answer (Q28, Synthesis). (a) Antigenic drift is the gradual accumulation of point mutations in hemagglutinin/neuraminidase that erode antibody recognition, so the vaccine strain must be reformulated annually to match circulating variants. (b) Antigenic shift is reassortment of genome segments (e.g., between human and avian/swine strains) producing a novel HA the population has no immunity to, which can ignite a pandemic. (c) ‘Original antigenic sin’ is the tendency of the immune system to preferentially recall antibodies against the first influenza strain encountered, blunting responses to newer drifted strains. See section 27.

29. The complement system (C1-C9) is a cascade of proteolytic activation that opsonises pathogens and lyses bacteria directly (MAC — membrane attack complex). Describe the three complement activation pathways (classical, lectin, alternative), naming the central converging point (C3 convertase), and explain how bacteria evade complement (factor H mimicry, capsule).

Answer (Q29, Synthesis). The classical pathway is triggered by antibody–antigen complexes binding C1q; the lectin pathway by mannose-binding lectin recognizing microbial carbohydrates; the alternative pathway by spontaneous C3 hydrolysis and direct surface deposition. All three converge on formation of C3 convertase, which cleaves C3 into C3a (anaphylatoxin) and C3b (opsonin), leading to the C5 convertase and assembly of the

membrane attack complex (C5b–C9). Bacteria evade complement by recruiting host factor H (or mimicking it) to accelerate C3b decay and by using polysaccharide capsules that block C3b deposition and MAC insertion. See section 27.

30. Natural killer (NK) cells kill virus-infected cells that downregulate MHC class I (a strategy used by many viruses to evade CTLs). Explain the “missing self” hypothesis: how do inhibitory KIR receptors normally inhibit NK killing, and how does MHC class I downregulation remove inhibition and trigger NK-mediated lysis?

Answer (Q30, Synthesis). Under the ‘missing-self’ hypothesis, NK cells continuously sample target cells: inhibitory KIRs (e.g., KIR2DL, KIR3DL) bind self MHC class I and deliver a dominant inhibitory signal that overrides activating receptor signals, sparing healthy cells. Many viruses down-regulate MHC class I to hide infected cells from CD8+ CTLs, but this removes the ligand for inhibitory KIRs. With inhibition lost and activating receptors still engaged, the NK cell is unleashed and lyses the MHC-low target via perforin/granzyme. See section 27.

Questions — Plant Structure and Water Relations

Instructor Use and Coverage Notes

- Coverage target: Calculate water potential and predict the direction of water movement.
- Model/data emphasis: Water-potential and transpiration-flux calculations.
- Assessment alignment: Visual Representations, Questions and Methods, Argumentation.
- Misconception probe: Water does not move because plants pull with intention; it follows potential gradients and cohesion.
- Transfer product: Transfer plant-water reasoning to drought, irrigation, forest physiology, and crop breeding.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 28 of the textbook — review that chapter before attempting the exercises below.

1. Name the three major tissue systems in plants. Give one cell type belonging to each.

Answer (Q1, Recall). The three plant tissue systems are dermal, ground, and vascular. Dermal tissue is the outer protective covering; a representative cell type is the epidermal cell (e.g., a guard cell or root-hair cell). Ground tissue fills the interior; parenchyma (thin-walled, living, photosynthetic or storage cells) is a representative type, alongside collenchyma and sclerenchyma. Vascular tissue is the long-distance transport network; xylem (tracheids, vessel elements) and phloem (sieve-tube elements, companion cells) are its cell types. See section 28. 2. What is the difference between dermal, ground, and vascular tissue?

Answer (Q2, Recall). Dermal tissue (epidermis plus cuticle, trichomes, root hairs) is a single outer protective layer that limits water loss and mediates exchange with the environment. Ground tissue (parenchyma, collenchyma, sclerenchyma) fills the body between dermal and vascular tissue, performing photosynthesis, storage, and mechanical support. Vascular tissue (xylem and phloem) is the internal long-distance transport network: xylem moves water and minerals upward, phloem moves sugars bidirectionally. The functional distinction is protection vs. bulk metabolism/support vs. transport. See section 28. 3. Define xylem and phloem. Which transports water and which transports sugars?

Answer (Q3, Recall). Xylem is the vascular tissue that conducts water and dissolved minerals upward from roots to shoots; its conducting cells (tracheids and vessel elements) are dead and lignified at maturity. Phloem is the vascular tissue that transports sugars (sucrose at 0.3–0.9 M) plus amino acids and signaling molecules bidirectionally from sources to sinks; its sieve-tube elements remain alive (though they lack a nucleus). Xylem transports water; phloem transports sugars. See section 28. 4. What are tracheids and vessel elements? How do they differ structurally?

Answer (Q4, Recall). Both are water-conducting xylem cells that are dead and lignified at maturity. Tracheids are long (1–5 mm), narrow, tapered cells; water passes between them only through bordered pit pairs, making them less efficient but more cavitation-resistant, and they are the sole conducting element in most gymnosperms. Vessel elements are shorter (0.2–1 mm) but much wider (up to about 500 μm) and stack end-to-end with perforation plates (dissolved end walls) to form open vessels, giving higher conductance but greater vulnerability to embolism; they occur mainly in angiosperms. See section 28. 5. Define water potential (Ψ). Write the equation $\Psi = \Psi_s + \Psi_p$.

Answer (Q5, Recall). Water potential (Ψ, units MPa) is the free energy of water per unit volume relative to pure water at atmospheric pressure; water moves spontaneously from higher to lower Ψ. The simplified form is $\Psi = \Psi_s + \Psi_p$, where Ψ_s is the osmotic (solute) potential ($\Psi_s = -iCRT$, always ≤ 0) and Ψ_p is the pressure (turgor) potential (positive in turgid cells, negative in xylem under tension). The full four-component form is $\Psi = \Psi_s + \Psi_p + \Psi_m + \Psi_g$ (matric and gravitational terms added). See section 28. 6. What is the Casparian strip? In which cell layer is it found and what does it do?

Answer (Q6, Recall). The Casparian strip is a band of lignin (deposited first) and suberin in the radial and transverse walls of endodermal cells, the single cell layer surrounding the vascular cylinder of the root. By fusing the cell wall to the plasma membrane it blocks the apoplast pathway, forcing all water and ions to cross a selective plasma membrane (the symplast/transmembrane route) before entering the stele. This makes the endodermis the root’s selective filter, controlling which ions reach the xylem. See section 28. 7. Define transpiration. What drives transpiration in leaves?

Answer (Q7, Recall). Transpiration is the evaporative loss of water vapor from the plant, mainly through open stomata in the leaf. It is driven by the steep water-potential (vapor-pressure) gradient between the leaf interior and the much drier atmosphere ($\Psi \approx -100$ MPa at 50% RH): water evaporates from mesophyll cell-wall surfaces into the substomatal air space and diffuses out the stomata. This evaporation generates the tension that pulls the xylem water column upward. See section 28. 8. What are stomata? What cells regulate their opening and closing?

Answer (Q8, Recall). Stomata are pores in the epidermis (mostly on the lower/abaxial leaf surface) through which CO₂ enters and water vapor and O₂ exit. Each pore is bounded by two kidney-shaped guard cells, which regulate aperture by changing their turgor: K⁺ influx (with Cl[–] and malate^{2–})

lowers Ψ_s , water enters osmotically, the guard cells swell and bow apart, and the stoma opens; solute efflux (e.g., via ABA→SLAC1) reverses this and the stoma closes. See section 28. 9. What is root pressure? Under what conditions does it occur?

Answer (Q9, Recall). Root pressure is a positive xylem pressure (0.05–0.5 MPa) generated when roots actively secrete mineral ions into the xylem, lowering xylem Ψ_s so that water follows osmotically and pushes the xylem column upward. It occurs mainly at night and in well-watered soil when transpiration is low or absent (it is largely absent during the day in most species). It can lift water only about 5 m, so it cannot account for ascent in tall trees, but it can refill embolised conduits overnight. See section 28. 10. Describe the pressure-flow (Münch) hypothesis for phloem transport.

Answer (Q10, Recall). The Münch pressure-flow hypothesis explains phloem transport as bulk flow driven by an osmotically generated turgor gradient. At a source (e.g., a mature leaf) sucrose is loaded into sieve tubes, lowering Ψ_s so water enters osmotically from adjacent xylem and raises turgor pressure. At a sink (root, fruit) sucrose is unloaded, Ψ_s rises, water leaves, and turgor falls. The resulting source-to-sink pressure difference drives bulk flow of phloem sap through the sieve-tube network; the direction is set by which tissue is loading vs. unloading. See section 28.

Questions 11–20: Application and Analysis

11. A plant cell has $\Psi_s = -0.9$ MPa and $\Psi_p = +0.4$ MPa. Calculate its Ψ . If placed in a solution with $\Psi = -0.3$ MPa, will water enter or leave the cell? What will change as the cell reaches equilibrium?

Answer (Q11, Application). Use $\Psi = \Psi_s + \Psi_p$. Substituting: $\Psi = (-0.9 \text{ MPa}) + (+0.4 \text{ MPa}) = -0.5 \text{ MPa}$. The external solution is at $\Psi = -0.3$ MPa, which is higher (less negative) than the cell's -0.5 MPa. Because water moves from higher to lower Ψ , water enters the cell. As water enters, the cell swells, Ψ_p rises (and Ψ_s becomes slightly less negative through dilution); equilibrium is reached when cell Ψ rises to -0.3 MPa to match the solution. See section 28. 12. The cohesion-tension theory explains xylem water transport. Explain each component: (a) cohesion (H-bonds between water molecules); (b) adhesion (attraction to xylem walls); (c) tension (negative pressure from leaf transpiration). How does this mechanism pull water to 100 m in tall trees?

Answer (Q12, Application). (a) Cohesion: hydrogen bonds hold water molecules together so a continuous column in the xylem can sustain large negative pressure (theoretical tensile strength about -140 MPa; observed -1 to -15 MPa) without breaking. (b) Adhesion: water's attraction to the hydrophilic, lignified xylem walls keeps the column from pulling away from the conduit and helps support it. (c) Tension: evaporation from mesophyll cell-wall menisci (Young–Laplace, $\Delta P = 2\gamma\cos\theta/r$) creates strongly negative pressure that is transmitted down the continuous column. In a 100 m redwood, transpiration-generated tension overcomes the about 1.0 MPa gravitational drop plus flow resistance, pulling water up entirely passively. See section 28. 13. A researcher applies ABA (abscisic acid) to stomatal guard cells. Predict: (a) what happens to K^+ channels (efflux activated); (b) what happens to guard cell turgor; (c) what happens to stomatal aperture; (d) how CO_2 supply to mesophyll cells changes.

Answer (Q13, Application). ABA binds PYR/PYL receptors, inhibiting PP2C phosphatases and activating SnRK2/OST1. (a) OST1 opens SLAC1 anion channels (Cl^- /malate²⁻ efflux) and activates GORK outward-rectifying K^+ channels while inhibiting inward K^+ channels, so net K^+ efflux occurs and inward K^+ is blocked. (b) Loss of K^+ , Cl^- and malate raises guard-cell Ψ_s by about 1.5 MPa; water exits osmotically and guard-cell turgor falls. (c) Guard cells deflate, so the stomatal aperture closes (within about 5–15 min). (d) With stomata closed, CO_2 supply to mesophyll cells decreases, reducing photosynthesis—the cost of conserving water. See section 28. 14. Compare apoplastic vs symplastic water transport from root epidermis to the xylem. What role does the Casparian strip play in forcing water through the symplastic pathway? Why is this gatekeeping important for ion selection?

Answer (Q14, Application). In the apoplast pathway water and ions move through cell walls and intercellular spaces without crossing a membrane (fast, non-selective); in the symplast pathway they move cell-to-cell through plasmodesmata after one membrane crossing (slower, selective). At the endodermis the Casparian strip (lignin + suberin fused to the plasma membrane) blocks the apoplast, forcing all water and solutes to cross a selective plasma membrane to enter the stele. This gatekeeping matters because membrane transporters and aquaporins then determine which ions (e.g., NO_3^- , K^+) are admitted and exclude toxic ions, preventing uncontrolled bulk-flow leakage into the xylem. See section 28. 15. Phloem loading concentrates sucrose in sieve tubes at the source. Explain: (a) the apoplastic loading pathway (H^+ -sucrose co-transporter); (b) how increased solute concentration in sieve tubes lowers Ψ_s ; (c) how water follows by osmosis, generating turgor pressure that drives bulk flow toward the sink.

Answer (Q15, Application). (a) Apoplastic loading: SWEET11/12 export sucrose from mesophyll to the cell-wall space; the companion-cell H^+ -ATPase builds a proton gradient that the SUT1/SUC2 H^+ -sucrose symporter uses to pump sucrose into the sieve-tube/companion-cell complex against its concentration gradient (up to about 1 M). (b) The high sucrose concentration sharply lowers sieve-tube Ψ_s (to about -2 to -3 MPa). (c) The low Ψ draws water in by osmosis from adjacent xylem, raising turgor (Ψ_p) at the source; the source-to-sink turgor difference then drives bulk flow of phloem sap toward sinks. See section 28. 16. Cavitation (air bubble formation) in xylem vessels can block water transport. Explain: (a) how tension increases cavitation risk during drought; (b) how pit membranes between vessel elements limit cavitation spread; (c) how some trees (ring-porous oaks) repair cavitated vessels at night via root pressure.

Answer (Q16, Application). (a) During drought, transpiration drives xylem tension more negative; at sufficiently negative pressure dissolved gas nucleates a bubble (cavitation) that expands into an embolism, air-locking the conduit. (b) Bordered pit membranes between conduits limit spread: in conifers the torus seats against the pit aperture (an aspirated pit) when a neighbor embolises; angiosperm homogeneous membranes resist air-seeding until breached, confining damage conduit-by-conduit. (c) At night transpiration ceases and roots actively secrete ions into the xylem, generating positive root pressure (0.05–0.5 MPa) that dissolves the trapped gas and refills embolised conduits—observed in ring-porous trees and species such as *Vitis* and *Laurus*. See section 28. 17. A potometer measures transpiration rate by tracking water uptake. If a leafy shoot uptakes 4.5 mL/h at 25°C and 2.0 mL/h at 15°C, calculate: (a) the Q_{10} for transpiration; (b) what factor associated with temperature change drives this difference; (c) why humidity must also be controlled.

Answer (Q17, Application). (a) $Q_{10} = (R_2/R_1)^{(10/\Delta T)} = (4.5/2.0)^{(10/(25-15))} = (2.25)^1 = 2.25$. (b) The dominant temperature-linked driver is the leaf-to-air vapor-pressure difference (Δw): warmer air greatly increases the saturation vapor pressure inside the leaf relative to ambient, steepening the gradient that drives transpiration $E = g_s \Delta w$ (warming also slightly raises water’s diffusion/evaporation rate). (c) Humidity must be held constant because ambient relative humidity directly sets Δw ; if humidity changed between trials it would alter transpiration independently of temperature and confound the measured Q_{10} . See section 28. 18. Mycorrhizal fungi dramatically increase root surface area and provide phosphorus to plants in exchange for photosynthetic carbon. Compare arbuscular mycorrhizae (AM, intracellular fungal hyphae) vs ectomycorrhizal (ECM, extracellular mantle). Estimate the increase in effective root absorptive area (10× to 1,000×) and explain why nearly 90% of plant species have mycorrhizal associations.

Answer (Q18, Application). Arbuscular mycorrhizae (AM) penetrate root cortical cells, forming intracellular arbuscules for nutrient exchange and an extensive external hyphal network; they associate with about 80% of land plants. Ectomycorrhizae (ECM) form an external sheath (mantle) plus an intercellular Hartig net without entering cells, typical of many forest trees. Because fungal hyphae are far thinner than roots, they explore soil pores roots cannot reach and increase effective absorptive surface roughly 10× to 1,000×. This is decisive for phosphorus, which diffuses very slowly and is rapidly depleted in a root-only depletion zone, explaining why about 90% of plant species rely on mycorrhizal symbiosis (trading photosynthetic carbon for P). See section 28. 19. Halophytes (salt-tolerant plants) grow in saline soils ($\Psi_s < -1.0$ MPa). Explain three strategies: (a) accumulation of compatible solutes (proline) to lower Ψ_s ; (b) ion compartmentalization into vacuoles (NHX1 Na^+/H^+ antiporter); (c) salt secretion via specialized salt glands.

Answer (Q19, Application). In saline soil ($\Psi_s < -1.0$ MPa) the soil Ψ is very negative, so halophytes must lower internal Ψ further to keep water moving inward while avoiding ion toxicity. (a) They synthesize compatible solutes such as proline and glycine betaine in the cytoplasm, lowering Ψ_s osmotically without poisoning enzymes. (b) They compartmentalise Na^+ into the vacuole via the tonoplast NHX1 Na^+/H^+ antiporter, using the toxic ion as a cheap vacuolar osmoticum while protecting the cytosol. (c) Some species export salt through specialized epidermal salt glands or bladders, secreting Na^+/Cl^- to the leaf surface. Together these maintain a favorable Ψ gradient for water uptake under salt stress. See section 28. 20. A plant anatomist sections a dicot stem and a monocot stem. List four differences in vascular bundle arrangement, cambium presence, cortex/pith proportions, and secondary growth capability.

Answer (Q20, Application). Four contrasts: (1) Vascular bundle arrangement—dicot stems have bundles in a single ring around the pith; monocot stems have bundles scattered throughout the ground tissue. (2) Vascular cambium—present between xylem and phloem in dicots (a continuous lateral meristem); absent or non-functional in monocots. (3) Cortex/pith organization—dicots show a distinct cortex and central pith separated by the bundle ring; monocots lack a discrete pith/cortex boundary because bundles are dispersed. (4) Secondary growth—dicots undergo secondary thickening (wood) via the cambium; monocots generally lack true secondary growth. See section 28.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the limits of the cohesion-tension theory: the maximum theoretical xylem tension is approximately −20 MPa, but measured tensions rarely exceed −3 MPa. Does this discrepancy refute the theory? Discuss the “vulnerability curve” (loss of hydraulic conductivity vs tension) and how different species show different cavitation thresholds. What evolutionary strategies balance xylem safety vs efficiency?

Answer (Q21, Synthesis). The discrepancy does not refute the theory. Cohesion-tension predicts metastable negative pressures sustained by water’s cohesion in narrow conduits, and direct evidence (Scholander pressure-bomb, in vivo MRI, pressure probes, synchrotron micro-CT, and synthetic-tree devices sustaining −22 MPa) confirms genuine tension. Most species operate well within their safety margin: vulnerability curves (percent loss of conductivity vs. tension) show a species-specific P50 where embolism becomes catastrophic, and conifers with torus-margo pits tolerate about −6 MPa whereas many ring-porous angiosperms cavitate near −2 MPa. Evolution tunes the safety–efficiency trade-off: wide vessels maximize conductance (Hagen–Poiseuille, $Q \propto r^4$) but cavitate easily; narrow tracheids sacrifice efficiency for embolism resistance—so operating tensions stay below P50 by design. The conditional cavitation threshold is not a universal failure point. See section 28. 22. Design an experiment to measure the hydraulic conductivity of a stem segment. Describe the apparatus (pressure head, flow rate measurement), the calculation ($K_h = \text{flow rate} \times \text{segment length} / \text{pressure difference}$), and how you would normalize for sapwood area. What would you expect for a conifer (tracheids primarily)

vs a diffuse-porous angiosperm (vessel elements)?

Answer (Q22, Synthesis). Hypothesis: hydraulic conductivity (K_h) scales with conduit diameter, so a vessel-bearing angiosperm conducts more per sapwood area than a tracheid-only conifer. Apparatus: mount a cut stem segment between a water reservoir and an outlet, apply a low constant pressure head (e.g., a fixed water column), and measure steady volumetric flow gravimetrically. Compute $K_h = (\text{flow rate} \times \text{segment length}) / \text{pressure difference}$, then normalize by dividing by sapwood cross-sectional area (specific conductivity). Control for embolism by flushing/vacuum-infiltrating and run replicate segments. Prediction from Hagen–Poiseuille ($Q \propto r^4$): a 200- μm vessel vs. a 30- μm tracheid gives a per-conduit flow ratio of $(200/30)^4 \approx 1.97 \times 10^3$, so the diffuse-porous angiosperm should show much higher specific conductivity than the conifer; a result with conifer \geq angiosperm would falsify the prediction. See section 28. 23. Evaluate the evidence that aquaporins regulate short-term water transport in roots. How does the abundance and phosphorylation state of root aquaporins (PIP1, PIP2 subfamilies) change in response to: (a) drought; (b) flooding; (c) diurnal light cycles? What does this imply about the relative importance of the apoplastic vs symplastic pathway under different environmental conditions?

Answer (Q23, Synthesis). Evidence (pressure-probe and reverse-osmosis experiments, plus aquaporin knockouts) shows root hydraulic conductance changes within minutes—too fast for anatomical change—implicating aquaporin gating, separate from the steady empirical fact that aquaporins also supply guard-cell water flux. (a) Drought: ABA and dephosphorylation generally close PIP aquaporins, reducing radial conductance and shifting flow toward the regulated transmembrane/symplast route. (b) Flooding/anoxia: cytosolic acidification and dephosphorylation close PIPs, lowering root water uptake (contributing to flooded-plant wilting). (c) Diurnal cycle: PIP abundance and phosphorylation rise during the day to support high transpiration and fall at night. Implication: when aquaporins dominate, the transmembrane/symplast pathway controls uptake; when they are downregulated the apoplast contributes relatively more, but this is conditional on stress state, not a universal hierarchy. See section 28. 24. Propose a bioengineering strategy to improve drought tolerance in crop plants by manipulating water transport. Compare three approaches: (a) engineering deeper root systems (overexpressing DRO1); (b) increasing xylem vessel diameter for greater hydraulic conductivity; (c) constitutively closing stomata (overexpressing OST1 kinase). For each, evaluate the trade-off between water conservation and carbon assimilation. Which strategy is most promising for wheat in arid environments?

Answer (Q24, Synthesis). (a) Deeper roots (DRO1 overexpression) reach deeper soil water with little carbon penalty and no loss of stomatal CO_2 uptake—high water access, minimal assimilation cost. (b) Wider xylem vessels raise conductivity ($Q \propto r^4$) and growth in good years but greatly increase cavitation vulnerability, so the gain collapses under severe drought (a safety–efficiency loss). (c) Constitutive stomatal closure (OST1 overexpression) strongly conserves water and raises water-use efficiency (e.g., WUE rising from about 100 to about 160 in worked chapter examples) but lowers CO_2 assimilation and yield potential. For wheat in arid environments the deeper-root strategy is most promising because it improves water supply without sacrificing carbon gain, whereas (b) is fragile under drought and (c) caps yield; combining (a) with mild (c) is the realistic optimum. The decision rule: maximize water access first, trade stomatal conductance only where water is the binding constraint. See section 28. 25. Phloem transport speed is about 1 m/h. Calculate: if a tree is 30 m tall and assimilate loading occurs in the canopy, how long does it take for sucrose to reach root tips? Compare this to xylem transport speed (about 10–40 m/h). What limits phloem transport speed (viscosity of concentrated sucrose solution, sieve plate resistance)?

Answer (Q25, Synthesis). At about 1 m/h phloem speed, sucrose loaded in a 30 m canopy reaches the root tips in time = distance/speed = 30 m \div 1 m/h = 30 hours. Xylem moves much faster (about 10–40 m/h), so the same 30 m would take only about 0.75–3 h—phloem transport is roughly 10–40 \times slower than xylem. Phloem speed is limited by the high viscosity of concentrated sucrose sap (0.3–1 M) and the hydraulic resistance of the sieve plates (narrow sieve pores, P-protein), which together constrain the bulk-flow rate that a given source-to-sink turgor gradient can sustain. See section 28. 26. Evaluate the evolutionary transition from tracheids (present in most vascular plants) to vessel elements (present in angiosperms and some gymnosperms). What anatomical changes (perforation plates, wider diameter) conferred increased hydraulic efficiency, and what trade-offs (increased vulnerability to cavitation) accompanied this transition? How does this relate to the ecological dominance of angiosperms?

Answer (Q26, Synthesis). The evidence: tracheids occur in all vascular plants and are the only conducting element in most gymnosperms, whereas vessel elements (shorter, much wider, end walls dissolved into perforation plates) evolved chiefly in angiosperms. Perforation plates and larger diameter remove most of the cell-to-cell resistance and, via Hagen–Poiseuille ($Q \propto r^4$), greatly raise hydraulic efficiency, supporting high transpiration and rapid growth. The trade-off is greater cavitation vulnerability—wide open vessels embolise and propagate air-locks more readily than narrow, pit-isolated tracheids. The boundary condition: this is not a universal “vessels are better” claim; in cold or drought-prone habitats embolism risk can favor tracheids. Higher conductance plausibly contributed to angiosperm ecological dominance in productive, well-watered environments, but the advantage is context-dependent rather than absolute. See section 28. 27. The pressure-flow model (Münch) for phloem transport makes predictions about: (a) turgor in source vs sink phloem; (b) the osmotic potential gradient between source and sink; (c) the effect of girdling (removing phloem) on sugar accumulation above the girdle. Evaluate each prediction using experimental evidence, and assess the main criticism of the model (can passive flow alone explain transport over >50 m?).

Answer (Q27, Synthesis). (a) Münch predicts higher turgor in source phloem than sink phloem; turgor-probe and aphid-stylet measurements confirm a source-to-sink pressure gradient. (b) It predicts a Ψ_s gradient set by loading—more negative Ψ_s (high sucrose, about -2 to -3 MPa) at the source, less negative at the sink; sap-sampling supports this, and removing lower leaves of soybean reverses flow within hours, consistent with passive bulk flow following the pressure gradient. (c) It predicts girdling (severing phloem) blocks downward sugar movement, causing carbohydrate accumulation above the girdle and starvation below—classically observed. Main criticism: in very tall trees (>50 m) sieve-plate resistance may make a single passive gradient insufficient; the resolution invokes relay loading/unloading and active maintenance of the gradient rather than abandoning pressure flow. See section 28. 28. Evaluate the role of plasmodesmata in cell-to-cell communication in plants. How do plasmodesmata allow selective symplastic transport (size exclusion limit about 1 kDa), what signals move through them (transcription factors like KNOTTED1, siRNAs), and how do viruses exploit plasmodesmata for cell-to-cell spread (movement proteins)?

Answer (Q28, Synthesis). Plasmodesmata are ER-lined cytoplasmic channels (about 40–60 nm) linking adjacent cells into a symplastic continuum, normally with a size-exclusion limit near about 1 kDa; their neck aperture is dynamically set by callose deposition, so under stress callose closes them and isolates cells. The evidence (dye-coupling, viral movement-protein studies) shows the limit is not fixed: developmental signals such as the transcription factor KNOTTED1 and silencing siRNAs traffic cell-to-cell through dilated plasmodesmata, and plant viruses encode movement proteins that bind their genome and gate plasmodesmata open to spread infection. The conclusion that plasmodesmata are simple fixed-size pores would change given this regulated, exploitable gating—they are actively controlled communication conduits, conditional on developmental and pathogen context. See section 28. 29. Climate change increases atmospheric CO_2 and temperature, both of which affect transpiration, stomatal conductance, and water-use efficiency. Evaluate the predicted effects on forest water balance: (a) increased $\text{CO}_2 \rightarrow$ partial stomatal closure \rightarrow reduced transpiration \rightarrow increased runoff; (b) increased temperature \rightarrow increased VPD \rightarrow increased transpiration \rightarrow drought stress. Which effect dominates in tropical forests vs boreal forests?

Answer (Q29, Synthesis). (a) Rising CO_2 triggers partial stomatal closure (CO_2 -sensing converging on SLAC1), lowering g_s and transpiration and raising intrinsic water-use efficiency ($\text{iWUE} = A_n/g_s$; chapter example WUE rising about $100 \rightarrow 160$), which can leave more soil water and increase catchment runoff. (b) Higher temperature raises the leaf-to-air vapor-pressure deficit, increasing $E = g_s \cdot \Delta w$ and pushing trees toward drought stress and cavitation despite partial closure. Which dominates is conditional: in tropical forests the warming/VPD effect tends to dominate (already warm, high evaporative demand, drought-driven dieback risk), whereas in boreal forests the CO_2 -fertilization/water-saving effect is relatively larger because evaporative demand and temperatures are lower. The net forest water balance therefore depends on biome, not a single universal direction. See section 28. 30. Critically evaluate whether the “hydraulic architecture” of a tree (the specific pattern of vessel diameters, vessel density, and branch tapering from base to tip) is optimized by natural selection for efficient water delivery. Apply Murray’s law (branching geometry) and the “safety vs efficiency” trade-off framework. What does damage from extreme drought events reveal about the limits of optimization?

Answer (Q30, Synthesis). Empirically, hydraulic architecture shows strong patterning: vessels widen basipetally (tip-to-base), branch junctions taper, and Murray’s law (conserving the sum of conduit radii cubed across branchings) predicts the diameter distribution that minimizes the carbon cost of achieving a given conductance—observed approximately in many species, evidence that selection optimizes water delivery within the safety–efficiency trade-off (wide conduits maximize $Q \propto r^4$ but cavitate readily). However, this optimization is conditional, not absolute: extreme drought drives widespread “hydraulic failure” and dieback (e.g., the 2011 Texas drought killed about 300 million trees), revealing that architectures tuned to historic climate envelopes are not optimal against novel extremes. What would change the “optimized” conclusion is evidence that trees routinely operate far from Murray’s-law predictions or fail well within their historical climate—so optimization holds within a bounded environmental range, not universally. See section 28.

Questions — Plant Reproduction and Development

Instructor Use and Coverage Notes

- Coverage target: Trace a plant life cycle and predict the consequence of disrupting one stage.
- Model/data emphasis: Life-cycle accounting and phyllotaxis/growth-pattern calculations.
- Assessment alignment: Visual Representations, Questions and Methods, Argumentation.
- Misconception probe: Pollen, spores, seeds, and gametes are not interchangeable terms.
- Transfer product: Transfer reproductive reasoning to agriculture, pollination ecology, and plant evolution.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 29 of the textbook — review that chapter before attempting the exercises below.

1. Describe the alternation of generations in plant life cycles. What is the gametophyte? What is the sporophyte?

Answer (Q1, Recall). Alternation of generations is the diphasic plant life cycle in which a diploid sporophyte and a haploid gametophyte alternate. The sporophyte (2n) produces haploid spores by meiosis in sporangia. Each spore grows by mitosis into the gametophyte (n), which produces gametes by mitosis. Fertilization (syngamy) of two gametes restores the diploid sporophyte. The sporophyte is the spore-producing diploid generation (dominant in vascular plants); the gametophyte is the gamete-producing haploid generation (dominant in bryophytes, reduced to a few cells in angiosperms). See section 29.

2. Name the male and female parts of a flower and state their functions.

Answer (Q2, Recall). The male part is the androecium, made of stamens (filament + anther); the anther produces pollen grains (the male gametophyte). The female part is the gynoecium (carpel/pistil), comprising stigma (receives pollen), style (pollen-tube passage), and ovary (encloses ovules). The stamen’s function is pollen production and delivery; the carpel’s function is pollen reception, pollen-tube guidance, and protection of the ovules in which fertilization occurs. (Imperfect flowers carry only one of these whorls.) See section 29.

3. What is pollination? Distinguish self-pollination from cross-pollination.

Answer (Q3, Recall). Pollination is the transfer of pollen from an anther to a receptive stigma (in angiosperms) or to the ovule (in gymnosperms), the step that precedes pollen-tube growth and fertilization. Both self- and cross-pollination achieve this transfer; the difference that changes genetic outcome is the source of pollen: self-pollination delivers pollen to a stigma of the same flower or plant (promoting homozygosity), whereas cross-pollination delivers pollen between different individuals (maintaining heterozygosity). Self-incompatibility systems exist specifically to block self-pollen and enforce outcrossing. See section 29.

4. What is double fertilization in angiosperms? What two structures result?

Answer (Q4, Recall). Double fertilization, the defining synapomorphy of angiosperms (discovered by Nawaschin, 1898), is the fusion of two sperm cells from one pollen tube with two cells of the embryo sac. One sperm fuses with the egg cell to form the diploid (2n) zygote, which develops into the embryo. The second sperm fuses with the central cell’s two polar nuclei to form the triploid (3n) primary endosperm nucleus, which develops into the nutritive endosperm. The two resulting structures are the embryo and the endosperm. See section 29.

5. What is a seed? Name its three components.

Answer (Q5, Recall). A seed is a mature, fertilized ovule: a packaged embryo with a stored food supply enclosed in a protective coat, allowing the new sporophyte to disperse and survive without external water for fertilization. Its three components are: (1) the embryo (the young sporophyte, with radicle, hypocotyl, and one or two cotyledons); (2) stored food (triploid endosperm in cereals, or female gametophyte tissue in gymnosperms, or cotyledons in many eudicots); and (3) the seed coat (testa), derived from the ovule integuments. See section 29.

6. What is a fruit? How does it develop after fertilization?

Answer (Q6, Recall). A fruit is the mature ovary wall (the pericarp: exocarp + mesocarp + endocarp), sometimes incorporating accessory tissue, that encloses and disperses the seeds. After fertilization, auxin from the developing seeds and gibberellins from the pericarp suppress the abscission program (fruit set); cytokinins then drive pericarp cell division and auxin/GA drive cell expansion; finally ripening occurs (in climacteric fruits via an autocatalytic ethylene burst that softens walls, accumulates sugars, and changes pigments). The pericarp differentiates into fleshy or dry fruit types adapted for dispersal. See section 29.

7. Define germination. Name three environmental factors required.

Answer (Q7, Recall). Germination is the resumption of growth by a quiescent embryo, beginning with imbibition of water and ending with radicle emergence; it occurs when the ABA/GA hormonal balance tips toward GA, allowing mobilization of stored reserves by α -amylase, lipases, and proteases. Three environmental factors required are: (1) water (imbibition activates metabolism), (2) oxygen (for aerobic respiration powering growth), and (3) a suitable temperature (within the species’ range; for many seeds an additional specific cue such as light/Pfr or cold stratification is also needed). See section 29.

8. What is vegetative reproduction? Give two examples.

Answer (Q8, Recall). Vegetative (asexual) reproduction is the production of new, genetically identical plants from somatic (non-reproductive) plant parts, without seeds or fertilization, so each offspring is a clone of the parent. Two examples: stolons/runners (horizontal above-ground stems that root and form daughter plants at nodes, as in strawberry) and rhizomes (horizontal underground stems with nodes and adventitious roots, as in ginger or bamboo). Bulbs, corms, tubers, adventitious plantlets, and layering are additional mechanisms. See section 29. 9. What is meristem tissue? Distinguish apical meristems from lateral meristems.

Answer (Q9, Recall). Meristematic tissue consists of undifferentiated, actively dividing cells that generate all new plant cells and tissues; the shared principle is that growth is localized to these stem-cell regions. Apical meristems occur at shoot and root tips (the SAM, regulated by the WUS-CLV3 feedback loop, and the RAM, with its quiescent center) and drive primary growth — increase in length. Lateral meristems (vascular cambium and cork cambium) form cylinders along stems and roots and drive secondary growth — increase in girth (wood and bark). The decisive difference is axis of growth: primary/length vs. secondary/thickness. See section 29. 10. What is photoperiodism? Distinguish long-day, short-day, and day-neutral plants.

Answer (Q10, Recall). Photoperiodism is a plant's flowering response to the relative lengths of day and night, with night length being the true measured signal (sensed via the phytochrome system). The shared principle is a critical night-length threshold that gates the floral transition. Short-day plants flower when the night exceeds a critical length (e.g., chrysanthemum, poinsettia); long-day plants flower when the night is shorter than a critical length (e.g., spinach, many cereals); day-neutral plants flower after sufficient vegetative growth regardless of photoperiod (e.g., tomato). The decisive contrast is the direction of the night-length threshold (or its absence). See section 29.

Questions 11–20: Application and Analysis

- Double fertilization: one sperm fuses with the egg (2n zygote), another fuses with the central cell (3n endosperm). Explain the evolutionary advantage of triploid endosperm vs a haploid nutritive tissue. Why is endosperm essential for seed development in cereals?

Answer (Q11, Application). In double fertilization one sperm yields the 2n zygote and the other yields the 3n endosperm. Triploid endosperm has the advantage that it forms only after fertilization (“payment on delivery”): unfertilised ovules do not develop nutritive tissue, so maternal resources are invested only in viable seeds. The 2 maternal : 1 paternal genome dosage also creates a regulated arena (PEG/MEG genomic imprinting via FIS-PRC2) balancing paternal nutrient-extraction genes against maternal rationing genes — fine-tuning provisioning across offspring, which a uniparental haploid tissue could not do. In cereals the endosperm is essential because it is the bulk storage tissue (starch 60–70%, storage proteins, oils) that nourishes the germinating seedling and supplies about 60% of human calories. See section 29. 12. SI (self-incompatibility) mechanisms prevent self-pollination. In gametophytic SI (e.g., *Nicotiana*), pollen S-RNases degrade RNA in incompatible (self) pollen tubes. Explain: (a) the molecular logic — why would a plant destroy its own pollen; (b) the advantage for genetic diversity; (c) how SI is overcome in commercial apple orchards (polliniser trees).

Answer (Q12, Application). (a) In gametophytic SI the style secretes S-RNases; an incoming pollen tube expresses SLF F-box proteins that tag and degrade only non-self S-RNases. When pollen carries a matching (self) S-haplotype, its SLFs cannot recognize the matching S-RNase, so the self S-RNase survives and destroys the tube's ribosomal RNA, arresting growth. The plant “destroys its own pollen” to prevent self-fertilization. (b) This enforces outcrossing, maintaining heterozygosity and avoiding inbreeding depression and accumulated genetic load. (c) Apple is gametophytic-SI, so a single self-incompatible cultivar sets little fruit; orchards interplant a compatible polliniser cultivar with a different S-genotype (and use bees) so cross-pollen carries non-matching S-alleles and fertilizes successfully. See section 29. 13. Seed dormancy allows seeds to delay germination until conditions are favorable. Explain: (a) the role of ABA (prevents germination) vs gibberellin (promotes germination); (b) why stratification (cold treatment) breaks dormancy in temperate-region seeds; (c) the ecological advantage of dormancy for fire-adapted species (heat-triggered germination).

Answer (Q13, Application). (a) Dormancy is governed by the ABA/GA balance: high ABA (acting through PYR/RCAR-PP2C-SnRK2 and stabilizing DELLA via DOG1) blocks germination, while GA promotes germination by triggering DELLA degradation, releasing α -amylase, lipase, and protease genes that mobilize reserves. (b) Cold-moist stratification (1–5 °C, weeks–months) progressively degrades ABA and induces GA-biosynthesis genes, shifting the balance toward germination — so temperate seeds shed in autumn germinate only after winter, timing emergence to spring. (c) For fire-adapted species, heat scarification cracks the impermeable testa and smoke-derived karrikins (via the KAI2 receptor) trigger germination, so seeds germinate after fire when competition is low and nutrients are released — an ecological advantage of enforced dormancy. See section 29. 14. Fruit types: distinguish fleshy fruits (berry, drupe, pome) from dry fruits (achene, capsule, legume). For each type, name an example species and explain how the fruit structure promotes seed dispersal (animal, wind, water, or ballistic).

Answer (Q14, Application). Both fleshy and dry fruits are matured pericarp; the difference that changes dispersal is whether the pericarp stays succulent (reward) or dries (mechanical/wind). Fleshy: a berry has an entirely fleshy pericarp (tomato, grape) and a drupe has a fleshy mesocarp plus stony endocarp (cherry, peach); a pome includes accessory receptacle tissue (apple) — all promote endozoochory (animals eat the fruit and void

hard seeds elsewhere). Dry: an achene is a dry one-seeded fruit (sunflower; dandelion's pappus gives wind dispersal/anemochory), a capsule dries and dehisces by pores/valves (poppy; wind-shaken/gravity), and a legume is a pod that splits explosively along two sutures (pea; ballistic dispersal). Fruit structure thus matches the dispersal vector. See section 29. 15. Arabidopsis ABCE model of floral organ identity: A genes → sepals; A+B → petals; B+C → stamens; C → carpels; E is required in most whorls. Predict the floral phenotype when: (a) the B gene is knocked out; (b) the A gene is knocked out; (c) both A and C are knocked out. What would each mutant flower look like?

Answer (Q15, Application). Using the ABC(E) model (A→sepal whorl 1; A+B→petal whorl 2; B+C→stamen whorl 3; C→carpel whorl 4; A and C are mutually antagonistic so loss of one lets the other spread): (a) B knockout (ap3/pi): no petals or stamens — whorls become sepal, sepal, carpel, carpel. (b) A knockout: C spreads into all whorls — carpel, stamen, stamen, carpel (whorls 1–2 become carpels because C now acts there). (c) A and C both knocked out (with E present): the antagonists are gone; B still acts in whorls 2–3, so the flower is sepal/leaf-like in whorl 1, then petal, petal, and leaf-like in whorl 4 — and, lacking C, the floral meristem is indeterminate, producing reiterated whorls. See section 29. 16. Pollen tube navigation: pollen tubes grow through the style following chemical gradients (e.g., LURE peptides from the synergid cells flanking the egg cell). Explain: (a) how Ca^{2+} oscillations drive directional tip growth; (b) the role of the filiform apparatus in synergid cells; (c) what happens if a pollen tube arrives at an already-fertilized ovule (polytubey block).

Answer (Q16, Application). (a) Pollen-tube tip growth is driven by a tip-focused cytosolic Ca^{2+} gradient (about 1.5–10 μM at the apex vs. about 150 nM in the shank); oscillating Ca^{2+} at the tip directs targeted exocytosis of wall vesicles (callose/pectin), so steering LURE-PRK6 signaling reorients the Ca^{2+} peak and bends growth toward the ovule. (b) The synergids' filiform apparatus is an elaborate cell-wall labyrinth at the micropylar pole that vastly increases secretory surface area, releasing the species-specific LURE peptides that guide the tube into the micropyle. (c) On arrival one synergid degenerates and the FERONIA–LORELEI complex triggers tube rupture and sperm release; once fertilization occurs, the persistent synergid is silenced/eliminated (synergid-FER signaling shut down), removing the LURE source so additional tubes are not attracted — the polytubey block preventing polyspermy. See section 29. 17. Apomixis (asexual seed production without fertilization) occurs naturally in some grasses and dandelions. Explain: (a) the mechanism (unreduced embryo sac, parthenogenesis); (b) why agriculture would benefit from engineered apomixis in hybrid crops (fixing heterosis permanently); (c) the rice synthetic-apomixis approach using MiMe plus a parthenogenesis trigger; (d) what field-translation risks remain.

Answer (Q17, Application). (a) Apomixis produces seeds without fertilization: an unreduced (2n) embryo sac forms by apospory from a somatic nucellar cell or diplospory by skipping meiosis, and its unreduced egg develops parthenogenetically into an embryo genetically identical to the mother; endosperm forms either autonomously or pseudogamously. (b) Engineering apomixis into hybrid crops could fix heterosis in self-perpetuating seed, so farmers could save F1 seed rather than re-making annual production crosses. (c) Rice synthetic apomixis combines MiMe (knockout of OSD1, PAIR1, REC8, turning meiosis toward mitosis and producing unreduced gametes) with a parthenogenesis trigger such as BBM expression or MATRI-LINEAL disruption, yielding maternal clones in seed across generations. (d) Translation still needs field seed-set data, rare aneuploid monitoring, stability across climates, gene-flow containment, and governance around who controls the self-propagating seed trait. See section 29. 18. Compare seed dispersal strategies: epizoochory (burs attaching to animal fur), endozoochory (fleshy fruits eaten by birds), anemochory (wind, e.g., dandelion pappus), hydrochory (water, coconut). For each, predict which seed/fruit trait is maximized (adhesion strength, palatability, surface area, buoyancy).

Answer (Q18, Application). All four are dispersal strategies of the matured pericarp/seed; the difference that changes the maximized trait is the vector. Epizoochory (burs such as burdock/cocklebur) maximizes adhesion strength — hooks/spines that grip animal fur or feathers. Endozoochory (fleshy berries/drupes eaten by birds) maximizes palatability and a nutritious, brightly colored pulp with a gut-resistant seed coat. Anemochory (dandelion pappus, maple samara) maximizes surface-area-to-mass ratio (plumes or wings increasing drag/lift for wind transport). Hydrochory (coconut) maximizes buoyancy and water/salt tolerance (fibrous, air-filled mesocarp for ocean rafting). Each fruit trait is tuned to its dispersal mechanism. See section 29. 19. The transition from vegetative to reproductive growth (floral transition) is controlled by the florigen protein FT (FLOWERING LOCUS T) produced in leaves and transported via phloem to the shoot apical meristem. Explain: (a) how photoperiod (sensed by CONSTANS protein in leaves) triggers FT expression; (b) how FT interacts with FD transcription factor at the meristem to activate floral identity genes (AP1); (c) why vernalisation (prolonged cold) is required for winter annuals.

Answer (Q19, Application). (a) Long days stabilize the CONSTANS (CO) protein in leaves (its degradation is light-gated through the circadian clock and phytochrome/cryptochrome); stable CO transcriptionally activates FT, the mobile florigen. (b) FT protein moves through the phloem to the shoot apical meristem, where it binds the bZIP transcription factor FD; the FT–FD complex activates floral meristem-identity genes (notably AP1) and the integrator SOC1, switching the meristem from vegetative to floral. (c) Winter annuals carry high FLC (FLOWERING LOCUS C), a MADS-box repressor that silences FT and SOC1; prolonged cold (vernalisation) epigenetically silences FLC via Polycomb H3K27me3, relieving repression so that the following long days can trigger flowering — ensuring they flower in spring, not before winter. See section 29. 20. Embryogenesis in plants establishes the apical-basal axis (shoot-root) and radial axis (epidermis-vascular tissue-ground tissue). Using Arabidopsis as a model, describe: (a)

the role of the asymmetric first division; (b) the signaling between the suspensor and the embryo proper; (c) the auxin gradient that specifies the root pole (PIN-mediated polar transport).

Answer (Q20, Application). In *Arabidopsis* embryogenesis the zygote is polarized, with PIN7 (apical) and PIN1 (basal) establishing an auxin gradient. (a) The asymmetric first division produces a small apical cell (gives rise to the embryo proper) and a large basal cell (gives rise mostly to the suspensor) — this fixes the apical–basal axis. (b) The suspensor anchors the embryo to maternal tissue, channels nutrients, and signals to pattern the basal (root) domain (WOX9), then undergoes programmed cell death after the globular stage; the embryo proper, via WOX2, patterns the apical domain. (c) PIN-mediated polar auxin transport creates an auxin maximum at the basal end (with ARF5/MONOPTEROS interpreting it) that specifies the root pole and the embryonic vascular axis; the radial axis (protoderm, procambium, ground meristem) is established at the globular–heart transition. See section 29.

Questions 21–30: Synthesis and Evaluation

21. Coevolution between flowering plants and their pollinators has shaped morphological diversity. Evaluate the evidence for pollination syndromes (e.g., red tubular flowers → hummingbird; white fragrant nocturnal → moth; UV-patterned → bee). Are syndromes perfect predictors? Use bees to explain why managed honey bees, bumblebees, solitary bees, and wild pollinator assemblages are not interchangeable. What does the “most effective pollinator” principle say about syndrome fidelity vs pollinator generalisation?

Answer (Q21, Synthesis). Pollination syndromes link floral traits to vectors (red, scentless, tubular, dilute nectar → birds; white, strongly fragrant, night-opening → hawkmoths; UV-patterned blue/yellow with landing platform → bees; small, scentless, copious dry pollen, feathery stigma → wind). The evidence is repeated convergent trait clustering across unrelated lineages and the matching of zygomorphic flowers to specialized pollinators vs. actinomorphic flowers to generalists. But syndromes are statistical biases, not deterministic keys: many plants are visited by multiple vectors, and the best visitor is the one delivering effective pollen transfer, not necessarily the most frequent visitor. Bees show the point. Managed honey bees provide movable colonies, bumblebees can buzz-pollinate some poricidal anthers, and solitary/wild bees may forage at different temperatures, flower heights, or times; wild pollinator visits can improve fruit set even where honey bees are present [Garibaldi et al., 2013]. The “most effective pollinator” principle predicts high syndrome fidelity where one reliable visitor dominates successful pollen transfer, and generalisation where effective visitors vary across years, sites, or climates. See section 29. 22. Design a breeding program to introduce self-incompatibility from a wild relative into a self-compatible crop species (e.g., tomato). Describe the genetic crosses required, how you would screen for SI expression, how a crop pangenome could reduce reference-bias around the S-locus, and the trade-off between enforced outcrossing (greater heterosis) and practical challenges (pollinator dependence).

Answer (Q22, Synthesis). Hypothesis: introgressing a functional S-locus from a self-incompatible wild relative will impose self-incompatibility on a self-compatible crop and increase outcrossing/heterosis. Crosses: make an interspecific F1 between the self-compatible crop and the SI wild relative (e.g., a wild S-RNase-bearing relative of tomato), then repeatedly backcross to the crop while selecting individuals that retain a functional, matched S-RNase + SLF haplotype (both pistil and pollen determinants must transfer together to function). Screen for SI expression by controlled self-pollination followed by aniline-blue staining of styles for arrested pollen tubes and by reduced self-seed set vs. successful cross seed set; the comparison/control is selfed vs. outcrossed plants, with replicate lines. A crop pangenome helps because wild-relative haplotypes, structural variants, or presence-absence variation near the S-locus may be absent from the elite reference genome, so selection markers should be validated against alternate haplotypes rather than one reference path [Schreiber et al., 2024]. Falsifying result: selfed plants set normal seed (SI not established). Trade-off: enforced outcrossing raises heterozygosity and potential hybrid vigour but creates obligate pollinator dependence and complicates inbred-line/seed production. See section 29. 23. Evaluate the hypothesis that the origin of the flower was a single evolutionary event (monophyletic origin of angiosperms). Cite evidence from: (a) molecular phylogenies (most angiosperms share a common ancestor); (b) fossil data (earliest undisputed flower fossils about 132 Mya); (c) the “evo-devo” evidence that the MADS-box gene family was duplicated and diversified at the base of angiosperms. What is “Darwin’s abominable mystery”?

Answer (Q23, Synthesis). “Darwin’s abominable mystery” is his term for the seemingly abrupt appearance and rapid Cretaceous diversification of flowering plants, which appeared to conflict with gradual evolution. Empirical evidence for a single (monophyletic) origin: (a) molecular phylogenies place all living angiosperms in one clade descended from a common ancestor (with Amborella/water lilies basal); (b) the earliest undisputed flower/pollen fossils (about 132 Mya, Early Cretaceous) appear after this divergence and show shared floral organization; (c) evo-devo evidence that the MADS-box gene family underwent duplication and sub/neofunctionalisation (the ABCDE classes) at the angiosperm base, providing the shared combinatorial floral toolkit. These are independent lines converging on one origin; the conclusion would change if a deeply divergent angiosperm lineage with an independent floral genetic toolkit were found, or if pre-Cretaceous unambiguous angiosperm fossils were confirmed. See section 29. 24. Parthenocarpy (seedless fruit production) can be induced by GA₃ application (seedless grapes) or by gene engineering (auxin- or GA-overproduction in ovary). Evaluate: (a) why seedless fruits are commercially valuable; (b) what transcriptional changes GA₃ induces in the ovary wall (cell expansion genes); (c) whether GM parthenocarpy would require approval as a GMO in the EU.

Answer (Q24, Synthesis). (a) Parthenocarpy produces seedless fruit, which is commercially valuable because consumers prefer no seeds (table grapes, watermelon, banana), shelf quality and processing improve, and fruit can set even when pollination fails (poor pollinator weather). (b) Mechanistically, seedless fruit is driven by auxin/GA signaling normally supplied by seeds: applied GA₃ (or engineered auxin/GA overproduction in the ovary) substitutes for the seed signal, transcriptionally activating cell-expansion genes (expansins, cell-wall-loosening and cell-cycle genes) in the pericarp so the ovary wall grows without fertilization — exactly the fruit-set/expansion program described for natural parthenocarps (banana, navel orange). (c) Whether GM parthenocarpy needs GMO approval is a regulatory judgement, not a settled mechanistic fact: in the EU a transgene-engineered parthenocarpic line would fall under GMO regulation, whereas chemically induced (GA₃-sprayed) seedlessness would not — so the answer is conditional on the method, and would change if regulatory definitions of “GMO” were revised. See section 29. 25. Evaluate the evolutionary transition from water-dependent reproduction (bryophytes — motile sperm requiring a water film) to water-independent reproduction (angiosperms — pollen grain, pollen tube, sealed ovule). What were the key innovations at each transition (vascular plants → seeds → flowers → enclosed ovules), and how did each innovation expand environmental range?

Answer (Q25, Synthesis). The empirical pattern is a graded reduction of water dependence and gametophyte size from bryophytes (free-living gametophyte, flagellated sperm needing a water film) through seedless vascular plants (dominant sporophyte but still swimming sperm), gymnosperms (pollen, sealed but naked ovule), to angiosperms (flowers, double fertilization, ovules enclosed in carpels). Key innovations and their range expansions: (1) vascular tissue + dominant sporophyte → tall, lignified bodies tolerating drier upland sites; (2) the seed → embryo packaged with food and protective coat, dispersal without external water; (3) pollen + pollen tube → fertilization with no water film, colonising arid habitats; (4) flowers/enclosed ovules + double fertilization → animal pollination, protected seeds, and post-fertilization provisioning, enabling explosive diversification. The boundary condition: this is a directional trend, not strict progress — bryophytes remain successful in moist niches, so each innovation expanded, rather than universally replaced, prior strategies. See section 29. 26. The seed coat (testa) provides physical and chemical protection against pathogens, UV, and desiccation. Evaluate the molecular basis of seed coat impermeability (suberin and lignin deposits) and how seed coat-imposed dormancy is released by scarification (physical damage) or microbial degradation. What trade-off exists between strong dormancy (survival) and rapid germination (competitive advantage)?

Answer (Q26, Synthesis). The testa is maternal integument tissue; its protective and dormancy-imposing function arises from a dense palisade of macrosclereids impregnated with suberin and lignin, making the coat water- and oxygen-impermeable (physical, PY dormancy) and chemically resistant to UV and pathogens. This coat-imposed dormancy is released when the barrier is breached: scarification (fire heat, gut-passage abrasion, freeze-thaw) or microbial/enzymatic degradation thins the testa, admitting water and O₂ so the embryo (already competent) germinates. The trade-off is ecological: strong, long dormancy maximizes bet-hedging survival across bad years and spreads germination risk, but delays establishment and cedes space to faster-germinating competitors; weak dormancy gives a rapid competitive head-start but risks germinating into lethal conditions. Selection tunes coat thickness/chemistry to the habitat’s disturbance regime. See section 29. 27. Epigenetic regulation of seed development: the MEDEA/FIE Polycomb complex prevents autonomous endosperm development before fertilization. After fertilization, paternal genome expression overcomes MEDEA repression (genomic imprinting). Evaluate: (a) why the paternal genome specifically is needed to initiate endosperm; (b) the parent-of-origin conflict hypothesis (Haig theory) applied to seed provisioning; (c) what happens in interploidy crosses (2x × 4x) where parental dosage is disrupted.

Answer (Q27, Synthesis). (a) Before fertilization the maternal FIS-PRC2 complex (MEDEA/MEA, FIE, FIS2, MSI1) deposits repressive H3K27me3, silencing endosperm-promoting paternally expressed genes (PEGs) and preventing autonomous endosperm. Because the maternal PEG alleles are imprinted-silenced, the paternal genome contributed at fertilization is specifically required to express PEGs and initiate endosperm proliferation. (b) Haig’s parent-of-origin conflict theory explains this: the paternal genome is selected to maximize resource extraction for its offspring (PEGs promote endosperm growth/nutrient transfer), while the maternal genome rations resources across multiple offspring (MEGs restrict growth) — the 2m:1p endosperm dosage is the arena of this conflict. (c) In interploidy crosses the PEG/MEG dosage balance (endosperm balance number) is broken: a paternal-excess cross (e.g., 2x × 4x pollen) overexpresses growth-promoting PEGs, causing endosperm overgrowth, failed cellularisation, and seed abortion (reciprocal maternal excess gives small, starved seeds). See section 29. 28. Evaluate the potential of synthetic seeds (somatic embryos encapsulated in alginate beads) for clonal propagation of elite crop genotypes. What are the technical challenges (desiccation tolerance of somatic embryos, germination rate, production at scale), and how do synthetic seeds compare to traditional seed in terms of cost, genetic uniformity, and epigenetic stability?

Answer (Q28, Synthesis). The empirical promise: somatic cells are totipotent and somatic embryogenesis (used commercially in oil palm, conifers, coffee) yields embryos that can be alginate-encapsulated as “synthetic seeds,” giving exact clones of an elite genotype with full genetic uniformity. The judgement, separated from the evidence: scalability is constrained by real technical challenges — somatic embryos generally lack the desiccation tolerance and dormancy of zygotic seeds (poor storage/shelf life), germination/conversion rates are often low and variable, bioreactor production is costly, and somaclonal/epigenetic variation can erode the intended uniformity. Compared with traditional seed they offer higher genetic fidelity to an elite clone but currently higher cost, lower robustness, and uncertain epigenetic stability. What would change the conclusion: demonstration

of desiccation-tolerant, dormancy-competent synthetic seeds with high conversion at commodity scale. See section 29. 29. Climate change alters flowering phenology (timing of first bloom). Evaluate: (a) how warming temperatures can alter vernalisation, florigen release, and pollen fertility; (b) what happens when plant flowering phenology shifts but pollinator phenology does not; (c) what field evidence would distinguish pollen heat failure from plant-pollinator phenological mismatch.

Answer (Q29, Synthesis). Empirical observations: long-term phenology datasets show first-bloom often advances with warming. Mechanistically, (a) warmer winters can be ambiguous — adequate cold is still needed for vernalisation (FLC silencing), warmer springs can accelerate FT/florigen-driven transition, and heat during male reproductive development can lower pollen viability. (b) If plant flowering advances but pollinator emergence, driven by different snowmelt or soil-temperature cues, does not shift equally, the flowering and foraging windows decouple, reducing pollination and seed set. (c) Distinguish mechanisms by measuring pollen viability and tube growth, hand-pollinated seed set, open-pollinated seed set, pollinator visitation timing, and cue models for flower opening versus pollinator emergence. Kudo and Cooper’s 19-year *Corydalis* study supports mismatch when early flowering preceded bumblebee emergence, while pollen assays would be needed to separate that from direct heat sterility. See section 29. 30. Critically evaluate CRISPR-based gene drives in wild plant populations: if a drive were engineered to spread herbicide resistance from a crop to its wild relatives, evaluate the ecological risks (invasive hybrid vigour, competitive dominance), the containment strategies (temporal/spatial/genetic containment), and the regulatory framework needed. Is there ever a scenario where a gene drive in plants would be ethically justified?

Answer (Q30, Synthesis). Empirical basis: gene drives bias inheritance so an engineered allele spreads through a population faster than Mendelian rates, and the chapter notes that escaped elite/engineered plant genotypes (e.g., apomictic hybrids, polyploids with heterosis) can become invasive and erode wild genetic diversity. The judgement: a drive spreading herbicide resistance into crop wild relatives carries serious ecological risks — creation of competitively dominant, hard-to-control “super-weeds,” loss of wild diversity, and difficult mitigation once released. Containment strategies, each imperfect, include spatial isolation, temporal separation of flowering, chloroplast transformation to limit pollen transfer, split or self-limiting drives, and sterility safeguards. Robust regulation would require ecological risk assessment, staged confined trials, monitoring endpoints, public engagement, and a mitigation plan consistent with National Academies guidance. Ethical justification is conditional, not categorical: it might be warranted for a clearly net-beneficial, well-contained, reversible application, and the conclusion would change with evidence that containment fails or harms exceed benefits. See section 29.

Questions — Plant Responses to the Environment

Instructor Use and Coverage Notes

- Coverage target: Predict a plant response from a signal and identify the likely hormone or pathway.
- Model/data emphasis: Dose-response, water-use-efficiency, and hormone-interaction reasoning.
- Assessment alignment: Visual Representations, Questions and Methods, Argumentation.
- Misconception probe: A plant response is not passive; plants actively regulate development and physiology without neurons.
- Transfer product: Transfer response logic to shade avoidance, drought, flowering, and crop management.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 30 of the textbook — review that chapter before attempting the exercises below.

1. What is a tropism? Name three types and state the stimulus for each.

Answer (Q1, Recall). A tropism is a directional growth response in which a plant grows toward or away from an environmental stimulus, the direction set by the stimulus and mediated by asymmetric auxin distribution and differential cell elongation. Three types: phototropism (stimulus: directional light — shoots bend toward blue light); gravitropism (stimulus: gravity — roots grow down, shoots grow up); thigmotropism (stimulus: touch/mechanical contact — tendrils coil around a support). Positive tropism is growth toward, negative is growth away from, the stimulus. See section 30.

2. What is auxin? Where is it produced and how does it move through the plant?

Answer (Q2, Recall). Auxin (indole-3-acetic acid, IAA) is the principal plant growth hormone, made primarily from tryptophan via the TAA1/YUCCA pathway in young leaves, the shoot apical meristem, and developing embryos. It moves by polar auxin transport (PAT), unique among hormones: PIN efflux carriers (PIN1–8) localized to specific cell faces set the flow direction, while AUX1/LAX influx carriers import it; transport is about 1 cm/h, basipetal in shoots and acropetal in roots. This directional flow underlies apical dominance, phototropism, and gravitropism. See section 30.

3. What is phototropism? What photoreceptor detects blue light (phototropin)?

Answer (Q3, Recall). Phototropism is the directional growth of a shoot toward (positive) or a root away from a light source, classically the bending of a shoot toward blue light. The blue-light photoreceptors are the phototropins PHOT1 and PHOT2 (LOV-domain flavoproteins): blue light forms an FMN–cysteine adduct, causing autophosphorylation, which triggers PIN3 relocalization and lateral auxin redistribution to the shaded side, where acid-growth-driven cell elongation bends the shoot toward the light (Cholodny–Went mechanism, quantified by Went 1926). See section 30.

4. What is gravitropism? How do amyloplasts (statoliths) detect gravity?

Answer (Q4, Recall). Gravitropism is directional growth relative to gravity: roots grow downward (positive) and shoots upward (negative). Gravity is sensed in specialized statocytes — root columella cells and shoot endodermal (starch-sheath) cells — that contain amyloplasts (statoliths), dense starch-filled plastids that sediment under gravity within seconds of reorientation. Their settling exerts a mechanical signal (via the actin cytoskeleton/ER and LAZY1 proteins) that relocates PIN3 to the new lower cell face, biasing auxin to the lower side; the resulting differential elongation bends the organ. See section 30.

5. Name four plant hormones other than auxin and state one major function of each.

Answer (Q5, Recall). Four hormones other than auxin: (1) gibberellin (GA) — promotes stem internode elongation and induces α -amylase for seed germination; (2) cytokinin — drives cell division and promotes lateral bud outgrowth/delays leaf senescence; (3) abscisic acid (ABA) — triggers stomatal closure under drought and maintains seed dormancy; (4) ethylene — a gaseous hormone that triggers climacteric fruit ripening, senescence, and abscission. (Jasmonates mediate wound/herbivore defense; salicylic acid mediates systemic acquired resistance.) See section 30.

6. What is ethylene? What role does it play in fruit ripening?

Answer (Q6, Recall). Ethylene is a gaseous plant hormone made from methionine via SAM → ACC (by ACC synthase) → ethylene (by ACC oxidase); because it is a gas it diffuses freely between cells and even between plants. In fruit ripening it is the master signal for climacteric fruits (banana, tomato, apple, avocado): an autocatalytic ethylene burst (System 2) is triggered by ripening transcription factors, then drives cell-wall softening (polygalacturonase, expansins), starch-to-sugar conversion, chlorophyll loss revealing carotenoids/anthocyanins, and aroma volatile production. Non-climacteric fruits (strawberry, grape, citrus) lack this burst. See section 30.

7. What is the phytochrome system? Distinguish Pr and Pfr forms.

Answer (Q7, Recall). The phytochrome system is a family of red/far-red photoreceptors (dimeric about 125 kDa chromoproteins bearing a phytochromobilin chromophore) that lets plants sense light quality, especially the red:far-red ratio. The shared principle is a reversible photoswitch between two forms. Pr is the red-absorbing form (λ_{max} 660 nm), inactive, synthesized in the dark, mainly cytoplasmic; Pfr is the far-red-absorbing form (λ_{max} 730 nm), the active form that moves to the nucleus and interacts with PIFs to drive responses. Red light converts Pr→Pfr; far-red light

(or dark thermal reversion) converts Pfr→Pr — the decisive R/FR reversibility diagnostic of phytochrome. See section 30. 8. What are plant defense responses to herbivory? Name two chemical defenses.

Answer (Q8, Recall). Plant defenses against herbivory are induced responses coordinated mainly by jasmonate (JA): wounding/chewing activates JA biosynthesis from linolenic acid via the LOX pathway, JA-Ile binds COI1, JAZ repressors are degraded, and MYC2 turns on defense genes. Two chemical defenses: (1) protease inhibitors that block the herbivore’s digestive enzymes, and (2) toxic secondary metabolites such as alkaloids (e.g., nicotine in tobacco) or glucosinolates (mustard-oil compounds in Brassicaceae); volatile terpenes are also released to attract the herbivore’s natural enemies. See section 30. 9. Define thigmotropism. Give one example.

Answer (Q9, Recall). Thigmotropism is a directional growth response to touch or mechanical contact, in which cells on the contact side stop elongating while cells on the opposite side continue, curving the organ around the stimulus. The classic example is tendril coiling in climbing plants such as peas, grapes, and cucumbers: within minutes of contact a tendril coils a full 360° around a support (a thigmonastic/thigmotropic response mediated by Ca²⁺ influx and jasmonate signaling). Root obstacle avoidance is another example. See section 30. 10. What is vernalisation? Which gene (FLC) is epigenetically silenced by prolonged cold?

Answer (Q10, Recall). Vernalisation is the promotion of flowering by prolonged cold exposure (weeks at about 4 °C), required by winter annuals and biennials so that they flower in spring rather than before winter. The gene epigenetically silenced is FLC (FLOWERING LOCUS C), a MADS-box transcription factor that represses the floral integrators FT and SOC1. Extended cold induces VIN3, which joins the VRN2–PRC2 Polycomb complex to deposit repressive H3K27me3 at the FLC locus; this silencing is mitotically maintained after return to warmth, relieving repression of FT/SOC1 so flowering proceeds. See section 30.

Questions 11–20: Application and Analysis

11. The Cholodny-Went model explains phototropism: auxin redistributes laterally to the shaded side, causing differential elongation. Describe the evidence: (a) agar block experiments; (b) PIN3 auxin efflux carrier redistribution; (c) auxin-responsive reporter (DR5::GFP). What alternative explanations (differential auxin sensitivity, flavonoid phototropins) have been proposed?

Answer (Q11, Application). Initiating condition: asymmetric blue light activates PHOT1/2; changed component: PIN3 relocates so auxin is exported toward the shaded side; intermediate mechanism: higher auxin there activates the H⁺-ATPase/expansin acid-growth pathway; observable outcome: the shaded side elongates more and the shoot bends toward light. Evidence: (a) Went’s agar-block experiments — auxin diffused from an illuminated coleoptile tip into agar, and the block placed asymmetrically on a decapitated coleoptile reproduced the bend, showing a transportable growth substance redistributed to the shaded side; (b) PIN3 immunolocalisation shows blue-light-triggered relocation from the basal to the lateral cell face; (c) the auxin-responsive DR5::GFP reporter shows higher signal on the shaded side. Proposed alternatives include differential auxin sensitivity (not just concentration) between sides and direct effects of phototropin/flavonoid signaling on growth. See section 30. 12. Gibberellins promote stem elongation by degrading DELLA growth repressors. Explain: (a) the molecular pathway (GA → GID1 receptor → DELLA ubiquitination → proteasome degradation); (b) how dwarf mutants (GA-deficient or DELLA gain-of-function) fail to elongate; (c) why the Green Revolution wheat varieties (Rht-B1b, Rht-D1b) carry semi-dominant DELLA mutations that reduce height and lodging.

Answer (Q12, Application). (a) Pathway: GA binds the soluble receptor GID1; the GA–GID1 complex binds DELLA repressors (GAI, RGA, RGL1–3), which are then ubiquitinated by the SCF^{SLY1} E3 ligase and degraded by the 26S proteasome; loss of DELLA releases growth-promoting transcription factors, driving internode elongation. (b) GA-deficient mutants make no GA so DELLA is never degraded — they are dwarf; DELLA gain-of-function mutants encode a non-degradable DELLA that stays bound regardless of GA, also producing dwarfs that fail to elongate. (c) Green Revolution wheat carries semi-dominant Rht-B1b/Rht-D1b alleles encoding GA-insensitive DELLA proteins; constitutive growth repression yields short, stiff straw that resists lodging while supporting heavy grain heads — the basis of high-yield semi-dwarf varieties. See section 30. 13. Ethylene triggers the triple response in dark-grown seedlings (shortened stem, thickened stem, horizontal growth). Design an experiment using: (a) the ethylene biosynthesis inhibitor AVG; (b) the ethylene-insensitive mutant *ein2*; (c) an ethylene-overproducing mutant (*eto1*) to confirm that each component of the triple response is ethylene-dependent.

Answer (Q13, Application). Hypothesis: each component of the triple response (short hypocotyl, thick hypocotyl, exaggerated apical hook) requires ethylene signaling. Comparison/controls: dark-grown wild-type seedlings with and without exogenous ethylene/ACC. Changed factors and predictions: (a) treat with the biosynthesis inhibitor AVG (blocks ACC synthase) — wild type should fail to show the triple response unless ACC is supplied downstream of the block (rescue); (b) the ethylene-insensitive *ein2* mutant should NOT show the triple response even when given ethylene/ACC (signaling is broken downstream of perception); (c) the ethylene-overproducing *eto1* mutant should show a constitutive triple response in air without added ethylene, abolished by AVG. Measured outcome: hypocotyl length/width and hook angle, with replication across many seedlings. Falsifying result: triple response persists in *ein2* with ethylene scavenged, or fails to appear in *eto1* — which would refute ethylene-dependence. See section 30. 14. Jasmonic acid (JA) mediates herbivore-induced defenses. When a caterpillar chews a leaf, systemin (a peptide signal) activates

JA biosynthesis, which induces protease inhibitors in distant unwounded leaves. Trace the entire signaling cascade: wounding → systemin release → systemin receptor → JA biosynthesis (from linolenic acid in chloroplast) → COI1-JAZ interaction → MYC2 transcription factor activation → PI gene expression.

Answer (Q14, Application). Initiating condition: a caterpillar chews a leaf, mechanically wounding cells and releasing the peptide systemin from prosystemin. Changed component: systemin binds its leucine-rich-repeat receptor kinase on plasma membranes near the wound, raising cytosolic Ca^{2+} and activating phospholipases that liberate linolenic acid from chloroplast membranes. Intermediate mechanism: linolenic acid enters the LOX/AOS octadecanoid pathway to make jasmonic acid, conjugated by JAR1 to active JA-Ile; JA-Ile binds COI1, recruiting JAZ repressors into the SCF^{COI1} complex for ubiquitination and 26S degradation. Observable outcome: freed MYC2 (and MYC3/4) transcription factors activate defense genes including protease-inhibitor (PI) genes, both locally and — because systemin/JA signals move through the phloem — in distant unwounded leaves, deterring further herbivory. See section 30. 15. Phytochrome interconversion: Pr (absorbs red 660 nm, inactive) \rightleftharpoons Pfr (absorbs far-red 730 nm, active). In a long-day plant, flowering is promoted by long photoperiods (short nights). Explain: (a) how the phytochrome system measures night length (Pfr → Pr reversion rate in the dark); (b) how a brief red flash in the middle of a long night promotes flowering; (c) how a subsequent far-red flash reverses this.

Answer (Q15, Application). (a) Phytochrome measures night length by Pfr decay: light drives Pr→Pfr, but in darkness Pfr slowly reverts to Pr (thermal reversion) and is degraded. After a long uninterrupted night, Pfr falls below a threshold; after a short night, Pfr stays high. The plant's circadian clock reads this Pfr level at a gated time (external-coincidence model) to register day length. (b) In a long-day plant, a brief red flash in the middle of a long night reconverts Pr→Pfr, restoring high Pfr and signaling a “short night,” which promotes flowering (the night-break effect). (c) An immediately following far-red flash reconverts Pfr→Pr, cancelling the red effect — restoring the “long night” state and abolishing flowering promotion. This R/FR reversibility is the classic phytochrome signature. See section 30. 16. Absciscic acid (ABA) promotes stomatal closure under drought stress. Explain the guard cell signaling cascade: ABA → RCAR/PYL receptor → PP2C inactivation → SnRK2 activation → SLAC1 anion channel opening → Cl^- and malate²⁻ efflux → K^+ efflux → turgor loss → stomata close.

Answer (Q16, Application). Initiating condition: soil water deficit raises ABA (NCED3 upregulated in roots; ABA delivered via xylem to guard cells). Changed component: ABA binds PYR/PYL/RCAR receptors. Intermediate mechanism: the ABA-receptor complex inhibits PP2C phosphatases (ABI1/ABI2/HAB1), releasing SnRK2 kinases (notably OST1/SnRK2.6) which autoactivate and phosphorylate targets: SLAC1 anion channels open (Cl^- and malate²⁻ efflux), depolarizing the membrane; the depolarization opens GORK outward K^+ channels (K^+ efflux) while inward K^+ channels are inhibited. Observable outcome: net loss of K^+ , Cl^- and malate raises guard-cell Ψ_s , water exits osmotically, turgor falls, and the stomata close — conserving water at the cost of reduced CO_2 uptake. See section 30. 17. Auxin dose-response curves differ between stems and roots: stems show maximum elongation at about 10^{-5} M auxin, while roots show maximum elongation at about 10^{-10} M auxin and are inhibited at concentrations that stimulate stems. Explain: (a) how this difference underlies gravitropism (auxin accumulates on the lower side, inhibiting root elongation while stimulating shoot elongation); (b) why 2,4-D (a synthetic auxin) is an effective herbicide for broadleaf plants.

Answer (Q17, Application). Initiating condition: roots and shoots have very different auxin dose-optima — shoot elongation peaks near 10^{-5} M, root elongation near 10^{-10} M, and concentrations that stimulate shoots strongly inhibit roots (via Aux/IAA stabilization and induced ethylene). (a) In gravitropism, statolith-triggered PIN3 relocalization sends extra auxin to the lower side of both organs; because this raises auxin above the root optimum, the lower side of the root elongates LESS and the root bends downward, whereas the same increase is at or below the shoot optimum, so the lower side of the shoot elongates MORE and the shoot bends upward — opposite responses from one redistribution. (b) 2,4-D is a synthetic, transport- and degradation-resistant auxin; sprayed on broadleaf (dicot) weeds it produces persistent supraoptimal auxin that triggers uncontrolled growth, ethylene/ABA overproduction, and lethal disorganisation, while narrow-leaved grasses (monocots) are more tolerant — making it a selective herbicide. See section 30. 18. Plants produce volatile organic compounds (VOCs) in response to herbivory that attract predators of the herbivore (“crying for help”). The lima bean-spider mite-predatory mite tritrophic system is a classic example. Explain: (a) which VOCs (terpenoids, green leaf volatiles) are emitted; (b) how neighboring undamaged plants “eavesdrop” via VOC-induced defensive gene expression; (c) whether this constitutes plant communication or merely an information-rich cue.

Answer (Q18, Application). Initiating condition: herbivore damage activates the JA pathway (MYC2/3/4). Changed component: the plant emits a herbivore-induced VOC blend. (a) The VOCs include green leaf volatiles (C6 aldehydes/alcohols from the LOX pathway, released within seconds of wounding) and inducible terpenoids such as (E)- β -ocimene and linalool synthesized over hours; these attract predatory mites and parasitic wasps that attack the herbivore (indirect defense; the lima bean-spider mite-predatory mite tritrophic system). (b) Neighboring undamaged plants “eavesdrop”: exposure to these VOCs primes or directly induces their own defensive gene expression (JA-responsive genes), so they mount faster defenses when attacked. (c) Whether this is “communication” is a judgement, not settled fact: it clearly functions as an information-rich cue, but it qualifies as true plant-to-plant signaling only if emission is favored by selection for the receiver's response (e.g., within-plant priming or kin benefit) rather than being incidental volatiles exploited by neighbors — the conclusion would change with evidence on the emitter's fitness benefit. See

section 30. 19. Circadian clock in plants: the core oscillator (CCA1/LHY → TOC1 → CCA1/LHY feedback loop) regulates about 30% of plant gene expression. Explain: (a) how the clock anticipates dawn (pre-dawn expression of photosynthesis genes); (b) how jet-lag experiments (sudden photoperiod shift) reveal resynchronisation kinetics; (c) why clock mutants (TOC1-ox) have reduced fitness under natural light-dark cycles.

Answer (Q19, Application). Initiating condition: the core clock — morning components CCA1/LHY repress evening genes, the evening loop (PRR9/7/5/TOC1) and the evening complex (ELF3-ELF4-LUX) feed back to repress CCA1/LHY — generates about 24 h oscillations controlling about 30% of plant genes. (a) The clock anticipates dawn: it ramps up photosynthesis, sucrose-metabolism, and light-harvesting gene transcription before lights-on, so machinery is ready at first light (a fitness advantage over purely reactive timing). (b) “Jet-lag” experiments suddenly shift the photoperiod; monitoring rhythmic reporters shows the clock re-entrains over several days with characteristic transient phase shifts, revealing resynchronisation kinetics and which components reset fastest. (c) Clock mutants such as TOC1-overexpressors run with the wrong period/phase, so anticipatory programs (photosynthesis, starch turnover, flowering) become misaligned with the real light–dark cycle; resonance experiments show such plants fix less carbon and have reduced growth/fitness under natural cycles. See section 30. 20. SAR (systemic acquired resistance) provides long-lasting, broad-spectrum pathogen protection. Following a localized pathogen infection, the signal molecule salicylic acid (SA) activates the SA pathway → NPR1 monomerisation → nuclear import → TGA transcription factor activation → PR (pathogenesis-related) gene expression. How does this confer resistance to secondary infections in distal tissues?

Answer (Q20, Application). Initiating condition: a localized pathogen infection triggers a hypersensitive response and a rise in salicylic acid, plus mobile signals (e.g., pipecolic/N-hydroxy-pipecolic acid, methyl-SA) that travel through the phloem to distal tissues. Changed component: in those distal tissues SA accumulates and reduces the cellular redox state, so the normally oligomeric NPR1 is reduced to monomers. Intermediate mechanism: monomeric NPR1 enters the nucleus and acts as a transcriptional coactivator with TGA bZIP transcription factors at PR-gene promoters. Observable outcome: broad-spectrum pathogenesis-related (PR) genes (PR-1, β -1,3-glucanase, thaumatin-like proteins) are expressed and defenses are “primed” plant-wide, so a secondary infection in previously uninfected tissue is met with a faster, stronger response — long-lasting systemic acquired resistance. See section 30.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the evidence for “plant intelligence” or “plant neurobiology” — the concept that plant signaling networks (electrical action potentials, calcium waves, hormone gradients) constitute a form of information processing analogous to animal brains. Critically assess: (a) what criteria define intelligence; (b) whether plants satisfy any of these; (c) the boundaries of legitimate analogy vs anthropomorphism.

Answer (Q21, Synthesis). Empirical evidence: plants do generate electrical signals (action-potential-like and variation potentials), propagating Ca^{2+} waves, and long-distance hormone/peptide signals (e.g., systemin/JA wound signaling, mycorrhizal-network transfer), and these networks support integration, memory-like priming, and adaptive responses without neurons. The judgement, separated from the evidence: (a) “intelligence” is variously defined as flexible problem-solving, learning, anticipation, and integrated decision-making; (b) plants meet weak criteria (habituation, anticipation via the clock, integrated stress responses) but show no evidence of centralised representation, neurons, or subjective cognition; (c) legitimate analogy ends where shared mechanism ends — calling signaling “neurobiology” risks anthropomorphism. What would change the conclusion: demonstration of associative learning that requires neural-like representation, or that the contested claims (e.g., active plant–plant signaling through common mycorrhizal networks, whose ecological significance remains debated) are robust and adaptive. The cautious position is “sophisticated distributed information processing,” not “a brain.” See section 30. 22. Design a CRISPR knockout experiment in Arabidopsis to determine whether the gravitropic response requires the starch-statolith mechanism (amyloplast sedimentation) or an alternative membrane-based mechanosensing pathway. What gene(s) would you knock out (PGM1 for starchless mutants), what phenotype would you measure, and what result would distinguish the two hypotheses?

Answer (Q22, Synthesis). Hypothesis: gravity perception requires amyloplast (starch-statolith) sedimentation; alternative: a starch-independent membrane mechanosensing pathway suffices. Manipulation: CRISPR-knock out PGM1 (plastidic phosphoglucomutase) to make starchless plants with low-density, non-sedimenting amyloplasts; controls are wild type and a complemented PGM1 line. Comparison/changed factor: starch presence/statolith mass, assayed by reorientation experiments. Measured outcome: root and shoot gravitropic curvature angle and latency after 90° reorientation, with replication across many seedlings and clinostat controls. Decision rule: if starchless pgm1 plants lose or strongly delay/weaken gravitropism, the starch-statolith mechanism is required; if they retain near-normal gravitropism, a starch-independent mechanosensing pathway is sufficient (the established result is reduced-but-not-abolished response, indicating statoliths greatly enhance, but are not absolutely required for, sensing). Falsifying result for the statolith hypothesis: full, normal-latency gravitropism in starchless plants. See section 30. 23. Evaluate the molecular mechanisms of plant adaptation to flooding stress (waterlogging and submergence). Compare: (a) the SUB1A strategy in rice (quiescence — ethylene → SUB1A → DELLA stabilization → growth arrest); (b) the SNORKEL strategy (escape — ethylene → SK1/SK2 → GA signaling → rapid internode elongation to escape floodwater). Under what flooding regimes is each strategy advantageous?

Answer (Q23, Synthesis). Empirical mechanisms: flooding causes hypoxia and ethylene accumulation (ACC oxidase is O_2 -limited so ethylene/ACC

builds up under water). (a) The quiescence strategy (SUB1A in rice): ethylene induces the ERF-VII transcription factor SUB1A, which stabilizes DELLA and dampens GA responses, arresting shoot elongation and conserving carbohydrate so the plant survives complete submergence. (b) The escape strategy (SNORKEL): in deepwater rice, ethylene induces SK1/SK2 ERF-VII genes that promote GA signaling, driving rapid internode elongation (up to about 25 cm/day) so leaves stay above water and keep photosynthesising/aerating. Conditional advantage (not universal): quiescence wins under brief, deep, flash flooding where the water recedes quickly (escape would waste reserves on growth that drowns); escape wins under prolonged, gradually rising floods where staying submerged means carbohydrate exhaustion and death. The “best” strategy depends entirely on flood depth and duration — the conclusion changes with the flooding regime. See section 30. 24. Climate change increases UV-B radiation at Earth’s surface due to ozone depletion. Evaluate plant UV-B responses: (a) UVR8 photoreceptor-mediated signaling → COP1-SPA → HY5 transcription factor → flavonoid/anthocyanin biosynthesis (sunscreen); (b) UV-B effects on DNA (CPD lesion formation) and repair (photolyase); (c) predicted impacts on crop productivity.

Answer (Q24, Synthesis). Initiating condition: increased surface UV-B. Changed component/(a): the UVR8 photoreceptor monomerises on UV-B absorption, interacts with COP1, and (analogous to the CRY/PhyB–COP1 logic) disrupts COP1–SPA so the transcription factor HY5 accumulates; HY5 drives flavonoid and anthocyanin biosynthesis, producing a UV-absorbing “sunscreen” in the epidermis plus antioxidant and DNA-repair gene expression. (b) UV-B directly damages DNA, forming cyclobutane pyrimidine dimers (CPDs) and 6-4 photoproducts; plants repair these largely by photolyases (photoreactivation using blue/UV-A light) and nucleotide-excision repair, limiting mutagenesis. (c) Predicted crop impacts: moderate UV-B is buffered by acclimation (flavonoid screening, repair), but elevated UV-B can reduce leaf area, photosynthesis, and yield in sensitive cultivars and shift secondary metabolism — magnitude is conditional on species, acclimation capacity, and co-occurring stresses, so projected productivity losses are uncertain rather than settled. See section 30. 25. Evaluate the evolutionary arms race between plants and herbivores. Using the example of glucosinolate-myrosinase system in Brassicaceae (the “mustard oil bomb”): (a) how the system works (glucosinolates are stored separately from myrosinase; upon tissue damage, they mix to produce toxic isothiocyanates); (b) how specialized herbivores (diamondback moth) detoxify isothiocyanates; (c) what countermeasure plant lineages have evolved (novel glucosinolates).

Answer (Q25, Synthesis). Empirical system: Brassicaceae deploy the glucosinolate–myrosinase “mustard-oil bomb.” (a) Glucosinolates are stored in S-cells separately from the enzyme myrosinase, sequestered in myrosin cells; tissue damage by a chewing herbivore mixes them, and myrosinase hydrolyses glucosinolates into toxic, reactive isothiocyanates that deter or poison generalist herbivores. (b) Specialist herbivores counter-adapt: the diamondback moth secretes a glucosinolate sulfatase that desulfates glucosinolates so myrosinase can no longer activate them, detoxifying the defense. (c) In response, plant lineages evolve novel glucosinolate side-chains and modifying enzymes (e.g., epithiospecifier/nitrile-forming proteins) that the specialist’s enzymes do not recognize — a recurring escalation. This is a coevolutionary arms race, but the outcome is conditional and lineage-specific, not a universal endpoint: the conclusion would change if a specialist evolved broad-spectrum detoxification or a plant evolved a defense the specialist cannot circumvent. See section 30. 26. Symbiotic nitrogen fixation (Rhizobium-legume): evaluate the molecular cross-talk leading to nodule formation: (a) plant-derived flavonoids → bacterial NodD → Nod factor production → root hair curling → infection thread → nodule primordia; (b) the oxygen paradox (nitrogenase is O₂-sensitive but Rhizobium needs aerobic respiration → leghaemoglobin O₂ buffering); (c) the autoregulation of nodulation (too many nodules are costly → CLE peptide negative feedback).

Answer (Q26, Synthesis). Empirical cross-talk: (a) Legume roots exude flavonoids that activate rhizobial NodD, inducing Nod-factor (lipochitooligosaccharide) synthesis; Nod factors bind NFR1/NFR5 LysM receptor kinases on root-hair cells, triggering Ca²⁺ spiking, root-hair curling, infection-thread formation, and cortical cell divisions that build the nodule primordium where rhizobia differentiate into N₂-fixing bacteroids. (b) The oxygen paradox: nitrogenase is irreversibly inactivated by O₂, yet bacteroids need O₂ for the ATP-intensive fixation reaction; the plant resolves this with leghaemoglobin, which buffers free O₂ to nanomolar levels while delivering a high O₂ flux to bacteroid respiration. (c) Nodulation is metabolically expensive, so it is autoregulated: early nodules trigger root-derived CLE peptides perceived by a shoot LRR receptor, generating a shoot-derived inhibitory signal that limits further nodule formation (autoregulation of nodulation). The judgement: these mechanisms are well supported but their quantitative balance is context-dependent (N status, host genotype) — the conclusion would change under altered soil nitrogen or symbiont compatibility. See section 30. 27. Evaluate the role of epigenetics in plant stress memory. After a heat stress episode, some plants show enhanced heat tolerance for weeks (priming). What molecular marks (H3K4me3 at HSP loci, small RNA populations, chromatin remodeling) mediate stress memory, and does this memory have transgenerational stability?

Answer (Q27, Synthesis). Empirical evidence: after a sublethal heat episode many plants show “thermomemory” — enhanced heat tolerance lasting days to weeks — associated with persistent active chromatin marks (notably H3K4me2/3 retained at HSP loci such as HSP70/HSP101), sustained accumulation of heat-shock transcription factors and HSP transcripts, altered small-RNA populations, and chromatin remodeling that keeps memory genes poised for rapid reactivation. The judgement, separated from the evidence: within-generation somatic priming is well documented and mechanistically grounded; transgenerational stability is contested — plants lack a strict germline–soma separation so some marks can in principle transmit, but most heat-induced marks are reset by demethylases/remodelers within a generation and reported transgenerational heat memory is weak and variable. What would change the conclusion: rigorous multi-generation studies showing stable, mark-dependent inheritance of heat tol-

erance independent of maternal/environmental confounds. So: robust somatic memory, uncertain and conditional transgenerational inheritance. See section 30. 28. Parasitic plants (*Striga*, *Orobanche*, dodder) exploit host plant signals to locate and attach to hosts. Evaluate: (a) how *Striga* seeds detect host-derived strigolactones as germination cues; (b) how the haustorium forms and penetrates host xylem/phloem; (c) why *Striga* is the most economically devastating weed in sub-Saharan Africa; (d) what control strategies (resistant crop varieties, suicidal germination stimulants) are being deployed.

Answer (Q28, Synthesis). Empirical mechanisms: (a) *Striga* (witchweed) seeds remain dormant until they detect host-root-exuded strigolactones, which (via a KAI2/HTL-type α/β -hydrolase receptor) trigger germination only near a suitable host. (b) The germinated radicle forms a haustorium — induced by host-derived quinone/phenolic signals — that adheres to and penetrates the host root, fusing with host xylem and phloem to siphon water, minerals, and photosynthate. (c) *Striga* is the most economically devastating weed in sub-Saharan Africa because it parasitises staple cereals (sorghum, maize, millet, upland rice), causes most damage underground before emergence, and produces tens of thousands of long-lived seeds, devastating subsistence yields. (d) Control strategies include *Striga*-resistant/low-strigolactone crop varieties, “suicidal germination” stimulants applied without a host so seeds germinate and die, herbicide-resistant (Imazapyr-coated) seed, trap/catch crops, and improved soil fertility. The judgement is conditional: efficacy varies with *Striga* species, host genotype, and farming system, so no single strategy is universally decisive. See section 30. 29. Evaluate the potential of “smart crops” engineered with synthetic hormone signaling circuits: e.g., a crop that closes stomata in response to soil moisture sensors (synthetic ABA-independent signaling), activates JA defenses primarily when herbivores are detected (synthetic promoter responsive to caterpillar oral secretions), and accelerates flowering under climate-variable conditions (synthetic florigen circuit). What are the engineering feasibility, field-validation, regulatory, and ecological risks?

Answer (Q29, Synthesis). Empirical basis: applied hormone biology already works at scale (Green Revolution GA-insensitive dwarfs, 1-MCP fruit storage, synthetic-auxin herbicides), and engineered promoters/receptors can rewire stomatal, defense, and flowering circuits. The judgement, separated from the evidence: (a) feasibility is partial — synthetic moisture-sensor-driven stomatal control, herbivore-oral-secretion-inducible JA defense, and a tunable florigen circuit can be demonstrated as modules, but stacking robust, low-leak, field-stable circuits is hard because background signaling, fitness cost, and environmental variability interact. (b) Field validation must show multi-season yield or fitness benefit, expression stability, measured water status, pest pressure, flowering synchrony, and off-target phenotypes, not just reporter activity. (c) Regulatory risk: transgenic synthetic circuits face GMO approval, which is jurisdiction-dependent. (d) Ecological risk: altered stomatal/defense/flowering behavior can have non-target effects on water cycling, pollinator timing, gene flow to wild relatives, and resistance evolution in pests. What would change the conclusion: stable, containable, net-beneficial circuits with quantified off-target and ecological effects. So promising but conditional, not settled. See section 30. 30. Critically assess the claim that plant volatile communication represents a form of “language”: (a) define what communication requires (sender, signal, receiver, response, evolved function); (b) evaluate whether plant VOC emission meets these criteria; (c) compare plant volatile signaling to animal pheromone communication; (d) assess the fitness benefit to the emitter (is it a true signal or an incidental cue exploited by neighbors?).

Answer (Q30, Synthesis). (a) Communication, in the biological sense, requires a sender, a signal, a receiver, a response in the receiver, and an evolved function such that producing the signal is favored by selection because of the receiver’s response. (b) Empirically, herbivore-induced plant VOCs have a clear sender (damaged plant), a structured signal (green leaf volatiles, terpenoids), receivers that respond (predators/parasitoids, neighboring plants, distal tissues of the same plant), and documented responses (attraction, defense priming) — meeting the first four criteria. (c) Compared with animal pheromones, plant VOC signaling shares chemical-blend information transfer and dose-dependence but typically lacks dedicated sensory organs and the tight sender–receiver coevolution of intraspecific pheromones. (d) The decisive, unresolved point is the emitter’s fitness benefit: it is a true signal only if emission is selected because receivers respond beneficially to the emitter (e.g., within-plant priming, kin benefit, or attracting bodyguards); otherwise it is an incidental cue exploited by eavesdroppers. The “language” claim therefore remains conditional, not settled, and would change with rigorous evidence on emitter fitness consequences. See section 30.

Questions — Circulation and Respiration

Instructor Use and Coverage Notes

- Coverage target: Calculate a transport or feedback variable and explain the compensatory response.
- Model/data emphasis: Cardiac-output, diffusion, oxygen-saturation, and feedback calculations.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Homeostasis is dynamic regulation, not an unchanging internal state.
- Transfer product: Transfer homeostatic reasoning to exercise, altitude, hemorrhage, fever, and shock.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 31 of the textbook — review that chapter before attempting the exercises below.

1. What is homeostasis? Give two examples of physiological variables maintained by homeostasis.

Answer (Q1, Recall). Homeostasis is the maintenance of a relatively stable internal environment despite external fluctuations, achieved mainly by negative feedback (a sensor detects a deviation, a control center compares it to a set point, and an effector opposes the change). Two examples of regulated variables: body core temperature (about 37 °C) and arterial blood pressure (and likewise blood glucose, pH, and osmolality). See section 31.

2. Describe the structure of the human heart. Name the four chambers and four valves.

Answer (Q2, Recall). The heart is a four-chambered muscular pump: two atria (thin-walled receiving chambers) and two ventricles (thick-walled pumping chambers), with the left side at higher pressure than the right. The four valves are the two atrioventricular valves (tricuspid on the right, mitral/bicuspid on the left) and the two semilunar valves (pulmonary and aortic), which enforce one-way flow. See section 31.

3. What is the cardiac cycle? Define systole and diastole.

Answer (Q3, Recall). The cardiac cycle is one complete sequence of atrial and ventricular contraction and relaxation that fills the heart and ejects blood. Systole is the contraction (ejection) phase, when ventricular pressure rises and blood is pumped out; diastole is the relaxation phase, when the chambers refill with blood. See section 31.

4. What is cardiac output (CO)? Write the formula $CO = HR \times SV$.

Answer (Q4, Recall). Cardiac output is the volume of blood the heart pumps per minute, given by $CO = HR (\times) SV$ (heart rate times stroke volume). At rest, CO (about 70 bpm) (\times) 70 mL (about 5) L/min. See section 31.

5. Describe the structure and function of arteries, veins, and capillaries.

Answer (Q5, Recall). Arteries carry blood away from the heart at high pressure; they have thick, elastic, muscular walls that buffer pulsatile flow and (as arterioles) regulate resistance. Capillaries are single-endothelial-cell-thick vessels where gas, nutrient, and waste exchange occurs. Veins carry blood back to the heart at low pressure; they are thin-walled, high-capacitance vessels with one-way valves that prevent backflow. See section 31.

6. What is blood pressure? What are typical systolic and diastolic values?

Answer (Q6, Recall). Blood pressure is the force exerted by blood against arterial walls, driven by cardiac output against total peripheral resistance ($MAP = CO (\times) TPR$). Typical values are systolic about 120 mmHg (during ventricular ejection) and diastolic about 80 mmHg (during ventricular relaxation), with a mean arterial pressure of about 93 mmHg. See section 31.

7. What is tidal volume? What is vital capacity?

Answer (Q7, Recall). Tidal volume is the volume of air moved into or out of the lungs in a single quiet breath (about 500 mL). Vital capacity is the maximum volume that can be exhaled after a maximal inhalation — the sum of tidal volume plus inspiratory and expiratory reserve volumes (about 4.5–5 L in a healthy adult). See section 31.

8. Describe the mechanics of ventilation (breathing): inhalation and exhalation.

Answer (Q8, Recall). Inhalation is active: the diaphragm and external intercostals contract, expanding the thorax; intrapleural and alveolar pressures fall below atmospheric, so air flows in. Quiet exhalation is passive: the muscles relax and elastic recoil of the lungs and chest wall raises alveolar pressure above atmospheric, so air flows out (forced expiration adds internal intercostal and abdominal muscle contraction). See section 31.

9. What is the oxygen-hemoglobin dissociation curve? What does its sigmoidal shape indicate?

Answer (Q9, Recall). The oxygen-hemoglobin dissociation curve plots hemoglobin O_2 saturation against PO_2 . Its sigmoidal (S) shape reflects cooperative binding: as each O_2 binds, hemoglobin shifts from the low-affinity T-state toward the high-affinity R-state. This means Hb loads O_2 nearly fully at high lung PO_2 yet unloads it steeply over the physiological range of tissue PO_2 , maximizing delivery. See section 31.

10. Define thermoregulation. Distinguish endotherms from ectotherms.

Answer (Q10, Recall). Thermoregulation is the homeostatic control of body temperature around a set point via heat production and heat exchange. Endotherms (mammals, birds) generate and regulate internal metabolic heat to keep core temperature stable (about 37 °C) independent of am-

bient temperature; ectotherms (fish, reptiles, invertebrates) have body temperatures that track the environment and rely mainly on behavioral thermoregulation. The mechanistic difference is internal metabolic heat production plus physiological regulation versus reliance on external heat. See section 31.

Questions 11–20: Application and Analysis

11. During exercise, HR increases from 70 to 160 bpm and SV from 70 mL to 120 mL. Calculate the CO at rest and during exercise. What is the fold-increase? What mechanisms increase HR (sympathetic → SA node → faster depolarization) and SV (Frank-Starling mechanism)?

Answer (Q11, Application). Using $CO = HR \times SV$: at rest $CO = 70 \text{ bpm} \times 70 \text{ mL} = 4,900 \text{ mL/min}$ (about 4.9 L/min; during exercise $CO = 160 \text{ bpm} \times 120 \text{ mL} = 19,200 \text{ mL/min}$ (about 19.2 L/min. That is about a 3.9-fold increase, within the normal range for an untrained adult. HR rises because sympathetic ((β_1)) stimulation and vagal withdrawal speed SA-node depolarization; SV rises through the Frank-Starling mechanism (increased venous return stretches cardiomyocytes, optimizing actin-myosin overlap) plus increased (β_1)-driven contractility. See section 31. 12. The Bohr effect: increased CO_2 and H^+ in exercising muscle shift the oxygen-hemoglobin dissociation curve rightward, decreasing Hb's O_2 affinity. Explain: (a) the molecular basis (protonation of His146 stabilizing the T-state); (b) the physiological benefit (enhanced O_2 unloading in active tissues); (c) what happens at the lungs (low CO_2 , high pH → leftward shift → enhanced O_2 loading).

Answer (Q12, Application). (a) In exercising muscle, CO_2 and H^+ rise; protons bind histidine residues (e.g., (β)His146) and CO_2 forms carbamino groups, stabilizing the low-affinity T-state and raising P_{50} (rightward shift). (b) The benefit is enhanced O_2 unloading exactly where metabolic demand is highest, increasing tissue O_2 extraction. (c) In the pulmonary capillaries CO_2 is exhaled and pH rises, so the curve shifts left (affinity increases), promoting efficient O_2 loading onto hemoglobin. See section 31. 13. Ventilation-perfusion (V/Q) matching ensures that regions of the lung receiving airflow also receive blood flow. Explain: (a) what happens when V/Q is high (dead space) vs low (shunt); (b) how local hypoxic pulmonary vasoconstriction (HPV) diverts blood from poorly ventilated alveoli; (c) why chronic lung disease (COPD) causes V/Q mismatch and hypoxaemia.

Answer (Q13, Application). (a) High V/Q means ventilation exceeds perfusion (dead space — ventilated but not perfused, wasting ventilation); low V/Q means perfusion exceeds ventilation (shunt — perfused but not oxygenated, causing hypoxaemia). (b) Hypoxic pulmonary vasoconstriction: alveolar hypoxia constricts the local pulmonary arterioles, diverting blood away from poorly ventilated regions toward better-ventilated ones, improving overall matching. (c) In COPD, airway obstruction and parenchymal destruction make ventilation regionally uneven, creating widespread V/Q mismatch (mixed dead space and shunt) that the lung cannot fully compensate for, producing chronic hypoxaemia. See section 31. 14. Blood pressure regulation: the baroreceptor reflex senses carotid sinus stretch. When BP drops: (a) baroreceptor firing decreases; (b) medullary cardiovascular center increases sympathetic output; (c) HR, contractility, and peripheral resistance increase; (d) BP is restored. What happens if the baroreceptor reflex fails (autonomic neuropathy)?

Answer (Q14, Application). (a) A fall in BP reduces carotid-sinus/aortic stretch, so baroreceptor afferent firing to the NTS decreases. (b) Reduced NTS input disinhibits the medullary sympathetic premotor neurons (RVLM) and withdraws vagal tone, so sympathetic output rises. (c) HR, contractility, arteriolar vasoconstriction (TPR), and venoconstriction (venous return) all increase. (d) Together these restore MAP within seconds. If the baroreflex fails (autonomic neuropathy), this rapid compensation is lost, producing orthostatic hypotension — standing causes an uncorrected BP fall with dizziness or syncope, and labile, poorly buffered blood pressure. See section 31. 15. Surfactant (produced by type II alveolar cells) reduces alveolar surface tension. Without surfactant: (a) what happens to alveolar compliance (Laplace's law: $P = 2T/r \rightarrow$ smaller alveoli collapse into larger ones); (b) what condition results in premature infants (NRDS — neonatal respiratory distress syndrome); (c) how is antenatal corticosteroid treatment used to mature fetal lungs?

Answer (Q15, Application). (a) Without surfactant, alveolar surface tension is high; by Laplace's law ($P = 2T/r$) a small alveolus generates higher collapse pressure than a large one, so small alveoli empty into larger ones, lowering compliance and causing diffuse atelectasis (and pulmonary edema). (b) In premature infants, immature type II pneumocytes make insufficient surfactant, causing neonatal respiratory distress syndrome (hyaline membrane disease). (c) Antenatal glucocorticoids (e.g., betamethasone) given to the mother accelerate fetal type II cell maturation and surfactant (DPPC) production, reducing NRDS severity. See section 31. 16. The kidney maintains blood osmolality homeostasis. ADH (vasopressin) is released from the posterior pituitary in response to high blood osmolality. Explain: (a) how ADH regulates AQP2 insertion into the collecting duct apical membrane; (b) why ADH deficiency produces dilute, voluminous urine (diabetes insipidus); (c) how alcohol inhibits ADH secretion and causes diuresis.

Answer (Q16, Application). (a) High plasma osmolality stimulates posterior-pituitary ADH release; ADH binds V_2 receptors on collecting-duct principal cells, raising cAMP/PKA, which inserts aquaporin-2 water channels into the apical membrane so water is reabsorbed and urine is concentrated. (b) ADH deficiency (central diabetes insipidus) leaves few apical AQP2 channels, so water is not reabsorbed and large volumes of dilute urine are produced. (c) Alcohol inhibits ADH secretion, reducing AQP2 insertion and causing a water diuresis (the basis of alcohol-

associated dehydration). See section 31. 17. Counter-current exchange in the vasa recta (renal medullary blood vessels) maintains the osmotic gradient established by the loop of Henle. Explain: (a) why the vasa recta loop parallel to the loop of Henle; (b) how ascending and descending limbs exchange solutes; (c) what would happen to medullary osmolality if the vasa recta were replaced by a single straight vessel.

Answer (Q17, Application). (a) The vasa recta hairpin parallel to the loop of Henle so blood can perfuse the medulla without dissipating the corticomedullary osmotic gradient. (b) As blood descends, water leaves and solute (NaCl, urea) enters; as it ascends, the reverse occurs, so the descending and ascending limbs passively exchange solute and water — countercurrent exchange that returns nearly isotonic blood to the cortex. (c) A single straight vessel would carry away medullary solute (washout) and deliver excess water, dissipating the gradient and impairing the kidney’s ability to concentrate urine. See section 31. 18. During cold exposure, thermoregulation maintains core temperature at 37°C. Trace the response: peripheral thermoreceptors → hypothalamus → sympathetic nervous system → cutaneous vasoconstriction → reduced heat loss + shivering → increased heat production. What is the set-point concept, and how does fever alter the set-point?

Answer (Q18, Application). Cold skin thermoreceptors signal the hypothalamic thermostat, which increases sympathetic outflow: cutaneous vasoconstriction reduces skin heat loss, shivering (and BAT non-shivering thermogenesis via UCP1) increases heat production, restoring core temperature toward 37 °C. The set-point is the target value the hypothalamus defends by activating opposing effectors around it. In fever, pyrogens (IL-1, IL-6, TNF) drive hypothalamic COX-2/PGE(₂), which raises the set-point; the body then uses normal cold-defense mechanisms (vasoconstriction, shivering/chills) to reach the new, higher set-point. See section 31. 19. The oxygen cascade describes the progressive decrease in PO₂ from atmosphere (160 mmHg) to mitochondria (about 1–3 mmHg). Identify each step: inspired air → alveolar air (104 mmHg, diluted by CO₂ and water vapor) → arterial blood (100 mmHg, some V/Q mismatch) → capillary blood → tissue → mitochondria. At which step is the largest PO₂ drop, and what determines its magnitude?

Answer (Q19, Application). The oxygen cascade: inspired air about 160 mmHg (->) humidified/alveolar gas about 104 mmHg (diluted by water vapor and CO(₂)) (->) arterial blood about 100 mmHg (small drop from V/Q mismatch and shunt) (->) capillary/tissue, falling steeply as O(₂) diffuses out (->) mitochondria about 1–3 mmHg. The largest drop is the tissue/cellular step (capillary to mitochondria, tens of mmHg), set by tissue O(₂) consumption rate, capillary density, and diffusion distance (Fick’s law); a smaller but key drop is inspired-to-alveolar, governed by the alveolar gas equation. See section 31. 20. Heart failure with reduced ejection fraction (HFrEF) results in an EF < 40% (normal 55–70%). Explain: (a) why reduced contractility leads to fluid retention (RAAS activation); (b) why diuretics provide symptomatic relief but do not improve survival; (c) how ACE inhibitors + beta-blockers + ARNI (sacubitril/valsartan) have been shown to reduce mortality.

Answer (Q20, Application). (a) Reduced ventricular contractility lowers stroke volume and effective arterial filling; the kidney senses underperfusion and activates RAAS (and sympathetic and ADH systems), causing Na(⁺) and water retention and congestion. (b) Diuretics relieve congestive symptoms (edema, dyspnoea) by offloading volume but do not interrupt the maladaptive neurohormonal remodeling that drives progression, so they do not improve survival. (c) ACE inhibitors/ARBs, evidence-based beta-blockers, mineralocorticoid antagonists, and ARNI (sacubitril/valsartan, which adds neprilysin inhibition to prolong protective natriuretic peptides while blocking AT(₁)) all blunt the RAAS/sympathetic remodeling cascade, and trials show they reduce mortality in HFrEF. See section 31.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the Frank-Starling mechanism at the molecular level: increased preload → increased sarcomere stretch → increased Ca²⁺ sensitivity of troponin C → increased force production. What molecular mechanism converts sarcomere length into increased Ca²⁺ sensitivity, and why does this relationship break down in dilated cardiomyopathy (DCM)?

Answer (Q21, Synthesis). Length-dependent activation is the molecular core of Frank-Starling: stretching the sarcomere toward optimal length (about 2.2 (μ)m) reduces interfilament lattice spacing and increases titin-mediated strain, which raises the Ca(²⁺) sensitivity of troponin C so more cross-bridges form per Ca(²⁺) transient, increasing force. The empirical evidence (stretch raises Ca(²⁺) sensitivity and force within the physiological range) is conditional on intact sarcomere geometry. In dilated cardiomyopathy the ventricle is overstretched beyond optimal overlap, the cytoskeleton/titin and Ca(²⁺)-handling proteins are remodeled, and the curve flattens — so the relationship breaks down. What would change the conclusion is operating outside the physiological length range or altered titin/troponin, which is exactly the DCM condition. See section 31. 22. Design an experiment to measure the maximal aerobic capacity (VO₂ max) of a human subject. Describe: the incremental exercise protocol (treadmill or cycle), the gas analysis measurements (O₂ consumption, CO₂ production, RER), and the criteria for reaching true VO₂ max. How does VO₂ max differ between trained athletes and sedentary individuals, and what factors (cardiac output, O₂ extraction, muscle mitochondrial density) limit performance?

Answer (Q22, Synthesis). Hypothesis: a graded exercise test will identify a true VO(₂)max plateau. Protocol: incremental treadmill or cycle ergometer with stepwise increases in workload to volitional exhaustion, with breath-by-breath gas analysis measuring O(₂) consumption, CO(₂) production, and RER. Criteria for true VO(₂)max: a plateau in VO(₂) despite rising workload, plus secondary markers (RER >1.10–1.15, HR

near age-predicted max, high blood lactate). Comparison/control: trained athletes vs sedentary subjects; trained subjects have markedly higher $\dot{V}O_{2\max}$. Limiting factors are mainly central (maximal cardiac output/ $\dot{V}O_2$ delivery) with peripheral contributions (a- $\dot{V}O_2$ difference, muscle mitochondrial/capillary density). A falsifying result is no $\dot{V}O_2$ plateau (use a verification bout). The conclusion is conditional on reaching true maximal effort. See section 31. 23. Evaluate the roles of the sympathetic and parasympathetic nervous systems in cardiovascular regulation via their respective neurotransmitters (norepinephrine $\rightarrow \beta_1$ receptors \rightarrow increased HR vs acetylcholine $\rightarrow M_2$ receptors \rightarrow decreased HR). What is “vagal tone” at rest, and why does denervation of the heart (cardiac transplant recipients) result in a resting HR of about 100 bpm?

Answer (Q23, Synthesis). Sympathetic norepinephrine acting on SA-node (β_1) receptors speeds diastolic depolarization (increases HR and contractility); parasympathetic acetylcholine acting on M_2 receptors hyperpolarises and slows the SA node (decreases HR). “Vagal tone” is the continuous resting parasympathetic restraint on the SA node: the intrinsic SA rate is about 100 bpm, but tonic vagal activity holds resting HR near 70 bpm. In a transplanted (denervated) heart the vagal input is absent, so the SA node fires near its intrinsic rate of about 100 bpm. The conclusion is conditional: it assumes the SA node and its intrinsic automaticity are intact, and partial reinnervation over years can lower the resting rate. See section 31. 24. Evaluate the physiological trade-off between capillary density and distance-limited O_2 diffusion: (a) use Fick’s law of diffusion ($J = D \times A \times \Delta P/d$) to explain why capillary density must increase in metabolically active tissues; (b) calculate the maximum O_2 diffusion distance (about 100 μm); (c) explain why tumors develop necrotic cores when they grow beyond 200 μm without angiogenesis.

Answer (Q24, Synthesis). (a) Fick’s law ($J = D(A)(\Delta P/d)$) shows flux falls as diffusion distance d increases, so metabolically active tissues must reduce inter-capillary distance (higher capillary density) to keep every cell within the diffusible O_2 range. (b) The Krogh-cylinder analysis gives a maximum viable O_2 diffusion radius of roughly 100 (μ)m from a capillary at physiological PO_2 and consumption. (c) A tumor growing beyond about 150–200 (μ)m from its nearest vessel exceeds this diffusion limit, so its core becomes hypoxic and necrotic unless it triggers angiogenesis (VEGF-driven neovascularisation). The conclusion is conditional on assumed D , consumption rate, and PO_2 ; changing these (e.g., higher capillary PO_2 or lower metabolic rate) shifts the critical distance. See section 31. 25. High altitude acclimatisation involves acute and chronic responses: acute (hyperventilation, increased HR); chronic (EPO \rightarrow erythrocytosis, 2,3-BPG increase, vascular remodeling). Evaluate: (a) how the carotid body senses hypoxia and triggers hyperventilation; (b) why respiratory alkalosis results; (c) how renal bicarbonate excretion compensates; (d) why chronic mountain sickness (Monge’s disease) can result from excessive erythropoiesis.

Answer (Q25, Synthesis). (a) Low inspired PO_2 at altitude reduces arterial PO_2 ; carotid-body glomus cells sense hypoxia (closing O_2 -sensitive K^{+} channels, depolarizing, releasing transmitter) and drive the medullary respiratory center to hyperventilate. (b) Hyperventilation blows off CO_2 , lowering arterial PCO_2 and producing respiratory alkalosis (which itself partly restrains the ventilatory response). (c) The kidney compensates over days by excreting bicarbonate (and reducing H^{+} excretion), normalizing pH and permitting fuller hyperventilation. (d) Chronic hypoxia drives EPO and erythrocytosis; in chronic mountain sickness (Monge’s disease), excessive erythropoiesis raises haematocrit and viscosity, causing pulmonary hypertension and impaired oxygen delivery despite high Hb. See section 31. 26. Evaluate the “oxygen paradox” in ischemia-reperfusion injury: restored oxygen supply to ischemic tissue generates ROS (via xanthine oxidase and Complex I) that cause greater damage than the ischemia itself. How do ROS cause injury (membrane lipid peroxidation, mitochondrial permeability transition pore opening), and what therapeutic strategies (hypothermia, ischemic pre-conditioning) mitigate reperfusion injury?

Answer (Q26, Synthesis). Ischemia depletes ATP and accumulates substrates (hypoxanthine, reduced electron carriers). On reperfusion, restored O_2 drives a burst of reactive oxygen species (xanthine oxidase, mitochondrial Complex I), which causes membrane lipid peroxidation, protein/DNA damage, Ca^{2+} overload, and opening of the mitochondrial permeability transition pore, triggering cell death — sometimes exceeding the original ischemic injury. Mitigation: therapeutic hypothermia (slows metabolism and ROS generation), ischemic pre- and post-conditioning (brief ischemia/reperfusion cycles activate protective kinase/mPTP pathways), and antioxidant or mPTP-targeted strategies. The conclusion is evidence-supported but conditional: the magnitude of reperfusion injury varies with ischemia duration and tissue, and conditioning benefits are not uniform across models, which is what would change the inference. See section 31. 27. Evaluate the hypothesis that endothermy evolved from aerobic capacity (the “aerobic capacity model”): selection for sustained locomotion \rightarrow increased mitochondrial density \rightarrow increased resting metabolic rate \rightarrow internal heat production \rightarrow endothermy. Compare this to the “parental care model” (selection for incubation of eggs \rightarrow endothermy). Which model is better supported by paleontological and comparative physiological evidence?

Answer (Q27, Synthesis). The aerobic-capacity model proposes endothermy arose because selection for sustained aerobic locomotion increased mitochondrial density and resting metabolic rate, with internal heat as a by-product later exploited for thermoregulation. The parental-care (and the related thermoregulatory/assimilation) model proposes selection acted directly on stable body temperature for incubation, development, or niche expansion. Comparative physiology (the link between maximal and resting metabolic rate, mitochondrial proliferation) gives some support to the aerobic-capacity model, while paleontological data (bone histology, growth rates, nesting behavior in dinosaurs/early mammals) are mixed. The honest answer is that the evidence is conditional and the models are not mutually exclusive; no single dataset is decisive, and new fossil metabolic proxies are what would shift the conclusion. See section 31. 28. The lymphatic system returns interstitial fluid to the bloodstream.

Evaluate: (a) how lymph is formed (Starling’s forces → net filtration at the arterial end of capillaries); (b) what happens when lymphatic drainage fails (lymphoedema — elephantiasis caused by parasitic nematode *Wuchereria bancrofti*); (c) the dual role of lymphatics in immune surveillance (dendritic cell migration to lymph nodes).

Answer (Q28, Synthesis). (a) Lymph forms because Starling forces produce net capillary filtration (about 10% of filtered fluid, plus leaked protein) that is not reabsorbed; this protein-rich interstitial fluid enters highly permeable blind-ended lymphatic capillaries by bulk flow. (b) When lymphatic drainage fails, protein-rich fluid accumulates as lymphoedema (e.g., filariasis from *Wuchereria bancrofti*, or post-surgical node dissection), which is non-pitting and prone to fibrosis and infection. (c) Lymphatics also serve immune surveillance: antigen-bearing dendritic cells migrate via afferent lymphatics to lymph nodes to prime adaptive responses. These are well-established mechanisms; the conditional element is that the relative contribution of filtration vs lymphatic load depends on capillary pressure and protein status, which is what would alter the edema interpretation. See section 31. 29. Diving mammals (Weddell seal, sperm whale) can hold their breath for >60 minutes while diving to >1,000 m. Evaluate four physiological adaptations: (a) bradycardia and peripheral vasoconstriction (dive reflex); (b) elevated myoglobin content (O₂ storage); (c) splenic contraction (autotransfusion of O₂-carrying RBCs); (d) tolerance of lactate (anaerobic metabolism during deep dives). How do these adaptations differ between pinnipeds and cetaceans?

Answer (Q29, Synthesis). Deep-diving mammals tolerate long apnoea via integrated adaptations: (a) the dive reflex — vagally mediated bradycardia plus selective peripheral vasoconstriction redistributes limited O₂ to heart and brain; (b) high muscle myoglobin greatly expands O₂ storage; (c) splenic contraction autotransfuses O₂-rich red cells, raising effective haematocrit during the dive; (d) tolerance of large lactate loads from anaerobic metabolism in hypoperfused tissues, cleared on surfacing. Pinnipeds (seals) rely more on large blood/spleen O₂ stores and pronounced bradycardia, often diving on exhalation to limit barotrauma and N₂ uptake, whereas cetaceans (whales) emphasize very high myoglobin and rapid gas exchange. The contrast (blood/spleen-dominant vs myoglobin-dominant strategies) is the boundary condition that frames the comparison. See section 31. 30. Critically evaluate the concept of “physiological reserve” — the excess capacity of organ systems beyond what is needed at rest (e.g., cardiac output can increase 5× during exercise, kidneys can maintain GFR with a single kidney). How does aging erode physiological reserve, and at what threshold does age-related reserve depletion produce clinical disease? Apply the concept to explain why the elderly are disproportionately vulnerable to COVID-19, heat waves, and surgical stress. Then transfer the same homeostatic-reserve logic to a salty high-protein meal with low water intake: predict plasma osmolality, ADH/aldosterone direction, hepatic urea production, urine concentration, and why desert mammals and freshwater fish handle nitrogen differently.

Answer (Q30, Synthesis). Physiological reserve is the excess functional capacity organ systems hold beyond resting needs (e.g., about 5-fold cardiac output rise in exercise, maintained GFR on one kidney). Aging erodes reserve through loss of cells, stiffer tissues, blunted maximal responses, and slowed homeostatic feedback; clinical disease emerges when a stressor demands more than the depleted reserve can supply (the variable crosses from compensated to decompensated). This explains elderly vulnerability: COVID-19 demands large pulmonary/immune reserve, heat waves demand cardiovascular and thermoregulatory reserve (skin blood flow, sweating), and surgery demands cardiac, renal, and pulmonary reserve — each exceeds diminished capacity. The meal transfer shows the same principle: a salty high-protein meal with low water intake raises plasma osmolality and nitrogen load; osmoreceptors drive ADH release, low effective volume can activate RAAS/aldosterone, amino-acid catabolism raises hepatic urea production, and intact renal reserve produces more concentrated urine. Desert mammals invest ATP in urea handling and a steep medullary gradient to conserve water; freshwater fish can excrete ammonia directly because water is abundant and ammonia can diffuse across gill surfaces. The conclusion is conditional: reserve loss is heterogeneous across individuals and organs, so chronological age alone does not set the threshold; functional measures and environmental water availability do. See section 31 and source notes in [National Institute of Diabetes and Digestive and Kidney Diseases \[2024a,b\]](#).

Questions — Nervous System and Neural Signaling

Instructor Use and Coverage Notes

- Coverage target: Predict behavioral or signal consequences from a circuit or structural perturbation.
- Model/data emphasis: Cable-length, conduction, and simple circuit calculations.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: The brain is not only neurons; glia and circuit context are essential to function.
- Transfer product: Transfer circuit reasoning to reflexes, sensory systems, learning, and disease.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 32 of the textbook — review that chapter before attempting the exercises below.

1. Name the two divisions of the nervous system. What does each contain?

Answer (Q1, Recall). The central nervous system (CNS) comprises the brain and spinal cord and integrates information. The peripheral nervous system (PNS) is all nervous tissue outside the CNS (12 cranial nerves and 31 spinal nerve pairs), subdivided into the somatic (voluntary) and autonomic (involuntary) divisions that connect the CNS to the body. See section 32. 2. What is a neuron? Draw and label the soma, dendrites, axon, and synaptic terminal.

Answer (Q2, Recall). A neuron is an excitable cell specialized for receiving, integrating, and transmitting electrical signals. The soma (cell body) houses the nucleus and does most protein synthesis; dendrites receive synaptic inputs; the axon conducts the action potential; and the axon terminal (bouton) releases neurotransmitter from synaptic vesicles onto the next cell. See section 32. 3. What is the resting membrane potential of a typical neuron? Which ion is most permeable at rest?

Answer (Q3, Recall). The resting membrane potential of a typical neuron is about -70 mV. K^+ is the most permeable ion at rest (highest conductance through KCNK leak channels), so the resting potential lies close to $E_K \approx -89$ mV. See section 32. 4. What is an action potential? Describe the four phases (resting, depolarization, repolarization, hyperpolarization).

Answer (Q4, Recall). An action potential is an all-or-none, regenerative depolarization that propagates along the axon. Phases: resting (-70 mV, K^+ leak dominant); depolarization (voltage-gated Na^+ channels open, V_m rises toward $+30$ mV); repolarization (Na^+ channels inactivate, voltage-gated K^+ channels open, V_m falls); and hyperpolarization (K^+ channels close slowly, dipping below rest before returning to -70 mV). See section 32. 5. What is the myelin sheath? Name the cells that produce myelin in the CNS and PNS.

Answer (Q5, Recall). The myelin sheath is a multilayered (up to about 100 wraps) insulating wrap of glial plasma membrane around an axon that increases membrane resistance and speeds conduction. Oligodendrocytes produce CNS myelin (one cell myelinates up to about 50 axons); Schwann cells produce PNS myelin (one cell per axon internode). See section 32. 6. What is saltatory conduction? How does it increase conduction velocity?

Answer (Q6, Recall). Saltatory conduction is the regeneration of the action potential only at nodes of Ranvier, where voltage-gated Na^+ channels are concentrated, so the impulse appears to “jump” between nodes. Myelin between nodes raises membrane resistance and lowers capacitance, letting current spread passively and rapidly down the internode, dramatically increasing conduction velocity for a given axon diameter. See section 32. 7. Define a synapse. Distinguish chemical from electrical synapses.

Answer (Q7, Recall). A synapse is the junction where one neuron communicates with a target cell. Chemical synapses transmit via neurotransmitter released from presynaptic vesicles (triggered by Ca^{2+} influx through Cav channels) acting on postsynaptic receptors, giving signal gain and a about 0.5 ms delay; electrical synapses use gap junctions for direct, bidirectional, near-instantaneous ionic current flow. See section 32. 8. Name three neurotransmitters and state one function of each.

Answer (Q8, Recall). Examples: glutamate is the main excitatory CNS transmitter (drives EPSPs via AMPA/NMDA receptors and LTP); GABA is the main inhibitory CNS transmitter (opens Cl^- channels via $GABA_A$); acetylcholine excites skeletal muscle at the neuromuscular junction and is the autonomic preganglionic transmitter. See section 32. 9. What is the reflex arc? Name its five components.

Answer (Q9, Recall). A reflex arc is the neural pathway producing a rapid, involuntary response to a stimulus. Five components: receptor (detects stimulus), afferent (sensory) neuron, integration center (CNS, e.g., spinal cord), efferent (motor) neuron, and effector (muscle or gland). See section 32. 10. Distinguish the somatic from the autonomic nervous system.

Answer (Q10, Recall). The somatic nervous system mediates voluntary control of skeletal muscle: single myelinated motor neurons run from CNS to effector and release ACh (excitatory only) at the neuromuscular junction. The autonomic nervous system controls involuntary visceral function via a two-neuron preganglionic/postganglionic chain and can excite or inhibit targets through its antagonistic sympathetic and parasympathetic divisions. See section 32.

Questions 11–20: Application and Analysis

11. The Goldman equation predicts resting membrane potential from the relative permeabilities of Na^+ , K^+ , and Cl^- . If a mutation doubles Na^+ permeability at rest (P_{Na} increases $2\times$), predict the new resting potential direction (depolarization toward $E_{\text{Na}} = +60 \text{ mV}$). Calculate using simplified Goldman equation.

Answer (Q11, Application). Use the GHK equation: at rest $P_K : P_{\text{Na}} : P_{\text{Cl}} \approx 1 : 0.04 : 0.45$ gives $V_m \approx -68 \text{ mV}$. Doubling P_{Na} to about 0.08 increases the weight of the inward Na^+ term (which pulls toward $E_{\text{Na}} = +60 \text{ mV}$), so the numerator/denominator ratio shifts and V_m moves a few mV more positive (depolarizes, to roughly -62 to -65 mV). This brings the membrane closer to threshold (-55 mV), increasing excitability. See section 32. 12. Multiple sclerosis (MS) destroys myelin in the CNS. Predict: (a) the effect on conduction velocity; (b) which neuronal functions are impaired first; (c) why remyelination therapies are being investigated; (d) why the PNS is relatively spared (different myelinating cells).

Answer (Q12, Application). (a) Conduction velocity falls sharply: loss of myelin lowers membrane resistance and raises capacitance, so passive current leaks out and saltatory conduction fails (slowed or blocked). (b) Functions requiring fast, heavily myelinated, long tracts fail first — vision (optic neuritis), motor coordination, sensory and bladder control. (c) Remyelination would restore the insulation needed for saltatory conduction and reverse deficits. (d) The PNS is relatively spared because Schwann cells (not the CNS oligodendrocytes/MOG-MBP autoantigens targeted in MS) make peripheral myelin. See section 32. 13. Local anaesthetics (lidocaine) block voltage-gated Na^+ channels. Explain: (a) why this prevents action potential generation; (b) why pain fibers (small, unmyelinated C fibers) are blocked before motor fibers (large, myelinated $\text{A}\alpha$ fibers); (c) is this use-dependent block (more block with higher firing frequency)?

Answer (Q13, Application). (a) Blocking voltage-gated Na^+ channels prevents the regenerative Na^+ influx, so depolarization cannot reach threshold and no action potential fires. (b) Small unmyelinated C (pain) fibers are blocked before large myelinated $\text{A}\alpha$ (motor) fibers because they have shorter internodal distances and a shorter critical length over which channels must be blocked, and smaller axons have higher surface-to-volume drug access. (c) Yes — lidocaine binds preferentially to open/inactivated channels, so rapidly firing (high-frequency) fibers accumulate more block: use-dependent block. See section 32. 14. The patellar (knee-jerk) reflex involves a monosynaptic stretch reflex arc. Trace the pathway: muscle spindle \rightarrow Ia afferent \rightarrow spinal cord (monosynaptic excitation of α -motor neuron) \rightarrow quadriceps contraction. Explain: (a) why the reflex is monosynaptic (no interneuron); (b) the role of reciprocal inhibition of the hamstring (via an inhibitory interneuron).

Answer (Q14, Application). Pathway: muscle stretch activates the muscle spindle, the Ia afferent fires and enters the dorsal root, synapses directly on the α -motor neuron in the ventral horn, which contracts the quadriceps to extend the knee. (a) It is monosynaptic because the Ia afferent excites the motor neuron with a single synapse (no interneuron), giving the shortest latency. (b) A branch of the Ia afferent excites an inhibitory interneuron that hyperpolarises the antagonist (hamstring) motor neuron — reciprocal inhibition — so the antagonist relaxes as the agonist contracts. See section 32. 15. Sensory adaptation: olfactory receptors rapidly adapt to constant odor exposure (within minutes). Explain: (a) the molecular mechanism ($\text{cAMP} \rightarrow \text{Ca}^{2+} \rightarrow \text{calmodulin} \rightarrow \text{reduced CNG channel sensitivity}$); (b) the difference between phasic (rapidly adapting) and tonic (slowly adapting) receptors; (c) one example of a tonic receptor.

Answer (Q15, Application). (a) Sustained odorant raises cAMP, opening CNG channels; Ca^{2+} entering binds calmodulin, which reduces the channel's cAMP sensitivity (negative feedback), so the receptor current declines despite continued stimulus. (b) Phasic (rapidly adapting) receptors respond mainly to stimulus change and fall silent during steady stimulation; tonic (slowly adapting) receptors fire continuously, encoding sustained stimulus intensity. (c) A tonic receptor example is the Merkel disc (sustained pressure) or muscle spindle (sustained stretch/position). See section 32. 16. The blood-brain barrier (BBB) restricts drug entry into the CNS. Explain: (a) the cellular basis (tight junctions between endothelial cells, pericytes, astrocyte end-feet); (b) which molecules can cross (small, lipophilic, $\text{MW} < 400$); (c) how L-DOPA (prodrug for dopamine) exploits amino acid transporters to bypass the BBB.

Answer (Q16, Application). (a) The BBB is formed by tight junctions (claudin-5, occludin, ZO) sealing brain endothelial cells, with pericytes and astrocyte endfeet maintaining the barrier — blocking paracellular passage of polar/large molecules. (b) Only small, lipophilic, low-molecular-weight molecules (O_2 , CO_2 , anaesthetics) diffuse freely. (c) Dopamine cannot cross, so L-DOPA is given: it is a large neutral amino acid carried across by the LAT1 transporter, then decarboxylated to dopamine inside the CNS — exploiting carrier-mediated transport to bypass the barrier. See section 32. 17. Neuroplasticity: after a stroke destroys the motor cortex controlling the right hand, the left hand often improves in dexterity over weeks. Explain: (a) cortical remapping (adjacent cortical areas take over); (b) the role of long-term potentiation (LTP) in this process; (c) why intensive rehabilitation (constraint-induced movement therapy) accelerates recovery.

Answer (Q17, Application). (a) Cortical remapping: surviving neurons in adjacent, undamaged cortex expand their receptive fields and take over functions of the lost region. (b) LTP underlies this rewiring — correlated activity (Hebbian) strengthens spared synapses via NMDA-receptor Ca^{2+} influx, CaMKII activation, and AMPA-receptor insertion, building new functional circuits. (c) Constraint-induced therapy forces intensive use of the affected limb, driving the correlated pre/postsynaptic activity that maximizes LTP and use-dependent remapping, so recovery accelerates. See section 32. 18. The autonomic nervous system has sympathetic (fight-or-flight) and parasympathetic (rest-and-digest) divisions. Compare: (a) preganglionic neurotransmitter (both ACh); (b) postganglionic neurotransmitter (sympathetic = NE, parasympathetic = ACh); (c) effects on heart rate, bronchioles, and GI motility.

Answer (Q18, Application). (a) Both divisions use ACh at the preganglionic synapse (on nicotinic receptors). (b) Postganglionically, sympathetic neurons release norepinephrine onto adrenergic receptors, while parasympathetic neurons release ACh onto muscarinic receptors. (c) Sympathetic activation increases heart rate (β_1), dilates bronchioles (β_2), and inhibits GI motility; parasympathetic activation decreases heart rate (M_2), constricts bronchioles (M_3), and increases GI motility and secretion. See section 32. 19. Pain processing: nociceptors detect tissue damage and transmit signals via A δ (sharp, fast) and C (dull, slow) fibers. Explain the gate control theory: how does activation of large-diameter A β touch fibers “close the gate” in the spinal cord dorsal horn, reducing pain transmission to the brain?

Answer (Q19, Application). Gate control: pain-carrying A δ /C fibers and large A β touch fibers both project to the dorsal horn. A β activity excites an inhibitory interneuron in the substantia gelatinosa that presynaptically/postsynaptically inhibits the projection (transmission) neuron carrying pain to the brain. Thus stimulating touch fibers (rubbing the area, or TENS) “closes the gate,” reducing the pain signal ascending the spinothalamic tract even though nociceptor input is unchanged. See section 32. 20. Glial cells (astrocytes, oligodendrocytes, microglia) outnumber neurons. Describe two functional roles of astrocytes beyond structural support: (a) glutamate uptake at synapses (preventing excitotoxicity); (b) regulation of extracellular K^+ ; (c) the “tripartite synapse” concept (astrocyte modulates synaptic strength via gliotransmitters).

Answer (Q20, Application). (a) Glutamate uptake: astrocyte EAAT1/EAAT2 transporters clear about 90% of synaptic glutamate, terminating signaling and preventing excitotoxic over-activation of NMDA receptors. (b) K^+ buffering: astrocytes take up activity-driven extracellular K^+ through Kir4.1 channels and redistribute it through the gap-junction-coupled syncytium, keeping the resting potential stable. (c) Tripartite synapse: the astrocyte process is a functional third partner that senses synaptic glutamate (astrocytic Ca^{2+} rise) and releases gliotransmitters (glutamate, ATP, D-serine) that modulate synaptic strength and plasticity. See section 32.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the “integrate-and-fire” model of neuronal computation: a neuron summates thousands of excitatory and inhibitory postsynaptic potentials (EP-SPs and IPSPs) and fires when threshold is reached. What are the limitations of this model (dendritic computation, non-linear integration, backpropagating APs), and how do modern computational neuroscience models address them?

Answer (Q21, Synthesis). The leaky integrate-and-fire model treats the neuron as a point that linearly sums EPSPs/IPSPs at the hillock and fires when it crosses about -55 mV. Limitations: it ignores active dendritic computation (NMDA spines and dendritic $\text{Na}^+/\text{Ca}^{2+}$ spikes make integration non-linear), location-dependent attenuation set by the length constant, shunting inhibition, and backpropagating action potentials that gate plasticity. Modern models address these with multi-compartment (cable-equation) Hodgkin-Huxley neurons, two-layer dendritic-subunit models, and adaptive exponential integrate-and-fire variants that approximate non-linear dendritic processing. See section 32. 22. Design an experiment to determine whether a newly discovered brain region is involved in spatial memory rather than procedural memory. Describe: (a) lesion studies (selective ablation); (b) electrophysiology (place cells, grid cells); (c) optogenetic activation/inhibition during a behavioral task; (d) what behavioral paradigms (Morris water maze, T-maze) you would use; (e) how a brain-cell atlas would help choose cell types without proving function by itself.

Answer (Q22, Synthesis). Hypothesis: the region is necessary/sufficient for spatial but not procedural memory. (a) Selectively lesion (or chemogenetically silence) the region and test spatial vs procedural tasks; predict spatial impairment with intact procedural learning. (b) Record single units for place cells/grid cells (spatial coding) and compare with a procedural-learning control area. (c) Use optogenetics to inhibit the region only during the spatial-encoding phase and, separately, activate it, confirming necessity and sufficiency. (d) Behavioral paradigms: Morris water maze and T-maze (spatial) versus rotarod or serial-reaction-time task (procedural); controls and replication distinguish spatial-specific from general deficits. (e) A brain-cell atlas can nominate region-specific neuronal, glial, or marker-gene targets for recording and perturbation, but atlas identity is not causal evidence; function still requires the lesion, recording, and perturbation tests [National Institute of Mental Health, 2023, Yao et al., 2023]. See section 32. 23. Evaluate the molecular basis of Alzheimer’s disease: (a) A β oligomer toxicity hypothesis; (b) tau hyperphosphorylation and neurofibrillary tangles; (c) the failure of anti-A β antibody therapies (lecanemab showed modest benefit, 27% slowing of decline). What does the modest efficacy of anti-A β antibodies tell us about the “amyloid cascade” as a therapeutic target?

Answer (Q23, Synthesis). (a) The A β -oligomer hypothesis holds soluble oligomers, not plaques, disrupt synapses and trigger toxicity. (b) Tau hyperphosphorylation forms intraneuronal neurofibrillary tangles whose spread tracks cognitive decline more tightly than amyloid load. (c) Anti-

A β antibodies (lecanemab, donanemab) clear plaques but only modestly slow decline (about 27%). The modest efficacy argues amyloid is an early trigger but not the sole driver: by symptom onset, downstream tau pathology, neuroinflammation, and synaptic loss are self-sustaining, so the linear “amyloid cascade” is incomplete and combination/earlier intervention is likely required. See section 32. 24. Evaluate the role of adult neurogenesis in the hippocampus: (a) evidence that new neurons are continuously generated in the subgranular zone of the dentate gyrus; (b) the functional role of newborn neurons in pattern separation (distinguishing similar memories); (c) the controversial evidence for adult neurogenesis in humans (Spalding et al., ¹⁴C birth-dating vs Sorrells et al., immunohistochemistry showing no new neurons after age 13).

Answer (Q24, Synthesis). (a) Evidence for adult hippocampal neurogenesis: BrdU/Ki67 labeling and Spalding’s ¹⁴C birth-dating indicate continued neuron generation in the dentate-gyrus subgranular zone. (b) Newborn granule cells support pattern separation, letting similar experiences be stored as distinct memories and aiding mood regulation. (c) The controversy: Sorrells et al. found essentially no proliferating neuroblasts after adolescence by immunohistochemistry, conflicting with the ¹⁴C and other immunostaining work. Resolution likely hinges on tissue fixation/marker specificity; the disagreement shows the conclusion depends on methodology, so the rate (not the existence) in adult humans remains unsettled. See section 32. 25. Evaluate the mechanism of general anaesthesia: despite >150 years of use, the molecular targets of volatile anaesthetics (sevoflurane, isoflurane) are incompletely understood. Current evidence implicates: (a) GABA_A receptor potentiation; (b) NMDA receptor inhibition; (c) two-pore domain K⁺ channel (TREK/TASK) activation. How does the combination of these effects produce unconsciousness, and why is the “unitary” theory of anaesthesia (one target) now rejected?

Answer (Q25, Synthesis). Volatile anaesthetics act on multiple low-affinity targets: (a) potentiating GABA_A receptors (enhanced inhibition), (b) inhibiting NMDA glutamate receptors (reduced excitation), and (c) opening two-pore K⁺ channels (TREK/TASK), hyperpolarising neurons. Together these depress thalamocortical and cortico-cortical signaling, dissolving the integrated activity required for consciousness. The unitary (single-target) theory is rejected because no one receptor accounts for all anaesthetic endpoints, different agents have different target profiles, and immobility, amnesia, and unconsciousness are dissociable and mediated at different sites. See section 32. 26. Evaluate the concept of “neural oscillations” — rhythmic brain activity at specific frequency bands (delta 1–4 Hz, theta 4–8 Hz, alpha 8–13 Hz, beta 13–30 Hz, gamma 30–100 Hz). What cognitive processes are associated with each band, and what evidence from EEG/MEG studies supports the idea that frequency-band-specific synchronisation enables “binding” of distributed cortical representations into a unified percept?

Answer (Q26, Synthesis). Band-cognition associations: delta — deep NREM sleep and memory consolidation; theta — hippocampal navigation and memory encoding; alpha — relaxed wakefulness and attentional suppression; beta — alert focus and motor planning; gamma — sensory binding and conscious perception. EEG/MEG evidence for the binding hypothesis: stimulus-locked gamma synchronisation across distributed cortical sites correlates with perceptual grouping, and disrupting synchrony degrades binding. The conclusion is conditional — gamma synchrony reliably correlates with binding but its causal necessity for a unified percept remains debated, so it is evidence-supported rather than settled. See section 32. 27. Chronic pain involves maladaptive plasticity (central sensitisation) in the spinal cord dorsal horn. Evaluate: (a) the molecular mechanism (NMDA receptor-dependent wind-up, glial activation, BDNF release); (b) why opioids provide temporary relief but worsen chronic pain through opioid-induced hyperalgesia (OIH); (c) what non-opioid alternatives (gabapentinoids, SNRI antidepressants, spinal cord stimulation) target central sensitisation.

Answer (Q27, Synthesis). (a) Central sensitisation: repetitive C-fiber input causes NMDA-receptor-dependent “wind-up” and removal of Mg²⁺ block, glial (microglia/astrocyte) activation, and BDNF release that lowers dorsal-horn neuron threshold and expands receptive fields. (b) Opioids relieve pain acutely via μ -receptor inhibition of transmission, but chronic use induces opioid-induced hyperalgesia through NMDA upregulation and glial activation, paradoxically worsening pain. (c) Non-opioid options target central sensitisation: gabapentinoids (block $\alpha_2\delta$ Ca²⁺-channel subunits), SNRIs (boost descending serotonin/noradrenergic inhibition), and spinal cord stimulation (gate-control activation of A β fibers). See section 32. 28. The enteric nervous system (ENS, “second brain”) contains about 500 million neurons controlling GI motility, secretion, and blood flow independently of the CNS. Evaluate: (a) why the ENS is sometimes called autonomous (it functions after vagotomy); (b) the evidence linking ENS dysfunction to Parkinson’s disease (α -synuclein aggregation begins in the ENS years before brain symptoms); (c) how the gut-brain axis connects the ENS to cognition and mood.

Answer (Q28, Synthesis). (a) The ENS is “autonomous” because its myenteric and submucosal plexuses contain full sensory-interneuron-motor circuits that generate peristalsis and secretion even after vagotomy. (b) Parkinson’s link: misfolded α -synuclein aggregates appear in enteric neurons years before motor symptoms and may spread retrogradely via the vagus to the brainstem (Braak hypothesis), so gut pathology can precede CNS disease. (c) The gut-brain axis connects the ENS to cognition/mood through vagal afferents, enteroendocrine and immune signaling, and microbial metabolites that influence CNS neurotransmission. See section 32. 29. Optogenetics uses light-activated ion channels (channelrhodopsin-2, halorhodopsin) to activate or inhibit specific neurons with millisecond precision. Evaluate: (a) the technical requirements (viral vector delivery of opsin gene, implanted fiber optic); (b) an experiment that optogenetics uniquely enables (e.g., activating and silencing the same neurons to confirm necessity and sufficiency for a behavior); (c) the path to clinical translation (optogenetic gene therapy for retinitis pigmentosa).

Answer (Q29, Synthesis). (a) Technical requirements: an AAV/lentiviral vector delivers an opsin gene under a cell-type-specific promoter, plus an implanted optical fiber and light source for millisecond control. (b) Optogenetics uniquely allows activating and silencing the same defined neurons during behavior to test both necessity (inhibition abolishes the behavior) and sufficiency (activation evokes it) with temporal precision impossible for lesions or drugs. (c) Clinical translation: optogenetic gene therapy (e.g., ChrimsonR delivered to retinal ganglion cells with light-amplifying goggles) is in trials for retinitis pigmentosa, restoring light responses to a degenerated retina. See section 32. 30. Critically evaluate the “connectome” project — the effort to map every synaptic connection in the human brain (about 86 billion neurons, about 150 trillion synapses). Is the connectome sufficient to understand brain function, or is dynamic activity (electrophysiology, neuromodulation) equally important? Compare the completed *C. elegans* connectome (302 neurons, fully mapped) to our understanding of worm behavior — does knowing the wiring diagram explain the animal’s behavior? Then apply the same evidence-boundary reasoning to a high-performance speech neuroprosthesis reported in one participant with paralysis.

Answer (Q30, Synthesis). The connectome (a static wiring diagram) is necessary but not sufficient: the same circuit produces different outputs depending on dynamic activity, neuromodulatory state, and synaptic strength. The fully mapped *C. elegans* connectome (302 neurons) still does not fully predict behavior, because neuromodulators (e.g., monoamines, peptides) reconfigure the functional circuit and synaptic weights/signs are not given by anatomy alone. So structure constrains but does not determine function — understanding the brain also requires electrophysiology and neuromodulation, making the human connectome a foundation rather than a complete explanation. A speech neuroprosthesis claim needs the same boundary: implanted electrodes directly record motor/speech-cortex activity during attempted speech, and a trained decoder converts those signals into text or avatar control in a defined task; the inference is decodable intention-related structure, not a general readout of private thought. Durable translation still depends on chronic signal stability, calibration burden, tissue response, infection risk, power, device replacement, performance outside the lab, consent, data ownership, privacy, autonomy, and access. See section 32 and Willett et al. [2023], Metzger et al. [2023].

Questions — Action Potentials and Synaptic Transmission

Instructor Use and Coverage Notes

- Coverage target: Predict how changing an ion gradient or channel conductance alters excitability.
- Model/data emphasis: Nernst/Goldman, Hodgkin-Huxley, and synaptic-current reasoning.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: An action potential is not electricity flowing like a wire; it is regenerated ion-channel dynamics.
- Transfer product: Transfer excitability reasoning to anesthesia, toxins, epilepsy, and neuromuscular disease.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 33 of the textbook — review that chapter before attempting the exercises below.

1. Define an action potential. What are the threshold, peak, and undershoot voltages?

Answer (Q1, Recall). An action potential (AP) is a rapid, all-or-nothing, self-propagating depolarization-repolarization of the neuronal membrane produced by the sequential opening of voltage-gated Na⁺ and K⁺ channels — the electrical signal of the nervous system. The canonical mammalian AP has four quantitative landmarks: resting potential ≈ -70 mV (set by K⁺ leak channels and Na⁺/K⁺-ATPase, matching the K⁺ Nernst potential); threshold ≈ -55 mV (voltage at which enough Nav1.x channels open that inward Na⁺ current overtakes outward K⁺ current, committing the membrane to firing); peak $\approx +30$ to $+40$ mV (approaches but never reaches E_{Na} $\approx +60$ mV, because Na⁺ channels begin inactivating before full equilibration); undershoot (afterhyperpolarization, AHP) ≈ -80 to -90 mV (voltage-gated K⁺ channels close slowly, briefly driving V_m past rest toward E_K ≈ -90 mV — the refractory period). Total duration about 1–2 ms in axons; propagation velocity 1 m/s (unmyelinated) to 120 m/s (myelinated, saltatory conduction). The Hodgkin–Huxley model (Nobel 1963) quantitatively reproduces every feature from four ODEs in m, h, n gating variables. See section 33.

2. What are voltage-gated Na⁺ channels? Describe their three states (closed, open, inactivated).
- Answer (Q2, Recall). Voltage-gated Na⁺ channels (Nav1.1–1.9, encoded by SCN1A–SCN11A) are membrane proteins whose pore opens in response to depolarization and carries the inward Na⁺ current of the action-potential upstroke; they are concentrated at nodes of Ranvier (about 1,000/μm² vs about 25/μm² under myelin). They cycle through three states: closed (at rest near -70 mV, activation/m gates shut but ready to open); open (depolarization past threshold opens the m gates within about 0.5 ms, Na⁺ rushes in, V rises toward E_{Na}); inactivated (the h “ball-and-chain” gate occludes the pore from inside about 1 ms after opening, so the channel cannot reopen regardless of stimulus until repolarization resets it — the basis of the absolute refractory period and unidirectional propagation). See section 33.

3. What is the absolute refractory period? What is the relative refractory period?
- Answer (Q3, Recall). The absolute refractory period (about 1–2 ms after the spike peak) is the interval when essentially all Na⁺ channels are in the inactivated state (h ≈ 0); no stimulus, however strong, can trigger a second action potential, which guarantees unidirectional propagation and caps maximum firing rate (about 500–1000 Hz). The relative refractory period (about 5–10 ms following the absolute period) is when Na⁺ channels are recovering from inactivation while K⁺ channels remain open and the membrane is hyperpolarised below rest (afterhyperpolarisation); a second spike is possible but requires a stronger-than-normal stimulus and has reduced amplitude. See section 33.

4. What is a compound action potential (CAP)? How does it differ from a single-neuron AP?
- Answer (Q4, Recall). A single-neuron action potential is the all-or-none about 100 mV spike of one axon, described by the Hodgkin–Huxley equations from the squid giant axon. A compound action potential (CAP) is the extracellularly recorded summed electrical signal of a whole nerve containing many axons with different diameters and conduction velocities. It differs from a single AP in being a graded, multi-peaked waveform: its amplitude grows with stimulus strength (recruiting more fibers, not “bigger” spikes), and it spreads out into separate humps with distance because fast (large, myelinated A) and slow (small, unmyelinated C) fibers progressively desynchronise. See section 33.

5. Define a synapse. Name the pre- and postsynaptic components.
- Answer (Q5, Recall). A synapse is the specialized junction at which one neuron communicates with a target cell. At a chemical synapse the presynaptic component is the axon terminal, containing neurotransmitter-filled vesicles, voltage-gated Ca²⁺ channels, and the active-zone release machinery (SNARE proteins, synaptotagmin-1). These are separated by the about 20 nm synaptic cleft from the postsynaptic component — the membrane bearing neurotransmitter receptors (ionotropic and metabotropic) clustered at the postsynaptic density. Transmission is unidirectional (presynaptic → postsynaptic), modifiable, and has a 0.5–2 ms synaptic delay; electrical synapses (gap junctions) instead couple cytoplasms directly and are bidirectional. See section 33.

6. What is a neurotransmitter vesicle? How is it released (Ca²⁺-dependent exocytosis)?
- Answer (Q6, Recall). A neurotransmitter (synaptic) vesicle is a about 40 nm membrane-bound organelle in the presynaptic terminal that stores a

quantum of neurotransmitter (about 5,000–10,000 molecules). Release is Ca^{2+} -dependent exocytosis: an arriving action potential opens voltage-gated Ca^{2+} channels; local Ca^{2+} rises to about 100 μM in a nanodomain and binds the C2 domains of synaptotagmin-1 (4–5 ions, giving steep about 4th-power cooperativity); synaptotagmin displaces the complexin clamp, the SNARE complex (synaptobrevin + syntaxin + SNAP-25) zippers fully, and the vesicle fuses with the plasma membrane, releasing transmitter into the cleft in <1 ms. See section 33. 7. What is an EPSP? What is an IPSP? How do they differ in ionic mechanism?

Answer (Q7, Recall). An EPSP (excitatory postsynaptic potential) is a transient depolarization that moves the membrane toward threshold, produced when an excitatory transmitter (e.g., glutamate) opens cation channels (AMPA/NMDA, Na^+/K^+ , some Ca^{2+}) so net inward current depolarizes the cell. An IPSP (inhibitory postsynaptic potential) is a hyperpolarising or shunting event that moves the membrane away from threshold, produced when an inhibitory transmitter (GABA, glycine) opens Cl^- channels (GABA_A, Cl^- influx) or K^+ channels (GABA_B-activated K^+ efflux). They differ in ionic mechanism: cation influx (depolarizing) for EPSPs vs anion influx / K^+ efflux (hyperpolarising/shunting) for IPSPs. See section 33. 8. Define temporal and spatial summation of postsynaptic potentials.

Answer (Q8, Recall). Postsynaptic potentials are graded and decremental, so a single EPSP rarely reaches threshold; the neuron sums inputs at the axon hillock. Temporal summation is the addition of successive EPSPs from the *same* synapse arriving within a few membrane time constants of each other, so the second begins before the first has decayed and the depolarisations add. Spatial summation is the addition of EPSPs (and IPSPs) from *different* synapses active at the same time on the dendrites/soma. If the net depolarization at the axon hillock exceeds threshold (about –55 mV), an all-or-none action potential is fired; IPSPs subtract from this sum. See section 33. 9. What is a neuromuscular junction? What neurotransmitter is released there?

Answer (Q9, Recall). The neuromuscular junction (NMJ) is the chemical synapse between a motor neuron's axon terminal and a skeletal muscle fiber's motor end-plate. The neurotransmitter released there is acetylcholine (ACh): an action potential opens presynaptic Ca^{2+} channels, ACh-containing vesicles fuse and release ACh, which binds muscle-type nicotinic ACh receptors ($\alpha_1\beta_1\delta\epsilon$ pentamers) opening Na^+/K^+ channels to generate the end-plate potential. The NMJ has a high quantal content and resting release probability about 0.1–0.4, giving a large safety factor; ACh is then cleared by acetylcholinesterase. See section 33. 10. What is long-term potentiation (LTP)? In which brain region was it first described?

Answer (Q10, Recall). Long-term potentiation (LTP) is an activity-dependent, long-lasting (hours to days) increase in synaptic efficacy following high-frequency stimulation — a leading cellular model of learning and memory. It was first described in the hippocampus, at the perforant-path inputs to the dentate gyrus (Bliss and Lømo, 1973), and is classically studied at the Schaffer-collateral → CA1 synapse. NMDA-receptor-dependent Ca^{2+} influx activates CaMKII, which phosphorylates and inserts AMPA receptors (early LTP); late LTP additionally requires CREB-driven gene expression and structural spine changes. See section 33.

Questions 11–20: Application and Analysis

- Using the Nernst equation ($E = (RT/zF) \ln([\text{ion}]_{\text{out}}/[\text{ion}]_{\text{in}})$), calculate the equilibrium potential for K^+ given $[\text{K}^+]_{\text{out}} = 5 \text{ mM}$ and $[\text{K}^+]_{\text{in}} = 150 \text{ mM}$ at 37°C. Then calculate E_{Na} with $[\text{Na}^+]_{\text{out}} = 145 \text{ mM}$ and $[\text{Na}^+]_{\text{in}} = 15 \text{ mM}$. Which equilibrium potential is closest to the resting membrane potential?

Answer (Q11, Application). At body temperature 310 K, $RT/F = (8.314 \times 310)/96485 = 0.0267 \text{ V} = 26.7 \text{ mV}$; using base-10 log, $(RT/F) \ln 10 = 26.7 \times 2.303 = 61.5 \text{ mV}$. For a monovalent cation ($z = +1$): $E = 61.5 \log_{10}([\text{X}]_{\text{out}}/[\text{X}]_{\text{in}}) \text{ mV}$. $E_{\text{K}}: 61.5 \times \log_{10}(5/150) = 61.5 \times \log_{10}(0.0333) = 61.5 \times (-1.477) = -90.8 \text{ mV}$. $E_{\text{Na}}: 61.5 \times \log_{10}(145/15) = 61.5 \times \log_{10}(9.667) = 61.5 \times 0.985 = +60.6 \text{ mV}$. Resting membrane potential $\approx -70 \text{ mV}$ — much closer to E_{K} (–91 mV) than E_{Na} (+61 mV), indicating that K^+ permeability dominates at rest ($P_{\text{K}} : P_{\text{Na}} : P_{\text{Cl}} \approx 1 : 0.04 : 0.45$). Why not exactly E_{K} ? Because of small but non-zero Na^+ leak, and the electrogenic Na^+/K^+ pump (see Goldman-Hodgkin-Katz). Clinical significance: hyperkalaemia (e.g., $[\text{K}^+]_{\text{out}} = 8 \text{ mM}$ raises E_{K} to –80 mV) *depolarizes* the resting potential — at rest the membrane is closer to threshold, but sustained depolarization inactivates Nav channels → muscle weakness, cardiac conduction block, asystole (EKG peaked T waves → widened QRS → sine wave → flatline). This is why hyperkalaemia is a medical emergency. See section 33. 12. Tetrodotoxin (TTX, from pufferfish) blocks voltage-gated Na^+ channels. Tetraethylammonium (TEA) blocks voltage-gated K^+ channels. Predict the effects on the action potential waveform when: (a) TTX alone is applied; (b) TEA alone; (c) both together.

Answer (Q12, Application). Initiating condition: a depolarizing stimulus normally triggers the Na^+ -driven upstroke and K^+ -driven repolarization. (a) TTX alone blocks voltage-gated Na^+ channels, removing the inward Na^+ current: the action potential is abolished entirely (no upstroke, no spike) — only passive subthreshold depolarization remains. (b) TEA alone blocks voltage-gated K^+ channels, removing the delayed-rectifier outward current: the upstroke is normal but repolarization is markedly slowed and incomplete, so the AP is greatly prolonged/broadened with a reduced or absent afterhyperpolarisation (and enhanced transmitter release). (c) Both together: with Na^+ entry blocked there is still no regenerative upstroke, so no action potential occurs; TEA's effect on repolarization is moot — the membrane only shows a slow passive response, demonstrating the AP requires the regenerative Na^+ conductance. See section 33. 13. Quantal analysis of neurotransmitter release: at the neuromuscular junction, each

synaptic vesicle contains about 10,000 ACh molecules (one “quantum”). The miniature end-plate potential (mEPP) = 0.4 mV. A normal EPSP = 40 mV. Estimate the quantal content ($m = \text{EPSP}/\text{mEPP}$). What parameter does the quantal content depend on (n = number of release sites, p = release probability)?

Answer (Q13, Application). Quantal model: $\text{EPP} = n \cdot p \cdot q$, where q (quantal size) is the postsynaptic response to one vesicle (the mEPP) and quantal content $m = \text{number of quanta released per stimulus} \approx \text{EPP}/\text{mEPP}$. Substituting the stated values: $m = 40 \text{ mV} \div 0.4 \text{ mV} = 100$ quanta per stimulus. (This linear estimate assumes responses sum approximately linearly and is reasonable when the EPP is not strongly attenuated by nonlinear summation.) Quantal content depends on $m = n \times p$, where n is the number of release-ready vesicles/release sites and p is the per-vesicle release probability (each about 0.1–0.4 at physiological Ca^{2+} at the NMJ). Thus m can fall if either n drops (Lambert–Eaton, vesicle depletion) or p drops (low extracellular Ca^{2+} , high Mg^{2+}) — a quantitatively interpretable, biologically plausible result. See section 33. 14. NMDA receptors are both ligand-gated (glutamate) AND voltage-gated (Mg^{2+} block removed at depolarized potentials). Explain: (a) why NMDA receptors function as “coincidence detectors” (both presynaptic glutamate and postsynaptic depolarization are required); (b) why this property is considered the molecular basis for Hebbian learning (“neurons that fire together, wire together”); (c) the Ca^{2+} signal that enters via NMDA receptors and triggers LTP.

Answer (Q14, Application). Initiating condition: glutamate is released and binds NMDA receptors, but at resting potential the pore is blocked by extracellular Mg^{2+} . (a) Coincidence detection: the channel conducts only when glutamate is bound (presynaptic activity) AND the postsynaptic cell is sufficiently depolarized to expel the voltage-dependent Mg^{2+} block — so both pre- and postsynaptic activity must occur together. (b) This implements Hebb’s postulate (“neurons that fire together wire together”): the synapse is strengthened precisely when presynaptic firing coincides with postsynaptic depolarization, the molecular basis of associative/Hebbian learning. (c) When both conditions are met the relieved NMDA channel admits a large Ca^{2+} influx into the spine; this Ca^{2+} activates CaMKII (autophosphorylated at T286), which phosphorylates and inserts AMPA receptors, inducing LTP. See section 33. 15. Myasthenia gravis (MG) is an autoimmune disease where antibodies target nicotinic ACh receptors at the NMJ. Predict: (a) whether the EPSP amplitude at the NMJ is increased or decreased; (b) the clinical manifestation (fatigable muscle weakness); (c) why acetylcholinesterase inhibitors (pyridostigmine) temporarily improve symptoms.

Answer (Q15, Application). Initiating condition: autoantibodies bind and crosslink/internalise muscle nicotinic ACh receptors at the NMJ, reducing functional receptor number. (a) With fewer receptors, the same quantal ACh release produces a smaller end-plate potential — EPSP/end-plate-potential amplitude is decreased, sometimes failing to reach the muscle fiber’s threshold so transmission fails at some junctions. (b) Clinically this gives fatigable muscle weakness: with repetitive activity presynaptic ACh release normally declines (rundown), and because the safety factor is already eroded, more junctions fail as activity continues — weakness worsens with use and improves with rest (ocular, bulbar, limb muscles). (c) Acetylcholinesterase inhibitors (pyridostigmine) block ACh breakdown in the cleft, so each released quantum acts longer and on more of the remaining receptors, raising the end-plate potential above threshold and temporarily improving strength. See section 33. 16. GABAergic inhibition: GABA_A receptors are Cl^- channels. In adult neurons $E_{\text{Cl}} \approx -70 \text{ mV}$ (inhibitory). In neonatal neurons $E_{\text{Cl}} \approx -40 \text{ mV}$ (excitatory because resting potential is about -55 mV). Explain: (a) why GABA is excitatory in neonatal neurons; (b) the developmental switch (upregulation of KCC2 Cl^- transporter); (c) why this has implications for neonatal seizure treatment.

Answer (Q16, Application). Initiating condition: GABA_A receptors are Cl^- channels, so their effect depends on E_{Cl} relative to resting potential and threshold. (a) In neonatal neurons intracellular $[\text{Cl}^-]$ is high ($E_{\text{Cl}} \approx -40 \text{ mV}$), which is *above* the resting potential (about -55 mV); opening GABA_A channels lets Cl^- flow *out*, depolarizing the cell toward -40 mV — so GABA is excitatory early in development. (b) The developmental switch is driven by upregulation of the neuronal K^+/Cl^- cotransporter KCC2, which extrudes Cl^- and lowers intracellular $[\text{Cl}^-]$, shifting E_{Cl} to $\approx -70 \text{ mV}$; now GABA_A opening hyperpolarises/shunts the cell — GABA becomes inhibitory in adults (with the early NKCC1 importer dominating before the switch). (c) Clinically this means classic GABA_A potentiators (benzodiazepines, phenobarbital) can be ineffective or paradoxically excitatory for neonatal seizures; strategies that lower intracellular Cl^- (e.g., NKCC1 inhibition with bumetanide as an adjunct) are being explored. See section 33. 17. Short-term plasticity: paired-pulse facilitation (PPF) occurs when the second of two closely-spaced stimuli evokes a larger EPSP. Explain the residual calcium hypothesis: Ca^{2+} from the first stimulus remains and adds to Ca^{2+} from the second stimulus, producing greater vesicle release. Predict: would PPF be increased or decreased by a Ca^{2+} chelator (BAPTA)?

Answer (Q17, Application). Initiating condition: paired-pulse facilitation occurs when two stimuli arrive within tens–hundreds of ms and the second EPSP is larger. Changed component: Ca^{2+} entering on the first action potential is not fully cleared (pumped/buffered) before the second spike. Intermediate mechanism: this residual Ca^{2+} sums with the Ca^{2+} influx from the second action potential; because release probability rises super-linearly (about 4th power) with presynaptic Ca^{2+} , the elevated total Ca^{2+} raises p and more vesicles fuse. Observable outcome: the second EPSP is larger (facilitation), most prominent at low- p synapses (e.g., parallel-fiber → Purkinje, $p \approx 0.05$). Prediction: a fast Ca^{2+} chelator such as BAPTA mops up the residual Ca^{2+} before the second spike, so PPF is decreased/abolished — directly testing and supporting the residual-calcium hypothesis. See section 33. 18. Excitotoxicity: excessive glutamate release (e.g., during stroke) causes neuronal death via NMDA receptor overactivation → excessive Ca^{2+} influx → mitochondrial dysfunction → ROS production → cell death. Explain: (a) why NMDA-blocking drugs (memantine, at low

doses) are neuroprotective in clinical trials; (b) why high-dose NMDA block causes psychotic symptoms (dissociative anaesthetics — ketamine); (c) what the narrow therapeutic window implies for stroke intervention.

Answer (Q18, Application). Initiating condition: excess synaptic glutamate (stroke/ischemia) overactivates NMDA receptors, causing pathological Ca^{2+} overload, mitochondrial failure, ROS, and neuronal death. (a) Memantine at low (therapeutic) doses is a low-affinity, fast-off, voltage-dependent open-channel blocker: it preferentially blocks the tonically over-activated NMDA channels in pathological conditions while leaving brief, phasic, physiological NMDA signaling largely intact — so it dampens excitotoxic Ca^{2+} entry without abolishing normal synaptic transmission, giving modest neuroprotection. (b) High-dose, high-affinity NMDA block (ketamine, PCP) also blocks physiological NMDA signaling needed for normal cortical/thalamic processing, producing dissociative anaesthesia and psychotomimetic (psychotic-like) symptoms. (c) The narrow therapeutic window — enough block to stop excitotoxicity but not so much as to impair normal NMDA function — plus a short post-stroke time window, explains why broad NMDA antagonists have largely failed as acute stroke neuroprotectants; the conclusion would change only with agents that selectively target the excitotoxic (extrasynaptic) pool. See section 33. 19. Synaptic vesicle recycling occurs via three modes: kiss-and-run (transient fusion pore, rapid), full collapse/clathrin-mediated endocytosis (5–20 s), and bulk endocytosis (during intense stimulation). Explain: (a) how each mode is suited to different firing rates; (b) what happens when recycling capacity is exceeded (synaptic depression); (c) the role of dynamin GTPase in clathrin-mediated endocytosis.

Answer (Q19, Application). Initiating condition: vesicle fusion adds membrane and depletes the releasable pool, so terminals must retrieve membrane and refill vesicles. (a) Kiss-and-run (transient fusion pore, then resealing) is fast and conserves the vesicle, suited to low/moderate firing where rapid local reuse keeps up with demand; full-collapse / clathrin-mediated endocytosis (about 5–20 s) cleanly recovers vesicle components at moderate sustained rates; bulk endocytosis internalises large membrane infoldings during intense, high-frequency activity when single-vesicle retrieval cannot match the membrane added. (b) When firing outpaces recycling, the readily releasable pool is not replenished and the synapse shows short-term depression (declining EPSP amplitude) until activity slows and pools refill. (c) Dynamin is a GTPase that assembles a collar around the neck of the budding clathrin-coated pit and, on GTP hydrolysis, mediates fission to pinch off the recycled vesicle; without dynamin function endocytosis stalls and vesicles cannot be retrieved. See section 33. 20. Long-term depression (LTD) at cerebellar parallel fiber-Purkinje cell synapses is triggered by climbing fiber co-activation $\rightarrow \text{Ca}^{2+} + \text{PKC} \rightarrow \text{AMPA}$ internalization. Explain: (a) how LTD differs from LTP mechanistically (removal vs insertion of receptors); (b) the role of LTD in motor learning (error correction signals from climbing fibers); (c) how cerebellar LTD produces adaptation in the vestibulo-ocular reflex.

Answer (Q20, Application). Initiating condition: at cerebellar parallel-fiber \rightarrow Purkinje-cell synapses, coincident parallel-fiber input with climbing-fiber activation produces a large Ca^{2+} signal plus PKC activation. (a) LTD vs LTP mechanism: low/specific Ca^{2+} patterns here drive AMPA-receptor *internalization* (phosphatase- and PKC-dependent endocytosis), weakening the synapse — the mirror image of LTP, where larger NMDA-mediated Ca^{2+} drives CaMKII-dependent AMPA-receptor *insertion* and strengthening; the direction is set by the amplitude/pattern of postsynaptic Ca^{2+} (BCM-style sliding threshold). (b) In motor learning, the climbing fiber carries an “error” or teaching signal; pairing it with the parallel-fiber inputs active during a faulty movement depresses exactly those synapses, so the Purkinje cell’s output is corrected on subsequent attempts. (c) For the vestibulo-ocular reflex, retinal-slip errors relayed by climbing fibers induce parallel-fiber LTD in the flocculus, re-tuning the gain so eye movements again precisely cancel head movements — cerebellar LTD as the substrate of VOR adaptation. See section 33.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the Hodgkin-Huxley (HH) model of the action potential (1952, Nobel Prize): using voltage-clamp data, they described Na^+ and K^+ conductances as m^3h and n^4 gating variables. Assess: (a) the key insight (ion-specific conductances with distinct kinetics); (b) the predictive power of the model (propagation velocity, frequency coding); (c) the limitations (no molecular detail, does not account for ion channel diversity, subthreshold oscillations).

Answer (Q21, Synthesis). Empirical evidence: Hodgkin and Huxley used voltage-clamp recordings from the squid giant axon to measure time- and voltage-dependent Na^+ and K^+ conductances and fit them with empirical gating variables (Na^+ as m^3h , K^+ as n^4). Separating evidence from judgement: (a) the key insight, strongly supported, is that excitability arises from independent, ion-specific, voltage- and time-dependent conductances with distinct kinetics — not a mysterious “membrane breakdown.” (b) Its predictive power is remarkable and well validated: from the fitted equations the model correctly predicts AP shape, threshold, refractory period, propagation velocity, and frequency coding without further tuning. (c) Limitations/boundary conditions: the m^3h/n^4 exponents are phenomenological, not molecular (no explicit channel structure), and the original model omits the diversity of channel subtypes, Ca^{2+} currents, subthreshold oscillations, and dendritic nonlinearities. What would change the evaluation: evidence that the gating formalism fails to capture a class of excitable behavior without ad hoc extension. So: a triumphantly predictive but admittedly empirical, extensible framework — not the final molecular word. See section 33. 22. Design an experiment to determine whether a specific synapse exhibits Hebbian LTP, anti-Hebbian LTP, or homeostatic plasticity. Describe: the stimulation protocols (high-frequency \rightarrow Hebbian, low-frequency \rightarrow homeostatic), the electrophysiological measurements (field EPSP slope), and the pharmacological tools (NMDA antagonist, AMPAR antagonist) needed to distinguish these forms.

Answer (Q22, Synthesis). Hypothesis: a given synapse expresses Hebbian LTP (input- and NMDA-dependent strengthening), anti-Hebbian/LTD (weakening), or homeostatic scaling (activity-set global gain), distinguishable by induction pattern and pharmacology. Design: record field EPSP slope (or whole-cell EPSC) at the test pathway with a separate independent control pathway. Changed factor = stimulation protocol: high-frequency/tetanic or theta-burst pairing to probe Hebbian LTP; low-frequency (1 Hz) stimulation to probe LTD; chronic activity blockade (TTX) or elevation to probe homeostatic scaling (measured as a multiplicative change in mEPSC amplitude across all synapses, not input-specific). Controls/replication: unstimulated control pathway must be unchanged (input-specificity), multiple slices/animals, interleaved conditions. Pharmacology to distinguish forms: an NMDA antagonist (APV) should block Hebbian LTP and NMDA-dependent LTD but not homeostatic scaling; an AMPA antagonist (CNQX) abolishes the synaptic response itself (a measurement control); homeostatic scaling persists under activity blockade. Decision rule: input-specific, NMDA-dependent potentiation = Hebbian LTP; input-specific NMDA-dependent depression = LTD; global, NMDA-independent, multiplicative change = homeostatic. Falsifying result: a “Hebbian LTP” that survives complete NMDA blockade and is not input-specific. See section 33. 23. Evaluate the “synaptic tagging and capture” hypothesis (Frey and Morris, 1997): early LTP is protein synthesis-independent (lasts about 1–2 h), while late LTP requires new protein synthesis. A weak stimulus sets a “tag” at activated synapses; the tag captures plasticity-related proteins (PRPs) synthesized in response to a strong stimulus at another input. Evaluate: (a) the evidence for this model; (b) how it explains input-specificity of LTP; (c) implications for memory consolidation.

Answer (Q23, Synthesis). Empirical claim: early LTP is protein-synthesis-independent (about 1–2 h) whereas late LTP requires new protein synthesis (CREB-dependent gene expression and structural change). (a) Evidence for synaptic tagging and capture (Frey & Morris, 1997): a weak tetanus that alone gives only decaying early LTP can be converted to persistent late LTP if a strong tetanus is delivered to a *separate* input on the same neuron shortly before/after — the strong input supplies diffusible plasticity-related proteins (PRPs) that are “captured” by a transient local tag set at the weakly stimulated synapse; protein-synthesis inhibitors block this rescue. (b) It explains input-specificity with shared resources: the tag is local and short-lived, so only recently activated synapses capture the cell-wide PRP pool, keeping potentiation specific to active inputs while allowing associative interactions across inputs. (c) Implications for memory consolidation: behavioral tagging predicts that a weak experience can be consolidated into long-term memory if a salient (PRP-inducing) event occurs nearby in time — a cellular basis for how arousal/novelty stabilizes otherwise transient memories. The judgement is well supported but conditional: it depends on tag identity (still incompletely defined) and on the temporal window — evidence that capture occurs without any local tag would weaken the model. See section 33. 24. Evaluate the role of astrocytic gliotransmission (release of glutamate, D-serine, ATP from astrocytes) in modulating synaptic plasticity. What evidence supports the “tripartite synapse” model, and what criticisms have been raised about the specificity of astrocytic Ca^{2+} signals and the difficulty of distinguishing neuronal from glial glutamate release?

Answer (Q24, Synthesis). Empirical evidence for the tripartite synapse: astrocytes ensheath synapses, show synaptically evoked Ca^{2+} elevations, supply the NMDA co-agonist D-serine, and can release glutamate/ATP that modulate transmission and plasticity; astrocytic Ca^{2+} also drives neurovascular coupling (synaptic glutamate → astrocyte Ca^{2+} → vasoactive arachidonic-acid metabolites onto arterioles), tying glial signaling to the BOLD signal. Separating evidence from judgement: the data establish that astrocytes can influence synapses, but the *physiological significance and specificity* are contested — IP3R2-knockout mice that lack astrocytic Ca^{2+} transients show largely normal synaptic plasticity in several studies, astrocytic Ca^{2+} signals are slow and spatially broad rather than synapse-specific, and it is technically hard to prove that detected glutamate is glial rather than neuronal. What would change the conclusion: cell-type-specific tools that selectively and reversibly silence only astrocytic release and reproducibly abolish a defined form of plasticity. So: gliotransmission is real and modulatory in some contexts but not established as a universal, synapse-specific controller of plasticity. See section 33. 25. Channelopathies: mutations in ion channels cause neurological diseases. Evaluate three examples: (a) SCN1A (Nav1.1) mutations → Dravet syndrome (severe childhood epilepsy); (b) KCNQ2/3 mutations → benign familial neonatal seizures; (c) CACNA1A mutations → familial hemiplegic migraine. For each, describe the channel, the mutation’s effect on neuronal excitability, and the therapeutic approach.

Answer (Q25, Synthesis). Channelopathies alter neuronal excitability through specific channel defects. (a) SCN1A (Nav1.1) — Dravet syndrome: loss-of-function in Nav1.1, which is enriched in inhibitory GABAergic interneurons, reduces interneuron firing → net disinhibition and severe early-childhood epilepsy; Na^+ -channel blockers (lamotrigine, carbamazepine) can paradoxically worsen it, so valproate/clobazam, stiripentol, and fenfluramine are used. (b) KCNQ2/3 — benign familial neonatal seizures: loss-of-function in the Kv7 (M-current) channels that normally restrain repetitive firing → hyperexcitability and neonatal seizures that usually remit; M-current openers (e.g., retigabine/ezogabine concept) and standard antiepileptics are options. (c) CACNA1A — familial hemiplegic migraine: gain-of-function in the Cav2.1 (P/Q-type) Ca^{2+} channel enhances glutamate release, lowering the threshold for cortical spreading depression → migraine with hemiplegic aura; prophylaxis (e.g., verapamil, acetazolamide, standard migraine preventives) is used. Causal chain in each: mutated channel → altered ionic current → shifted excitatory/inhibitory balance → the observed clinical syndrome, guiding mechanism-specific therapy. See section 33. 26. Evaluate the dopamine hypothesis of schizophrenia: (a) traditional version (excess D_2 receptor signaling in mesolimbic pathway); (b) revised version (hypo-dopaminergia in prefrontal cortex, hyper-dopaminergia in striatum); (c) the glutamate hypothesis (NMDA receptor hypofunction). How do these hypotheses explain the positive symptoms

(hallucinations, delusions) and negative symptoms (flat affect, cognitive deficits) of schizophrenia?

Answer (Q26, Synthesis). Empirical evidence: D2-antagonist antipsychotic potency correlates with D2 affinity, amphetamine (dopamine-releasing) exacerbates psychosis, and PET shows elevated striatal dopamine synthesis in schizophrenia; NMDA antagonists (ketamine, PCP) reproduce positive and negative/cognitive symptoms. Separating evidence from judgement: (a) the traditional hypothesis (excess mesolimbic D2 signaling) explains positive symptoms (hallucinations, delusions) and the efficacy of D2 blockers, but not negative/cognitive symptoms. (b) The revised hypothesis (striatal hyper-dopaminergia plus prefrontal hypo-dopaminergia) accounts for positive symptoms (striatal excess) and negative/cognitive deficits (cortical D1 hypofunction impairing working memory). (c) The glutamate hypothesis (NMDA-receptor hypofunction, especially on inhibitory interneurons) provides an upstream cause that can produce downstream dopamine dysregulation and explains the full symptom spectrum including cognitive deficits. The conclusion is conditional, not settled: no single transmitter abnormality is necessary and sufficient, and what would change it is mechanistically targeted treatments (e.g., effective non-D2 agents) demonstrating which node is causal. See section 33. 27. Spike-timing-dependent plasticity (STDP): if the presynaptic neuron fires before the postsynaptic neuron (within about 20 ms), the synapse is strengthened (LTP). If after, the synapse is weakened (LTD). Evaluate: (a) the molecular mechanism (STDP timing depends on NMDA receptor/ Ca^{2+} dynamics); (b) the computational significance (STDP allows precise temporal learning of sequences); (c) how STDP differs in inhibitory vs excitatory synapses.

Answer (Q27, Synthesis). Initiating condition: STDP makes synaptic change depend on the millisecond order of pre- and postsynaptic spikes. (a) Mechanism: if the presynaptic spike precedes the postsynaptic spike (within about 20 ms), glutamate is bound when the back-propagating action potential depolarizes the spine and relieves NMDA Mg^{2+} block, producing a large coincident Ca^{2+} transient that activates $\text{CaMKII} \rightarrow \text{LTP}$; if the order is reversed, only a small/delayed Ca^{2+} signal occurs, preferentially activating phosphatases ($\text{PP1/calcineurin} \rightarrow \text{LTD}$ — the sign is set by NMDA-receptor-controlled Ca^{2+} amplitude/timing (BCM-like). (b) Computational significance: because potentiation requires “cause before effect,” STDP lets networks learn temporal order and predictive sequences, sharpen input timing, and self-stabilize — a biologically grounded learning rule for sequence and causal learning. (c) Excitatory vs inhibitory: excitatory synapses follow the classic asymmetric pre-before-post $\rightarrow \text{LTP}$ window; many inhibitory (GABAergic) synapses show different, often symmetric or sign-inverted timing rules and rely on Ca^{2+} sources/signaling distinct from postsynaptic NMDA receptors, so inhibitory STDP tunes E/I balance rather than feedforward drive. See section 33. 28. Evaluate the molecular mechanism of presynaptic neurotransmitter release: Ca^{2+} entry \rightarrow synaptotagmin-1 (Ca^{2+} sensor) \rightarrow conformational change \rightarrow interaction with SNARE complex \rightarrow fusion pore opening \rightarrow transmitter release. Specifically: why is synaptotagmin-1 the timing sensor (low Ca^{2+} affinity, fast kinetics, about 200 μs from Ca^{2+} binding to fusion), and what does the about 4th power Ca^{2+} dependence of release tell us about the number of Ca^{2+} ions needed to trigger a single vesicle fusion event?

Answer (Q28, Synthesis). Empirical mechanism: Ca^{2+} entering through nearby voltage-gated channels binds synaptotagmin-1's C2A/C2B domains, which then displaces the complexin clamp and drives full SNARE-complex (synaptobrevin–syntaxin–SNAP-25) zippering, opening the fusion pore and releasing transmitter; NSF/ α -SNAP later disassemble SNAREs for reuse. Separating evidence from judgement: synaptotagmin-1 is identified as the *fast timing* sensor because it has relatively low Ca^{2+} affinity (so it responds only to the brief, high Ca^{2+} nanodomain right at the channel mouth, not to bulk Ca^{2+}) and fast binding/unbinding kinetics (release follows Ca^{2+} entry in about 200 μs), which is exactly what is needed to lock release to the action potential. The steep, approximately 4th-power dependence of release rate on $[\text{Ca}^{2+}]$ indicates that roughly four (cooperatively bound) Ca^{2+} ions must bind synaptotagmin to trigger a single vesicle fusion event — explaining why small Ca^{2+} changes produce large, switch-like changes in release. The conclusion is well supported but conditional on synaptotagmin-1 as the dominant sensor; some synapses use other synaptotagmin isoforms with different Ca^{2+} affinities, which would shift the quantitative relationship. See section 33. 29. Evaluate the clinical utility of transcranial magnetic stimulation (TMS) for modulating neural circuits non-invasively. How does TMS induce action potentials in cortical neurons, what stimulation patterns produce LTP-like (theta-burst) vs LTD-like (continuous low-frequency) effects, and what is the evidence for therapeutic efficacy in treatment-resistant depression?

Answer (Q29, Synthesis). Empirical basis: TMS uses a rapidly changing magnetic field to induce an electric field in cortex strong enough to depolarize axons/neurons and evoke action potentials non-invasively (measurable as motor-evoked potentials when over motor cortex). Separating evidence from judgement: stimulation pattern shapes the after-effect — intermittent theta-burst and high-frequency ($\geq 5\text{--}10\text{ Hz}$) repetitive TMS produce LTP-like lasting increases in cortical excitability, whereas continuous theta-burst and low-frequency (about 1 Hz) rTMS produce LTD-like decreases, plausibly engaging NMDA/ Ca^{2+} -dependent plasticity analogous to LTP/LTD. Therapeutic efficacy is supported but conditional: randomized trials and meta-analyses show prefrontal rTMS produces a real but moderate antidepressant effect in treatment-resistant depression (FDA-cleared, with newer accelerated/theta-burst protocols), yet response is heterogeneous, effect sizes are modest, and durability/optimal targeting are unsettled. What would change the conclusion: large rigorously sham-controlled trials showing the benefit is non-specific or not durable. So: a mechanistically grounded, clinically useful but not universally curative intervention. See section 33. 30. Critically evaluate the concept of the “synaptome” — the catalog of synapse types and their molecular composition across the brain. Using proteomics of isolated synaptosomes, researchers have identified >1,000 proteins at excitatory synapses. Evaluate: (a) what the molecular diversity of synapses implies for circuit function; (b) whether the synaptome concept is more informative than the connectome for understanding brain computation; (c) how synaptome-level mutations (SHANK3,

PSD-95) cause neurodevelopmental disorders.

Answer (Q30, Synthesis). Empirical basis: synaptosome proteomics identifies >1,000 proteins at excitatory postsynaptic densities (e.g., PSD-95, SHANK, glutamate receptors, scaffolds), and synaptome mapping shows that synapse molecular composition varies systematically across brain regions and cell types. Separating evidence from judgement: (a) this molecular diversity implies that “a synapse” is not uniform — different molecular types confer different plasticity rules, kinetics, and Ca^{2+} handling, so circuit computation depends on *which* synapse types connect which neurons, not merely on wiring. (b) Whether the synaptome is “more informative than the connectome” is a conditional claim, not settled: the connectome specifies the wiring graph while the synaptome specifies the weights/plasticity at each edge — they are complementary, and computation arguably requires both; claiming superiority overstates current evidence. (c) Synaptome-level mutations cause neurodevelopmental disorders by disrupting postsynaptic organization: SHANK3 (a master PSD scaffold) loss causes Phelan–McDermid syndrome/autism, and PSD-95 (DLG4) disruption impairs receptor anchoring and plasticity, linking single scaffold proteins to circuit-level dysfunction. The conclusion would change if synaptome diversity proved not to map onto functional/behavioral differences. See section 33.

Questions — Endocrine Signaling and Homeostasis

Instructor Use and Coverage Notes

- Coverage target: Predict the consequence of changing a hormone, receptor, or axis set-point.
- Model/data emphasis: Hormone feedback and dose-response reasoning.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: A hormone surge is not always pathological; context and set-point matter.
- Transfer product: Transfer endocrine reasoning to metabolism, stress, and development.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 34 of the textbook — review that chapter before attempting the exercises below.

1. What is the endocrine system? How does it differ from the nervous system in signaling speed and duration?

Answer (Q1, Recall). The endocrine system is the network of glands that secrete hormones into the blood to regulate physiology body-wide. Compared with the nervous system, endocrine signaling is slower (seconds to hours rather than milliseconds) and longer-lasting (minutes to days rather than brief), because it relies on chemical hormones travelling via the circulation to all cells bearing the receptor rather than fast electrical transmission across a narrow synapse. See section 34.

2. Name the major endocrine glands and one hormone secreted by each.

Answer (Q2, Recall). Major glands and a representative hormone each: hypothalamus (releasing hormones, e.g., CRH); anterior pituitary (ACTH, GH); thyroid (T4/T3); parathyroid (PTH); adrenal cortex (cortisol); adrenal medulla (epinephrine); endocrine pancreas (insulin from (beta)-cells); gonads (testosterone or oestradiol); pineal (melatonin). See section 34.

3. Distinguish peptide hormones from steroid hormones in terms of synthesis, transport, and receptor location.

Answer (Q3, Recall). Peptide hormones are made on ribosomes as preprohormones, stored in secretory granules, travel free in plasma, and act fast on plasma-membrane receptors (RTKs/GPCRs). Steroid hormones are synthesized on demand from cholesterol (not stored), carried bound to plasma proteins (e.g., CBG, SHBG), and act slowly via intracellular nuclear receptors that alter gene transcription. The receptor location (membrane vs nuclear) is the mechanistic difference that makes peptide signaling rapid/transient and steroid signaling slow/persistent. See section 34.

4. What is the hypothalamic-pituitary axis? Name one releasing hormone and one tropic hormone.

Answer (Q4, Recall). The hypothalamic-pituitary axis is the hierarchical control loop in which the hypothalamus secretes releasing hormones that drive anterior-pituitary tropic hormones, which in turn stimulate a peripheral target gland, with negative feedback at each level. Example: hypothalamic CRH (releasing hormone) stimulates pituitary ACTH (tropic hormone), which stimulates adrenal cortisol. See section 34.

5. What is negative feedback? Give an example involving the thyroid gland.

Answer (Q5, Recall). Negative feedback is regulation in which a system’s output inhibits the steps that produced it, stabilizing the variable around a set point. Thyroid example: rising free T3/T4 inhibits hypothalamic TRH and pituitary TSH secretion, reducing further thyroid hormone output; if T3/T4 fall, TRH and TSH rise again, restoring levels. See section 34.

6. What is cortisol? Name its target tissues and three physiological effects.

Answer (Q6, Recall). Cortisol is a glucocorticoid steroid made in the adrenal cortex (zona fasciculata) under ACTH control. Target tissues include liver, muscle, adipose, and immune cells (acting via the nuclear glucocorticoid receptor). Three effects: stimulates hepatic gluconeogenesis (mobilizing amino acids from muscle), is immunosuppressive/anti-inflammatory (inhibits NF-(kappa)B and cytokine production), and promotes lipolysis. See section 34.

7. What are the components of innate immunity? Name four.

Answer (Q7, Recall). Innate immunity is the rapid, non-specific, germline-encoded first line of defense. Four components: physical/chemical barriers (skin, mucus, lysozyme); phagocytes (neutrophils, macrophages, dendritic cells); the complement system; and NK cells (plus inflammation and interferons). See section 34.

8. What is a Toll-like receptor (TLR)? Name a ligand for TLR4.

Answer (Q8, Recall). A Toll-like receptor is a germline-encoded pattern-recognition receptor on the plasma membrane or endosomes that detects conserved pathogen molecules (PAMPs) and triggers inflammatory or antiviral signaling. The ligand for TLR4 is bacterial lipopolysaccharide (LPS), characteristic of Gram-negative bacteria. See section 34.

9. What is the complement system? What are its three outcomes (opsonisation, MAC, inflammation)?

Answer (Q9, Recall). The complement system is a cascade of about 30 plasma proteins that, once triggered (classical, lectin, or alternative pathway), generate C3/C5 convertases. Its three outcomes are opsonisation (C3b coats pathogens for phagocytosis), the membrane attack complex (C5b-9 lyses target cells), and inflammation (anaphylatoxins C3a/C5a recruit and activate leukocytes). See section 34.

10. Define phagocytosis. Name two professional phagocytes.

Answer (Q10, Recall). Phagocytosis is the receptor-mediated engulfment of particles or microbes into a phagosome that fuses with lysosomes to destroy the cargo. Two professional phagocytes: neutrophils and macrophages (dendritic cells also phagocytose). See section 34.

Questions 11–20: Application and Analysis

11. The HPA axis: CRH (hypothalamus) → ACTH (anterior pituitary) → cortisol (adrenal cortex). Cortisol feeds back negatively on CRH and ACTH secretion. If a patient has an adrenal tumor autonomously producing cortisol, predict: (a) ACTH levels; (b) CRH levels; (c) contralateral adrenal gland size; (d) response to the dexamethasone suppression test.

Answer (Q11, Application). An autonomous cortisol-secreting adrenal tumor produces high cortisol independent of ACTH. (a) ACTH is low (suppressed by negative feedback). (b) CRH is low (also feedback-suppressed). (c) The contralateral adrenal atrophies because, without ACTH trophic support, the normal cortex shrinks. (d) On the dexamethasone suppression test cortisol fails to suppress (it is autonomous and not under pituitary control), confirming an ACTH-independent adrenal source. See section 34.

12. Insulin (from pancreatic β -cells) and glucagon (from α -cells) have opposing metabolic effects. Compare: (a) the stimulus for secretion of each; (b) the target tissue responses (liver, muscle, adipose); (c) the blood glucose level at which each dominates. What happens in Type 1 Diabetes (complete β -cell destruction)?

Answer (Q12, Application). (a) Insulin is secreted when blood glucose rises (after a meal); glucagon is secreted when glucose falls (fasting). (b) Insulin drives hepatic/muscle glycogen synthesis, muscle/adipose GLUT4 glucose uptake, and adipose lipogenesis; glucagon drives hepatic glycogenolysis and gluconeogenesis. (c) Insulin dominates at high glucose (5.5 mmol/L postprandial), glucagon at low glucose (fasting). In Type 1 diabetes, autoimmune (beta)-cell destruction abolishes insulin, so glucose stays high, cells starve, unopposed glucagon drives hyperglycaemia and ketoacidosis. See section 34.

13. Thyroid hormones (T_3/T_4) are unusual peptide-derived hormones that act like steroids (entering cells, binding nuclear receptors). Explain: (a) why T_3/T_4 can cross membranes (lipophilic due to iodination); (b) how T_3 binds thyroid hormone receptors ($TR\alpha/TR\beta$) to regulate gene transcription; (c) why hypothyroidism causes bradycardia, fatigue, and weight gain.

Answer (Q13, Application). (a) T_3/T_4 are lipophilic because heavy iodination of the tyrosine-derived rings lets them cross the lipid bilayer (entering cells via MCT8/MCT10). (b) T_3 binds nuclear $TR(\alpha)/TR(\beta)$, which heterodimerise with RXR on thyroid response elements; without T_3 the receptor recruits corepressors and represses genes, while T_3 binding swaps in coactivators and activates transcription. (c) Hypothyroidism slows metabolism: reduced Na^{+}/K^{+} -ATPase and BMR cause fatigue and weight gain, and loss of (β_1) -receptor upregulation plus reduced cardiac drive causes bradycardia. See section 34.

14. The inflammasome (NLRP3) is activated by diverse danger signals (K^{+} efflux, ROS, crystal particles). Trace: (a) NLRP3 oligomerisation; (b) ASC adaptor recruitment; (c) caspase-1 activation; (d) IL-1 β and IL-18 maturation and release; (e) pyroptosis (inflammatory cell death). Name two diseases where NLRP3 is inappropriately activated.

Answer (Q14, Application). (a) A priming signal (TLR/NF-(κ)B) upregulates NLRP3 and pro-IL-1(β); a second signal (K^{+} efflux, ROS, crystals) triggers NLRP3 oligomerisation. (b) NLRP3 recruits the ASC adaptor, which polymerizes into a speck. (c) ASC clusters pro-caspase-1, enabling autocatalytic caspase-1 activation. (d) Active caspase-1 cleaves pro-IL-1(β) and pro-IL-18 to their mature secreted forms. (e) Caspase-1 also cleaves gasdermin D, whose N-terminal pores cause pyroptosis (lytic inflammatory death). Inappropriate NLRP3 activation occurs in gout (urate crystals) and cryopyrin-associated periodic syndromes (CAPS). See section 34.

15. Neutrophils are the first responders to bacterial infection. Describe their killing mechanisms: (a) phagocytosis and phagolysosome fusion; (b) respiratory burst (NADPH oxidase → superoxide → HOCl via myeloperoxidase); (c) NETosis (neutrophil extracellular trap formation). What disease results from NADPH oxidase deficiency (CGD)?

Answer (Q15, Application). (a) Neutrophils recognize and engulf opsonised bacteria into a phagosome that fuses with granules to form a phagolysosome. (b) The respiratory burst: assembled NADPH oxidase generates superoxide, dismutated to H_2O_2 ; myeloperoxidase converts $H_2O_2 + Cl^-$ to bactericidal hypochlorous acid (HOCl). (c) NETosis: the neutrophil extrudes decondensed chromatin studded with antimicrobial proteins (NETs) that trap and kill extracellular bacteria. NADPH oxidase deficiency causes chronic granulomatous disease (CGD), with recurrent catalase-positive infections. See section 34.

16. Evaluate the integration of endocrine and immune systems: cortisol (a glucocorticoid) suppresses inflammation by: (a) inhibiting NF- κ B transcription factor; (b) reducing prostaglandin synthesis (inhibiting PLA₂ and COX-2); (c) inducing lymphocyte apoptosis. Why do critically ill ICU patients sometimes develop adrenal insufficiency, and why does physiological stress-dose hydrocortisone improve sepsis survival?

Answer (Q16, Application). Cortisol restrains inflammation through several converging mechanisms: (a) ligand-bound GR tethers and inhibits NF-(kappa)B (transrepression), shutting off cytokine genes; (b) it induces annexin A1 and suppresses PLA₂ and COX-2, cutting prostaglandin synthesis; (c) it drives apoptosis of lymphocytes and shifts cytokines toward IL-10. Critically ill patients can develop “critical-illness-related corticosteroid insufficiency” (relative adrenal insufficiency plus tissue glucocorticoid resistance), so HPA output is inadequate for the inflammatory load. Stress-dose hydrocortisone restores vascular catecholamine responsiveness and dampens excessive inflammation, which improves shock reversal; however, the survival benefit is condition-dependent (clearest in vasopressor-refractory septic shock) — that conditionality is what would change the conclusion. See section 34.

17. Evaluate the molecular mechanisms of endocrine disruptors (BPA, phthalates, pesticides): how do these chemicals interfere with hormone signaling (estrogenic, anti-androgenic, thyroid-disrupting), at what environmental concentrations are effects seen (non-monotonic dose-response), and what evidence from wildlife populations (feminisation of male fish, reproductive abnormalities in alligators) supports endocrine disruption in the environment?

Answer (Q17, Application). Endocrine disruptors interfere with hormone signaling by mimicking or blocking receptors (BPA is weakly oestrogenic; phthalates are anti-androgenic) and by perturbing hormone synthesis, transport, or thyroid signaling. The evidence includes non-monotonic dose-response curves, where low developmental doses can produce effects absent or different at high doses, complicating classical toxicology thresholds. Wildlife data (feminisation/intersex in male fish below sewage outfalls, reduced phallus size and altered sex ratios in alligators at contaminated lakes) support real environmental endocrine disruption. The conclusion is evidence-supported but conditional: non-monotonic dosing and species/timing differences mean strength of inference depends on exposure window and endpoint, which is what would change it. See section 34.

18. Design an experiment to determine whether a newly discovered peptide is a hormone: (a) demonstrate that it is secreted into the bloodstream in response to a physiological stimulus; (b) show that it has a target tissue with specific receptors; (c) prove that removing the source gland eliminates the response and that hormone replacement restores it; (d) show that the response is dose-dependent.

Answer (Q18, Application). Hypothesis: peptide X is a hormone. Design: (a) show it is released into blood and rises in response to a defined physiological stimulus (measure plasma X before/after, with stimulus vs sham control); (b) demonstrate a distant target tissue expressing specific high-affinity receptors (radioligand binding/displacement); (c) perform a classic ablation-replacement experiment — surgically/genetically remove the source gland, show the response disappears, then restore it by exogenous X (necessity and sufficiency, with vehicle controls and replication); (d) establish a dose-response relationship (graded effect with graded X). A falsifying result is loss of effect despite receptor occupancy or no response on replacement, indicating it is not the causal hormone. See section 34.

19. Evaluate the concept of “trained immunity” — epigenetic reprogramming of innate immune cells (monocytes/macrophages) by prior pathogen exposure, resulting in enhanced responses to subsequent unrelated infections. How does BCG vaccination induce trained immunity (H3K4me3 at inflammatory gene promoters, mTOR-dependent metabolic shift from OXPHOS to glycolysis), and what are the implications for broad-spectrum vaccine development?

Answer (Q19, Application). Trained immunity is the epigenetic and metabolic reprogramming of innate cells (monocytes/macrophages) so that a prior exposure heightens responses to later, unrelated infections. BCG induces it by depositing activating histone marks (H3K4me3, H3K27ac) at inflammatory gene promoters and by an mTOR/HIF-1(alpha)-driven metabolic shift from oxidative phosphorylation toward aerobic glycolysis, priming faster cytokine output. The implication is the prospect of broad-spectrum vaccines that confer non-specific protection. The conclusion is conditional: effect size varies with host, timing, and pathogen, and durability is finite — heterogeneous clinical-trial outcomes are what would change the inference. See section 34.

20. Evaluate the evolutionary conservation and divergence of the HPA axis: fish have an HPI axis (hypothalamic-pituitary-interrenal), amphibians have an HPA axis with cortisol, and birds have corticosterone. What does this conservation tell us about the fundamental biological requirement for glucocorticoid stress response across vertebrates?

Answer (Q20, Application). Across vertebrates the stress axis is conserved in architecture but divergent in the terminal steroid: fish use the hypothalamic-pituitary-interrenal (HPI) axis, amphibians and mammals an HPA axis with cortisol, and birds and rodents use corticosterone. This

deep conservation of a CRH-ACTH-glucocorticoid loop indicates a fundamental, selectively maintained requirement for a rapid, glucocorticoid-mediated stress response (energy mobilization and immune modulation) in vertebrate survival. The inference is strong but comparative: it rests on homology arguments, and discovery of a vertebrate lineage lacking the axis or using an unrelated mediator would weaken the universality claim. See section 34.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the therapeutic potential of checkpoint immunotherapy combined with endocrine modulation: tumor-associated macrophages (TAMs) are often immunosuppressive (M2-polarized). Propose a strategy combining: (a) CSF1R inhibitor to repolarise TAMs; (b) anti-PD-1 to release T cell checkpoint brakes; (c) low-dose dexamethasone to reduce treatment-related inflammation without suppressing anti-tumor immunity. What preclinical evidence supports this combination?

Answer (Q21, Synthesis). Proposed combination: (a) a CSF1R inhibitor depletes/repolarises immunosuppressive M2 tumor-associated macrophages toward an antitumour phenotype; (b) anti-PD-1 releases the checkpoint brake on tumor-infiltrating T cells, restoring cytotoxicity; (c) low-dose dexamethasone limits treatment-related cytokine toxicity while, at low doses, sparing effector T-cell function. Preclinical support: CSF1R blockade plus checkpoint inhibition shows synergistic tumor control in mouse models by remodeling the myeloid compartment and increasing CD8(+) infiltration. The conclusion is conditional — glucocorticoids can blunt antitumour immunity if dosed too high, so the net benefit depends on dose and timing, which is what would change it. See section 34.

22. The pineal gland produces melatonin in response to darkness (via the suprachiasmatic nucleus → sympathetic → pinealocyte). Evaluate: (a) the circadian rhythm of melatonin secretion; (b) the evidence for melatonin’s role in sleep-wake regulation vs a “darkness signal”; (c) the efficacy of exogenous melatonin for jet lag and shift work disorder; (d) the immunomodulatory effects of melatonin (anti-inflammatory, antioxidant, NK cell activation).

Answer (Q22, Synthesis). (a) Melatonin secretion is circadian: the SCN drives a sympathetic signal to the pineal so melatonin rises in darkness (night) and is suppressed by light. (b) Evidence favors melatonin acting primarily as a “darkness/timing signal” entraining circadian phase rather than a direct hypnotic, since it shifts sleep timing more than it sedates. (c) Exogenous melatonin is modestly effective for jet lag and circadian (shift-work/delayed-phase) disorders, mainly via phase-shifting when timed correctly. (d) Melatonin also has immunomodulatory effects (antioxidant, anti-inflammatory, NK-cell enhancing). These conclusions are evidence-supported but conditional on dose and timing; mistimed dosing can shift rhythms the wrong way, which is what would change the inference. See section 34.

23. Evaluate autoinflammatory diseases (distinct from autoimmune): conditions caused by inappropriate innate immune activation without autoantibodies. Using familial Mediterranean fever (FMF, pyrin mutations) as a case study: (a) how does mutant pyrin activate the inflammasome; (b) why does colchicine (inhibiting neutrophil migration) work as treatment; (c) how does IL-1 blockade (anakinra, canakinumab) provide definitive treatment?

Answer (Q23, Synthesis). Familial Mediterranean fever is autoinflammatory: it arises from dysregulated innate immunity (excess IL-1) without autoantibodies or autoreactive T cells. (a) Mutant pyrin escapes normal inhibitory phosphorylation and assembles an ASC-dependent pyrin inflammasome, activating caspase-1 and driving IL-1(β)/pyroptosis. (b) Colchicine works by disrupting microtubules, impairing neutrophil migration and inflammasome assembly, preventing attacks. (c) IL-1 blockade (anakinra, canakinumab) neutralizes the pathway’s effector cytokine, providing definitive control in colchicine-resistant disease. The framework is well supported; its limitation is that this is an evidence-based model of a specific monogenic syndrome, and atypical genotypes/phenotypes are what would qualify the conclusion. See section 34.

24. The gut-brain-immune axis: enteroendocrine cells in the gut produce >30 hormones (GLP-1, PYY, CCK, serotonin) that signal to the brain and immune system. Evaluate: (a) how gut serotonin (>90% of body’s serotonin) modulates gut motility and immune cell function; (b) the evidence linking gut endocrine dysfunction to IBS (irritable bowel syndrome); (c) how GLP-1 receptor agonists (semaglutide) affect not just glucose metabolism but also neuroinflammation.

Answer (Q24, Synthesis). (a) Gut enterochromaffin cells make >90% of body serotonin, which regulates gut motility/secretion and also modulates immune cells (mucosal mast cells, T cells) and signals to the brain via vagal afferents. (b) Evidence links altered enteroendocrine/serotonin signaling and low-grade immune activation to IBS, where dysregulated motility and visceral hypersensitivity track with these changes. (c) GLP-1 receptor agonists (semaglutide) act beyond glucose/appetite: GLP-1R on CNS and immune cells mediates anti-neuroinflammatory effects in preclinical models. These links are conditional and largely associative/preclinical; causal human data are limited, which is what would change the conclusion. See section 34.

25. Critically evaluate the concept of “immunometabolism” — the idea that metabolic reprogramming of immune cells determines their functional polarization. Using the M1 (pro-inflammatory, glycolytic) vs M2 (anti-inflammatory, OXPHOS) macrophage paradigm: (a) how does TCA cycle disruption in M1 macrophages lead to itaconate and succinate accumulation; (b) how does succinate stabilize HIF-1α and promote IL-1β production; (c) why targeting immunometabolism (e.g., dimethyl fumarate activating Nrf2) is a therapeutic frontier? Then apply the chapter’s evidence-map habit to reproductive

physiology: what evidence separates ovulation timing, sperm production, tubal transport, uterine receptivity, endocrine feedback, implantation, and age-dependent gamete quality after 12 months without conception?

Answer (Q25, Synthesis). Immunometabolism holds that the metabolic state of an immune cell determines its function. (a) In M1 macrophages the TCA cycle is “broken” at two points (after citrate and after succinate), so citrate is diverted to itaconate and succinate accumulates. (b) Accumulated succinate inhibits prolyl hydroxylases, stabilizing HIF-1(α), which transactivates pro-IL-1(β), reinforcing the inflammatory glycolytic program; M2 cells instead rely on oxidative phosphorylation and fatty-acid oxidation. (c) Targeting this metabolism (e.g., dimethyl fumarate activating Nrf2 and altering succinate/GAPDH) is a therapeutic frontier for inflammatory disease. The reproductive transfer starts with time-bounded criteria and then separates mechanisms: menstrual history and ovulation testing for ovulatory timing; semen analysis for count, motility, and morphology; tubal patency testing for transport; uterine imaging and endometrial history for receptivity; TSH/prolactin/FSH/LH/estradiol or indicated endocrine tests for feedback disruptions; pregnancy-loss or implantation history for early developmental failure; and age plus ovarian-reserve markers as context rather than destiny. The conclusion is a differential diagnosis, not a label: infertility can arise from one dominant bottleneck or from several modest constraints interacting. See section 34 and [Centers for Disease Control and Prevention \[2024b\]](#).

26. Adrenal medulla catecholamines (epinephrine, norepinephrine) are released in response to sympathetic stimulation. Compare: (a) the receptor subtypes activated by each (α_1 , α_2 , β_1 , β_2); (b) the effects on heart rate, blood vessels, and bronchioles; (c) why pheochromocytoma (adrenal medullary tumor) causes paroxysmal hypertension.

Answer (Q26, Synthesis). (a) Epinephrine activates (α_1), (β_1), and (β_2) receptors; norepinephrine acts mainly on (α_1)/(α_2) and (β_1) with little (β_2) effect. (b) Both raise heart rate/contractility ((β_1)); epinephrine causes net vasodilation in skeletal muscle and bronchodilation ((β_2)), whereas norepinephrine predominantly vasoconstricts ((α_1)), raising peripheral resistance. (c) A pheochromocytoma is a chromaffin-cell tumor that releases catecholamine surges, producing paroxysmal hypertension, palpitations, and sweating. See section 34.

27. Growth hormone (GH) from the anterior pituitary has both direct and indirect (via IGF-1 from the liver) effects. Explain: (a) the GH pulse pattern (nocturnal secretion regulated by GHRH and somatostatin); (b) the metabolic effects of GH (lipolysis, anti-insulin, protein synthesis); (c) why acromegaly (GH excess in adults) causes the symptoms it does.

Answer (Q27, Synthesis). (a) GH is secreted in pulses, largest during slow-wave sleep, under stimulatory GHRH and inhibitory somatostatin from the hypothalamus. (b) Directly, GH is lipolytic and anti-insulin (“diabetogenic”); indirectly, via hepatic IGF-1, it promotes protein synthesis and tissue/linear growth. (c) In adults the epiphyses are fused, so GH excess (acromegaly) cannot increase height; instead IGF-1-driven soft-tissue and bone growth enlarges hands, feet, and jaw, while the anti-insulin effect causes glucose intolerance. See section 34.

28. Dendritic cells (DCs) bridge innate and adaptive immunity. Explain: (a) how immature DCs in tissues sample antigens via macropinocytosis and TLR activation; (b) how DC maturation involves upregulation of MHC class II and co-stimulatory molecules (CD80/86); (c) how mature DCs migrate to lymph nodes to activate naïve T cells (antigen presentation). Why are DCs the most potent professional antigen-presenting cells?

Answer (Q28, Synthesis). (a) Immature tissue DCs are highly endocytic, sampling antigen by macropinocytosis/phagocytosis while TLR engagement signals infection. (b) PRR signals mature the DC: it upregulates MHC II loaded with processed peptide and co-stimulatory CD80/CD86, and reduces further uptake. (c) Maturation induces CCR7, guiding the DC up CCL19/21 gradients to the lymph node T-cell zone, where it presents peptide-MHC to naïve T cells. DCs are the most potent APCs because they uniquely provide all three signals (peptide-MHC, co-stimulation, and polarizing cytokines) needed to prime naïve T cells, including by cross-presentation. See section 34.

29. Parathyroid hormone (PTH) and calcitonin regulate blood calcium. PTH increases Ca^{2+} by: (a) stimulating osteoclasts (bone resorption); (b) increasing renal Ca^{2+} reabsorption; (c) activating 1α -hydroxylase (vitamin D activation \rightarrow intestinal Ca^{2+} absorption). Calcitonin decreases Ca^{2+} by inhibiting osteoclasts. What disease results from PTH excess (hyperparathyroidism)?

Answer (Q29, Synthesis). PTH raises blood Ca^{2+} : (a) it stimulates osteoclastic bone resorption (indirectly, via RANKL on osteoblasts); (b) it increases distal-tubule renal Ca^{2+} reabsorption (and phosphate excretion); (c) it activates renal $1(\alpha)$ -hydroxylase to make calcitriol, boosting intestinal Ca^{2+} absorption. Calcitonin opposes this by inhibiting osteoclasts. PTH excess (primary hyperparathyroidism) causes hypercalcaemia with bone demineralisation, kidney stones, and the classic “bones, stones, groans, psychiatric moans.” See section 34.

30. Natural killer (NK) cells use the “missing self” mechanism: inhibitory KIR receptors bind MHC class I on normal cells and suppress killing. Virus-infected cells and tumor cells often downregulate MHC I, releasing the NK cell from inhibition. Explain: (a) the activating receptors (NKG2D, recognizing stress ligands MICA/MICB); (b) how the balance of activating vs inhibiting signals determines the NK cell response; (c) how cancer immunotherapy exploits NK cells (bispecific engagers).

Answer (Q30, Synthesis). (a) NK activating receptors such as NKG2D recognize stress-induced ligands (MICA/MICB, ULBPs) upregulated on infected or transformed cells. (b) The response is set by the integration of activating versus inhibitory (KIR-MHC I) signals: when activating signals

exceed inhibition (e.g., MHC I downregulated but stress ligands present), the NK cell kills via perforin/granzyme and secretes IFN-(gamma). (c) Immunotherapy exploits this by bispecific NK-cell engagers (e.g., BiKEs/TriKEs) that bridge an NK activating receptor (CD16) to a tumor antigen, forcing targeted lysis. See section 34.

Questions — Immune System Architecture

Instructor Use and Coverage Notes

- Coverage target: Predict the consequence of changing an antigen, cell population, or checkpoint.
- Model/data emphasis: Immune-memory, cytokine, and recognition reasoning.
- Assessment alignment: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Immunity is not just attack; recognition, tolerance, memory, and regulation are equally central.
- Transfer product: Transfer immunity reasoning to vaccination, autoimmunity, infection, and cancer therapy.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 35 of the textbook — review that chapter before attempting the exercises below.

1. Adrenal medulla catecholamines (epinephrine, norepinephrine) are released in response to sympathetic stimulation. Compare: (a) the receptor subtypes activated by each (α_1 , α_2 , β_1 , β_2); (b) the effects on heart rate, blood vessels, and bronchioles; (c) why pheochromocytoma (adrenal medullary tumor) causes paroxysmal hypertension.

Answer (Q1, Recall). (a) Epinephrine activates (α_1), (β_1), and (β_2) receptors; norepinephrine acts mainly on (α_1)/(α_2) and (β_1) with little (β_2) effect. (b) Both raise heart rate/contractility ((β_1)); epinephrine causes net vasodilation in skeletal muscle and bronchodilation ((β_2)), whereas norepinephrine predominantly vasoconstricts ((α_1)), raising peripheral resistance. (c) A pheochromocytoma is a chromaffin-cell tumor that releases catecholamine surges, producing paroxysmal hypertension, palpitations, and sweating. See section 35.
2. Growth hormone (GH) from the anterior pituitary has both direct and indirect (via IGF-1 from the liver) effects. Explain: (a) the GH pulse pattern (nocturnal secretion regulated by GHRH and somatostatin); (b) the metabolic effects of GH (lipolysis, anti-insulin, protein synthesis); (c) why acromegaly (GH excess in adults) causes the symptoms it does.

Answer (Q2, Recall). (a) GH is secreted in pulses, largest during slow-wave sleep, under stimulatory GHRH and inhibitory somatostatin from the hypothalamus. (b) Directly, GH is lipolytic and anti-insulin (“diabetogenic”); indirectly, via hepatic IGF-1, it promotes protein synthesis and tissue/linear growth. (c) In adults the epiphyses are fused, so GH excess (acromegaly) cannot increase height; instead IGF-1-driven soft-tissue and bone growth enlarges hands, feet, and jaw, while the anti-insulin effect causes glucose intolerance. See section 35.
3. Dendritic cells (DCs) bridge innate and adaptive immunity. Explain: (a) how immature DCs in tissues sample antigens via macropinocytosis and TLR activation; (b) how DC maturation involves upregulation of MHC class II and co-stimulatory molecules (CD80/86); (c) how mature DCs migrate to lymph nodes to activate naïve T cells (antigen presentation). Why are DCs the most potent professional antigen-presenting cells?

Answer (Q3, Recall). (a) Immature tissue DCs are highly endocytic, sampling antigen by macropinocytosis/phagocytosis while TLR engagement signals infection. (b) PRR signals mature the DC: it upregulates MHC II loaded with processed peptide and co-stimulatory CD80/CD86, and reduces further uptake. (c) Maturation induces CCR7, guiding the DC up CCL19/21 gradients to the lymph node T-cell zone, where it presents peptide-MHC to naive T cells. DCs are the most potent APCs because they uniquely provide all three signals (peptide-MHC, co-stimulation, and polarizing cytokines) needed to prime naive T cells, including by cross-presentation. See section 35.
4. Parathyroid hormone (PTH) and calcitonin regulate blood calcium. PTH increases Ca^{2+} by: (a) stimulating osteoclasts (bone resorption); (b) increasing renal Ca^{2+} reabsorption; (c) activating 1α -hydroxylase (vitamin D activation → intestinal Ca^{2+} absorption). Calcitonin decreases Ca^{2+} by inhibiting osteoclasts. What disease results from PTH excess (hyperparathyroidism)?

Answer (Q4, Recall). PTH raises blood Ca^{2+} : (a) it stimulates osteoclastic bone resorption (indirectly, via RANKL on osteoblasts); (b) it increases distal-tubule renal Ca^{2+} reabsorption (and phosphate excretion); (c) it activates renal $1(\alpha)$ -hydroxylase to make calcitriol, boosting intestinal Ca^{2+} absorption. Calcitonin opposes this by inhibiting osteoclasts. PTH excess (primary hyperparathyroidism) causes hypercalcaemia with bone demineralisation, kidney stones, and the classic “bones, stones, groans, psychiatric moans.” See section 35.
5. Natural killer (NK) cells use the “missing self” mechanism: inhibitory KIR receptors bind MHC class I on normal cells and suppress killing. Virus-infected cells and tumor cells often downregulate MHC I, releasing the NK cell from inhibition. Explain: (a) the activating receptors (NKG2D, recognizing stress ligands MICA/MICB); (b) how the balance of activating vs inhibiting signals determines the NK cell response; (c) how cancer immunotherapy exploits NK cells (bispecific engagers).

Answer (Q5, Recall). (a) NK activating receptors such as NKG2D recognize stress-induced ligands (MICA/MICB, ULBPs) upregulated on infected or transformed cells. (b) The response is set by the integration of activating versus inhibitory (KIR-MHC I) signals: when activating signals ex-

ceed inhibition (e.g., MHC I downregulated but stress ligands present), the NK cell kills via perforin/granzyme and secretes IFN-(gamma). (c) Immunotherapy exploits this by bispecific NK-cell engagers (e.g., BiKEs/TriKEs) that bridge an NK activating receptor (CD16) to a tumor antigen, forcing targeted lysis. See section 35.

6. Evaluate the integration of endocrine and immune systems: cortisol (a glucocorticoid) suppresses inflammation by: (a) inhibiting NF-κB transcription factor; (b) reducing prostaglandin synthesis (inhibiting PLA₂ and COX-2); (c) inducing lymphocyte apoptosis. Why do critically ill ICU patients sometimes develop adrenal insufficiency, and why does physiological stress-dose hydrocortisone improve sepsis survival?

Answer (Q6, Recall). Cortisol restrains inflammation through several converging mechanisms: (a) ligand-bound GR tethers and inhibits NF-(kappa)B (transrepression), shutting off cytokine genes; (b) it induces annexin A1 and suppresses PLA₂ and COX-2, cutting prostaglandin synthesis; (c) it drives apoptosis of lymphocytes and shifts cytokines toward IL-10. Critically ill patients can develop “critical-illness-related corticosteroid insufficiency” (relative adrenal insufficiency plus tissue glucocorticoid resistance), so HPA output is inadequate for the inflammatory load. Stress-dose hydrocortisone restores vascular catecholamine responsiveness and dampens excessive inflammation, which improves shock reversal; however, the survival benefit is condition-dependent (clearest in vasopressor-refractory septic shock) — that conditionality is what would change the conclusion. See section 35.

7. Evaluate the molecular mechanisms of endocrine disruptors (BPA, phthalates, pesticides): how do these chemicals interfere with hormone signaling (estrogenic, anti-androgenic, thyroid-disrupting), at what environmental concentrations are effects seen (non-monotonic dose-response), and what evidence from wildlife populations (feminisation of male fish, reproductive abnormalities in alligators) supports endocrine disruption in the environment?

Answer (Q7, Recall). Endocrine disruptors interfere with hormone signaling by mimicking or blocking receptors (BPA is weakly oestrogenic; phthalates are anti-androgenic) and by perturbing hormone synthesis, transport, or thyroid signaling. The evidence includes non-monotonic dose-response curves, where low developmental doses can produce effects absent or different at high doses, complicating classical toxicology thresholds. Wildlife data (feminisation/intersex in male fish below sewage outfalls, reduced phallus size and altered sex ratios in alligators at contaminated lakes) support real environmental endocrine disruption. The conclusion is evidence-supported but conditional: non-monotonic dosing and species/timing differences mean strength of inference depends on exposure window and endpoint, which is what would change it. See section 35.

8. Design an experiment to determine whether a newly discovered peptide is a hormone: (a) demonstrate that it is secreted into the bloodstream in response to a physiological stimulus; (b) show that it has a target tissue with specific receptors; (c) prove that removing the source gland eliminates the response and that hormone replacement restores it; (d) show that the response is dose-dependent.

Answer (Q8, Recall). Hypothesis: peptide X is a hormone. Design: (a) show it is released into blood and rises in response to a defined physiological stimulus (measure plasma X before/after, with stimulus vs sham control); (b) demonstrate a distant target tissue expressing specific high-affinity receptors (radioligand binding/displacement); (c) perform a classic ablation-replacement experiment — surgically/genetically remove the source gland, show the response disappears, then restore it by exogenous X (necessity and sufficiency, with vehicle controls and replication); (d) establish a dose-response relationship (graded effect with graded X). A falsifying result is loss of effect despite receptor occupancy or no response on replacement, indicating it is not the causal hormone. See section 35.

9. Evaluate the concept of “trained immunity” — epigenetic reprogramming of innate immune cells (monocytes/macrophages) by prior pathogen exposure, resulting in enhanced responses to subsequent unrelated infections. How does BCG vaccination induce trained immunity (H3K4me3 at inflammatory gene promoters, mTOR-dependent metabolic shift from OXPHOS to glycolysis), and what are the implications for broad-spectrum vaccine development?

Answer (Q9, Recall). Trained immunity is the epigenetic and metabolic reprogramming of innate cells (monocytes/macrophages) so that a prior exposure heightens responses to later, unrelated infections. BCG induces it by depositing activating histone marks (H3K4me3, H3K27ac) at inflammatory gene promoters and by an mTOR/HIF-1(alpha)-driven metabolic shift from oxidative phosphorylation toward aerobic glycolysis, priming faster cytokine output. The implication is the prospect of broad-spectrum vaccines that confer non-specific protection. The conclusion is conditional: effect size varies with host, timing, and pathogen, and durability is finite — heterogeneous clinical-trial outcomes are what would change the inference. See section 35.

10. Evaluate the evolutionary conservation and divergence of the HPA axis: fish have an HPI axis (hypothalamic-pituitary-interrenal), amphibians have an HPA axis with cortisol, and birds have corticosterone. What does this conservation tell us about the fundamental biological requirement for glucocorticoid stress response across vertebrates?

Answer (Q10, Recall). Across vertebrates the stress axis is conserved in architecture but divergent in the terminal steroid: fish use the hypothalamic-pituitary-interrenal (HPI) axis, amphibians and mammals an HPA axis with cortisol, and birds and rodents use corticosterone. This deep conservation of a CRH-ACTH-glucocorticoid loop indicates a fundamental, selectively maintained requirement for a rapid, glucocorticoid-mediated stress response (energy mobilization and immune modulation) in vertebrate survival. The inference is strong but comparative: it rests on homol-

ogy arguments, and discovery of a vertebrate lineage lacking the axis or using an unrelated mediator would weaken the universality claim. See section 35.

Questions 11–20: Application and Analysis

11. Evaluate the therapeutic potential of checkpoint immunotherapy combined with endocrine modulation: tumor-associated macrophages (TAMs) are often immunosuppressive (M2-polarized). Propose a strategy combining: (a) CSF1R inhibitor to repolarise TAMs; (b) anti-PD-1 to release T cell checkpoint brakes; (c) low-dose dexamethasone to reduce treatment-related inflammation without suppressing anti-tumor immunity. What preclinical evidence supports this combination?

Answer (Q11, Application). Proposed combination: (a) a CSF1R inhibitor depletes/repolarises immunosuppressive M2 tumor-associated macrophages toward an antitumour phenotype; (b) anti-PD-1 releases the checkpoint brake on tumor-infiltrating T cells, restoring cytotoxicity; (c) low-dose dexamethasone limits treatment-related cytokine toxicity while, at low doses, sparing effector T-cell function. Preclinical support: CSF1R blockade plus checkpoint inhibition shows synergistic tumor control in mouse models by remodeling the myeloid compartment and increasing CD8(+) infiltration. The conclusion is conditional — glucocorticoids can blunt antitumour immunity if dosed too high, so the net benefit depends on dose and timing, which is what would change it. See section 35.

12. The pineal gland produces melatonin in response to darkness (via the suprachiasmatic nucleus → sympathetic → pinealocyte). Evaluate: (a) the circadian rhythm of melatonin secretion; (b) the evidence for melatonin’s role in sleep-wake regulation vs a “darkness signal”; (c) the efficacy of exogenous melatonin for jet lag and shift work disorder; (d) the immunomodulatory effects of melatonin (anti-inflammatory, antioxidant, NK cell activation).

Answer (Q12, Application). (a) Melatonin secretion is circadian: the SCN drives a sympathetic signal to the pineal so melatonin rises in darkness (night) and is suppressed by light. (b) Evidence favors melatonin acting primarily as a “darkness/timing signal” entraining circadian phase rather than a direct hypnotic, since it shifts sleep timing more than it sedates. (c) Exogenous melatonin is modestly effective for jet lag and circadian (shift-work/delayed-phase) disorders, mainly via phase-shifting when timed correctly. (d) Melatonin also has immunomodulatory effects (antioxidant, anti-inflammatory, NK-cell enhancing). These conclusions are evidence-supported but conditional on dose and timing; mistimed dosing can shift rhythms the wrong way, which is what would change the inference. See section 35.

13. Evaluate autoinflammatory diseases (distinct from autoimmune): conditions caused by inappropriate innate immune activation without autoantibodies. Using familial Mediterranean fever (FMF, pyrin mutations) as a case study: (a) how does mutant pyrin activate the inflammasome; (b) why does colchicine (inhibiting neutrophil migration) work as treatment; (c) how does IL-1 blockade (anakinra, canakinumab) provide definitive treatment?

Answer (Q13, Application). Familial Mediterranean fever is autoinflammatory: it arises from dysregulated innate immunity (excess IL-1) without autoantibodies or autoreactive T cells. (a) Mutant pyrin escapes normal inhibitory phosphorylation and assembles an ASC-dependent pyrin inflammasome, activating caspase-1 and driving IL-1(beta)/pyroptosis. (b) Colchicine works by disrupting microtubules, impairing neutrophil migration and inflammasome assembly, preventing attacks. (c) IL-1 blockade (anakinra, canakinumab) neutralizes the pathway’s effector cytokine, providing definitive control in colchicine-resistant disease. The framework is well supported; its limitation is that this is an evidence-based model of a specific monogenic syndrome, and atypical genotypes/phenotypes are what would qualify the conclusion. See section 35.

14. The gut-brain-immune axis: enteroendocrine cells in the gut produce >30 hormones (GLP-1, PYY, CCK, serotonin) that signal to the brain and immune system. Evaluate: (a) how gut serotonin (>90% of body’s serotonin) modulates gut motility and immune cell function; (b) the evidence linking gut endocrine dysfunction to IBS (irritable bowel syndrome); (c) how GLP-1 receptor agonists (semaglutide) affect not just glucose metabolism but also neuroinflammation.

Answer (Q14, Application). (a) Gut enterochromaffin cells make >90% of body serotonin, which regulates gut motility/secretion and also modulates immune cells (mucosal mast cells, T cells) and signals to the brain via vagal afferents. (b) Evidence links altered enteroendocrine/serotonin signaling and low-grade immune activation to IBS, where dysregulated motility and visceral hypersensitivity track with these changes. (c) GLP-1 receptor agonists (semaglutide) act beyond glucose/appetite: GLP-1R on CNS and immune cells mediates anti-neuroinflammatory effects in preclinical models. These links are conditional and largely associative/preclinical; causal human data are limited, which is what would change the conclusion. See section 35.

15. Critically evaluate the concept of “immunometabolism” — the idea that metabolic reprogramming of immune cells determines their functional polarization. Using the M1 (pro-inflammatory, glycolytic) vs M2 (anti-inflammatory, OXPHOS) macrophage paradigm: (a) how does TCA cycle disruption in M1 macrophages lead to itaconate and succinate accumulation; (b) how does succinate stabilize HIF-1α and promote IL-1β production; (c) why targeting immunometabolism (e.g., dimethyl fumarate activating Nrf2) is a therapeutic frontier? Then apply the chapter’s evidence-map habit to reproductive physiology: what evidence separates ovulation timing, sperm production, tubal transport, uterine receptivity, endocrine feedback, implantation, and age-dependent gamete quality after 12 months without conception?

Answer (Q15, Application). Immunometabolism holds that the metabolic state of an immune cell determines its function. (a) In M1 macrophages the TCA cycle is “broken” at two points (after citrate and after succinate), so citrate is diverted to itaconate and succinate accumulates. (b) Accumulated succinate inhibits prolyl hydroxylases, stabilizing HIF-1(alpha), which transactivates pro-IL-1(beta), reinforcing the inflammatory glycolytic program; M2 cells instead rely on oxidative phosphorylation and fatty-acid oxidation. (c) Targeting this metabolism (e.g., dimethyl fumarate activating Nrf2 and altering succinate/GAPDH) is a therapeutic frontier for inflammatory disease. The reproductive transfer starts with time-bounded criteria and then separates mechanisms: menstrual history and ovulation testing for ovulatory timing; semen analysis for count, motility, and morphology; tubal patency testing for transport; uterine imaging and endometrial history for receptivity; TSH/prolactin/FSH/LH/estradiol or indicated endocrine tests for feedback disruptions; pregnancy-loss or implantation history for early developmental failure; and age plus ovarian-reserve markers as context rather than destiny. The conclusion is a differential diagnosis, not a label: infertility can arise from one dominant bottleneck or from several modest constraints interacting. See section 35 and [Centers for Disease Control and Prevention \[2024b\]](#).

16. What is the endocrine system? How does it differ from the nervous system in signaling speed and duration?

Answer (Q16, Application). The endocrine system is the network of glands that secrete hormones into the blood to regulate physiology body-wide. Compared with the nervous system, endocrine signaling is slower (seconds to hours rather than milliseconds) and longer-lasting (minutes to days rather than brief), because it relies on chemical hormones travelling via the circulation to all cells bearing the receptor rather than fast electrical transmission across a narrow synapse. See section 35.

17. Name the major endocrine glands and one hormone secreted by each.

Answer (Q17, Application). Major glands and a representative hormone each: hypothalamus (releasing hormones, e.g., CRH); anterior pituitary (ACTH, GH); thyroid (T4/T3); parathyroid (PTH); adrenal cortex (cortisol); adrenal medulla (epinephrine); endocrine pancreas (insulin from (beta)-cells); gonads (testosterone or oestradiol); pineal (melatonin). See section 35.

18. Distinguish peptide hormones from steroid hormones in terms of synthesis, transport, and receptor location.

Answer (Q18, Application). Peptide hormones are made on ribosomes as preprohormones, stored in secretory granules, travel free in plasma, and act fast on plasma-membrane receptors (RTKs/GPCRs). Steroid hormones are synthesized on demand from cholesterol (not stored), carried bound to plasma proteins (e.g., CBG, SHBG), and act slowly via intracellular nuclear receptors that alter gene transcription. The receptor location (membrane vs nuclear) is the mechanistic difference that makes peptide signaling rapid/transient and steroid signaling slow/persistent. See section 35.

19. What is the hypothalamic-pituitary axis? Name one releasing hormone and one tropic hormone.

Answer (Q19, Application). The hypothalamic-pituitary axis is the hierarchical control loop in which the hypothalamus secretes releasing hormones that drive anterior-pituitary tropic hormones, which in turn stimulate a peripheral target gland, with negative feedback at each level. Example: hypothalamic CRH (releasing hormone) stimulates pituitary ACTH (tropic hormone), which stimulates adrenal cortisol. See section 35.

20. What is negative feedback? Give an example involving the thyroid gland.

Answer (Q20, Application). Negative feedback is regulation in which a system’s output inhibits the steps that produced it, stabilizing the variable around a set point. Thyroid example: rising free T3/T4 inhibits hypothalamic TRH and pituitary TSH secretion, reducing further thyroid hormone output; if T3/T4 fall, TRH and TSH rise again, restoring levels. See section 35.

Questions 21–30: Synthesis and Evaluation

21. What is cortisol? Name its target tissues and three physiological effects.

Answer (Q21, Synthesis). Cortisol is a glucocorticoid steroid made in the adrenal cortex (zona fasciculata) under ACTH control. Target tissues include liver, muscle, adipose, and immune cells (acting via the nuclear glucocorticoid receptor). Three effects: stimulates hepatic gluconeogenesis (mobilizing amino acids from muscle), is immunosuppressive/anti-inflammatory (inhibits NF-(kappa)B and cytokine production), and promotes lipolysis. See section 35.

22. What are the components of innate immunity? Name four.

Answer (Q22, Synthesis). Innate immunity is the rapid, non-specific, germline-encoded first line of defense. Four components: physical/chemical barriers (skin, mucus, lysozyme); phagocytes (neutrophils, macrophages, dendritic cells); the complement system; and NK cells (plus inflammation and interferons). See section 35.

23. What is a Toll-like receptor (TLR)? Name a ligand for TLR4.

- Answer (Q23, Synthesis). A Toll-like receptor is a germline-encoded pattern-recognition receptor on the plasma membrane or endosomes that detects conserved pathogen molecules (PAMPs) and triggers inflammatory or antiviral signaling. The ligand for TLR4 is bacterial lipopolysaccharide (LPS), characteristic of Gram-negative bacteria. See section 35.
24. What is the complement system? What are its three outcomes (opsonisation, MAC, inflammation)?
- Answer (Q24, Synthesis). The complement system is a cascade of about 30 plasma proteins that, once triggered (classical, lectin, or alternative pathway), generate C3/C5 convertases. Its three outcomes are opsonisation (C3b coats pathogens for phagocytosis), the membrane attack complex (C5b-9 lyses target cells), and inflammation (anaphylatoxins C3a/C5a recruit and activate leukocytes). See section 35.
25. Define phagocytosis. Name two professional phagocytes.
- Answer (Q25, Synthesis). Phagocytosis is the receptor-mediated engulfment of particles or microbes into a phagosome that fuses with lysosomes to destroy the cargo. Two professional phagocytes: neutrophils and macrophages (dendritic cells also phagocytose). See section 35.
26. The HPA axis: CRH (hypothalamus) → ACTH (anterior pituitary) → cortisol (adrenal cortex). Cortisol feeds back negatively on CRH and ACTH secretion. If a patient has an adrenal tumor autonomously producing cortisol, predict: (a) ACTH levels; (b) CRH levels; (c) contralateral adrenal gland size; (d) response to the dexamethasone suppression test.
- Answer (Q26, Synthesis). An autonomous cortisol-secreting adrenal tumor produces high cortisol independent of ACTH. (a) ACTH is low (suppressed by negative feedback). (b) CRH is low (also feedback-suppressed). (c) The contralateral adrenal atrophies because, without ACTH trophic support, the normal cortex shrinks. (d) On the dexamethasone suppression test cortisol fails to suppress (it is autonomous and not under pituitary control), confirming an ACTH-independent adrenal source. See section 35.
27. Insulin (from pancreatic β -cells) and glucagon (from α -cells) have opposing metabolic effects. Compare: (a) the stimulus for secretion of each; (b) the target tissue responses (liver, muscle, adipose); (c) the blood glucose level at which each dominates. What happens in Type 1 Diabetes (complete β -cell destruction)?
- Answer (Q27, Synthesis). (a) Insulin is secreted when blood glucose rises (after a meal); glucagon is secreted when glucose falls (fasting). (b) Insulin drives hepatic/muscle glycogen synthesis, muscle/adipose GLUT4 glucose uptake, and adipose lipogenesis; glucagon drives hepatic glycogenolysis and gluconeogenesis. (c) Insulin dominates at high glucose (5.5 mmol/L postprandial), glucagon at low glucose (fasting). In Type 1 diabetes, autoimmune (beta)-cell destruction abolishes insulin, so glucose stays high, cells starve, unopposed glucagon drives hyperglycaemia and ketoacidosis. See section 35.
28. Thyroid hormones (T_3/T_4) are unusual peptide-derived hormones that act like steroids (entering cells, binding nuclear receptors). Explain: (a) why T_3/T_4 can cross membranes (lipophilic due to iodination); (b) how T_3 binds thyroid hormone receptors ($TR\alpha/TR\beta$) to regulate gene transcription; (c) why hypothyroidism causes bradycardia, fatigue, and weight gain.
- Answer (Q28, Synthesis). (a) T_3/T_4 are lipophilic because heavy iodination of the tyrosine-derived rings lets them cross the lipid bilayer (entering cells via MCT8/MCT10). (b) T_3 binds nuclear $TR(\alpha)/TR(\beta)$, which heterodimerise with RXR on thyroid response elements; without T_3 the receptor recruits corepressors and represses genes, while T_3 binding swaps in coactivators and activates transcription. (c) Hypothyroidism slows metabolism: reduced Na^{+}/K^{+} -ATPase and BMR cause fatigue and weight gain, and loss of (β_1)-receptor upregulation plus reduced cardiac drive causes bradycardia. See section 35.
29. The inflammasome (NLRP3) is activated by diverse danger signals (K^{+} efflux, ROS, crystal particles). Trace: (a) NLRP3 oligomerisation; (b) ASC adaptor recruitment; (c) caspase-1 activation; (d) IL-1 β and IL-18 maturation and release; (e) pyroptosis (inflammatory cell death). Name two diseases where NLRP3 is inappropriately activated.
- Answer (Q29, Synthesis). (a) A priming signal (TLR/NF-(κ))B upregulates NLRP3 and pro-IL-1(β); a second signal (K^{+} efflux, ROS, crystals) triggers NLRP3 oligomerisation. (b) NLRP3 recruits the ASC adaptor, which polymerizes into a speck. (c) ASC clusters pro-caspase-1, enabling autocatalytic caspase-1 activation. (d) Active caspase-1 cleaves pro-IL-1(β) and pro-IL-18 to their mature secreted forms. (e) Caspase-1 also cleaves gasdermin D, whose N-terminal pores cause pyroptosis (lytic inflammatory death). Inappropriate NLRP3 activation occurs in gout (urate crystals) and cryopyrin-associated periodic syndromes (CAPS). See section 35.
30. Neutrophils are the first responders to bacterial infection. Describe their killing mechanisms: (a) phagocytosis and phagolysosome fusion; (b) respiratory burst (NADPH oxidase → superoxide → HOCl via myeloperoxidase); (c) NETosis (neutrophil extracellular trap formation). What disease results from NADPH oxidase deficiency (CGD)?
- Answer (Q30, Synthesis). (a) Neutrophils recognize and engulf opsonised bacteria into a phagosome that fuses with granules to form a phagolysosome. (b) The respiratory burst: assembled NADPH oxidase generates superoxide, dismutated to H_2O_2 ; myeloperoxidase converts H_2O_2

+ Cl^- to bactericidal hypochlorous acid (HOCl). (c) NETosis: the neutrophil extrudes decondensed chromatin studded with antimicrobial proteins (NETs) that trap and kill extracellular bacteria. NADPH oxidase deficiency causes chronic granulomatous disease (CGD), with recurrent catalase-positive infections. See section 35.

Questions — Population Ecology and Growth Models

Instructor Use and Coverage Notes

- Coverage target: Calculate a growth or sampling parameter and interpret its conservation meaning.
- Model/data emphasis: Exponential/logistic growth, mark-recapture, and matrix projection.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Carrying capacity is not a fixed magic number; it changes with resources, interactions, and disturbance.
- Transfer product: Transfer population models to fisheries, invasive species, epidemiology, and endangered species.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 36 of the textbook — review that chapter before attempting the exercises below.

1. Define population ecology. What are the four demographic parameters that influence population size?

Answer (Q1, Recall). Population ecology is the study of the factors that determine the size, density, distribution, age structure, and growth of populations over time. The four demographic parameters that change population size are natality (births), mortality (deaths), immigration (entry), and emigration (exit): $\Delta N = (B + I) - (D + E)$. Births and immigration add individuals; deaths and emigration remove them. See section 36. 2. What is the exponential growth model? Write its equation.

Answer (Q2, Recall). The exponential growth model describes population dynamics when per-capita birth and death rates are constant and resources are effectively unlimited — every individual reproduces at the same rate regardless of population density. Differential form: $\frac{dN}{dt} = rN$, where N is population size and r = intrinsic rate of increase = (birth rate – death rate) with units time^{-1} . Integrated form: $N_t = N_0 e^{rt}$. Doubling time $T_2 = \ln 2/r \approx 0.693/r$. Key numerical benchmarks: bacteria (*E. coli* in rich medium) $r \approx 1.4 \text{ h}^{-1}$ (doubling every about 30 min); humans globally today $r \approx 0.01 \text{ yr}^{-1}$ (doubling every about 70 years); historic humans up to 1960 doubled every about 35 years. Classical biological example: the re-introduction of ring-necked pheasants to Protection Island (1937) — 8 birds → 1898 in 5 years, almost exactly exponential before running into food limits. Because pure exponential growth is biologically unsustainable, this model is an idealisation valid only for the initial “colonization” or “bloom” phase — crucial for biosecurity (invasive species) and public health (epidemic R_0) calculations. See section 36. 3. What is the logistic growth model? Write its equation and define K (carrying capacity).

Answer (Q3, Recall). The logistic growth model (Verhulst 1838; rediscovered Pearl & Reed 1920) extends exponential growth by adding density-dependent self-limitation: $\frac{dN}{dt} = rN\left(1 - \frac{N}{K}\right)$, where K is the carrying capacity — the equilibrium population size supported by resources in a given environment. When $N \ll K$, the $(1 - N/K)$ term ≈ 1 and growth is near-exponential; as $N \rightarrow K$, growth slows; at $N = K$, $dN/dt = 0$. Integrated form: $N(t) = \frac{K}{1 + \left(\frac{K - N_0}{N_0}\right)e^{-rt}}$, a sigmoid (S-shaped) curve with inflection at $N = K/2$ (point of maximum growth rate $dN/dt_{\text{max}} = rK/4$). K is not a physical constant: it reflects the resource ceiling — food, water, nesting sites, disease pressure — and can shift with environmental change. Classical biological example: yeast in batch culture (Gause 1934) fit the logistic almost exactly with $K \approx 665 \text{ cells/mL}$ and $r \approx 0.22 \text{ h}^{-1}$. Modern fisheries management uses the logistic to define maximum sustainable yield (MSY) at $N = K/2$; harvesting above MSY drives fisheries to collapse (North Atlantic cod, 1992). See section 36. 4. What are r-selected and K-selected species? Give one example of each.

Answer (Q4, Recall). r-selected species maximize the intrinsic rate of increase r : many small offspring, little parental care, early reproduction, short lifespan, Type III survivorship — favored in unstable or unpredictable environments (e.g., dandelions, mosquitoes, weedy annual plants). K-selected species are adapted to live near carrying capacity K : few large offspring, heavy parental investment, late reproduction, long lifespan, Type I survivorship — favored in stable, crowded environments (e.g., elephants, oak trees). See section 36. 5. Define survivorship curve. Describe Types I, II, and III.

Answer (Q5, Recall). A survivorship curve plots the proportion of an original cohort still alive (l_x , log scale) against age. Type I (late loss): low juvenile mortality, most deaths in old age (humans, large mammals) — convex curve. Type II (constant loss): death probability roughly constant at all ages (many songbirds, rodents, hydra) — straight line. Type III (early loss): very high juvenile mortality, survivors are long-lived (oysters, oak trees, sea turtles) — concave curve. See section 36. 6. What is the mark-recapture method? Write the Lincoln-Petersen equation.

Answer (Q6, Recall). Mark-recapture estimates the size of a mobile population: capture a sample, mark and release them, then later take a second sample and count the marked recaptures. The Lincoln–Petersen estimator is $\hat{N} = \frac{M \cdot C}{R}$, where M = number marked in the first sample, C = total caught in the second sample, and R = marked individuals recaptured. It assumes a closed population, no mark loss, and equal catchability. See section 36. 7. What is population density? Distinguish crude density from ecological density.

Answer (Q7, Recall). Population density is the number of individuals per unit area or volume ($D = N/\text{area}$). Crude density uses total habitat area as the denominator, including space the species cannot use. Ecological (specific) density uses only the area actually occupied or usable by the species, so it more accurately reflects the local intensity of intraspecific interaction and resource demand. See section 36. 8. Define natality, mortality, immigration, and emigration.

Answer (Q8, Recall). Natality is the per-capita birth rate (new individuals produced by reproduction). Mortality is the per-capita death rate. Immigration is the movement of individuals *into* the population from elsewhere. Emigration is the movement of individuals *out* of the population. Natality and immigration increase N ; mortality and emigration decrease it: $\Delta N = (B + I) - (D + E)$. See section 36. 9. What is a life table? What parameters does it include?

Answer (Q9, Recall). A life table is an age-specific summary of survival and reproduction in a cohort. It records, for each age class x : n_x (number alive), l_x (survivorship, proportion surviving from birth), d_x (deaths in the interval), q_x (age-specific mortality rate), and m_x (age-specific fecundity). From it one computes net reproductive rate $R_0 = \sum l_x m_x$, generation time T , and $r \approx \ln(R_0)/T$. See section 36. 10. What is the difference between density-dependent and density-independent limiting factors?

Answer (Q10, Recall). Density-dependent factors change in per-capita effect as population density changes — they intensify as N rises and provide regulatory feedback (competition for food, predation, disease, parasitism, accumulation of wastes). Density-independent factors affect the same *fraction* of individuals regardless of density (weather, fire, flood, drought, habitat destruction). Density-dependent factors stabilize populations near K ; density-independent ones cause fluctuations not tied to abundance. See section 36.

Questions 11–20: Application and Analysis

11. An *E. coli* population starts with $N_0 = 100$ cells. The intrinsic rate of increase $r = 0.693 \text{ h}^{-1}$ (doubling time = 1 hour). Calculate N_t at $t = 5$ hours using $N_t = N_0 e^{rt}$. At what time would the population reach 10^6 cells?

Answer (Q11, Application). Exponential model $N_t = N_0 e^{rt}$ with $N_0 = 100$, $r = 0.693 \text{ h}^{-1}$. At $t = 5 \text{ h}$: $N_5 = 100 e^{0.693 \times 5} = 100 e^{3.465} \approx 100 \times 31.96 \approx 3200$ cells (equivalently $100 \times 2^5 = 3200$, since r gives a 1-hour doubling time). Time to reach 10^6 : $t = \frac{\ln(10^6/100)}{0.693} = \frac{\ln(10^4)}{0.693} = \frac{9.21}{0.693} \approx 13.3$ hours (≈ 13.3 doublings). See section 36. 12. A deer population ($K = 1,000$) starts at $N = 50$ and grows logistically with $r = 0.3/\text{year}$. Calculate dN/dt at $N = 50$, $N = 500$, and $N = 900$. At which population size is growth rate highest? What happens to growth rate as N approaches K ?

Answer (Q12, Application). Logistic model $\frac{dN}{dt} = rN\left(1 - \frac{N}{K}\right)$, $r = 0.3 \text{ yr}^{-1}$, $K = 1000$. At $N = 50$: $0.3(50)(1 - 0.05) = 15 \times 0.95 \approx 14.3 \text{ ind/yr}$. At $N = 500$: $0.3(500)(1 - 0.5) = 150 \times 0.5 = 75 \text{ ind/yr}$. At $N = 900$: $0.3(900)(1 - 0.9) = 270 \times 0.1 = 27 \text{ ind/yr}$. Absolute growth rate is highest at $N = K/2 = 500$ ($dN/dt_{\max} = rK/4 = 75$). As $N \rightarrow K$, the $(1 - N/K)$ term $\rightarrow 0$, so $dN/dt \rightarrow 0$ and the population levels off. See section 36. 13. In a mark-recapture study: 200 butterflies are captured, marked, and released. A week later, 250 butterflies are captured, of which 40 are marked. Estimate population size using the Lincoln-Petersen formula. What assumptions must hold for this estimate to be valid?

Answer (Q13, Application). Lincoln-Petersen estimator: $\hat{N} = \frac{M \cdot C}{R}$, where M = first-capture marked (200), C = second-capture total (250), R = recaptured marked (40). Substitute: $\hat{N} = \frac{200 \times 250}{40} = \frac{50\,000}{40} = 1250$ butterflies. More bias-corrected Chapman estimator (for small samples): $\hat{N} = \frac{(M+1)(C+1)}{R+1} - 1 = \frac{201 \times 251}{41} - 1 = 1230 - 1 = 1229$ — about 2 % smaller; use this when $R < 20$ or when sample sizes are uneven.

Approximate 95 % confidence interval via $SE(\hat{N}) \approx \sqrt{\frac{M^2 C (C - R)}{R^3}} \approx \sqrt{\frac{200^2 \cdot 250 \cdot 210}{40^3}} \approx 181$; $CI \approx 1250 \pm 355 \rightarrow$ about [895, 1605] butterflies. Assumptions that must hold: (i) Closed population (no births, deaths, immigration, emigration between capture occasions — “closed” to N change); (ii) marks are not lost or overlooked; (iii) marking does not affect recapture probability (no trap-shyness, mark-induced predation, or reduced fitness); (iv) every individual has equal capture probability on both occasions (no sex-, age-, or site-heterogeneity); (v) sufficient mixing so that recaptured marked fraction is representative of the marked-to-total ratio in the full population. Violations bias the estimate — typically *upward* with trap-shyness, *downward* with heterogeneity. See section 36. 14. A population crash occurs when a population overshoots K (exceeds carrying capacity) and resources are depleted, causing K to decline. Using the logistic model, explain: (a) why the population exceeds K (time lag in density-dependent response); (b) the population trajectory after overshooting (damped oscillations vs extinction); (c) a real-world example (reindeer on St. Matthew Island).

Answer (Q14, Application). (a) Density-dependent regulation acts with a time lag: by the time food shortage depresses births and raises deaths, N has already shot past K because the prior reproduction was committed. (b) With a modest lag the population shows damped oscillations converging on K ; with a long lag or severe resource destruction K itself collapses and the population may crash toward extinction rather than oscillate. (c) St. Matthew Island reindeer: 29 introduced in 1944 grew to about 6,000 by 1963, overgrazed the slow-growing lichen, then crashed to about 42 by 1966 — overshoot followed by resource destruction and near-extinction, not damped oscillation. See section 36. 15. Compare r -selected (small, many offspring, high mortality, short lifespan) and K -selected (large, few offspring, low mortality, long lifespan) strategies. Place the following

organisms on the r-K continuum: elephant, dandelion, oak tree, mosquito, whale, annual grass. Explain why the r/K model is now considered an oversimplification.

Answer (Q15, Application). r-selected = small body, many offspring, high mortality, short life (fast end); K-selected = large body, few offspring, low mortality, long life (slow end). Ordering from r toward K: annual grass \approx dandelion \approx mosquito (r-end) \rightarrow oak tree \rightarrow elephant \approx whale (K-end). The r/K dichotomy is an oversimplification because life-history traits vary continuously and somewhat independently, environments are rarely cleanly stable or unstable, and modern demographic (life-history) theory predicts strategies from age-specific mortality and reproductive value rather than a single r-K axis. See section 36. 16. A Type I survivorship curve (e.g., humans) shows high survival until old age. A Type III curve (e.g., sea turtles) shows high juvenile mortality with high adult survival. Calculate: if a sea turtle lays 100 eggs per year and 2% survive to adulthood, what is the expected number of adult recruits per year? How many years of reproduction are needed to replace a dying adult (assume one-for-one replacement)?

Answer (Q16, Application). Adult recruits = $100 \times 0.02 = 2$ adults per year. Under strict one-for-one replacement, each turtle must produce one surviving adult to replace itself; at 2 recruits per reproductive year that requires only about 0.5 year of reproduction per adult replaced, but because each turtle replaces *itself* plus a mate's contribution, sustaining the population requires each female to survive and reproduce long enough to yield about 1 surviving daughter — so high adult survival across many reproductive years is essential. The Type III pattern means conservation gains come mainly from protecting adults and subadults (highest reproductive value), not eggs. See section 36. 17. The Allee effect describes a positive relationship between population density and per capita growth rate at low densities (below a threshold, the population cannot recover). Explain: (a) three mechanisms (mate finding difficulty, loss of cooperative defense, genetic problems from inbreeding); (b) how the Allee effect creates an extinction vortex for small populations; (c) what conservation strategies address the Allee effect.

Answer (Q17, Application). (a) Mate-finding failure (too few encounters at low density), loss of cooperative behaviors (group defense, cooperative foraging/hunting, predator dilution), and inbreeding/genetic decline (loss of heterozygosity, fixation of deleterious alleles). (b) Below the Allee threshold per-capita growth becomes negative, so small size lowers fitness, which lowers size further — a self-reinforcing extinction vortex coupling demographic and genetic decay. (c) Conservation responses raise effective density: translocation/augmentation to push N above threshold, captive breeding and head-starting, habitat consolidation, genetic rescue (introducing unrelated individuals), and protecting aggregation/breeding sites. See section 36. 18. Age-structured population models (Leslie matrix): a population with two age classes (juvenile and adult) has the following transition rates: juvenile survival = 0.5, adult survival = 0.8, adult fecundity = 3 juveniles/adult. Write the Leslie matrix and project the population for two time steps from an initial vector of [100 juveniles, 50 adults].

Answer (Q18, Application). Leslie matrix $A = \begin{pmatrix} 0 & 3 \\ 0.5 & 0.8 \end{pmatrix}$ (top row = fecundity, sub-diagonal = juvenile \rightarrow adult survival, adult self-loop = adult survival). Start $n(0) = (100, 50)^T$. Step 1: juveniles = $0 \cdot 100 + 3 \cdot 50 = 150$; adults = $0.5 \cdot 100 + 0.8 \cdot 50 = 50 + 40 = 90 \rightarrow (150, 90)$. Step 2: juveniles = $3 \cdot 90 = 270$; adults = $0.5 \cdot 150 + 0.8 \cdot 90 = 75 + 72 = 147 \rightarrow (270, 147)$. Total grows from 150 to 240 to 417. See section 36. 19. Source-sink metapopulation dynamics: a "source" habitat (birth rate > death rate) produces emigrants that maintain a "sink" population (death rate > birth rate). Using a specific example (e.g., wetland birds using good-quality vs poor-quality wetlands), explain: (a) why the sink population would go extinct without immigration from the source; (b) what happens if the source habitat is destroyed; (c) implications for habitat conservation priority.

Answer (Q19, Application). (a) In a sink, deaths exceed births ($\lambda < 1$), so without a continual inflow of emigrants the local population declines deterministically to extinction. (b) If the source habitat is destroyed, the emigrant subsidy stops; the sink can no longer be propped up and both subpopulations decline — overall metapopulation collapse, sometimes after a deceptive lag. (c) Apparent occupancy is misleading: a crowded sink is not a healthy population. Conservation priority should weight per-capita productivity (source status), protecting net exporters even if they hold fewer individuals, and avoiding investment in ecological-trap sinks. See section 36. 20. Climate change is shifting species' ranges poleward and upslope. Evaluate: (a) the evidence from range shift data (butterflies, birds, trees); (b) why some species cannot keep pace (dispersal limitation, habitat fragmentation); (c) how population viability analysis (PVA) is used to predict extinction risk under different warming scenarios.

Answer (Q20, Application). (a) Long-term datasets show poleward/upslope range-margin shifts averaging on the order of kilometers per decade and earlier phenology in butterflies, birds, and trees, broadly tracking isotherm movement. (b) Species lag because of limited dispersal ability, habitat fragmentation blocking movement corridors, slow life cycles (long-lived trees), and dependence on biotic partners that do not move in step. (c) PVA projects extinction probability by combining vital rates with climate-driven scenarios for habitat and demographic parameters, comparing persistence under different warming trajectories to rank management options (corridors, assisted migration). The conclusion would change if dispersal or adaptive capacity were higher than assumed. See section 36.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the applicability of the logistic growth model to real populations: where does it succeed (general S-shaped growth curves in laboratory conditions) and where does it fail (time lags, environmental stochasticity, age structure, Allee effects)? Propose a more realistic model that incorporates at least two of these omitted features.

Answer (Q21, Synthesis). The logistic succeeds as a description of bounded, S-shaped growth in simple, resource-limited settings (lab cultures of yeast, *Paramecium*, flour beetles) and as a management abstraction (MSY at $K/2$). It fails when there are reproductive time lags, environmental stochasticity, age/stage structure, or Allee effects at low density — all assumed away by instantaneous, deterministic, unstructured density dependence. A more realistic model adds a delay and stochasticity, e.g. a delayed logistic with environmental noise $\frac{dN}{dt} = rN\left(1 - \frac{N(t-\tau)}{K}\right) + \sigma N \xi(t)$, or a stochastic stage-structured (Leslie/Lefkovitch) matrix with an Allee threshold. See section 36. 22. Design a long-term population monitoring program for a threatened species (e.g., African wild dog, *Lycaon pictus*). Describe: (a) the sampling methodology (camera traps, aerial surveys, genetic mark-recapture using faecal DNA); (b) the demographic parameters to estimate (λ = finite rate of increase, survival by age class, reproductive output); (c) how you would build a PVA model and define minimum viable population (MVP) size.

Answer (Q22, Synthesis). (a) Sampling: camera-trap grids and aerial/transect surveys for density, plus genetic mark-recapture from faecal DNA to identify individuals and packs without handling. (b) Parameters: finite rate of increase λ , age/stage-specific survival, reproductive output (litter size, breeding-female fraction), and dispersal among packs. (c) PVA: build a stochastic stage-structured matrix parameterized by those vital rates, add demographic and environmental stochasticity and inbreeding effects, run many simulations, and define MVP as the smallest size giving $\geq 95\%$ persistence over about 100 generations; use sensitivity/elasticity to identify the rate (typically adult survival) with greatest leverage on λ . See section 36. 23. Evaluate invasive species population dynamics: the brown tree snake (*Boiga irregularis*) invaded Guam after WWII and caused the extinction of most native forest birds. Using population ecology theory: (a) what growth model best describes the initial invasion (exponential growth in the absence of natural enemies); (b) what new carrying capacity was reached; (c) what control strategies (traps, acetaminophen-laced dead mice) have been attempted, and why are they insufficient?

Answer (Q23, Synthesis). (a) The initial invasion is near-exponential ($dN/dt = rN$): no native predators or competitors and abundant naive bird prey, so per-capita growth is unchecked. (b) Once prey were depleted and intraspecific limitation set in, the snake population settled at a new, prey-poor carrying capacity sustained on lizards, small mammals, and birds' eggs. (c) Control (live traps, hand-capture, acetaminophen-baited dead neonatal mice, detector dogs, barriers) is insufficient because the population is large, cryptic, arboreal, and reproduces faster than removal — control suppresses but cannot eradicate, so the realistic goal is interdiction to prevent spread to other islands. See section 36. 24. Evaluate the concept of “ecological traps” — habitats that appear attractive to organisms but result in reduced fitness (e.g., sea turtles attracted to coastal lights, birds nesting in mowed agricultural fields). How do ecological traps arise (evolutionary mismatch between environmental cues and habitat quality), and how might they contribute to population decline in rapidly changing environments?

Answer (Q24, Synthesis). An ecological trap arises from an evolutionary mismatch: animals evolved to use environmental cues (light, vegetation structure, openness) that reliably predicted habitat quality, but human-altered environments decouple the cue from actual fitness, so organisms preferentially settle in low-fitness habitat. Sea turtle hatchlings orient to the brightest horizon (historically the sea, now coastal lighting); birds select tall grass that is now mown mid-nesting. Traps depress population growth more than simple habitat loss because they actively draw individuals away from good habitat, and they worsen as the rate of environmental change outpaces the evolution of new cue responses. See section 36. 25. The maximum sustainable yield (MSY) of a fishery occurs at $N = K/2$ in the logistic model. Evaluate: (a) why harvesting at MSY maximizes catch; (b) why MSY is inherently unstable (small perturbations can push the population toward collapse); (c) why modern fisheries management uses precautionary approaches (reference points below MSY, no-take zones) rather than attempting to maintain stocks at MSY.

Answer (Q25, Synthesis). (a) From the logistic, dN/dt is maximized at $N = K/2$ (yield = $rK/4$), so harvesting that holds the stock at $K/2$ extracts the largest sustainable surplus production. (b) MSY is unstable because at $K/2$ the population has no buffer: any overestimate of K or r , environmental downturn, or slight over-harvest pushes N below $K/2$ where surplus production falls, so a fixed quota then accelerates decline toward collapse. (c) Modern management is therefore precautionary — target biomass above $K/2$, set harvest control rules and limit reference points below MSY, and use no-take reserves — to keep a margin against estimation error and stochasticity (cf. North Atlantic cod, 1992). See section 36. 26. Evaluate the role of demographic stochasticity vs environmental stochasticity in small population extinction risk. Using Monte Carlo simulations: (a) at what population size does demographic stochasticity dominate ($N < 50$); (b) how does environmental stochasticity affect populations of any size (droughts, disease outbreaks); (c) what does the combination of both stochastic forces imply for the “50/500 rule” in conservation genetics ($N_e > 50$ to avoid inbreeding, > 500 to maintain evolutionary potential)?

Answer (Q26, Synthesis). (a) Demographic stochasticity (chance variation in individual births/deaths and sex ratio) dominates extinction risk only in small populations, roughly $N < 50$, because random fluctuations scale relative to mean and can erase a small population by bad luck. (b) Environmental stochasticity (droughts, disease, severe weather) affects vital rates of populations of any size simultaneously and so threatens even large populations. (c) Together they justify the 50/500 rule: an effective size $N_e > 50$ buffers short-term inbreeding and demographic accidents, while $N_e > 500$ retains the additive genetic variance needed for long-term adaptive (evolutionary) response to environmental change. See section 36. 27. Human population grew exponentially from about 1 billion (1800) to about 8 billion (2024). Evaluate: (a) which technological advances removed carrying capacity limits (agriculture, medicine, energy); (b) the demographic transition model (stages I–IV) and where different countries are; (c)

whether global population will stabilize (UN WPP 2024 median projection: peak near 10.3 billion in the mid-2080s, then about 10.2 billion by 2100) or decline, and the assumptions underlying different projections.

Answer (Q27, Synthesis). (a) The Agricultural (Haber–Bosch nitrogen, mechanization, Green Revolution), medical/sanitation (vaccines, antibiotics, clean water cutting mortality), and energy (fossil fuels for food, transport, fertilizer) revolutions repeatedly raised the effective human K . (b) The demographic transition moves societies from Stage I (high birth/death), through Stage II (death falls, rapid growth), Stage III (birth falls), to Stage IV (low birth/death, near-stable) — most high-income countries are at IV/V, many low-income countries still in II/III. (c) UN WPP 2024 projects a median peak near 10.3 billion in the mid-2080s and a slight decline toward about 10.2 billion by 2100; outcomes hinge on fertility-decline assumptions — faster decline yields earlier stabilization or decline, slower decline yields continued growth. See section 36. 28. Evaluate the “landscape of fear” concept: predator presence alters prey behavior (reduced foraging time, habitat avoidance), which reduces prey population growth rate even without direct predation. Using the wolf-elk-aspen trophic cascade in Yellowstone as a case study, evaluate the evidence that wolf reintroduction changed elk behavior enough to allow aspen regeneration, and whether this qualifies as a “landscape of fear” effect or simply reduced elk density.

Answer (Q28, Synthesis). The Yellowstone wolf–elk–aspen case shows aspen recruitment improving after the 1995 wolf reintroduction. The genuine landscape of fear claim is that predation *risk* (not just predation mortality) alters elk behavior — less browsing in risky riparian zones — releasing aspen. The empirical difficulty is separating this trait-mediated (behavioral) effect from the simple density-mediated effect of fewer elk (also driven by hunting, drought, and bears). Evidence that would settle it: aspen release localized to high-risk microhabitats while elk density is statistically controlled. Current data support a contribution from fear but cannot fully isolate it from density reduction. See section 36. 29. Evaluate the mathematical basis for chaos in ecological populations: discrete-time logistic models ($N_{t+1} = rN_t(1 - N_t/K)$) with high r ($r > 2.57$) produce chaotic dynamics where population size is deterministic but unpredictable. What does chaos imply for long-term population prediction, and how can evidence of chaos be detected in real population time series (e.g., flour beetles, *Tribolium*)?

Answer (Q29, Synthesis). In the discrete logistic map $N_{t+1} = rN_t(1 - N_t/K)$, raising the growth parameter takes the dynamics through a period-doubling cascade (stable point \rightarrow 2-cycle \rightarrow 4-cycle \rightarrow ... \rightarrow chaos beyond $r \approx 3.57$ in the standard map form). Chaos means trajectories are deterministic but exhibit sensitive dependence on initial conditions, so long-term point prediction is impossible even with a perfect model. Detecting it in real series (e.g., *Tribolium* flour beetles, where it was experimentally demonstrated) requires estimating a positive Lyapunov exponent, reconstructing the attractor, and ruling out mere stochastic noise via nonlinear time-series methods. See section 36. 30. Critically evaluate the concept of “planetary boundaries” (Stockholm Resilience Center, 2009) in relation to human population ecology. Of the nine identified boundaries (climate change, biodiversity loss, nitrogen cycling, etc.), which have been transgressed, and how do population density, consumption patterns, and technology interact to determine whether human civilisation is operating within sustainable limits?

Answer (Q30, Synthesis). Planetary boundaries define a ‘safe operating space’ across nine Earth-system processes; transgression risks abrupt, large-scale change. Boundaries assessed as crossed include climate change, biosphere integrity (biodiversity/genetic loss), biogeochemical flows (nitrogen and phosphorus), land-system change, freshwater change, and novel entities. Human impact is the product of population \times per-capita consumption \times technology (the IPAT relation): affluent low-population societies can transgress boundaries through consumption, while technology can raise or lower intensity. Population ecology reframes humanity as a population whose realized impact, not headcount alone, determines whether it operates within environmental limits. See section 36.

Questions — Community Interactions and Succession

Instructor Use and Coverage Notes

- Coverage target: Predict how changing one species or resource alters community structure.
- Model/data emphasis: Lotka-Volterra-style interaction reasoning.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: A species interaction is not permanently good or bad; the sign can change with context.
- Transfer product: Transfer interaction reasoning to restoration, agriculture, and invasion biology.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 37 of the textbook — review that chapter before attempting the exercises below.

1. Define a biological community. How does it differ from a population?

Answer (Q1, Recall). A biological community is all the populations of different species that live together and interact in a defined area at a given time. A population is a single species; a community is the assemblage of many interacting species (its species composition and relative abundances). The community level adds biotic interactions — competition, predation, mutualism — that do not exist within a single population. See section 37.

2. Name five types of species interactions. Give one example of each.

Answer (Q2, Recall). (1) Competition (−/−): two barnacle species for rock space. (2) Predation (+/−): lynx eating hares. (3) Herbivory (+/−): deer browsing on shrubs. (4) Mutualism (+/+): bees pollinating flowers. (5) Parasitism (+/−): tapeworm in a host gut. (Commensalism, +/0, e.g., barnacles on a whale, is a sixth.) Signs denote the per-capita fitness effect on each partner. See section 37.

3. What is interspecific competition? State the competitive exclusion principle (Gause’s law).

Answer (Q3, Recall). Interspecific competition occurs when individuals of different species use the same limiting resource, reducing each other’s growth or survival. The competitive exclusion principle (Gause’s law) states that two species competing for the *same* limiting resource cannot coexist indefinitely at constant values; the more efficient competitor drives the other to local extinction unless they partition the niche. See section 37.

4. What is a niche? Distinguish fundamental niche from realized niche.

Answer (Q4, Recall). A niche is the multidimensional set of environmental conditions and resources a species uses and the role it plays (Hutchinson’s *n*-dimensional hypervolume). The fundamental niche is the full range of conditions where a species *could* persist ($r \geq 0$) in the absence of competitors. The realized niche is the usually smaller portion it actually occupies after biotic interactions (competition, predation) restrict it. See section 37.

5. What is predation? Name two anti-predator adaptations.

Answer (Q5, Recall). Predation is an interaction in which one organism (the predator) kills and consumes another (the prey), benefiting the predator (+) and harming the prey (−). Two anti-predator adaptations: cryptic coloration / camouflage (e.g., stick insects) and chemical defense with aposematic warning coloration (e.g., poison dart frogs); others include Batesian/Müllerian mimicry, mechanical defenses, and behavioral predator avoidance. See section 37.

6. Define mutualism. Give one obligate and one facultative example.

Answer (Q6, Recall). Mutualism is a +/+ interaction in which both species gain a net fitness benefit. Obligate mutualism: neither partner can survive without the other — e.g., a lichen (fungus + alga/cyanobacterium), or the fig-fig-wasp pollination system. Facultative mutualism: beneficial but not essential — e.g., many flowering plants and generalist bee pollinators, where each can persist using alternative partners. See section 37.

7. What is a food web? How does it differ from a food chain?

Answer (Q7, Recall). A food chain is a single linear sequence of who-eats-whom (producer → primary consumer → secondary consumer → ...). A food web is the interconnected network of many overlapping food chains in a community, showing that most consumers have multiple prey and most prey have multiple predators. The web representation captures omnivory, alternative pathways, and the redundancy that buffers communities against single-link loss. See section 37.

8. What is a keystone species? Give one classic example.

Answer (Q8, Recall). A keystone species has an effect on community structure that is disproportionately large relative to its abundance or biomass; removing it causes major changes in species composition. Classic example: Paine’s (1966) sea star *Pisaster ochraceus* — removing this predator let the mussel *Mytilus californianus* monopolize the rock, collapsing intertidal diversity from about 15 species to about 8. See section 37.

9. Define ecological succession. Distinguish primary from secondary succession.

Answer (Q9, Recall). Ecological succession is the directional change in species composition of a community over time following a disturbance or on new substrate. Primary succession begins on lifeless substrate with no soil (lava flows, glacial till, new volcanic island); pioneers like lichens and mosses must first build soil, so it takes centuries. Secondary succession follows a disturbance that leaves soil and propagules intact (after fire, abandoned farmland) and proceeds much faster, in decades. See section 37.

10. What is species richness? How does it differ from species diversity (Shannon index)?

Answer (Q10, Recall). Species richness is simply the *number* of species present (S). Species diversity combines richness *and* evenness (how equally individuals are distributed among species). The Shannon index $H' = -\sum p_i \ln p_i$ rises with both more species and more even abundances; two communities with the same richness differ in H' if one is dominated by a single species while the other is even. See section 37.

Questions 11–20: Application and Analysis

11. The Lotka-Volterra competition model uses two equations: $dN_1/dt = r_1N_1(K_1 - N_1 - \alpha_{12}N_2)/K_1$ and $dN_2/dt = r_2N_2(K_2 - N_2 - \alpha_{21}N_1)/K_2$. If $K_1 = 1,000$, $K_2 = 800$, $\alpha_{12} = 0.5$, $\alpha_{21} = 1.2$, predict the outcome of competition. Under what conditions do two species coexist ($K_1/\alpha_{12} > K_2$ AND $K_2/\alpha_{21} > K_1$)?

Answer (Q11, Application). Compare each species’ carrying capacity to the other’s competitive ceiling. Species 1: persists alone at $K_1 = 1000$; species 2 invades if $K_2 > K_1/\alpha_{21} = 1000/1.2 \approx 833$ — since $K_2 = 800 < 833$, species 2 cannot invade an established species 1. Species 2: species 1 invades if $K_1 > K_2/\alpha_{12} = 800/0.5 = 1600$ — since $K_1 = 1000 < 1600$, species 1 also cannot invade an established species 2. This is the founder-controlled / unstable-equilibrium case: the outcome depends on initial densities and one species excludes the other. Stable coexistence requires $K_1 < K_2/\alpha_{12}$ and $K_2 < K_1/\alpha_{21}$ (interspecific competition weaker than intraspecific for both), which fails here. See section 37.

12. Paine’s classic experiment (1966) removed the sea star *Pisaster ochraceus* from intertidal rocks. The result was dominance by the mussel *Mytilus californianus*, which outcompeted most other sessile species. Explain: (a) why *Pisaster* is a keystone predator; (b) how its removal reduced species diversity; (c) the concept of “keystone species” and why biomass alone does not predict ecological importance.

Answer (Q12, Application). (a) *Pisaster* preferentially eats the competitively dominant mussel, preventing it from monopolizing space, so the predator controls the outcome of competition among its prey. (b) Removing *Pisaster* released *Mytilus*, which outcompeted barnacles, algae, and other sessile species for primary space; richness fell from about 15 to about 8 species. (c) A keystone species exerts community-wide control out of proportion to its biomass; abundance/biomass alone is a poor predictor of importance because a low-biomass predator can govern diversity while a high-biomass dominant may simply occupy space — the test is the magnitude of change after removal per unit biomass. See section 37.

13. Character displacement: Darwin’s finches on islands where two species coexist show greater beak size divergence than on islands where they occur alone. Explain: (a) the mechanism (sympatric competition selects for niche divergence); (b) the evidence from *Geospiza fortis* and *G. fuliginosa* beak depth distributions; (c) how this relates to niche partitioning.

Answer (Q13, Application). (a) Where two competitors are sympatric, individuals with extreme (divergent) trait values suffer less competition for shared resources, so selection drives the species’ niches — and the morphological traits that set them — apart (character displacement). (b) On islands with both *G. fortis* and *G. fuliginosa*, beak-depth distributions are shifted apart and barely overlap, whereas on single-species islands each shows an intermediate beak matching the full seed spectrum. (c) This is the evolutionary route to niche (resource) partitioning: divergent beaks let the species specialize on different seed sizes, reducing competitive overlap and permitting stable coexistence. See section 37.

14. Trophic cascades: when wolves were reintroduced to Yellowstone, elk herbivory decreased, allowing aspen and willow regeneration, which stabilized stream banks and increased beaver populations. Trace this top-down trophic cascade: wolves → elk behavior change → vegetation recovery → stream geomorphology change → beaver habitat expansion. Is this primarily a density-mediated or trait-mediated cascade?

Answer (Q14, Application). Causal chain: wolves reduce elk numbers and keep elk from lingering in risky riparian zones → less browsing on aspen, willow, cottonwood → woody vegetation recovers along streams → root systems and shade stabilize banks and lower water temperature → beaver gain food and dam-building material → beaver ponds further reshape stream geomorphology and create wetland habitat. It is a mixed cascade: a strong trait-mediated component (elk change *where and how* they forage out of fear) operating alongside a density-mediated component (fewer elk overall). See section 37.

15. Mycorrhizal networks (“wood-wide web”) connect trees underground, potentially allowing nutrient and carbon transfer between individuals. Evaluate the evidence: (a) $^{13}\text{C}/^{15}\text{N}$ labeling experiments showing carbon transfer between Douglas fir and paper birch; (b) whether transfer is mutualistic (mother trees

provisioning seedlings) or incidental (fungal self-interest); (c) the evidence from Simard’s studies and the controversy around the “mother tree” narrative.

Answer (Q15, Application). (a) Dual-isotope ($^{13}\text{C}/^{15}\text{N}$) pulse-labeling shows net carbon moving between Douglas fir and paper birch through shared ectomycorrhizal networks, with direction depending on shading and source–sink gradients. (b) The contested question is *function*: transfer may reflect adaptive ‘mother-tree’ provisioning of kin seedlings, or it may be incidental flux serving the fungus’s own carbon economy with trees as competing sinks. (c) Simard’s labeling and kin-recognition studies support directed transfer, but critics (e.g., Karst et al.) argue field evidence for fitness-relevant, adaptive provisioning is weak and the ‘mother tree’ narrative outruns the data — passive diffusion within a fungal network remains a sufficient explanation for much of the signal. See section 37.

16. Evaluate the intermediate disturbance hypothesis (IDH, Connell 1978): species diversity is maximized at intermediate disturbance frequency/intensity. Evaluate: (a) the mechanism (low disturbance → competitive exclusion; high disturbance → primarily ruderals survive); (b) empirical support from coral reef and tropical forest studies; (c) criticisms (meta-analyses showing weak or inconsistent support for IDH).

Answer (Q16, Application). (a) Mechanism: at low disturbance, superior competitors monopolize resources and exclude others; at high disturbance, only fast-colonizing ruderals tolerant of frequent destruction survive; at intermediate disturbance both competitors and colonizers coexist, peaking diversity. (b) Support: Connell’s coral-reef and tropical-forest work and many stream-invertebrate studies show humped diversity–disturbance curves. (c) Criticism: large meta-analyses (e.g., Mackey & Currie; Fox 2013) find the humped pattern is the minority outcome and IDH conflates several mechanisms; the conclusion would change if diversity responded monotonically once productivity and spatial scale are controlled. IDH is best treated as one possible pattern, not a general law. See section 37.

17. Design an experiment to test whether a suspected keystone species is truly a keystone (disproportionate effect on community structure relative to its biomass). Describe: (a) the removal experiment design; (b) what community metrics (species richness, evenness, biomass distribution) you would measure before and after removal; (c) how you would distinguish keystone effects from dominant species effects.

Answer (Q17, Application). Hypothesis: the focal species exerts community control disproportionate to its biomass. Design: replicated, randomized removal (exclusion) plots versus untouched control plots of the same habitat, with the focal species the only manipulated factor; include ‘biomass control’ plots removing an equal biomass of a non-suspect dominant. Metrics before and after: species richness, evenness/Shannon H' , relative abundance (biomass) distribution, and identity of competitive dominants, tracked over enough time for the community to respond. Decision rule: a keystone causes large structural change *per unit biomass removed*; a dominant causes change roughly proportional to its large biomass. Replication and a falsifying outcome (no divergence from controls) are required. See section 37.

18. Evaluate the “biodiversity-ecosystem function” (BEF) debate: does higher species diversity lead to greater ecosystem productivity? Cite: (a) the Cedar Creek grassland experiments (Tilman); (b) the “sampling effect” (more species → more likely to include a highly productive species) vs “complementarity effect” (niche partitioning → more complete resource use); (c) implications for conservation (“every species matters” vs “some species are redundant”).

Answer (Q18, Application). (a) Tilman’s long-term Cedar Creek grassland plots show higher plant diversity yields greater and more stable productivity and nutrient retention. (b) The sampling (selection) effect attributes this to diverse plots being more likely to *contain* a single highly productive species; the complementarity effect attributes it to niche partitioning and facilitation so resources are used more completely — long-term data and additive-partitioning analyses indicate complementarity strengthens over time. (c) Implication: redundancy provides insurance under variable conditions, so ‘some species are redundant’ holds only in a constant environment; across environments and time most species contribute, supporting broad conservation. The conclusion would change if productivity tracked only the single best species regardless of richness. See section 37.

19. Evaluate the role of facilitation (positive interactions) vs competition in structuring communities under environmental stress. The stress gradient hypothesis (SGH) predicts facilitation dominates in harsh environments and competition in benign ones. Evaluate the evidence from: (a) alpine cushion plants facilitating other species; (b) coral reef structure facilitating fish diversity; (c) exceptions where competition dominates even under stress.

Answer (Q19, Application). The stress-gradient hypothesis predicts net positive interactions (facilitation) dominate under harsh conditions and competition dominates in benign ones. (a) Alpine cushion plants ameliorate temperature, wind, and moisture, raising the richness of species sheltered beneath them — facilitation increases with elevation/stress. (b) Reef-building corals create physical structure that facilitates high fish and invertebrate diversity. (c) Exceptions: under extreme resource stress (severe drought) facilitation can collapse back to competition for the scarce resource, and strong consumer pressure can override it — so the SGH is a useful generalization whose sign depends on whether stress is resource-based or non-resource and on the trophic context. See section 37.

20. Biological invasions: invasive species can restructure entire communities. Evaluate three hypotheses for why invasive species succeed: (a) enemy release hypothesis (no predators/parasites in new range); (b) novel weapons hypothesis (allelochemicals that native species cannot tolerate); (c) empty niche hypothesis (exploiting unused resources). For each, cite one case study.

Answer (Q20, Application). (a) Enemy release: introduced species escape their coevolved predators/parasites and reallocate resources to growth/reproduction — e.g., invasive *Spartina* or purple loosestrife thriving without specialist herbivores. (b) Novel weapons: an invader deploys allelochemicals against which naive natives have no tolerance — e.g., spotted knapweed (*Centaurea*) (–)-catechin root exudates suppressing native plants. (c) Empty niche: the invader exploits resources unused by the resident community — e.g., zebra mussels filter-feeding suspended particles in the Great Lakes, a previously underused resource. Each hypothesis predicts different evidence (release from enemies, allelopathic suppression, or resource opportunity), and they can act jointly. See section 37.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the concept of “ecological networks” beyond food webs: mutualistic networks (plant-pollinator, plant-seed disperser) show a nested structure where specialist species interact with a subset of the partners of generalist species. What does nestedness imply for: (a) network stability (resilience to species loss); (b) the order of species extinction under habitat loss; (c) the importance of highly connected “hub” species for network integrity?

Answer (Q21, Synthesis). Mutualistic networks are typically nested: specialists interact with subsets of the partners that generalists use, and generalists interact mostly with each other. (a) Nestedness buffers stability/robustness because specialists are ‘cushioned’ by redundant generalist partners, so random species loss is well tolerated. (b) Under habitat loss, specialists with few partners go extinct first, while generalists persist longest. (c) Highly connected hub species are critical: targeted loss of generalist hubs triggers rapid co-extinction cascades, so network robustness depends disproportionately on protecting a small set of well-connected species. See section 37.

22. Evaluate Hubbell’s Neutral Theory of Biodiversity (2001): species are ecologically equivalent, and community composition is determined by stochastic birth, death, and migration rather than niche differences. Compare neutral theory predictions with niche-based models: (a) what patterns can neutral theory explain (species-abundance distributions, species-area relationships); (b) what it cannot (functional trait differences, competitive exclusion); (c) is neutral theory “wrong but useful”?

Answer (Q22, Synthesis). (a) Hubbell’s neutral theory assumes per-capita ecological equivalence and explains community patterns from stochastic birth, death, dispersal, and speciation; it reproduces realistic species-abundance distributions and species-area relationships remarkably well. (b) It cannot account for functional-trait differences, deterministic competitive exclusion, niche partitioning, or many dynamic predictions (e.g., realistic extinction times often fail). (c) It is best regarded as ‘wrong but useful’: a powerful null model whose successful static predictions show that pattern alone cannot prove niche processes, even though species are demonstrably not equivalent. The conclusion would change if measured demographic rates showed no systematic interspecific differences. See section 37.

23. Climate change is causing phenological mismatches between interacting species (e.g., caterpillar peak occurring before oak leaf-out, but after great tit breeding initiation). Evaluate: (a) the evidence from long-term phenological datasets; (b) whether species can adapt quickly enough (evolutionary rescue vs extinction); (c) what community-level consequences emerge from cascading mismatches across multiple trophic levels.

Answer (Q23, Synthesis). (a) Long-term datasets (e.g., Wytham Wood great tits, oak–winter-moth) show interacting species advancing their phenology at different rates, opening timing gaps between consumer demand and resource peaks. (b) Whether species track the shift depends on the speed and heritability of the response: evolutionary rescue or phenotypic plasticity can realign timing for short-generation species, but slow-life-history species risk decline or local extinction. (c) Because mismatches propagate across trophic levels (plant → herbivore → predator), effects cascade: consumer recruitment falls, predator populations decline, and community-level synchrony erodes, potentially restructuring food webs even when no species is directly killed by temperature. See section 37.

24. Evaluate the concept of “alternative stable states” in ecological communities: an ecosystem can exist in multiple stable configurations (e.g., clear-water lake vs turbid-water lake), and transitions between states (regime shifts) are driven by perturbations that push the system past a tipping point. Using the shallow lake eutrophication example: (a) what drives the regime shift; (b) why is the shift often irreversible (hysteresis); (c) what early warning signals predict an approaching tipping point?

Answer (Q24, Synthesis). (a) In shallow lakes, gradual nutrient (P) loading erodes the clear, macrophyte-dominated state; a perturbation (storm, fish change) past a tipping point flips the lake to a turbid, phytoplankton-dominated state stabilized by feedbacks (turbidity shades out plants, sediment resuspension, loss of zooplankton refugia). (b) The shift shows hysteresis: because the alternative state is self-reinforcing, simply lowering nutrients back to the original level does *not* restore clear water — recovery requires a much larger reduction or active intervention (biomanipulation). (c) Early-warning signals of an approaching tipping point include critical slowing down — rising temporal autocorrelation and variance, and slower recovery from small perturbations (flickering). See section 37.

25. Critically evaluate the use of ecological network analysis for predicting the cascading effects of species extinction. Using simulated extinction sequences (removing species from most to least connected): (a) how do co-extinction cascades propagate through food webs; (b) why do mutualistic networks (plant-pollinator) collapse more rapidly than antagonistic networks (predator-prey) under targeted extinction; (c) what does this imply for setting conservation

priorities in species-rich ecosystems?

Answer (Q25, Synthesis). (a) Removing species and tracking secondary (co-)extinctions shows cascades propagate fastest when highly connected species are lost, because many partners depend on them; loss of basal/hub species triggers the largest collapses. (b) Mutualistic networks collapse faster under targeted removal than antagonistic ones because mutualism lacks the compensatory dynamics of predator–prey systems (no prey release; partners cannot substitute a lost obligate mutualist), so dependent specialists are lost rapidly. (c) Implication: in species-rich systems, conservation should prioritize topologically central / highly connected species and the interactions themselves, not just rare or charismatic species — but model assumptions (static topology, fixed dependencies) limit precision and would change predictions if rewiring is possible. See section 37.

26. Island biogeography theory (MacArthur and Wilson, 1967): species richness on an island results from a balance between immigration (decreasing with distance from mainland) and extinction (increasing with island size decrease). Apply this to habitat islands: predict species richness on forest fragments of 1 ha, 10 ha, and 1,000 ha that are 5 km from a large continuous forest. What does the “species-area relationship” ($S = cA^z$) predict?

Answer (Q26, Synthesis). Island/MacArthur–Wilson theory: richness equilibrates where the immigration rate (falls with isolation) equals the extinction rate (rises as area shrinks); the species–area relationship $S = cA^z$ summarizes the area effect, with $z \approx 0.25$ for habitat islands. Holding c and z constant, going from 1 ha to 10 ha multiplies S by $10^{0.25} \approx 1.78$, and $1 \rightarrow 1000$ ha by $1000^{0.25} \approx 5.6$. So a 1000 ha fragment supports roughly 5–6× the species of a 1 ha fragment; the 5 km isolation lowers all values equally by depressing immigration. The practical lesson: a few large fragments retain far more species than many tiny ones of equal total area. See section 37.

27. Herbivore-plant coevolution has produced elaborate chemical defense systems. The milkweed (*Asclepias*) – monarch butterfly (*Danaus plexippus*) system illustrates escalation: (a) milkweed produces cardenolides (toxic Na^+/K^+ -ATPase inhibitors); (b) monarch larvae sequester cardenolides for their own defense; (c) monarch Na^+/K^+ -ATPase has evolved resistance mutations. Trace this coevolutionary arms race.

Answer (Q27, Synthesis). Coevolutionary arms race (reciprocal selection): (1) milkweed evolves cardenolides, cardiac glycosides that block the Na^+/K^+ -ATPase of herbivores; (2) this selects monarch larvae that tolerate and sequester the toxins, gaining their own chemical defense against birds (aposematism); (3) sequestration is enabled by target-site insensitivity — amino-acid substitutions in the monarch’s Na^+/K^+ -ATPase that confer resistance; (4) milkweeds with higher or novel cardenolide profiles are then favored, escalating the cycle. The result is reciprocal adaptation and a diffuse coevolutionary escalation between defense and counter-defense. See section 37.

28. Primary succession on volcanic islands (e.g., Surtsey, Iceland, formed 1963): pioneer species (lichens, mosses) → grasses → shrubs → woodland. Explain the facilitation model: how do early colonisers modify the environment (soil formation, nitrogen fixation) to enable later successional stages?

Answer (Q28, Synthesis). In the facilitation model, early colonizers make conditions less extreme and enable later species. On bare volcanic rock, lichens and mosses weather the substrate and trap organic matter, building the first soil; nitrogen-fixing pioneers (e.g., legumes, *Frankia*- or cyanobacteria-associated plants) add fixed nitrogen to the otherwise N-poor surface; accumulating soil, moisture retention, and nutrients then allow grasses, then shrubs, then trees to establish. Each stage modifies the environment in ways that favor the next — and often makes conditions worse for the pioneers themselves. See section 37.

29. Calculate the Shannon diversity index ($H' = -\sum p_i \ln p_i$) for a community with 4 species at proportions: 0.50, 0.25, 0.15, 0.10. Then calculate for a community with 4 species at equal proportions (0.25 each). Which community is more diverse? What does evenness contribute to diversity?

Answer (Q29, Synthesis). $H' = -\sum p_i \ln p_i$. Community A (0.50, 0.25, 0.15, 0.10): $-(0.50 \ln 0.50 + 0.25 \ln 0.25 + 0.15 \ln 0.15 + 0.10 \ln 0.10) = -(-0.347 - 0.347 - 0.285 - 0.230) \approx 1.21$. Community B (0.25 each): $-4(0.25 \ln 0.25) = -4(-0.347) = 1.39 (= \ln 4, \text{ the maximum for 4 species})$. Community B is more diverse even though both have richness $S = 4$, because it is perfectly even. Evenness raises diversity: for a fixed number of species, H' is maximized when all species are equally abundant and minimized when one species dominates. See section 37.

30. Parasitoids (e.g., parasitoid wasps) lay eggs inside or on host insects; the larva consumes the host from inside. Compare parasitoid-host dynamics to classical predator-prey dynamics: (a) why parasitoid search efficiency matters (Nicholson-Bailey model); (b) why parasitoid-host systems tend toward unstable oscillations in simple models; (c) what stabilizing mechanisms exist in nature (spatial refugia, host immunity).

Answer (Q30, Synthesis). (a) In the Nicholson–Bailey model, the fraction of hosts escaping parasitism depends on parasitoid search efficiency (attack rate a) and parasitoid density; each parasitized host yields the next parasitoid generation, tightly coupling the two. (b) Because reproduction is discrete and perfectly density-dependent with a built-in time lag (one host generation), the simple model is inherently unstable — it produces diverging oscillations leading to extinction of one or both. (c) Real systems persist via stabilizing mechanisms: spatial heterogeneity and host refugia (a protected fraction of hosts), aggregated parasitoid attack, host density dependence, host immune defenses, and parasitoid interference — all of which add negative feedback that damps the oscillations. See section 37.

Questions — Biodiversity and Food Webs

Instructor Use and Coverage Notes

- Coverage target: Calculate a diversity or species-area metric and interpret its ecological meaning.
- Model/data emphasis: Shannon, species-area, and network connectance reasoning.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Richness alone does not equal functional stability.
- Transfer product: Transfer biodiversity reasoning to conservation planning and habitat fragmentation.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 38 of the textbook — review that chapter before attempting the exercises below.

1. Island biogeography theory (MacArthur and Wilson, 1967): species richness on an island results from a balance between immigration (decreasing with distance from mainland) and extinction (increasing with island size decrease). Apply this to habitat islands: predict species richness on forest fragments of 1 ha, 10 ha, and 1,000 ha that are 5 km from a large continuous forest. What does the “species-area relationship” ($S = cA^z$) predict?

Answer (Q1, Recall). Island/MacArthur–Wilson theory: richness equilibrates where the immigration rate (falls with isolation) equals the extinction rate (rises as area shrinks); the species–area relationship $S = cA^z$ summarizes the area effect, with $z \approx 0.25$ for habitat islands. Holding c and z constant, going from 1 ha to 10 ha multiplies S by $10^{0.25} \approx 1.78$, and $1 \rightarrow 1000$ ha by $1000^{0.25} \approx 5.6$. So a 1000 ha fragment supports roughly 5–6× the species of a 1 ha fragment; the 5 km isolation lowers all values equally by depressing immigration. The practical lesson: a few large fragments retain far more species than many tiny ones of equal total area. See section 38.

2. Herbivore-plant coevolution has produced elaborate chemical defense systems. The milkweed (*Asclepias*) – monarch butterfly (*Danaus plexippus*) system illustrates escalation: (a) milkweed produces cardenolides (toxic Na^+/K^+ -ATPase inhibitors); (b) monarch larvae sequester cardenolides for their own defense; (c) monarch Na^+/K^+ -ATPase has evolved resistance mutations. Trace this coevolutionary arms race.

Answer (Q2, Recall). Coevolutionary arms race (reciprocal selection): (1) milkweed evolves cardenolides, cardiac glycosides that block the Na^+/K^+ -ATPase of herbivores; (2) this selects monarch larvae that tolerate and sequester the toxins, gaining their own chemical defense against birds (aposematism); (3) sequestration is enabled by target-site insensitivity — amino-acid substitutions in the monarch’s Na^+/K^+ -ATPase that confer resistance; (4) milkweeds with higher or novel cardenolide profiles are then favored, escalating the cycle. The result is reciprocal adaptation and a diffuse co-evolutionary escalation between defense and counter-defense. See section 38.

3. Primary succession on volcanic islands (e.g., Surtsey, Iceland, formed 1963): pioneer species (lichens, mosses) → grasses → shrubs → woodland. Explain the facilitation model: how do early colonisers modify the environment (soil formation, nitrogen fixation) to enable later successional stages?

Answer (Q3, Recall). In the facilitation model, early colonizers make conditions less extreme and enable later species. On bare volcanic rock, lichens and mosses weather the substrate and trap organic matter, building the first soil; nitrogen-fixing pioneers (e.g., legumes, *Frankia*- or cyanobacteria-associated plants) add fixed nitrogen to the otherwise N-poor surface; accumulating soil, moisture retention, and nutrients then allow grasses, then shrubs, then trees to establish. Each stage modifies the environment in ways that favor the next — and often makes conditions worse for the pioneers themselves. See section 38.

4. Calculate the Shannon diversity index ($H' = -\sum p_i \ln p_i$) for a community with 4 species at proportions: 0.50, 0.25, 0.15, 0.10. Then calculate for a community with 4 species at equal proportions (0.25 each). Which community is more diverse? What does evenness contribute to diversity?

Answer (Q4, Recall). $H' = -\sum p_i \ln p_i$. Community A (0.50, 0.25, 0.15, 0.10): $-(0.50 \ln 0.50 + 0.25 \ln 0.25 + 0.15 \ln 0.15 + 0.10 \ln 0.10) = -(-0.347 - 0.347 - 0.285 - 0.230) \approx 1.21$. Community B (0.25 each): $-4(0.25 \ln 0.25) = -4(-0.347) = 1.39$ ($= \ln 4$, the maximum for 4 species). Community B is more diverse even though both have richness $S = 4$, because it is perfectly even. Evenness raises diversity: for a fixed number of species, H' is maximized when all species are equally abundant and minimized when one species dominates. See section 38.

5. Parasitoids (e.g., parasitoid wasps) lay eggs inside or on host insects; the larva consumes the host from inside. Compare parasitoid-host dynamics to classical predator-prey dynamics: (a) why parasitoid search efficiency matters (Nicholson-Bailey model); (b) why parasitoid-host systems tend toward unstable oscillations in simple models; (c) what stabilizing mechanisms exist in nature (spatial refugia, host immunity).

Answer (Q5, Recall). (a) In the Nicholson–Bailey model, the fraction of hosts escaping parasitism depends on parasitoid search efficiency (attack rate a) and parasitoid density; each parasitized host yields the next parasitoid generation, tightly coupling the two. (b) Because reproduction is discrete and perfectly density-dependent with a built-in time lag (one host generation), the simple model is inherently unstable — it produces

diverging oscillations leading to extinction of one or both. (c) Real systems persist via stabilizing mechanisms: spatial heterogeneity and host refugia (a protected fraction of hosts), aggregated parasitoid attack, host density dependence, host immune defenses, and parasitoid interference — all of which add negative feedback that damps the oscillations. See section 38.

6. Evaluate the intermediate disturbance hypothesis (IDH, Connell 1978): species diversity is maximized at intermediate disturbance frequency/intensity. Evaluate: (a) the mechanism (low disturbance → competitive exclusion; high disturbance → primarily ruderals survive); (b) empirical support from coral reef and tropical forest studies; (c) criticisms (meta-analyses showing weak or inconsistent support for IDH).

Answer (Q6, Recall). (a) Mechanism: at low disturbance, superior competitors monopolize resources and exclude others; at high disturbance, only fast-colonizing ruderals tolerant of frequent destruction survive; at intermediate disturbance both competitors and colonizers coexist, peaking diversity. (b) Support: Connell’s coral-reef and tropical-forest work and many stream-invertebrate studies show humped diversity–disturbance curves. (c) Criticism: large meta-analyses (e.g., Mackey & Currie; Fox 2013) find the humped pattern is the minority outcome and IDH conflates several mechanisms; the conclusion would change if diversity responded monotonically once productivity and spatial scale are controlled. IDH is best treated as one possible pattern, not a general law. See section 38.

7. Design an experiment to test whether a suspected keystone species is truly a keystone (disproportionate effect on community structure relative to its biomass). Describe: (a) the removal experiment design; (b) what community metrics (species richness, evenness, biomass distribution) you would measure before and after removal; (c) how you would distinguish keystone effects from dominant species effects.

Answer (Q7, Recall). Hypothesis: the focal species exerts community control disproportionate to its biomass. Design: replicated, randomized removal (exclusion) plots versus untouched control plots of the same habitat, with the focal species the only manipulated factor; include ‘biomass control’ plots removing an equal biomass of a non-suspect dominant. Metrics before and after: species richness, evenness/Shannon H' , relative abundance (biomass) distribution, and identity of competitive dominants, tracked over enough time for the community to respond. Decision rule: a keystone causes large structural change *per unit biomass removed*; a dominant causes change roughly proportional to its large biomass. Replication and a falsifying outcome (no divergence from controls) are required. See section 38.

8. Evaluate the “biodiversity-ecosystem function” (BEF) debate: does higher species diversity lead to greater ecosystem productivity? Cite: (a) the Cedar Creek grassland experiments (Tilman); (b) the “sampling effect” (more species → more likely to include a highly productive species) vs “complementarity effect” (niche partitioning → more complete resource use); (c) implications for conservation (“every species matters” vs “some species are redundant”).

Answer (Q8, Recall). (a) Tilman’s long-term Cedar Creek grassland plots show higher plant diversity yields greater and more stable productivity and nutrient retention. (b) The sampling (selection) effect attributes this to diverse plots being more likely to *contain* a single highly productive species; the complementarity effect attributes it to niche partitioning and facilitation so resources are used more completely — long-term data and additive-partitioning analyses indicate complementarity strengthens over time. (c) Implication: redundancy provides insurance under variable conditions, so ‘some species are redundant’ holds only in a constant environment; across environments and time most species contribute, supporting broad conservation. The conclusion would change if productivity tracked only the single best species regardless of richness. See section 38.

9. Evaluate the role of facilitation (positive interactions) vs competition in structuring communities under environmental stress. The stress gradient hypothesis (SGH) predicts facilitation dominates in harsh environments and competition in benign ones. Evaluate the evidence from: (a) alpine cushion plants facilitating other species; (b) coral reef structure facilitating fish diversity; (c) exceptions where competition dominates even under stress.

Answer (Q9, Recall). The stress-gradient hypothesis predicts net positive interactions (facilitation) dominate under harsh conditions and competition dominates in benign ones. (a) Alpine cushion plants ameliorate temperature, wind, and moisture, raising the richness of species sheltered beneath them — facilitation increases with elevation/stress. (b) Reef-building corals create physical structure that facilitates high fish and invertebrate diversity. (c) Exceptions: under extreme resource stress (severe drought) facilitation can collapse back to competition for the scarce resource, and strong consumer pressure can override it — so the SGH is a useful generalization whose sign depends on whether stress is resource-based or non-resource and on the trophic context. See section 38.

10. Biological invasions: invasive species can restructure entire communities. Evaluate three hypotheses for why invasive species succeed: (a) enemy release hypothesis (no predators/parasites in new range); (b) novel weapons hypothesis (allelochemicals that native species cannot tolerate); (c) empty niche hypothesis (exploiting unused resources). For each, cite one case study.

Answer (Q10, Recall). (a) Enemy release: introduced species escape their coevolved predators/parasites and reallocate resources to growth/reproduction — e.g., invasive *Spartina* or purple loosestrife thriving without specialist herbivores. (b) Novel weapons: an invader deploys allelochemicals against which naive natives have no tolerance — e.g., spotted knapweed (*Centaurea*) (–)-catechin root exudates suppressing native plants. (c) Empty niche: the invader exploits resources unused by the resident community — e.g., zebra mussels filter-feeding suspended particles in the Great Lakes, a previously underused resource. Each hypothesis predicts different evidence (release from enemies, allelopathic suppression,

or resource opportunity), and they can act jointly. See section 38.

Questions 11–20: Application and Analysis

11. Evaluate the concept of “ecological networks” beyond food webs: mutualistic networks (plant-pollinator, plant-seed disperser) show a nested structure where specialist species interact with a subset of the partners of generalist species. What does nestedness imply for: (a) network stability (resilience to species loss); (b) the order of species extinction under habitat loss; (c) the importance of highly connected “hub” species for network integrity?

Answer (Q11, Application). Mutualistic networks are typically nested: specialists interact with subsets of the partners that generalists use, and generalists interact mostly with each other. (a) Nestedness buffers stability/robustness because specialists are ‘cushioned’ by redundant generalist partners, so random species loss is well tolerated. (b) Under habitat loss, specialists with few partners go extinct first, while generalists persist longest. (c) Highly connected hub species are critical: targeted loss of generalist hubs triggers rapid co-extinction cascades, so network robustness depends disproportionately on protecting a small set of well-connected species. See section 38.

12. Evaluate Hubbell’s Neutral Theory of Biodiversity (2001): species are ecologically equivalent, and community composition is determined by stochastic birth, death, and migration rather than niche differences. Compare neutral theory predictions with niche-based models: (a) what patterns can neutral theory explain (species-abundance distributions, species-area relationships); (b) what it cannot (functional trait differences, competitive exclusion); (c) is neutral theory “wrong but useful”?

Answer (Q12, Application). (a) Hubbell’s neutral theory assumes per-capita ecological equivalence and explains community patterns from stochastic birth, death, dispersal, and speciation; it reproduces realistic species-abundance distributions and species-area relationships remarkably well. (b) It cannot account for functional-trait differences, deterministic competitive exclusion, niche partitioning, or many dynamic predictions (e.g., realistic extinction times often fail). (c) It is best regarded as ‘wrong but useful’: a powerful null model whose successful static predictions show that pattern alone cannot prove niche processes, even though species are demonstrably not equivalent. The conclusion would change if measured demographic rates showed no systematic interspecific differences. See section 38.

13. Climate change is causing phenological mismatches between interacting species (e.g., caterpillar peak occurring before oak leaf-out, but after great tit breeding initiation). Evaluate: (a) the evidence from long-term phenological datasets; (b) whether species can adapt quickly enough (evolutionary rescue vs extinction); (c) what community-level consequences emerge from cascading mismatches across multiple trophic levels.

Answer (Q13, Application). (a) Long-term datasets (e.g., Wytham Wood great tits, oak–winter-moth) show interacting species advancing their phenology at different rates, opening timing gaps between consumer demand and resource peaks. (b) Whether species track the shift depends on the speed and heritability of the response: evolutionary rescue or phenotypic plasticity can realign timing for short-generation species, but slow-life-history species risk decline or local extinction. (c) Because mismatches propagate across trophic levels (plant → herbivore → predator), effects cascade: consumer recruitment falls, predator populations decline, and community-level synchrony erodes, potentially restructuring food webs even when no species is directly killed by temperature. See section 38.

14. Evaluate the concept of “alternative stable states” in ecological communities: an ecosystem can exist in multiple stable configurations (e.g., clear-water lake vs turbid-water lake), and transitions between states (regime shifts) are driven by perturbations that push the system past a tipping point. Using the shallow lake eutrophication example: (a) what drives the regime shift; (b) why is the shift often irreversible (hysteresis); (c) what early warning signals predict an approaching tipping point?

Answer (Q14, Application). (a) In shallow lakes, gradual nutrient (P) loading erodes the clear, macrophyte-dominated state; a perturbation (storm, fish change) past a tipping point flips the lake to a turbid, phytoplankton-dominated state stabilized by feedbacks (turbidity shades out plants, sediment resuspension, loss of zooplankton refugia). (b) The shift shows hysteresis: because the alternative state is self-reinforcing, simply lowering nutrients back to the original level does *not* restore clear water — recovery requires a much larger reduction or active intervention (biomanipulation). (c) Early-warning signals of an approaching tipping point include critical slowing down — rising temporal autocorrelation and variance, and slower recovery from small perturbations (flickering). See section 38.

15. Critically evaluate the use of ecological network analysis for predicting the cascading effects of species extinction. Using simulated extinction sequences (removing species from most to least connected): (a) how do co-extinction cascades propagate through food webs; (b) why do mutualistic networks (plant-pollinator) collapse more rapidly than antagonistic networks (predator-prey) under targeted extinction; (c) what does this imply for setting conservation priorities in species-rich ecosystems?

Answer (Q15, Application). (a) Removing species and tracking secondary (co-)extinctions shows cascades propagate fastest when highly connected species are lost, because many partners depend on them; loss of basal/hub species triggers the largest collapses. (b) Mutualistic networks collapse faster under targeted removal than antagonistic ones because mutualism lacks the compensatory dynamics of predator–prey systems (no prey release; partners cannot substitute a lost obligate mutualist), so dependent specialists are lost rapidly. (c) Implication: in species-rich systems,

conservation should prioritize topologically central / highly connected species and the interactions themselves, not just rare or charismatic species — but model assumptions (static topology, fixed dependencies) limit precision and would change predictions if rewiring is possible. See section 38.

16. Define a biological community. How does it differ from a population?

Answer (Q16, Application). A biological community is all the populations of different species that live together and interact in a defined area at a given time. A population is a single species; a community is the assemblage of many interacting species (its species composition and relative abundances). The community level adds biotic interactions — competition, predation, mutualism — that do not exist within a single population. See section 38.

17. Name five types of species interactions. Give one example of each.

Answer (Q17, Application). (1) Competition (−/−): two barnacle species for rock space. (2) Predation (+/−): lynx eating hares. (3) Herbivory (+/−): deer browsing on shrubs. (4) Mutualism (+/+): bees pollinating flowers. (5) Parasitism (+/−): tapeworm in a host gut. (Commensalism, +/0, e.g., barnacles on a whale, is a sixth.) Signs denote the per-capita fitness effect on each partner. See section 38.

18. What is interspecific competition? State the competitive exclusion principle (Gause’s law).

Answer (Q18, Application). Interspecific competition occurs when individuals of different species use the same limiting resource, reducing each other’s growth or survival. The competitive exclusion principle (Gause’s law) states that two species competing for the *same* limiting resource cannot coexist indefinitely at constant values; the more efficient competitor drives the other to local extinction unless they partition the niche. See section 38.

19. What is a niche? Distinguish fundamental niche from realized niche.

Answer (Q19, Application). A niche is the multidimensional set of environmental conditions and resources a species uses and the role it plays (Hutchinson’s *n*-dimensional hypervolume). The fundamental niche is the full range of conditions where a species *could* persist ($r \geq 0$) in the absence of competitors. The realized niche is the usually smaller portion it actually occupies after biotic interactions (competition, predation) restrict it. See section 38.

20. What is predation? Name two anti-predator adaptations.

Answer (Q20, Application). Predation is an interaction in which one organism (the predator) kills and consumes another (the prey), benefiting the predator (+) and harming the prey (−). Two anti-predator adaptations: cryptic coloration / camouflage (e.g., stick insects) and chemical defense with aposematic warning coloration (e.g., poison dart frogs); others include Batesian/Müllerian mimicry, mechanical defenses, and behavioral predator avoidance. See section 38.

Questions 21–30: Synthesis and Evaluation

21. Define mutualism. Give one obligate and one facultative example.

Answer (Q21, Synthesis). Mutualism is a +/+ interaction in which both species gain a net fitness benefit. Obligate mutualism: neither partner can survive without the other — e.g., a lichen (fungus + alga/cyanobacterium), or the fig–fig-wasp pollination system. Facultative mutualism: beneficial but not essential — e.g., many flowering plants and generalist bee pollinators, where each can persist using alternative partners. See section 38.

22. What is a food web? How does it differ from a food chain?

Answer (Q22, Synthesis). A food chain is a single linear sequence of who-eats-whom (producer → primary consumer → secondary consumer → ...). A food web is the interconnected network of many overlapping food chains in a community, showing that most consumers have multiple prey and most prey have multiple predators. The web representation captures omnivory, alternative pathways, and the redundancy that buffers communities against single-link loss. See section 38.

23. What is a keystone species? Give one classic example.

Answer (Q23, Synthesis). A keystone species has an effect on community structure that is disproportionately large relative to its abundance or biomass; removing it causes major changes in species composition. Classic example: Paine’s (1966) sea star *Pisaster ochraceus* — removing this predator let the mussel *Mytilus californianus* monopolize the rock, collapsing intertidal diversity from about 15 species to about 8. See section 38.

24. Define ecological succession. Distinguish primary from secondary succession.

Answer (Q24, Synthesis). Ecological succession is the directional change in species composition of a community over time following a disturbance or on new substrate. Primary succession begins on lifeless substrate with no soil (lava flows, glacial till, new volcanic island); pioneers like lichens

and mosses must first build soil, so it takes centuries. Secondary succession follows a disturbance that leaves soil and propagules intact (after fire, abandoned farmland) and proceeds much faster, in decades. See section 38.

25. What is species richness? How does it differ from species diversity (Shannon index)?

Answer (Q25, Synthesis). Species richness is simply the *number* of species present (S). Species diversity combines richness *and* evenness (how equally individuals are distributed among species). The Shannon index $H' = -\sum p_i \ln p_i$ rises with both more species and more even abundances; two communities with the same richness differ in H' if one is dominated by a single species while the other is even. See section 38.

26. The Lotka-Volterra competition model uses two equations: $dN_1/dt = r_1 N_1 (K_1 - N_1 - \alpha_{12} N_2)/K_1$ and $dN_2/dt = r_2 N_2 (K_2 - N_2 - \alpha_{21} N_1)/K_2$. If $K_1 = 1,000$, $K_2 = 800$, $\alpha_{12} = 0.5$, $\alpha_{21} = 1.2$, predict the outcome of competition. Under what conditions do two species coexist ($K_1/\alpha_{12} > K_2$ AND $K_2/\alpha_{21} > K_1$)?

Answer (Q26, Synthesis). Compare each species' carrying capacity to the other's competitive ceiling. Species 1: persists alone at $K_1 = 1000$; species 2 invades if $K_2 > K_1/\alpha_{21} = 1000/1.2 \approx 833$ — since $K_2 = 800 < 833$, species 2 cannot invade an established species 1. Species 2: species 1 invades if $K_1 > K_2/\alpha_{12} = 800/0.5 = 1600$ — since $K_1 = 1000 < 1600$, species 1 also cannot invade an established species 2. This is the founder-controlled / unstable-equilibrium case: the outcome depends on initial densities and one species excludes the other. Stable coexistence requires $K_1 < K_2/\alpha_{12}$ and $K_2 < K_1/\alpha_{21}$ (interspecific competition weaker than intraspecific for both), which fails here. See section 38.

27. Paine's classic experiment (1966) removed the sea star *Pisaster ochraceus* from intertidal rocks. The result was dominance by the mussel *Mytilus californianus*, which outcompeted most other sessile species. Explain: (a) why *Pisaster* is a keystone predator; (b) how its removal reduced species diversity; (c) the concept of "keystone species" and why biomass alone does not predict ecological importance.

Answer (Q27, Synthesis). (a) *Pisaster* preferentially eats the competitively dominant mussel, preventing it from monopolizing space, so the predator controls the outcome of competition among its prey. (b) Removing *Pisaster* released *Mytilus*, which outcompeted barnacles, algae, and other sessile species for primary space; richness fell from about 15 to about 8 species. (c) A keystone species exerts community-wide control out of proportion to its biomass; abundance/biomass alone is a poor predictor of importance because a low-biomass predator can govern diversity while a high-biomass dominant may simply occupy space — the test is the magnitude of change after removal per unit biomass. See section 38.

28. Character displacement: Darwin's finches on islands where two species coexist show greater beak size divergence than on islands where they occur alone. Explain: (a) the mechanism (sympatric competition selects for niche divergence); (b) the evidence from *Geospiza fortis* and *G. fuliginosa* beak depth distributions; (c) how this relates to niche partitioning.

Answer (Q28, Synthesis). (a) Where two competitors are sympatric, individuals with extreme (divergent) trait values suffer less competition for shared resources, so selection drives the species' niches — and the morphological traits that set them — apart (character displacement). (b) On islands with both *G. fortis* and *G. fuliginosa*, beak-depth distributions are shifted apart and barely overlap, whereas on single-species islands each shows an intermediate beak matching the full seed spectrum. (c) This is the evolutionary route to niche (resource) partitioning: divergent beaks let the species specialize on different seed sizes, reducing competitive overlap and permitting stable coexistence. See section 38.

29. Trophic cascades: when wolves were reintroduced to Yellowstone, elk herbivory decreased, allowing aspen and willow regeneration, which stabilized stream banks and increased beaver populations. Trace this top-down trophic cascade: wolves → elk behavior change → vegetation recovery → stream geomorphology change → beaver habitat expansion. Is this primarily a density-mediated or trait-mediated cascade?

Answer (Q29, Synthesis). Causal chain: wolves reduce elk numbers and keep elk from lingering in risky riparian zones → less browsing on aspen, willow, cottonwood → woody vegetation recovers along streams → root systems and shade stabilize banks and lower water temperature → beaver gain food and dam-building material → beaver ponds further reshape stream geomorphology and create wetland habitat. It is a mixed cascade: a strong trait-mediated component (elk change *where and how* they forage out of fear) operating alongside a density-mediated component (fewer elk overall). See section 38.

30. Mycorrhizal networks ("wood-wide web") connect trees underground, potentially allowing nutrient and carbon transfer between individuals. Evaluate the evidence: (a) $^{13}\text{C}/^{15}\text{N}$ labeling experiments showing carbon transfer between Douglas fir and paper birch; (b) whether transfer is mutualistic (mother trees provisioning seedlings) or incidental (fungal self-interest); (c) the evidence from Simard's studies and the controversy around the "mother tree" narrative.

Answer (Q30, Synthesis). (a) Dual-isotope ($^{13}\text{C}/^{15}\text{N}$) pulse-labeling shows net carbon moving between Douglas fir and paper birch through shared ectomycorrhizal networks, with direction depending on shading and source-sink gradients. (b) The contested question is *function*: transfer may reflect adaptive 'mother-tree' provisioning of kin seedlings, or it may be incidental flux serving the fungus's own carbon economy with trees as competing sinks. (c) Simard's labeling and kin-recognition studies support directed transfer, but critics (e.g., Karst et al.) argue field evidence for fitness-relevant, adaptive provisioning is weak and the 'mother tree' narrative outruns the data — passive diffusion within a fungal network remains a sufficient explanation for much of the signal. See section 38.

Questions — Ecosystem Ecology

Instructor Use and Coverage Notes

- Coverage target: Calculate a flux or efficiency and explain which pool or process limits the system.
- Model/data emphasis: Energy-flow, productivity, and nutrient-budget calculations.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Energy flows through ecosystems, but matter cycles; confusing the two breaks many explanations.
- Transfer product: Transfer ecosystem reasoning to eutrophication, carbon budgets, agriculture, and climate feedback.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 39 of the textbook — review that chapter before attempting the exercises below.

1. Define an ecosystem. What are its biotic and abiotic components?

Answer (Q1, Recall). An ecosystem is a community of organisms together with the physical and chemical environment they interact with, linked by energy flow and nutrient cycling. Biotic components are the living parts: producers (autotrophs), consumers (herbivores, carnivores, omnivores), and decomposers. Abiotic components are nonliving factors: sunlight, temperature, water, air (CO₂, O₂), inorganic nutrients (N, P), and soil. See section 39. 2. What is primary productivity? Distinguish GPP, NPP, and NEP.

Answer (Q2, Recall). Primary productivity is the rate at which autotrophs fix energy into organic matter. GPP (gross primary production) is total carbon fixed by photosynthesis. NPP is GPP minus autotroph respiration ($NPP = GPP - R_a$), the energy available to consumers. NEP (net ecosystem production) is NPP minus heterotroph respiration; $NEP > 0$ means the ecosystem is a net carbon sink. See section 39. 3. What is a trophic level? Name four trophic levels in a food chain.

Answer (Q3, Recall). A trophic level is a feeding position defined by the number of energy-transfer steps from the energy source. Four levels: producers (autotrophs, grass), primary consumers (herbivores, grasshopper), secondary consumers (carnivores, shrew), tertiary consumers (top carnivores, hawk). Decomposers process dead matter from every level. See section 39. 4. What is ecological efficiency? What is the typical transfer efficiency between trophic levels?

Answer (Q4, Recall). Ecological (trophic transfer) efficiency is the percentage of energy at one trophic level incorporated into biomass at the next. The typical value is about 10 percent (Lindeman’s ten-percent rule); the rest is lost to respiration, egestion, or goes unconsumed. Because efficiency compounds across levels, food chains are short and top-predator biomass is small. See section 39. 5. Define the carbon cycle. Name the major carbon reservoirs on Earth.

Answer (Q5, Recall). The carbon cycle is the global movement of carbon among reservoirs via photosynthesis, respiration, decomposition, combustion, and ocean exchange. Major reservoirs: the atmosphere (CO₂, CH₄), the oceans (largest active reservoir, dissolved inorganic carbon), terrestrial biomass and soils, and the very large slow-turnover sedimentary rocks and fossil fuels. See section 39. 6. What is the nitrogen cycle? Name the four major transformations.

Answer (Q6, Recall). The nitrogen cycle moves N among atmospheric N₂, organic N, and inorganic forms. Four major microbial transformations: nitrogen fixation (N₂ to ammonium, by Rhizobium, cyanobacteria, industrially Haber-Bosch); ammonification (organic N to ammonium by decomposers); nitrification (ammonium to nitrite to nitrate); and denitrification (nitrate to N₂ returned to the atmosphere under anoxic conditions). See section 39. 7. What is the phosphorus cycle? How does it differ from the nitrogen and carbon cycles?

Answer (Q7, Recall). The phosphorus cycle moves P from rock weathering into soil and water (as phosphate), through organisms, and back to sediments. Unlike the N and C cycles it has no significant atmospheric (gaseous) phase: it is a purely sedimentary cycle driven by slow weathering and burial, so P is often the limiting nutrient and cannot be replenished from the air. See section 39. 8. What is the water cycle (hydrological cycle)? Name the major fluxes.

Answer (Q8, Recall). The hydrological cycle is the continuous global movement of water among atmosphere, land, and oceans driven by solar energy and gravity. Major fluxes: evaporation, plant transpiration (together, evapotranspiration), condensation, precipitation, runoff to streams and oceans, and infiltration recharging groundwater. See section 39. 9. What is eutrophication? What nutrients cause it and why?

Answer (Q9, Recall). Eutrophication is nutrient over-enrichment of a water body that triggers excessive algal growth, followed by decomposition that depletes dissolved oxygen and can cause hypoxic dead zones. It is caused chiefly by phosphorus (usual limiting nutrient in freshwater) and nitrogen

(often limiting in marine systems) from fertilizer runoff, sewage, and detergents. See section 39. 10. Define decomposition. What organisms are primary decomposers, and how do termites and ants change the detrital pathway?

Answer (Q10, Recall). Decomposition is the microbial and detritivore breakdown of dead organic matter, releasing inorganic nutrients (mineralization) and CO₂ via heterotrophic respiration. Primary decomposers are bacteria and fungi (saprotrophs), assisted by detritivores (earthworms, millipedes, woodlice, soil arthropods) that fragment litter and increase surface area for microbial attack. Termites add symbiotic lignocellulose digestion and mound/galleried soil structure; ants fragment and move organic matter, excavate mineral soil, and redistribute nutrients. They are not primary microbial decomposers, but they engineer the physical and biological conditions under which decomposition proceeds. See section 39.

Questions 11–20: Application and Analysis

11. In a grassland ecosystem, GPP = 5,000 kcal/m²/yr and plant respiration = 3,000 kcal/m²/yr. Calculate NPP. If herbivores consume 20% of NPP and their assimilation efficiency is 40%, calculate secondary production at the herbivore level. How much energy reaches the top predator (3rd consumer) assuming 10% transfer efficiency?

Answer (Q11, Application). $NPP = GPP - R_a = 5000 - 3000 = 2000$ kcal per m² per yr. Herbivores consume 20 percent of NPP: $0.20 \times 2000 = 400$ ingested. Secondary production at the herbivore level = $400 \times 0.40 = 160$ kcal per m² per yr. At 10 percent transfer per step: 2nd consumer = $160 \times 0.10 = 16$; 3rd consumer = $16 \times 0.10 = 1.6$. The steep drop is why high trophic levels support little biomass. See section 39. 12. The inverted biomass pyramid of the open ocean: phytoplankton biomass is much lower than zooplankton biomass at any instant, yet phytoplankton NPP exceeds zooplankton production. Explain this paradox using turnover rate (phytoplankton divide daily; zooplankton live weeks to months).

Answer (Q12, Application). Phytoplankton have an extremely high turnover rate (cells divide roughly daily), so their tiny standing biomass is grazed almost as fast as produced and never accumulates; zooplankton turn over slowly (weeks to months) so their biomass accumulates and exceeds that of their food at any instant. Biomass (a stock) is inverted, but production rate (a flux) is not, because flux equals biomass times turnover, and high turnover compensates for low standing stock. See section 39. 13. Nitrogen fixation by *Rhizobium* in legume root nodules adds about 200 kg N/ha/yr to agricultural soils. Haber-Bosch industrial fixation produces about 150 Tg N/yr globally. Compare: (a) the energy cost of each; (b) the environmental consequences of excess reactive nitrogen (N₂O greenhouse gas, aquatic eutrophication, acid rain); (c) why reducing fertiliser overuse is critical for planetary health.

Answer (Q13, Application). (a) *Rhizobium* fixation runs on plant photosynthate (about 16 ATP per N₂), biologically free to the farmer; Haber-Bosch is fossil-fuel intensive. (b) Excess reactive N causes N₂O emission (a potent greenhouse gas), nitrate leaching to aquatic eutrophication and hypoxic dead zones, and NO_x to acid rain (the nitrogen cascade). (c) Humans now fix more N than all natural processes combined, so cutting fertilizer over-application is essential to limit climate, water-quality, and biodiversity damage. See section 39. 14. The biological pump in the ocean: surface phytoplankton fix CO₂ → organic particles sink → deep ocean decomposition releases CO₂ → CO₂ is sequestered for centuries. Calculate: if the biological pump sequesters about 11 Gt C/yr and anthropogenic emissions are about 10 Gt C/yr, what fraction of emissions is the biological pump offsetting? What would happen to atmospheric CO₂ if the biological pump weakened by 20%?

Answer (Q14, Application). Fraction of emissions offset = $11 \div 10 = 1.1$ (about 110 percent of current anthropogenic emissions, though the natural pump is roughly balanced by upwelling and is not a net anthropogenic sink). If the pump weakened by 20 percent, sequestration falls from 11 to $11 \times 0.8 = 8.8$ Gt C per yr, a loss of 2.2 Gt C per yr of downward export, leaving more CO₂ in the surface ocean and atmosphere and raising atmospheric CO₂ (a positive climate feedback). See section 39. 15. A mesocosm experiment measures primary productivity using the light-dark bottle method. The light bottle shows dissolved O₂ increase of 3 mg/L over 24 hours. The dark bottle shows O₂ decrease of 1.5 mg/L. Calculate: (a) NPP (net change in light bottle); (b) respiration (O₂ loss in dark bottle); (c) GPP (NPP + R). Convert to carbon units assuming 1 mg O₂ = 0.375 mg C.

Answer (Q15, Application). Dark bottle change equals respiration only; light bottle change equals photosynthesis minus respiration (NPP). (a) NPP equals light-bottle O₂ gain = +3 mg O₂ per L per 24h. (b) Respiration equals dark-bottle O₂ loss = 1.5. (c) GPP equals NPP plus R = $3 + 1.5 = 4.5$. In carbon units (times 0.375): NPP about 1.13, R about 0.56, GPP about 1.69 mg C per L per 24h. See section 39. 16. Phosphorus is the limiting nutrient in most freshwater ecosystems (unlike marine systems where nitrogen often limits). Explain: (a) why P availability limits productivity (no atmospheric reservoir; P cycles primarily through rock weathering); (b) how agricultural runoff causes lake eutrophication (Schindler’s whole-lake experiments); (c) why banning phosphate detergents was effective in lake recovery.

Answer (Q16, Application). (a) P limits productivity because it has no atmospheric reservoir; supply depends on slow rock weathering so phosphate is chronically scarce and adding it directly boosts algal growth. (b) Schindler’s whole-lake experiments fertilized one basin with C plus N and the other with C plus N plus P; only the P-amended basin bloomed with cyanobacteria, proving P drives freshwater eutrophication. (c) Banning phosphate detergents removed a major point-source P input; because P is limiting, cutting it directly reduced blooms and lakes recovered. See section 39. 17. Decomposition rates vary with temperature and moisture. Using the “k constant” for leaf litter decomposition (mass remaining =

$M_0 e^{-kt}$): if $k = 0.5/\text{yr}$ in a temperate forest and $k = 2.0/\text{yr}$ in a tropical forest, calculate the time for 90% decomposition in each ecosystem. What does this imply for nutrient cycling rates?

Answer (Q17, Application). Exponential decay $M \div M_0 = e^{-kt}$; for 90 percent loss the ratio is 0.1, so $t = -\ln(0.1) \div k = 2.303 \div k$. Temperate ($k = 0.5$ per yr): $t \approx 4.6$ years. Tropical ($k = 2.0$ per yr): $t \approx 1.15$ years. Faster decomposition in the warm moist tropics means rapid nutrient turnover, so tropical soils are nutrient-poor and vulnerable to loss when forest is cleared. See section 39. 18. The sulfur cycle includes atmospheric SO_2 (from volcanic eruptions and fossil fuel combustion), which forms sulfuric acid (H_2SO_4) in clouds. Trace: $\text{SO}_2 \rightarrow$ sulfate aerosol \rightarrow acid rain \rightarrow soil and lake acidification \rightarrow biological damage. Name the specific impacts on: (a) fish populations; (b) forest soil chemistry (Al^{3+} toxicity); (c) building materials (limestone dissolution).

Answer (Q18, Application). Combustion and volcanism release SO_2 , oxidized to sulfate aerosol and H_2SO_4 , producing acid rain (pH below about 4.5) and soil and lake acidification. (a) Fish: low pH disrupts ion regulation and gill function; acid-sensitive species disappear below about pH 5. (b) Forest soils: acidity mobilizes toxic Al^{3+} and leaches base cations (Ca^{2+} , Mg^{2+}), damaging fine roots and mycorrhizae. (c) Buildings: acid dissolves CaCO_3 in limestone and marble, eroding monuments. See section 39. 19. Carbon budget: the global carbon budget (2024) estimates: fossil fuel emissions = 9.9 Gt C/yr; land-use change emissions = 1.0 Gt C/yr; ocean sink = 2.8 Gt C/yr; land sink = 3.3 Gt C/yr; atmospheric growth = 4.8 Gt C/yr. Verify: do sources = sinks + atmospheric growth? What is the “residual” and what does it reveal about our understanding of the carbon cycle?

Answer (Q19, Application). Mass balance: sources equal fossil fuel plus land-use = $9.9 + 1.0 = 10.9$ Gt C per yr. Sinks plus atmospheric growth equal ocean plus land plus atmosphere = $2.8 + 3.3 + 4.8 = 10.9$. They balance exactly here, so the budget residual is 0 in this dataset. In real Global Carbon Budget assessments the terms rarely close perfectly; the nonzero budget imbalance reflects measurement uncertainty (mainly the land sink and land-use term) and the limits of quantitative understanding. See section 39. 20. Wetlands serve as both carbon sinks and methane (CH_4) sources. Evaluate: (a) how waterlogged, anoxic conditions promote methanogenesis (acetoclastic vs hydrogenotrophic pathways); (b) the 100-year global warming potential of CH_4 (about 27–30 \times CO_2 depending on fossil vs biogenic accounting in IPCC AR6); (c) the net climate effect of wetlands — do they cool or warm the planet considering both C sequestration and CH_4 emission?

Answer (Q20, Application). (a) Waterlogging makes wetland soils anoxic; once O_2 , nitrate, and sulfate are depleted, methanogens produce CH_4 via the acetoclastic pathway (acetate to CH_4 plus CO_2) and the hydrogenotrophic pathway (CO_2 plus H_2 to CH_4). (b) CH_4 has a 100-year GWP of roughly 27 to 30 times CO_2 (IPCC AR6). (c) Net effect is timescale-dependent: wetlands are persistent long-term carbon sinks (peat) but strong short-term CH_4 sources, so they can warm over short horizons and cool over millennia depending on the GWP horizon chosen. See section 39.

Questions 21–30: Synthesis and Evaluation

- Evaluate the concept of “planetary boundaries” for biogeochemical cycles (Rockström et al., 2009). Which cycles have transgressed safe operating spaces (nitrogen, phosphorus, climate change), and what does this mean for Earth system stability? Propose specific policy interventions for the nitrogen cycle that would bring humanity back within the safe boundary.

Answer (Q21, Synthesis). Planetary boundaries (Rockstrom et al., 2009) define a safe operating space for nine Earth-system processes. The biogeochemical-flows boundary (nitrogen and phosphorus) is the most severely transgressed (human N fixation far exceeds the limit), and climate change and biosphere integrity are also beyond their boundaries, risking abrupt change. Nitrogen interventions: raise nitrogen-use efficiency (precision fertilization, slow-release forms), expand legume rotations and cover crops, restore riparian buffers and wetlands to denitrify runoff, improve manure and wastewater treatment, and shift diets away from N-intensive ruminant food. See section 39. 22. Design an ecosystem-scale experiment (like Biosphere 2) to test whether a simplified ecosystem (5 trophic levels, 50 species) can maintain biogeochemical cycling in a sealed environment. What are the critical species you would include, what cycling processes must be maintained (C, N, P, H_2O), and what failure modes would you predict?

Answer (Q22, Synthesis). Hypothesis: a 50-species, five-trophic-level sealed system can sustain closed C, N, P, and water cycling. Critical species: diverse photosynthetic producers (oxygen and NPP), decomposer bacteria and fungi (mineralization), N-fixing and nitrifying and denitrifying microbes, herbivores and predators to regulate producers, and detritivores. Maintain balanced GPP versus total respiration, N fixation versus denitrification, P recycling, and water recharge. Compare replicated mesocosms to an open-system control. Predicted failure modes (Biosphere 2 lessons): oxygen drawdown, CO_2 swings, trophic collapse, and nutrient lockup. See section 39. 23. Evaluate the “metabolic theory of ecology” (MTE, Brown et al., 2004): body mass and temperature determine metabolic rate, which scales ecosystem processes (productivity, decomposition, nutrient flux). What does MTE predict about the response of tropical vs boreal ecosystem productivity to climate warming, and where does MTE break down (nutrient limitation, biodiversity effects)?

Answer (Q23, Synthesis). MTE (Brown et al., 2004) holds metabolic rate scales with body mass (proportional to mass to the three-quarter power) and temperature (Boltzmann factor), so productivity, decomposition, and nutrient flux follow size and temperature. It predicts warming accelerates

rates more in cold boreal systems than in already-warm tropical ones, and decomposition may rise faster than NPP, releasing soil carbon. MTE breaks down where nutrient or water limitation (not temperature) controls rates and where biodiversity, community composition, and acclimation matter. See section 39. 24. Evaluate the role of fire as an ecosystem process: (a) how fire releases nutrients (P, K) from biomass; (b) how fire-adapted ecosystems (savanna, chaparral, boreal forest) depend on periodic fire for regeneration; (c) how fire suppression in fire-dependent ecosystems leads to fuel accumulation and catastrophic megafires; (d) how indigenous fire management (“cool burns”) can be integrated into modern land management.

Answer (Q24, Synthesis). (a) Fire mineralizes nutrients: combustion converts biomass to ash releasing plant-available P, K, Ca while volatilizing much N and C. (b) Fire-adapted systems (savanna, chaparral, boreal forest) depend on periodic fire (serotinous cones, fire-cued germination, resprouting) to recycle nutrients and reset succession. (c) Suppression in fire-dependent systems lets fuel build up, so eventual fires become high-intensity megafires. (d) Indigenous cool burns (frequent, low-intensity, patchy) reduce fuel loads; integrating them with modern management lowers catastrophic-fire risk while keeping biodiversity. See section 39. 25. Evaluate the evidence that ocean acidification (decreasing pH from CO₂ absorption, currently pH 8.1 → projected 7.8 by 2100) threatens marine ecosystems: (a) what organisms are most affected (calcifiers — corals, pteropods, coccolithophores); (b) how does reduced aragonite saturation state ($\Omega_{ar} < 1$) dissolve CaCO₃ shells; (c) what cascading ecosystem effects are predicted; (d) is there evidence of evolutionary adaptation to lower pH in any marine organisms?

Answer (Q25, Synthesis). (a) Most affected are calcifiers building CaCO₃: corals, pteropods, coccolithophores, mollusc and echinoderm larvae, foraminifera. (b) Added CO₂ lowers carbonate-ion concentration and the aragonite saturation state; when omega-aragonite is below 1, seawater is corrosive and aragonite shells dissolve faster than they form. (c) Cascading effects: weakened reefs lose habitat and biodiversity, pteropod loss disrupts polar food webs, and acidification impairs fish olfaction. (d) Adaptation is limited but present (some corals, coccolithophores, vent populations), generally insufficient versus the rate of change. See section 39. 26. Evaluate the concept of “natural capital” — valuing ecosystem services (pollination, water purification, carbon storage) in monetary terms. Using Costanza et al. (1997, updated 2014) estimates of global ecosystem services at \$125 trillion/yr: (a) is monetary valuation of nature scientifically valid; (b) does it effectively change policy; (c) what ethical concerns arise from commodifying nature?

Answer (Q26, Synthesis). Costanza et al. (1997; updated 2014 to about 125 trillion dollars per yr) monetized global ecosystem services. (a) Validity: heuristic, not precise; it uses benefit transfer and treats nonlinear non-substitutable life-support services as if marginal and additive, so it argues an order-of-magnitude case that nature’s value is enormous, not a balance-sheet figure. (b) Policy: framing services in money has shifted policy (payments for ecosystem services, REDD+, natural-capital accounting) but evidence of consistent outcome change is mixed. (c) Ethics: commodification may crowd out intrinsic value and misprice irreplaceable systems. See section 39. 27. Evaluate the role of permafrost thaw in the global carbon cycle: about 1,500 Gt C is stored in permafrost (twice atmospheric carbon). As Arctic warming thaws permafrost: (a) what forms of carbon are released (CO₂ from aerobic decomposition, CH₄ from anaerobic decomposition); (b) what is the “permafrost carbon feedback” and how much warming does it add to existing projections; (c) is permafrost thaw a tipping point (irreversible once initiated)?

Answer (Q27, Synthesis). (a) Aerobic decomposition in drained thawed soils releases CO₂; anaerobic decomposition in waterlogged thaw ponds releases CH₄ (higher per-molecule GWP). (b) The permafrost carbon feedback is the self-amplifying loop warming to thaw to gas release to more warming, adding on the order of 0.2 to 0.4 degC extra warming this century (large uncertainty) beyond standard projections. (c) It behaves as a slow-onset, effectively irreversible tipping element on human timescales; whether there is one sharp global threshold versus gradual region-by-region loss is debated. See section 39. 28. Evaluate the concept of “novel ecosystems” — ecosystems with no historical analog, arising from human activity (urban ecosystems, post-mining landscapes, invasive-dominated habitats). Should conservation efforts attempt to restore historical ecosystems or manage novel ecosystems for desired functions? Use a specific example to argue both sides.

Answer (Q28, Synthesis). Novel ecosystems are human-created assemblages with no historical analog (urban systems, post-mining land, invasive-dominated habitats) that will not return to a historical baseline without continuous intervention. Restore-historical view (removing invasive Tamarisk from a riparian system): historical states preserve native biodiversity and coevolved interactions; abandoning baselines risks shifting-baseline syndrome. Manage-for-function view (same system): if hydrology and climate changed irreversibly, full restoration is infeasible, so managing for functions (erosion control, carbon, habitat) yields more value. The defensible answer is context-dependent. See section 39. 29. Evaluate geoengineering approaches targeting biogeochemical cycles: (a) ocean iron fertilization (stimulating phytoplankton growth to increase biological pump CO₂ sequestration); (b) enhanced weathering (grinding silicate rocks to accelerate CO₂ consumption); (c) bioenergy with carbon capture and storage (BECCS). For each, evaluate the scale of CO₂ removal, the ecological risks, and the technological readiness.

Answer (Q29, Synthesis). (a) Ocean iron fertilization stimulates phytoplankton and the biological pump, but trials show weak, uncertain, short-lived net export with bloom and hypoxia risks; low readiness and confidence. (b) Enhanced weathering: ground silicate consumes CO₂ as bicarbonate, potentially large and long-lived but energy- and land-intensive with trace-metal risks; moderate potential, early readiness. (c) BECCS: grow biomass, use for energy, store CO₂ geologically; most mature and scalable but competes for land, water, and biodiversity and needs secure storage. None

substitutes for emissions cuts. See section 39. 30. Critically evaluate whether Earth’s biogeochemical cycles constitute a self-regulating system (Gaia hypothesis, Lovelock 1979). Specifically: (a) what evidence supports biological regulation of atmospheric O₂ at about 21%; (b) what evidence supports biological regulation of ocean salinity; (c) what is the difference between “strong Gaia” (Earth as a superorganism) and “weak Gaia” (life influences but does not control the environment); (d) which version, if either, is scientifically defensible?

Answer (Q30, Synthesis). The Gaia hypothesis (Lovelock 1979) proposes life and environment form a self-regulating system maintaining habitability. (a) Atmospheric O₂ near 21 percent is biologically produced and held in a narrow window (below about 15 percent fires cease; above about 25 percent even wet vegetation burns). (b) Ocean salinity has stayed near 3.5 percent for eons via biological and geological removal, though abiotic processes contribute strongly. (c) Strong Gaia claims a purposeful superorganism regulating conditions for life; weak Gaia claims life merely influences and is coupled to geochemistry via feedbacks. (d) Only weak Gaia (Earth System Science) is scientifically defensible. See section 39.

Questions — Biomes and Conservation Biology

Instructor Use and Coverage Notes

- Coverage target: Evaluate a conservation scenario using evidence, tradeoffs, and uncertainty.
- Model/data emphasis: Species-area, risk, and prioritization calculations.
- Assessment alignment: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Misconception probe: Conservation is decision-making under constraints and uncertainty, not only preserving untouched nature.
- Transfer product: Transfer conservation reasoning to land use, climate corridors, restoration, and environmental justice.
- Grading focus: award full credit for mechanism, evidence, boundary conditions, and units when a calculation is required.
- Suggested use: draw one recall item, one application item, and one synthesis item when building a short quiz from this bank.

Questions 1–10: Recall and Comprehension

This activity accompanies section 40 of the textbook — review that chapter before attempting the exercises below.

1. Define a biome. What two abiotic factors primarily determine biome distribution?

Answer (Q1, Recall). A biome is a large-scale ecological region defined by its characteristic climate and the vegetation and animal communities adapted to it (e.g., tropical rainforest, desert, tundra). The two abiotic factors that primarily determine terrestrial biome distribution are temperature and precipitation (mean annual values and their seasonality), as captured by Whittaker’s climate-vegetation diagram. See section 40. 2. Name six major terrestrial biomes and list their characteristic temperature and precipitation ranges.

Answer (Q2, Recall). Six major terrestrial biomes (approximate ranges): tropical rainforest (about 25-30 degC, more than 2000 mm/yr); savanna (20-30 degC, 500-1500 mm with a dry season); desert (wide range, often hot 20-45 degC, less than 250 mm/yr); temperate grassland (cold winters to warm summers, 250-900 mm); temperate deciduous forest (about 5-20 degC, 750-1500 mm); boreal forest/taiga (cold, about -5 to 5 degC, 300-900 mm); tundra (very cold, below 0 degC mean, less than 250 mm). See section 40. 3. What is the difference between weather and climate?

Answer (Q3, Recall). Weather is the short-term state of the atmosphere (temperature, precipitation, wind) at a place over hours to days. Climate is the long-term statistical pattern of weather (means and variability) at a location over decades (conventionally 30-year averages). The decisive difference: weather is instantaneous and variable; climate is the aggregated, long-run distribution that determines which biome can occur there. See section 40. 4. What is biodiversity? Distinguish genetic, species, and ecosystem diversity.

Answer (Q4, Recall). Biodiversity is the variety of life at all levels of organization. Genetic diversity is variation in alleles and genotypes within and among populations of a species (raw material for adaptation). Species diversity is the number and relative abundance of species in a community. Ecosystem diversity is the variety of habitats, biotic communities, and ecological processes across a landscape or region. They differ in scale: gene to population to community to landscape. See section 40. 5. Define an endangered species. What organization maintains the Red List?

Answer (Q5, Recall). An endangered species is one assessed as facing a very high risk of extinction in the wild in the near future (IUCN category Endangered; the U.S. Endangered Species Act uses ‘in danger of extinction throughout all or a significant portion of its range’). The IUCN (International Union for Conservation of Nature) maintains the Red List of Threatened Species. See section 40. 6. What is habitat fragmentation? Why does it threaten biodiversity?

Answer (Q6, Recall). Habitat fragmentation is the breaking of continuous habitat into smaller, isolated patches by human land use. It threatens biodiversity by reducing patch area (smaller populations, higher extinction risk), increasing isolation (less dispersal and gene flow, lower rescue and recolonization), and increasing edge effects (altered microclimate, predation, invasion), pushing many species below minimum viable population size. See section 40. 7. Name three causes of the current biodiversity crisis.

Answer (Q7, Recall). Three causes of the current biodiversity crisis (the modern ‘HIPPO’/IPBES drivers): (1) habitat loss and land/sea-use change; (2) overexploitation (overharvest, hunting, fishing); (3) climate change. Pollution and invasive species are two additional major drivers. See section 40. 8. What is a biodiversity hotspot? Name two examples.

Answer (Q8, Recall). A biodiversity hotspot is a region with exceptional species richness and endemism (more than 1500 endemic vascular plants) that has already lost more than 70 percent of its original natural vegetation (Myers/Conservation International criteria), making it both irreplaceable and threatened. Examples: the Tropical Andes and Madagascar (others include the Mediterranean Basin and Sundaland). See section 40. 9. What is an in situ conservation strategy? What is an ex situ strategy?

Answer (Q9, Recall). In situ conservation protects species in their natural habitat (national parks, reserves, protected areas), preserving ecological and evolutionary processes. Ex situ conservation maintains organisms outside their natural habitat (zoos, botanical gardens, captive breeding, seed

banks, gene/cryobanks), used as a backup when in situ protection alone cannot prevent extinction. See section 40. 10. Define sustainability. What are the three pillars of sustainability?

Answer (Q10, Recall). Sustainability is meeting present needs without compromising the ability of future generations to meet their own needs (Brundtland definition). Its three pillars are environmental (ecological integrity and resource limits), economic (viable livelihoods and prosperity), and social (equity, health, and well-being); durable solutions must satisfy all three. See section 40.

Questions 11–20: Application and Analysis

11. The species-area relationship ($S = cA^z$, where $z \approx 0.25$ for oceanic islands) predicts that reducing habitat area by 90% reduces species number by about 50%. Calculate: if a 10,000 km² forest is reduced to 1,000 km², and the original forest had 200 bird species, how many bird species are expected in the remaining fragment? What assumptions does this model make?

Answer (Q11, Application). Species-area relationship $S = cA^z$, so $S_2/S_1 = (A_2/A_1)^z$. Area falls from 10000 to 1000 km², a 10-fold reduction, with $z = 0.25$: $S_2 = 200 \times (1000/10000)^{0.25} = 200 \times (0.1)^{0.25} = 200 \times 0.562 \approx 112$ bird species (a loss of about 88 species, roughly 44 percent). Assumptions: the relationship and z apply to this system, the fragment is at new equilibrium (ignores extinction-debt time lag), no edge effects or matrix effects, and habitat is otherwise homogeneous. See section 40. 12. EDGE scores (Evolutionarily Distinct and Globally Endangered) are used to prioritize species for conservation investment. The aye-aye (*Daubentonia madagascariensis*) — the sole living member of its family — has a very high EDGE score. Explain: (a) what evolutionary distinctiveness means; (b) why losing an “edge species” results in greater phylogenetic diversity loss than losing a species in a species-rich clade; (c) how EDGE scoring changes conservation priorities compared to a focus on charisma.

Answer (Q12, Application). (a) Evolutionary distinctiveness measures how isolated a species is on the tree of life (long branch with few close relatives), summarizing unique evolutionary history. (b) Losing an ‘EDGE’ species like the aye-aye, the sole member of its family, erases a long, unshared branch and far more phylogenetic diversity (unique genes and traits) than losing one of many similar species in a species-rich clade, where relatives retain most shared history. (c) EDGE scoring redirects priorities toward irreplaceable, evolutionarily unique but overlooked taxa rather than only charismatic megafauna, maximizing preserved evolutionary history per conservation dollar. See section 40. 13. Minimum viable population (MVP) analysis: a PVA model estimates that a population of 500 individuals has a 95% probability of persisting for 100 years, but a population of 50 has a 20% chance. Identify three factors incorporated in the model (demographic stochasticity, environmental stochasticity, inbreeding depression) and explain how each reduces persistence probability.

Answer (Q13, Application). (a) Demographic stochasticity: random variation in individual births, deaths, and sex ratio; in small populations chance alone can cause a run of deaths or all-male offspring, driving extinction even when mean growth is positive. (b) Environmental stochasticity: year-to-year fluctuations in conditions (droughts, disease, storms) hit the whole population at once, depressing survival/reproduction and increasing variance in growth rate. (c) Inbreeding depression: small populations lose heterozygosity and express deleterious recessive alleles, lowering fertility and survival. All three intensify as N falls, so a population of 50 has far lower persistence probability than 500 (the basis of the 50/500 rule). See section 40. 14. Climate change is shifting biome boundaries: the boreal-temperate boundary is moving northward, and the Sahel-Sahara boundary is fluctuating. Predict the consequences for: (a) species that cannot migrate fast enough (boreal specialists trapped in shrinking habitat); (b) agricultural zones (expansion of growing season in formerly cold regions); (c) novel community assemblages (no-analog communities formed by differential range shifts).

Answer (Q14, Application). (a) Boreal specialists cannot track the poleward/upslope shift fast enough (slow dispersal, fragmentation, no land left at high latitude); their suitable climate envelope shrinks and they face range contraction and extinction risk. (b) Agricultural zones expand into formerly cold regions as growing seasons lengthen and frost-free periods increase, shifting cultivation poleward (though soils and daylength may not match). (c) Because species shift at different rates and directions, communities reshuffle into no-analog (novel) assemblages with new species combinations and interactions not seen historically, complicating prediction and management. See section 40. 15. Coral reef bleaching occurs when accumulated heat stress disrupts the coral-Symbiodiniaceae partnership. Explain: (a) how degree-heating-week evidence links heat exposure to symbiont photosystem stress, reactive oxygen species, and symbiont loss; (b) why recovery depends on repeated heat exposure, water quality, recruitment, and symbiont community composition rather than a fixed clock; (c) how assisted evolution or symbiont turnover could improve local resilience while still failing as a substitute for climate mitigation.

Answer (Q15, Application). DHW is an exposure metric: sustained positive temperature anomalies increase stress on algal photosystems, promote reactive oxygen species and photodamage, and trigger host stress responses that reduce or expel symbionts, leaving the coral energy-limited. Recovery is variable because it depends on mortality severity, recruitment, herbivory, sediment and nutrient stress, disease pressure, and whether surviving hosts or symbionts have heat-tolerant traits. Assisted evolution, selective breeding, probiotics, or symbiont turnover can shift local tolerance in some settings, but they do not remove the external heat driver or ocean-acidification risk. Defensible management therefore pairs local resilience actions with emissions reduction and monitoring, not a claim that corals can simply adapt away the problem. See section 40. 16. Protected

areas currently cover about 17% of land and about 8% of ocean. The Kunming-Montreal Global Biodiversity Framework (2022) targets 30% by 2030 (“30 by 30”). Evaluate: (a) whether area alone is sufficient (effective management, connectivity, representativeness); (b) the concept of “half-Earth” (Wilson, 2016 — protecting 50% of Earth’s surface); (c) the social justice concerns (indigenous displacement, land rights).

Answer (Q16, Application). (a) Area alone is insufficient: protection must also be effectively managed, well-connected, and ecologically representative; many ‘paper parks’ deliver little because of weak enforcement, poor placement, or isolation. (b) Wilson’s ‘Half-Earth’ proposes protecting about 50 percent of Earth’s surface to retain most species, an ambitious target grounded in species-area logic but facing huge land-use and political constraints. (c) Social-justice concerns: ‘fortress conservation’ has historically displaced Indigenous and local peoples and ignored land rights; equitable ‘30 by 30’ must secure tenure, recognize Indigenous-managed lands, and ensure benefit-sharing rather than exclusion. See section 40. 17. Invasive species economic damage: the global estimated cost of invasive species is >\$423 billion/yr (2019). Using the example of the invasive cane toad (*Rhinella marina*) in Australia: (a) what was the original purpose of introduction; (b) what ecological impacts have occurred (native predator mortality from toad toxin); (c) what control strategies have been attempted (biological control, trapping, gene drive research).

Answer (Q17, Application). (a) The cane toad was deliberately introduced to Queensland in 1935 as a biological control agent against cane beetles in sugarcane. (b) It failed to control the beetles and instead spread widely; its potent bufotoxin kills naive native predators (quolls, goannas, snakes, freshwater crocodiles) that try to eat it, causing steep declines, while it also preys on and competes with native fauna. (c) Control attempts include hand-trapping and tadpole traps (using toad pheromone/bufadienolide lures), exclusion fencing around water, community ‘toad busting’, conditioned taste aversion to protect predators, and research into gene-drive or genetic biocontrol; none has achieved landscape-scale eradication. See section 40. 18. Payment for ecosystem services (PES): Costa Rica’s PES program pays landowners to conserve forest (carbon storage, water regulation). Evaluate: (a) how PES monetises ecosystem services; (b) evidence of effectiveness (Costa Rica reversed deforestation); (c) criticisms (additionality — would forests have been conserved anyway? Equity — do poor landowners benefit or are payments captured by wealthy elites?).

Answer (Q18, Application). (a) PES pays landowners for the ecosystem services their land provides (carbon storage, watershed/water regulation, biodiversity, scenic value), funded via fuel taxes, water fees, and carbon finance, internalizing previously unpriced benefits. (b) Costa Rica’s program coincided with a reversal of deforestation and roughly a doubling of forest cover since the 1980s, indicating effectiveness in a strong-governance setting. (c) Criticisms: additionality (paying for forest that would have been kept anyway), leakage (clearing shifts elsewhere), permanence, and equity (payments and titling may favor wealthier landowners over poor or untitled holders). The conclusion would change if rigorous counterfactual evaluation showed low additionality. See section 40. 19. The IPBES Global Assessment estimates that about one million species are threatened, while the IPBES Transformative Change Assessment argues that biodiversity loss is driven by economic, governance, and social systems as well as local habitat conversion. Evaluate: (a) how threatened-species estimates combine assessed taxa, extrapolation, and habitat trends; (b) how GBIF occurrence records complement, but cannot replace, IUCN/IPBES risk assessment; (c) why food systems, healthy diets, agroecology, fisheries, and commodity supply chains belong inside conservation biology; (d) how to distinguish evidence-based transformative change from vague sustainability branding.

Answer (Q19, Application). Treat the one-million estimate as a synthesis, not a direct census of every species: well-assessed groups, Red List categories, habitat-loss data, species-area relationships, and extrapolation to poorly known taxa all contribute uncertainty. GBIF adds open occurrence evidence about where and when taxa have been recorded, but those points need coordinate, date, taxonomy, duplicate, and sampling-bias filters before being interpreted as range or abundance evidence; IUCN/IPBES then synthesize risk, drivers, and policy relevance [GBIF Secretariat, 2026, International Union for Conservation of Nature, 2025, Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services, 2024]. Food systems matter because agriculture, fisheries, trade, food waste, diet affordability, fertilizer runoff, pesticide use, and habitat conversion are direct biodiversity drivers; changing them affects nutrition, livelihoods, and ecosystems together. Evidence-based transformative change names levers and indicators: land-use policy, rights and tenure, subsidy reform, diversified farming, sustainable harvest rules, pollinator habitat, healthy-diet affordability, and measured biodiversity outcomes. Branding is weaker when it lacks baselines, distributional effects, monitoring, or a mechanism connecting the intervention to reduced pressure on species and ecosystems. See section 40. 20. Rewilding involves reintroducing apex predators and megafauna to restore ecosystem function. Evaluate the Eurasian rewilding movement (European bison in Romania, wolves in Germany, lynx in UK): (a) what ecological functions are restored; (b) what human-wildlife conflict arises; (c) the evidence from existing rewilding projects (Oostvaardersplassen, Netherlands) — successes and failures.

Answer (Q20, Application). (a) Rewilding restores ecological functions: large herbivores (European bison) drive grazing and vegetation heterogeneity; apex predators (wolves, lynx) restore top-down control and trophic cascades, increasing structural and species diversity. (b) Human-wildlife conflict arises: livestock depredation by wolves/lynx, perceived risk, competition over land, and the politics of large carnivores near settlements. (c) Oostvaardersplassen showed both: it generated dense large-grazer populations and habitat dynamics, but lack of predators plus a fenced, food-limited area led to mass winterstarvation and a public-ethics backlash, prompting culling/feeding policy changes, evidence that bounded rewilding without predators or migration routes can fail welfare and ecological goals. See section 40.

Questions 21–30: Synthesis and Evaluation

21. Evaluate the “extinction debt” concept: habitat destruction in the past has committed species to future extinction even if no further habitat is lost, because small fragments cannot sustain viable populations over decades. Using the example of tropical forest fragmentation (Ferraz et al., 2003): (a) how is extinction debt estimated; (b) how long is the time lag (about 20–100 years); (c) what does this imply for current biodiversity assessments (we are underestimating the true impact of past deforestation)?

Answer (Q21, Synthesis). (a) Extinction debt is estimated by comparing current species richness in fragments to the lower equilibrium predicted by the post-fragmentation area (species-area relationship) and by tracking ‘relaxation’ through long-term monitoring; the gap is the debt. (b) The relaxation time lag is long, roughly decades to a century (about 20-100 years for tropical forest birds; Ferraz et al. 2003 estimated multi-decade half-lives), so committed extinctions unfold slowly. (c) Implication: current biodiversity assessments understate the true impact of past deforestation, because many ‘surviving’ species are functionally committed to extinction; the conclusion would change if fragments received enough restoration/connectivity to raise their effective area and pay down the debt. See section 40. 22. Design a conservation genetics program for a critically endangered species (e.g., California condor, about 500 individuals): describe (a) the genetic assessment (genomic sequencing of sampled individuals, measurement of heterozygosity and inbreeding coefficient); (b) the breeding management strategy (maximizing N_e , using mean kinship to minimize inbreeding); (c) the genetic rescue strategy (introducing individuals from a genetically distinct population to restore lost alleles). What are the risks of genetic rescue (outbreeding depression)?

Answer (Q22, Synthesis). Hypothesis: managed breeding plus genetic rescue raises fitness and persistence versus unmanaged breeding (control = continued inbred breeding; falsifying result = no improvement or reduced fitness). (a) Assessment: genome-sequence all about 500 individuals, estimate individual heterozygosity, inbreeding coefficient F , relatedness, and known deleterious alleles. (b) Breeding management: pair individuals to maximize effective population size and minimize mean kinship, equalize family sizes, and avoid known lethal alleles. (c) Genetic rescue: introduce a few individuals from a genetically distinct conspecific population to restore lost alleles and heterozygosity; monitor offspring fitness. Risk: outbreeding depression (loss of local adaptation or coadapted gene complexes), so introduce cautiously and track replicated breeding lines. See section 40. 23. Evaluate climate-smart conservation: traditional conservation aims to protect current biodiversity in current locations. Climate change requires protecting future habitats and enabling species movement. Evaluate three climate-smart strategies: (a) connectivity corridors between protected areas; (b) assisted migration (moving species to suitable future habitat); (c) protecting climate refugia (areas predicted to remain climatically stable). What are the risks of each?

Answer (Q23, Synthesis). (a) Connectivity corridors link protected areas so species can track shifting climate; risk: corridors can also spread invasives, disease, or fire, and may not align with future climate paths. (b) Assisted migration moves species to predicted-suitable future habitat; risk: the translocated species may become invasive or disrupt recipient communities, and predictions are uncertain. (c) Protecting climate refugia conserves areas expected to stay climatically stable (topographic/microclimatic); risk: refugia are hard to identify reliably, may be small, and can still fail under high warming. A defensible strategy treats these as a portfolio under uncertainty, with monitoring; the judgment changes if downscaled climate projections or species-distribution models prove unreliable. See section 40. 24. Evaluate the role of indigenous and traditional ecological knowledge (ITEK) in conservation: (a) the evidence that indigenous-managed lands have higher biodiversity than conventional protected areas; (b) the UN IPBES recognition of ITEK as an evidence base equal to scientific knowledge; (c) the challenges of integrating ITEK with Western science (different epistemologies, power dynamics, intellectual property).

Answer (Q24, Synthesis). (a) Evidence: Indigenous-managed and Indigenous-owned lands frequently show biodiversity and intactness equal to or greater than conventional protected areas (e.g., comparable or lower deforestation and higher vertebrate persistence), indicating effective stewardship. (b) IPBES explicitly recognizes Indigenous and local knowledge as a legitimate evidence base alongside science and centers it in its global assessments. (c) Challenges to integration: different epistemologies (relational vs. reductionist), historical power asymmetries and marginalization, risks of extractive ‘knowledge mining’, intellectual-property and consent issues, and the need for genuine co-governance rather than tokenism. The conclusion would weaken if outcome differences disappeared after controlling for remoteness and land-use pressure. See section 40. 25. Evaluate the concept of “de-extinction” in the context of conservation biology: if woolly mammoths could be de-extincted (via CRISPR editing of Asian elephant genome), would this be a conservation priority? Discuss: (a) the opportunity cost (diverting funds from existing species); (b) the ecological benefit (restoring mammoth steppe ecosystem, permafrost preservation); (c) the ethical questions (welfare of first-generation animals, ecological risk).

Answer (Q25, Synthesis). (a) Opportunity cost: de-extinction is extremely expensive and could divert scarce funding and attention from thousands of extant species that could be saved more cheaply now. (b) Potential ecological benefit: a cold-adapted proxy could help restore mammoth-steppe grazing dynamics and possibly slow permafrost thaw, but the ecological outcome is speculative and unproven at scale. (c) Ethics: welfare of surrogate Asian elephants and first-generation animals, the animal is a genetically engineered proxy not a true mammoth, release into changed ecosystems carries invasion and disease risk, and it may foster moral hazard (‘extinction is reversible’). On current evidence it is not a defensible conservation

priority versus preventing extinctions; this would change only if it became cheap, low-risk, and ecologically validated. See section 40. 26. Evaluate the impact of plastic pollution on marine biomes: (a) microplastic ingestion by marine organisms across trophic levels; (b) bioaccumulation and biomagnification of associated chemical pollutants (phthalates, BPA); (c) the “plastisphere” — microbial communities colonising marine plastic that can include pathogens; (d) policy interventions (single-use plastic bans, Extended Producer Responsibility).

Answer (Q26, Synthesis). (a) Microplastics are ingested across trophic levels from zooplankton to fish, seabirds, and whales, causing physical blockage, false satiation, and reduced growth/reproduction. (b) Plastics sorb and leach hydrophobic pollutants and additives (phthalates, BPA, PCBs) that can bioaccumulate and biomagnify, with endocrine-disrupting effects up the food web (though magnification efficiency is debated). (c) The ‘plastisphere’ is a distinct microbial biofilm on marine plastic that can host pathogens and harmful taxa and rafts them across oceans. (d) Policy: single-use plastic bans, Extended Producer Responsibility, deposit-return schemes, and a global plastics treaty target sources; effectiveness depends on upstream production cuts, not just cleanup. The conclusion would change if exposure levels proved below toxicological thresholds in situ. See section 40. 27. Evaluate Nature-based Solutions (NbS) to climate change: (a) reforestation and afforestation (potential about 10 Gt CO₂/yr); (b) peatland and mangrove restoration; (c) regenerative agriculture (soil carbon sequestration). For each, evaluate the permanence of carbon storage, the biodiversity co-benefits, and the risk of “greenwashing” (using NbS to justify continued fossil fuel use).

Answer (Q27, Synthesis). (a) Reforestation/afforestation can sequester carbon (often cited around 10 Gt CO₂/yr potential) but storage is impermanent (fire, drought, harvest, pests) and monocultures provide weak biodiversity benefit; native, diverse forests are better. (b) Peatland and mangrove (blue carbon) restoration store dense, long-lived carbon and deliver strong biodiversity and coastal-protection co-benefits, but are vulnerable to drainage and degradation. (c) Regenerative agriculture builds soil carbon with food and resilience co-benefits, but gains are modest, reversible, and hard to verify. The central risk across all is greenwashing: NbS used to offset rather than cut fossil emissions. A defensible position treats NbS as complementary to deep decarbonization, with permanence safeguards and rigorous monitoring; the judgment changes if storage proves non-permanent at scale. See section 40. 28. Evaluate the role of zoos and botanical gardens (ex situ conservation) in preventing extinction: (a) the success stories (Arabian oryx, black-footed ferret, California condor — saved from extinction by captive breeding); (b) the limitations (genetic bottlenecks, behavioral domestication, space constraints); (c) the shift from “Noah’s Ark” (saving species) to “conservation hubs” (research, education, advocacy).

Answer (Q28, Synthesis). (a) Successes: captive breeding rescued the Arabian oryx, black-footed ferret, and California condor from the brink and enabled reintroduction. (b) Limitations: small founder numbers cause genetic bottlenecks and inbreeding, captivity selects for domestication and erodes wild behaviors, space and cost cap how many species can be held, and reintroduction often fails without habitat. (c) The field has shifted from a ‘Noah’s Ark’ framing (warehousing species) to ‘conservation hubs’ that integrate research, reintroduction science, public education, advocacy, and funding for in situ work, with ex situ as one tool in an integrated strategy rather than an end in itself. See section 40. 29. Evaluate the “triage” approach to conservation: given limited resources, should we focus on: (a) species most likely to be saved (pragmatic triage); (b) species with highest evolutionary distinctiveness (phylogenetic triage); (c) species with greatest functional importance (ecosystem triage)? Compare these approaches using a specific threatened community (e.g., coral reef, tropical forest), and discuss the ethical implications of explicitly choosing to let some species go extinct.

Answer (Q29, Synthesis). (a) Pragmatic triage funds species with the best cost-effectiveness of recovery, maximizing species saved but abandoning hard cases. (b) Phylogenetic triage prioritizes evolutionarily distinct species, preserving the most evolutionary history but possibly losing functionally key common species. (c) Ecosystem triage prioritizes functionally important species (keystones, foundation species) to preserve ecosystem services and integrity. On a coral reef, ecosystem triage would prioritize reef-building corals and key herbivores; phylogenetic triage might prioritize an isolated lineage; pragmatic triage might fund the cheapest wins. Ethically, explicit triage forces transparent, value-laden choices to let some species go extinct under resource limits; the appropriate criterion depends on whether the goal is total species, evolutionary history, or ecosystem function, and the judgment changes with the budget and stated objective. See section 40. 30. Critically evaluate whether the concept of “ecological footprint” (measuring human demand on Earth’s biocapacity in global hectares) is a scientifically rigorous and policy-useful metric. Compare ecological footprint to alternative sustainability metrics (planetary boundaries, natural capital accounting, genuine progress indicator). What does each capture that others miss, and which is most actionable for policy change?

Answer (Q30, Synthesis). The ecological footprint converts human resource demand and waste into the bioproductive area (global hectares) required, compared against biocapacity. Strengths: a single intuitive, communicable overshoot metric. Weaknesses: it leans heavily on a carbon-uptake-land component, is sensitive to methodological choices, omits many impacts (toxics, freshwater depletion, biodiversity loss), and is criticized as not fully rigorous. Planetary boundaries capture multiple Earth-system processes and thresholds but are not aggregated or directly policy-priced. Natural-capital accounting prices stocks/flows of ecosystem services (useful for finance, but commodifies and misses non-market values). The genuine progress indicator adjusts economic welfare for environmental and social costs (good for policy framing, weak on ecological thresholds). Each captures something the others miss; planetary boundaries are most scientifically defensible for limits, while footprint and GPI are more directly

actionable for communicating and steering policy. See section 40.

Appendix A — Curriculum Map

This appendix is generated from `src/biology/curriculum.py` and `src/biology/alignment.py`. It links each chapter to its companion lab, question bank, model/data skill, misconception probe, transfer task, and standards/skills alignment so the textbook can be composed into different course formats without losing pedagogical coherence.

Unit 0

— Systems Science and Emergence

- Chapter: section [0.1](#).
- Lab: [Lab A — Systems Science and Emergence](#).
- Question bank: [Questions — Systems Science and Emergence](#).
- Big idea: Biological explanation improves when parts, interactions, feedback, and scale are kept in view together.
- Core concepts: systems boundaries, feedback, emergence, state variables.
- Framework alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: Box-and-arrow causal models with explicit inputs, outputs, and feedback signs. Translate a verbal biological system into variables, links, and testable predictions.
- Misconception probe: A system is not just a list of parts; the interactions are part of the explanation.
- Transfer task: Apply the same feedback map to a cell, organism, and ecosystem, then name what changes at each scale.

— Complex Adaptive Systems

- Chapter: section [0.2](#).
- Lab: [Lab B — Complex Adaptive Systems](#).
- Question bank: [Questions — Complex Adaptive Systems](#).
- Big idea: Local rules can generate population-level patterns without a central controller.
- Core concepts: nonlinearity, self-organization, attractors, power laws.
- Framework alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: Agent-rule and scaling arguments for emergent biological patterns. Distinguish deterministic trends from stochastic variation in repeated simulations.
- Misconception probe: Emergence is not mysterious; it is a reproducible consequence of interactions plus constraints.
- Transfer task: Compare flocking, immune activation, and microbial biofilms as adaptive systems.

— Active Inference and Free Energy

- Chapter: section [0.3](#).
- Lab: [Lab C — Active Inference and Free Energy](#).
- Question bank: [Questions — Active Inference and Free Energy](#).
- Big idea: Living systems reduce uncertainty by acting on the world as well as by updating internal models.
- Core concepts: prediction error, Bayesian updating, policy selection, homeostasis.
- Framework alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: Bayesian belief updating and expected-free-energy-style policy comparison. Read a small probability table and update a prediction after new evidence.
- Misconception probe: Active inference is not passive prediction; action changes the sensory data that arrive next.
- Transfer task: Map prediction-error reasoning onto chemotaxis, thermoregulation, and attention.

— History and Philosophy of Biology

- Chapter: section [0.4](#).

- Lab: **Lab D — History and Philosophy of Biology.**
- Question bank: **Questions — History and Philosophy of Biology.**
- Big idea: Biology is a changing evidence practice: its concepts of life, function, species, inheritance, and self are revised by new observations, instruments, models, and social values.
- Core concepts: biological explanation, historical evidence, function, species concepts, values in science.
- Framework alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: Concept-map and evidence-matrix comparisons among historical claims, mechanisms, and model assumptions. Classify source excerpts as observation, experiment, model, mechanism, or value-laden inference.
- Misconception probe: History is not a list of dates; it explains why current biological concepts are powerful, limited, and revisable.
- Transfer task: Transfer source-analysis reasoning to modern debates about species, genetics, microbiomes, and biomedical ethics.

Unit I

— Atoms, Molecules, and Chemical Bonds

- Chapter: section 1.
- Lab: **Lab — Atoms, Molecules, and Chemical Bonds.**
- Question bank: **Questions — Atoms, Molecules, and Chemical Bonds.**
- Big idea: Atomic structure constrains the bonds, charges, and geometries that make biological molecules possible.
- Core concepts: valence, electronegativity, formal charge, isotopes.
- Framework alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.
- Practice cadence: Concept Explanation, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Formal charge and electronegativity-difference reasoning. Use tabular atomic data to predict polarity, solubility, and biological reactivity.
- Misconception probe: Weak interactions are not unimportant; many weak interactions together dominate structure and specificity.
- Transfer task: Use atomic reasoning to explain a medical tracer, enzyme cofactor, or membrane-solubility problem.

— Water — The Molecule of Life

- Chapter: section 2.
- Lab: **Lab — Water — The Molecule of Life.**
- Question bank: **Questions — Water — The Molecule of Life.**
- Big idea: Water's polarity, hydrogen bonding, and ionization make cells physically possible.
- Core concepts: hydrogen bonding, cohesion, pH, buffers.
- Framework alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.
- Practice cadence: Concept Explanation, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Henderson-Hasselbalch and pH-scale calculations. Convert between pH, hydrogen ion concentration, and buffer ratios.
- Misconception probe: Water is not an inert background; it is an active participant in structure and reaction chemistry.
- Transfer task: Transfer water-property reasoning to blood buffering, plant transport, or protein folding.

— Biological Macromolecules

- Chapter: section 3.
- Lab: **Lab — Biological Macromolecules.**
- Question bank: **Questions — Biological Macromolecules.**
- Big idea: Macromolecule structure links monomer chemistry to biological function and information storage.
- Core concepts: polymers, dehydration synthesis, protein structure, nucleic acids.
- Framework alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.
- Practice cadence: Concept Explanation, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Polymerization energetics and sequence-to-structure reasoning. Classify molecules from structural evidence rather than names alone.
- Misconception probe: Structure is not decoration; small chemical changes can redirect function and recognition.

- Transfer task: Explain how a mutation, lipid substitution, or glycosylation change propagates to phenotype.

— Enzymes and the Kinetics of Catalysis

- Chapter: section 4.
- Lab: Lab — Enzymes and the Kinetics of Catalysis.
- Question bank: Questions — Enzymes and the Kinetics of Catalysis.
- Big idea: Enzymes accelerate reactions by stabilizing transition states without changing thermodynamic endpoints.
- Core concepts: activation energy, Michaelis-Menten kinetics, inhibition, allostery.
- Framework alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.
- Practice cadence: Concept Explanation, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Michaelis-Menten, Lineweaver-Burk, and inhibition-pattern calculations. Fit or interpret enzyme-rate data and identify which parameter changed.
- Misconception probe: A catalyst changes rate, not the equilibrium constant or the sign of delta G.
- Transfer task: Apply enzyme-kinetic reasoning to drug dosing, metabolic control, or diagnostic assays.

Unit II

— Cell Theory and Cell Types

- Chapter: section 5.
- Lab: Lab — Cell Theory and Cell Types.
- Question bank: Questions — Cell Theory and Cell Types.
- Big idea: Cells are bounded, evolving systems whose size and organization reflect physical constraints.
- Core concepts: cell theory, surface area, microscopy, prokaryote/eukaryote comparison.
- Framework alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Questions and Methods, Argumentation.
- Model/data skill: Surface-area-to-volume scaling. Infer cellular constraints from measurements, micrographs, and scale bars.
- Misconception probe: Cells are not just small bags of fluid; boundaries and internal organization create function.
- Transfer task: Transfer scale reasoning to eggs, neurons, root hairs, and microbial colonies.

— Cell Structure and Organelles

- Chapter: section 6.
- Lab: Lab — Cell Structure and Organelles.
- Question bank: Questions — Cell Structure and Organelles.
- Big idea: Organelle structure partitions work, traffic, information, and energy inside eukaryotic cells.
- Core concepts: organelles, endomembrane system, cytoskeleton, motor proteins.
- Framework alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Questions and Methods, Argumentation.
- Model/data skill: Compartment-flow and motor-transport calculations. Trace a molecule through compartments using evidence from labels or perturbations.
- Misconception probe: Organelles are dynamic process hubs, not static textbook icons.
- Transfer task: Apply compartment logic to secretion, apoptosis, infection, or cell division.

— Membrane Structure and Transport

- Chapter: section 7.
- Lab: Lab — Membrane Structure and Transport.
- Question bank: Questions — Membrane Structure and Transport.
- Big idea: Membranes convert gradients, permeability, and selective transport into cellular physiology.
- Core concepts: bilayers, diffusion, osmosis, electrochemical gradients.

- Framework alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Questions and Methods, Argumentation.
- Model/data skill: Nernst, Goldman, osmotic, and facilitated-transport calculations. Interpret transport data from gradients, rates, and membrane potentials.
- Misconception probe: Equilibrium does not mean equal concentration; charge and permeability matter.
- Transfer task: Transfer gradient logic to neurons, kidneys, roots, and mitochondrial membranes.

— Cell Signaling and Communication

- Chapter: section 8.
- Lab: Lab — Cell Signaling and Communication.
- Question bank: Questions — Cell Signaling and Communication.
- Big idea: Cells communicate by converting external signals into regulated intracellular decisions.
- Core concepts: receptors, second messengers, signal amplification, feedback.
- Framework alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Questions and Methods, Argumentation.
- Model/data skill: Ligand-receptor occupancy and dose-response reasoning. Read pathway diagrams and infer the effect of agonists, antagonists, or mutations.
- Misconception probe: A pathway diagram is a causal model, not a memorization chart.
- Transfer task: Apply signaling logic to hormones, neurotransmitters, immune receptors, or cancer mutations.

Unit III

— Bioenergetics and Cellular Respiration

- Chapter: section 9.
- Lab: Lab — Bioenergetics and Cellular Respiration.
- Question bank: Questions — Bioenergetics and Cellular Respiration.
- Big idea: Cells harvest free energy by coupling redox chemistry to phosphoryl transfer and ion gradients.
- Core concepts: free energy, redox, glycolysis, oxidative phosphorylation.
- Framework alignment: Vision & Change: Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis.
- Model/data skill: Delta G, ATP yield, and electron-carrier accounting. Track carbon, electrons, and ATP across a pathway.
- Misconception probe: ATP is not stored energy in a vague sense; it is a coupling currency with defined reaction chemistry.
- Transfer task: Transfer energy accounting to exercise, fermentation, hypoxia, and mitochondrial disease.

— Photosynthesis

- Chapter: section 10.
- Lab: Lab — Photosynthesis.
- Question bank: Questions — Photosynthesis.
- Big idea: Photosynthesis couples light-driven electron flow to carbon fixation and planetary productivity.
- Core concepts: photosystems, electron transport, Calvin cycle, photorespiration.
- Framework alignment: Vision & Change: Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis.
- Model/data skill: Photon, ATP/NADPH, and Calvin-cycle stoichiometry. Interpret light-response and carbon-fixation data.
- Misconception probe: Plants do not eat sunlight; they use light energy to reduce carbon using electrons and enzymes.
- Transfer task: Transfer photosynthetic constraints to crops, algae, climate, or ecosystem productivity.

— Metabolic Integration and Regulation

- Chapter: section 11.
- Lab: Lab — Metabolic Integration and Regulation.
- Question bank: Questions — Metabolic Integration and Regulation.
- Big idea: Metabolism is a regulated network that reallocates flux across tissues, time, and nutrient states.
- Core concepts: flux, energy charge, hormonal control, fed/fasted states.
- Framework alignment: Vision & Change: Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis.
- Model/data skill: Energy charge, control points, and pathway-flux comparisons. Use pathway evidence to infer which metabolic state or tissue is active.
- Misconception probe: A pathway is not a one-way assembly line; reversibility and regulation define the real route.
- Transfer task: Apply metabolic network reasoning to diabetes, fasting, exercise, or cancer metabolism.

Unit IV

— DNA Replication and the Cell Cycle

- Chapter: section 12.
- Lab: Lab — DNA Replication and the Cell Cycle.
- Question bank: Questions — DNA Replication and the Cell Cycle.
- Big idea: Genome copying is accurate because chemistry, enzyme proofreading, and checkpoints cooperate.
- Core concepts: semiconservative replication, polymerase, proofreading, checkpoints.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.
- Practice cadence: Concept Explanation, Questions and Methods, Argumentation.
- Model/data skill: Replication-fork speed, error-rate, and cell-cycle timing calculations. Interpret replication or cell-cycle data from timing, labeling, or checkpoint perturbations.
- Misconception probe: High fidelity is not automatic; it is built from multiple partially redundant safeguards.
- Transfer task: Transfer replication logic to cancer, aging, viral replication, or antibiotic targets.

— Gene Expression

- Chapter: section 13.
- Lab: Lab — Gene Expression.
- Question bank: Questions — Gene Expression.
- Big idea: Gene expression translates sequence information into regulated RNA and protein products.
- Core concepts: transcription, translation, codons, RNA processing.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.
- Practice cadence: Concept Explanation, Questions and Methods, Argumentation.
- Model/data skill: Reading-frame, codon, and expression-output calculations. Convert DNA/RNA sequence data into predicted molecular products.
- Misconception probe: A gene is not simply a protein recipe; context controls when, where, and how much product appears.
- Transfer task: Apply expression logic to mutations, biotechnology, development, and disease diagnostics.

— Mutations, CRISPR, and Genomics

- Chapter: section 14.
- Lab: Lab — Mutations, CRISPR, and Genomics.
- Question bank: Questions — Mutations, CRISPR, and Genomics.
- Big idea: Genomic variation becomes biological consequence through sequence context, repair, and selection.
- Core concepts: mutation classes, DNA repair, CRISPR, genome analysis.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.
- Practice cadence: Concept Explanation, Questions and Methods, Argumentation.

- Model/data skill: Mutation-rate, edit-efficiency, and sequence-comparison calculations. Classify variants and predict likely molecular effect from sequence evidence.
- Misconception probe: Not every mutation is harmful, and not every harmful mutation changes a protein sequence.
- Transfer task: Transfer variant reasoning to cancer genomics, ancestry, gene therapy, or microbial evolution.

— Chromatin and Epigenetic Mechanisms

- Chapter: section 15.
- Lab: Lab — Chromatin and Epigenetic Mechanisms.
- Question bank: Questions — Chromatin and Epigenetic Mechanisms.
- Big idea: Cells create stable yet reversible expression states through chromatin, DNA marks, and regulatory circuits.
- Core concepts: chromatin, methylation, histone modification, enhancers.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.
- Practice cadence: Concept Explanation, Questions and Methods, Argumentation.
- Model/data skill: Regulatory-state and expression-ratio reasoning. Interpret chromatin or expression evidence from simple regulatory datasets.
- Misconception probe: Epigenetic does not mean independent of DNA sequence or permanently inherited.
- Transfer task: Apply regulation logic to differentiation, imprinting, cancer, or environmental responses.

— Epigenetic Inheritance and Disease

- Chapter: section 16.
- Lab: Lab — Epigenetic Inheritance and Disease.
- Question bank: Questions — Epigenetic Inheritance and Disease.
- Big idea: Three-dimensional genome organization and epigenetic inheritance link regulatory architecture to disease phenotypes.
- Core concepts: 3D genome, phase separation, imprinting, epigenetic inheritance.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.
- Practice cadence: Concept Explanation, Questions and Methods, Argumentation.
- Model/data skill: Chromatin-loop, inheritance, and disease-risk reasoning. Interpret Hi-C, imprinting, or transgenerational datasets with causal caution.
- Misconception probe: A chromatin contact map is not proof of function without perturbation.
- Transfer task: Apply inheritance logic to cancer, developmental disorders, and environmental exposure.

Unit V

— Mendelian Principles and Probability

- Chapter: section 17.
- Lab: Lab — Mendelian Principles and Probability.
- Question bank: Questions — Mendelian Principles and Probability.
- Big idea: Mendelian segregation and probability explain inheritance when alleles assort independently.
- Core concepts: segregation, independent assortment, Punnett squares, probability.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.
- Practice cadence: Statistical Tests and Data Analysis, Representing and Describing Data.
- Model/data skill: Punnett, binomial, and chi-square calculations. Use cross data to infer genotype probabilities.
- Misconception probe: Dominant does not mean common, stronger, or better.
- Transfer task: Transfer Mendelian probability to model organisms and introductory human genetics.

— Mendelian Extensions and Human Genetics

- Chapter: section 18.
- Lab: Lab — Mendelian Extensions and Human Genetics.
- Question bank: Questions — Mendelian Extensions and Human Genetics.
- Big idea: Extensions to Mendelian ratios and human pedigree analysis reveal when simple dominance fails.

- Core concepts: incomplete dominance, epistasis, pedigrees, penetrance.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.
- Practice cadence: Statistical Tests and Data Analysis, Representing and Describing Data.
- Model/data skill: Pedigree, epistasis, and multi-locus probability calculations. Infer inheritance mode and extension mechanism from family or cross data.
- Misconception probe: A single-gene model is a starting hypothesis, not the default for every trait.
- Transfer task: Transfer extension reasoning to counseling, GWAS interpretation, and breeding.

— Chromosomal Inheritance and Linkage

- Chapter: section 19.
- Lab: Lab — Chromosomal Inheritance and Linkage.
- Question bank: Questions — Chromosomal Inheritance and Linkage.
- Big idea: Genes travel on chromosomes, so linkage, recombination, and chromosome structure shape inheritance.
- Core concepts: linkage, recombination, sex linkage, chromosomal rearrangements.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.
- Practice cadence: Statistical Tests and Data Analysis, Representing and Describing Data.
- Model/data skill: Recombination frequency and three-point mapping. Infer gene order or chromosomal mechanism from offspring counts.
- Misconception probe: Independent assortment applies to unlinked loci, not to every pair of genes.
- Transfer task: Transfer linkage reasoning to disease mapping, breeding, and genome assemblies.

— Population Genetics

- Chapter: section 20.
- Lab: Lab — Population Genetics.
- Question bank: Questions — Population Genetics.
- Big idea: Allele frequencies change when assumptions about random mating, population size, and fitness are violated.
- Core concepts: Hardy-Weinberg, selection, mutation, genetic drift.
- Framework alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.
- Practice cadence: Statistical Tests and Data Analysis, Representing and Describing Data.
- Model/data skill: Hardy-Weinberg and allele-frequency recurrence calculations. Estimate genotype or allele frequencies from population data.
- Misconception probe: Hardy-Weinberg is a null model, not a claim that populations do not evolve.
- Transfer task: Apply population-genetic reasoning to screening, conservation, and pathogen evolution.

Unit VI

— Natural Selection and Adaptation

- Chapter: section 21.
- Lab: Lab — Natural Selection and Adaptation.
- Question bank: Questions — Natural Selection and Adaptation.
- Big idea: Natural selection is differential reproductive success acting on heritable variation in context.
- Core concepts: variation, fitness, adaptation, selection coefficient.
- Framework alignment: Vision & Change: Evolution, Systems; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Natural Selection and Evolution, Interdependent Relationships in Ecosystems.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Selection coefficient and allele-frequency trajectory calculations. Interpret fitness data and distinguish selection from other forces.
- Misconception probe: Evolution is not goal-directed progress; it is local change in populations under constraints.
- Transfer task: Transfer selection reasoning to antibiotics, pesticide resistance, cancer, or climate adaptation.

— Genetic Drift, Gene Flow, and Speciation

- Chapter: section 22.

- Lab: **Lab — Genetic Drift, Gene Flow, and Speciation.**
- Question bank: **Questions — Genetic Drift, Gene Flow, and Speciation.**
- Big idea: Chance, population structure, and barriers to gene flow can generate divergence even without adaptive change.
- Core concepts: drift, effective population size, gene flow, speciation.
- Framework alignment: Vision & Change: Evolution, Systems; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Natural Selection and Evolution, Interdependent Relationships in Ecosystems.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Fixation probability, effective population size, and migration-selection balance. Distinguish stochastic from directional change in allele-frequency data.
- Misconception probe: Random does not mean patternless; stochastic processes have predictable distributions.
- Transfer task: Apply drift reasoning to endangered populations, founder effects, and island radiations.

— **Phylogenetics and the Tree of Life**

- Chapter: section **23.**
- Lab: **Lab — Phylogenetics and the Tree of Life.**
- Question bank: **Questions — Phylogenetics and the Tree of Life.**
- Big idea: Phylogenies are evidence-based hypotheses about ancestry, not ladders of progress.
- Core concepts: homology, tree topology, parsimony, molecular clocks.
- Framework alignment: Vision & Change: Evolution, Systems; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Natural Selection and Evolution, Interdependent Relationships in Ecosystems.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Tree-distance, parsimony, and molecular-clock calculations. Read trees correctly and map traits or sequences onto branches.
- Misconception probe: Living species are cousins, not ancestors of one another.
- Transfer task: Transfer tree thinking to pathogens, conservation units, gene families, and development.

Unit VII

— **Bacteria, Archaea, and Viruses**

- Chapter: section **24.**
- Lab: **Lab — Bacteria, Archaea, and Viruses.**
- Question bank: **Questions — Bacteria, Archaea, and Viruses.**
- Big idea: Microbial diversity reflects different cell architectures, genomes, metabolisms, and evolutionary histories.
- Core concepts: prokaryotic structure, archaea, viruses, horizontal gene transfer.
- Framework alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: Growth-rate, genome-size, and dilution calculations. Interpret microbial observations from growth, sequence, or structural evidence.
- Misconception probe: Viruses are not simply tiny bacteria; they use fundamentally different replication logic.
- Transfer task: Apply microbial diversity reasoning to antibiotics, biotechnology, ecology, and outbreaks.

— **Microbial Ecology and the Microbiome**

- Chapter: section **25.**
- Lab: **Lab — Microbial Ecology and the Microbiome.**
- Question bank: **Questions — Microbial Ecology and the Microbiome.**
- Big idea: Microbes organize communities, cycles, and host physiology through interactions and metabolism.
- Core concepts: microbiomes, symbiosis, diversity, biogeochemical cycling.
- Framework alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: Diversity indices, richness estimates, and interaction-network reasoning. Compute or interpret community metrics from abundance data.
- Misconception probe: A microbiome is not automatically beneficial; context determines the effect.

- Transfer task: Transfer microbial ecology to soils, oceans, digestion, disease, and climate feedbacks.

— Host Immunity and Vaccines

- Chapter: section 26.
- Lab: [Lab — Host Immunity and Vaccines](#).
- Question bank: [Questions — Host Immunity and Vaccines](#).
- Big idea: Host immunity and vaccination reshape pathogen transmission by changing susceptible fractions.
- Core concepts: innate immunity, adaptive immunity, vaccination, herd immunity.
- Framework alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: Herd-immunity threshold and basic immunological reasoning. Interpret antibody, cellular, and vaccine-response evidence.
- Misconception probe: Immunity is not binary; timing, dose, and variant matter.
- Transfer task: Transfer immunity reasoning to outbreak response and clinical decision-making.

— Antimicrobial Resistance and Epidemiology

- Chapter: section 27.
- Lab: [Lab — Antimicrobial Resistance and Epidemiology](#).
- Question bank: [Questions — Antimicrobial Resistance and Epidemiology](#).
- Big idea: Antimicrobial resistance and epidemic dynamics emerge from pathogen evolution and transmission networks.
- Core concepts: antibiotic resistance, R_0 , transmission, surveillance.
- Framework alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.
- Practice cadence: Questions and Methods, Representing and Describing Data, Argumentation.
- Model/data skill: R_0 , resistance-mechanism, and outbreak-trajectory calculations. Interpret resistance assays and outbreak curves.
- Misconception probe: R_0 is not a fixed property of a pathogen alone; it depends on host behavior and environment.
- Transfer task: Transfer resistance and epidemiology reasoning to stewardship and public-health policy.

Unit VIII

— Plant Structure and Water Relations

- Chapter: section 28.
- Lab: [Lab — Plant Structure and Water Relations](#).
- Question bank: [Questions — Plant Structure and Water Relations](#).
- Big idea: Plant form is an engineering solution to water movement, support, gas exchange, and growth.
- Core concepts: xylem, phloem, water potential, transpiration.
- Framework alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Structure and Function, Matter and Energy in Organisms and Ecosystems.
- Practice cadence: Visual Representations, Questions and Methods, Argumentation.
- Model/data skill: Water-potential and transpiration-flux calculations. Interpret plant-water data from pressure, solute, and humidity measurements.
- Misconception probe: Water does not move because plants pull with intention; it follows potential gradients and cohesion.
- Transfer task: Transfer plant-water reasoning to drought, irrigation, forest physiology, and crop breeding.

— Plant Reproduction and Development

- Chapter: section 29.
- Lab: [Lab — Plant Reproduction and Development](#).
- Question bank: [Questions — Plant Reproduction and Development](#).
- Big idea: Plant reproduction integrates life cycles, development, dispersal, and environmental timing.
- Core concepts: alternation of generations, flowers, seeds, development.
- Framework alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Structure and Function, Matter and Energy in Organisms and Ecosystems.

- Practice cadence: Visual Representations, Questions and Methods, Argumentation.
- Model/data skill: Life-cycle accounting and phyllotaxis/growth-pattern calculations. Track ploidy, tissue origin, and reproductive stage from diagrams or observations.
- Misconception probe: Pollen, spores, seeds, and gametes are not interchangeable terms.
- Transfer task: Transfer reproductive reasoning to agriculture, pollination ecology, and plant evolution.

— Plant Responses to the Environment

- Chapter: section 30.
- Lab: Lab — Plant Responses to the Environment.
- Question bank: Questions — Plant Responses to the Environment.
- Big idea: Plants sense environmental signals and respond through growth, hormones, and physiological regulation.
- Core concepts: tropisms, hormones, photoperiodism, stress responses.
- Framework alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Structure and Function, Matter and Energy in Organisms and Ecosystems.
- Practice cadence: Visual Representations, Questions and Methods, Argumentation.
- Model/data skill: Dose-response, water-use-efficiency, and hormone-interaction reasoning. Interpret plant response data across light, gravity, water, and hormone treatments.
- Misconception probe: A plant response is not passive; plants actively regulate development and physiology without neurons.
- Transfer task: Transfer response logic to shade avoidance, drought, flowering, and crop management.

Unit IX

— Circulation and Respiration

- Chapter: section 31.
- Lab: Lab — Circulation and Respiration.
- Question bank: Questions — Circulation and Respiration.
- Big idea: Animal transport systems maintain gradients that let cells exchange gases, nutrients, heat, and wastes.
- Core concepts: cardiac output, gas exchange, homeostasis, feedback.
- Framework alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Cardiac-output, diffusion, oxygen-saturation, and feedback calculations. Interpret physiological data from pressure, flow, saturation, or set-point changes.
- Misconception probe: Homeostasis is dynamic regulation, not an unchanging internal state.
- Transfer task: Transfer homeostatic reasoning to exercise, altitude, hemorrhage, fever, and shock.

— Nervous System and Neural Signaling

- Chapter: section 32.
- Lab: Lab — Nervous System and Neural Signaling.
- Question bank: Questions — Nervous System and Neural Signaling.
- Big idea: Nervous systems compute with cells whose structure shapes information flow and behavior.
- Core concepts: neurons, glia, circuits, sensory processing.
- Framework alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Cable-length, conduction, and simple circuit calculations. Interpret neural data from anatomy, timing, or lesion evidence.
- Misconception probe: The brain is not only neurons; glia and circuit context are essential to function.
- Transfer task: Transfer circuit reasoning to reflexes, sensory systems, learning, and disease.

— Action Potentials and Synaptic Transmission

- Chapter: section 33.

- Lab: **Lab — Action Potentials and Synaptic Transmission.**
- Question bank: **Questions — Action Potentials and Synaptic Transmission.**
- Big idea: Electrical excitability and synaptic transmission convert ion gradients into rapid communication.
- Core concepts: action potentials, ion channels, synapses, plasticity.
- Framework alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Nernst/Goldman, Hodgkin-Huxley, and synaptic-current reasoning. Interpret voltage traces, conductance changes, and synaptic perturbations.
- Misconception probe: An action potential is not electricity flowing like a wire; it is regenerated ion-channel dynamics.
- Transfer task: Transfer excitability reasoning to anesthesia, toxins, epilepsy, and neuromuscular disease.

— Endocrine Signaling and Homeostasis

- Chapter: section 34.
- Lab: **Lab — Endocrine Signaling and Homeostasis.**
- Question bank: **Questions — Endocrine Signaling and Homeostasis.**
- Big idea: Hormone feedback loops coordinate long-range physiological homeostasis.
- Core concepts: hormones, feedback, receptors, homeostasis.
- Framework alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Hormone feedback and dose-response reasoning. Interpret endocrine time courses, panels, and perturbations.
- Misconception probe: A hormone surge is not always pathological; context and set-point matter.
- Transfer task: Transfer endocrine reasoning to metabolism, stress, and development.

— Immune System Architecture

- Chapter: section 35.
- Lab: **Lab — Immune System Architecture.**
- Question bank: **Questions — Immune System Architecture.**
- Big idea: Innate and adaptive immunity integrate recognition, effector function, tolerance, and memory.
- Core concepts: innate immunity, adaptive immunity, tolerance, immunotherapy.
- Framework alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.
- Practice cadence: Visual Representations, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Immune-memory, cytokine, and recognition reasoning. Interpret immune titers, cytokine profiles, or perturbation data.
- Misconception probe: Immunity is not just attack; recognition, tolerance, memory, and regulation are equally central.
- Transfer task: Transfer immunity reasoning to vaccination, autoimmunity, infection, and cancer therapy.

Unit X

— Population Ecology and Growth Models

- Chapter: section 36.
- Lab: **Lab — Population Ecology and Growth Models.**
- Question bank: **Questions — Population Ecology and Growth Models.**
- Big idea: Population change reflects births, deaths, movement, age structure, and density dependence.
- Core concepts: exponential growth, logistic growth, life tables, population viability.
- Framework alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Exponential/logistic growth, mark-recapture, and matrix projection. Use abundance or age-structure data to estimate growth and risk.
- Misconception probe: Carrying capacity is not a fixed magic number; it changes with resources, interactions, and disturbance.

- Transfer task: Transfer population models to fisheries, invasive species, epidemiology, and endangered species.

— Community Interactions and Succession

- Chapter: section 37.
- Lab: [Lab — Community Interactions and Succession](#).
- Question bank: [Questions — Community Interactions and Succession](#).
- Big idea: Communities are structured by pairwise species interactions and successional change.
- Core concepts: competition, predation, mutualism, succession.
- Framework alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Lotka-Volterra-style interaction reasoning. Interpret abundance, interaction, or disturbance data from communities.
- Misconception probe: A species interaction is not permanently good or bad; the sign can change with context.
- Transfer task: Transfer interaction reasoning to restoration, agriculture, and invasion biology.

— Biodiversity and Food Webs

- Chapter: section 38.
- Lab: [Lab — Biodiversity and Food Webs](#).
- Question bank: [Questions — Biodiversity and Food Webs](#).
- Big idea: Biodiversity patterns, food webs, and island biogeography scale from local interactions to landscape structure.
- Core concepts: food webs, keystone species, species-area, diversity indices.
- Framework alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Shannon, species-area, and network connectance reasoning. Interpret food-web, richness, or biogeography datasets.
- Misconception probe: Richness alone does not equal functional stability.
- Transfer task: Transfer biodiversity reasoning to conservation planning and habitat fragmentation.

— Ecosystem Ecology

- Chapter: section 39.
- Lab: [Lab — Ecosystem Ecology](#).
- Question bank: [Questions — Ecosystem Ecology](#).
- Big idea: Ecosystems couple energy flow and matter cycling across organisms, environments, and time.
- Core concepts: primary productivity, trophic efficiency, nutrient cycles, decomposition.
- Framework alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Energy-flow, productivity, and nutrient-budget calculations. Trace matter and energy through food webs and biogeochemical cycles.
- Misconception probe: Energy flows through ecosystems, but matter cycles; confusing the two breaks many explanations.
- Transfer task: Transfer ecosystem reasoning to eutrophication, carbon budgets, agriculture, and climate feedback.

— Biomes and Conservation Biology

- Chapter: section 40.
- Lab: [Lab — Biomes and Conservation Biology](#).
- Question bank: [Questions — Biomes and Conservation Biology](#).
- Big idea: Biodiversity patterns and conservation decisions emerge from climate, history, disturbance, and human choice.
- Core concepts: biomes, biodiversity, extinction risk, conservation planning.

- Framework alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.
- Practice cadence: Representing and Describing Data, Statistical Tests and Data Analysis, Argumentation.
- Model/data skill: Species-area, risk, and prioritization calculations. Use maps, trend data, and threat categories to justify conservation priorities.
- Misconception probe: Conservation is decision-making under constraints and uncertainty, not only preserving untouched nature.
- Transfer task: Transfer conservation reasoning to land use, climate corridors, restoration, and environmental justice.

Appendix B — Instructor Orchestration Guide

This appendix is generated from the same curriculum and alignment records that populate chapter Study Blueprints. It gives instructors a compact sequence for turning the textbook into lectures, labs, quizzes, and transfer tasks without hand-rebuilding a course map.

Reusable Teaching Loop

1. Launch from a phenomenon. Begin with a case, dataset, model failure, or observed pattern that makes the chapter question necessary.
2. Model the mechanism. Ask students to draw, compute, simulate, or annotate the causal structure before reading the full explanation.
3. Gather evidence. Use the companion lab as the measurement and reproducibility surface for the chapter.
4. Check transfer. Use the question bank to sample recall, application, data interpretation, and argumentation.
5. Close the loop. Return to the transfer task and require a claim, evidence, reasoning, and uncertainty statement.

Chapter Orchestration Matrix

Unit 0

— Systems Science and Emergence

- Core thread: Use systems diagrams, uncertainty, and feedback as recurring sense-making tools.
- Instructor move: Launch from a phenomenon, have students model it with Box-and-arrow causal models with explicit inputs, outputs, and feedback signs, then test the model through data.
- Formative check: Ask students to translate a verbal biological system into variables, links, and testable predictions and then answer: given a biological scenario, identify the system boundary, feedback loop, and missing measurement.
- Summative product: Apply the same feedback map to a cell, organism, and ecosystem, then name what changes at each scale.
- Lab/question pair: **Lab A — Systems Science and Emergence; Questions — Systems Science and Emergence.**
- External alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

— Complex Adaptive Systems

- Core thread: Use systems diagrams, uncertainty, and feedback as recurring sense-making tools.
- Instructor move: Launch from a phenomenon, have students model it with Agent-rule and scaling arguments for emergent biological patterns, then test the model through data.
- Formative check: Ask students to distinguish deterministic trends from stochastic variation in repeated simulations and then answer: explain an observed population pattern from individual-level rules and identify one falsifiable prediction.
- Summative product: Compare flocking, immune activation, and microbial biofilms as adaptive systems.
- Lab/question pair: **Lab B — Complex Adaptive Systems; Questions — Complex Adaptive Systems.**
- External alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

— Active Inference and Free Energy

- Core thread: Use systems diagrams, uncertainty, and feedback as recurring sense-making tools.
- Instructor move: Launch from a phenomenon, have students model it with Bayesian belief updating and expected-free-energy-style policy comparison, then test the model through data.
- Formative check: Ask students to read a small probability table and update a prediction after new evidence and then answer: calculate a posterior belief and explain what action would reduce uncertainty or restore a set point.
- Summative product: Map prediction-error reasoning onto chemotaxis, thermoregulation, and attention.
- Lab/question pair: **Lab C — Active Inference and Free Energy; Questions — Active Inference and Free Energy.**
- External alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

— History and Philosophy of Biology

- Core thread: Use systems diagrams, uncertainty, and feedback as recurring sense-making tools.
- Instructor move: Launch from a phenomenon, have students model it with Concept-map and evidence-matrix comparisons among historical claims, mechanisms, and model assumptions, then test the model through data.

- Formative check: Ask students to classify source excerpts as observation, experiment, model, mechanism, or value-laden inference and then answer: given a biological claim, identify the practice that produced it, the evidence standard it used, and one philosophical assumption it carries.
- Summative product: Transfer source-analysis reasoning to modern debates about species, genetics, microbiomes, and biomedical ethics.
- Lab/question pair: **Lab D — History and Philosophy of Biology; Questions — History and Philosophy of Biology.**
- External alignment: Vision & Change: Systems, Structure and function; AP Biology: Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

Unit I

— Atoms, Molecules, and Chemical Bonds

- Core thread: Connect chemical structure, water, polymers, and catalysis to biological mechanism.
- Instructor move: Launch from a phenomenon, have students model it with Formal charge and electronegativity-difference reasoning, then test the model through data.
- Formative check: Ask students to use tabular atomic data to predict polarity, solubility, and biological reactivity and then answer: predict bond polarity, formal charge, or isotope behavior and connect it to a biological consequence.
- Summative product: Use atomic reasoning to explain a medical tracer, enzyme cofactor, or membrane-solubility problem.
- Lab/question pair: **Lab — Atoms, Molecules, and Chemical Bonds; Questions — Atoms, Molecules, and Chemical Bonds.**
- External alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.

— Water — The Molecule of Life

- Core thread: Connect chemical structure, water, polymers, and catalysis to biological mechanism.
- Instructor move: Launch from a phenomenon, have students model it with Henderson-Hasselbalch and pH-scale calculations, then test the model through data.
- Formative check: Ask students to convert between pH, hydrogen ion concentration, and buffer ratios and then answer: calculate a pH or buffer ratio and interpret what it means for a biological system.
- Summative product: Transfer water-property reasoning to blood buffering, plant transport, or protein folding.
- Lab/question pair: **Lab — Water — The Molecule of Life; Questions — Water — The Molecule of Life.**
- External alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.

— Biological Macromolecules

- Core thread: Connect chemical structure, water, polymers, and catalysis to biological mechanism.
- Instructor move: Launch from a phenomenon, have students model it with Polymerization energetics and sequence-to-structure reasoning, then test the model through data.
- Formative check: Ask students to classify molecules from structural evidence rather than names alone and then answer: given a molecular feature, infer likely solubility, interaction partners, or cellular role.
- Summative product: Explain how a mutation, lipid substitution, or glycosylation change propagates to phenotype.
- Lab/question pair: **Lab — Biological Macromolecules; Questions — Biological Macromolecules.**
- External alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.

— Enzymes and the Kinetics of Catalysis

- Core thread: Connect chemical structure, water, polymers, and catalysis to biological mechanism.
- Instructor move: Launch from a phenomenon, have students model it with Michaelis-Menten, Lineweaver-Burk, and inhibition-pattern calculations, then test the model through data.
- Formative check: Ask students to fit or interpret enzyme-rate data and identify which parameter changed and then answer: infer V_{max} , K_m , or inhibition type from data and justify the mechanistic interpretation.
- Summative product: Apply enzyme-kinetic reasoning to drug dosing, metabolic control, or diagnostic assays.
- Lab/question pair: **Lab — Enzymes and the Kinetics of Catalysis; Questions — Enzymes and the Kinetics of Catalysis.**

- External alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems, Structure and Function.

Unit II

— Cell Theory and Cell Types

- Core thread: Revisit boundaries, compartments, and signals as causal models of cellular work.
- Instructor move: Launch from a phenomenon, have students model it with Surface-area-to-volume scaling, then test the model through data.
- Formative check: Ask students to infer cellular constraints from measurements, micrographs, and scale bars and then answer: use size or microscopy evidence to classify a cell and predict a constraint on exchange.
- Summative product: Transfer scale reasoning to eggs, neurons, root hairs, and microbial colonies.
- Lab/question pair: **Lab — Cell Theory and Cell Types; Questions — Cell Theory and Cell Types.**
- External alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.

— Cell Structure and Organelles

- Core thread: Revisit boundaries, compartments, and signals as causal models of cellular work.
- Instructor move: Launch from a phenomenon, have students model it with Compartment-flow and motor-transport calculations, then test the model through data.
- Formative check: Ask students to trace a molecule through compartments using evidence from labels or perturbations and then answer: predict which organelle or cytoskeletal process is disrupted from a phenotype.
- Summative product: Apply compartment logic to secretion, apoptosis, infection, or cell division.
- Lab/question pair: **Lab — Cell Structure and Organelles; Questions — Cell Structure and Organelles.**
- External alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.

— Membrane Structure and Transport

- Core thread: Revisit boundaries, compartments, and signals as causal models of cellular work.
- Instructor move: Launch from a phenomenon, have students model it with Nernst, Goldman, osmotic, and facilitated-transport calculations, then test the model through data.
- Formative check: Ask students to interpret transport data from gradients, rates, and membrane potentials and then answer: calculate or predict ion movement and explain which force dominates.
- Summative product: Transfer gradient logic to neurons, kidneys, roots, and mitochondrial membranes.
- Lab/question pair: **Lab — Membrane Structure and Transport; Questions — Membrane Structure and Transport.**
- External alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.

— Cell Signaling and Communication

- Core thread: Revisit boundaries, compartments, and signals as causal models of cellular work.
- Instructor move: Launch from a phenomenon, have students model it with Ligand-receptor occupancy and dose-response reasoning, then test the model through data.
- Formative check: Ask students to read pathway diagrams and infer the effect of agonists, antagonists, or mutations and then answer: predict the outcome of perturbing one pathway component and justify the causal chain.
- Summative product: Apply signaling logic to hormones, neurotransmitters, immune receptors, or cancer mutations.
- Lab/question pair: **Lab — Cell Signaling and Communication; Questions — Cell Signaling and Communication.**
- External alignment: Vision & Change: Structure and function, Systems, Information flow, exchange, and storage; AP Biology: Systems Interactions, Information Storage and Transmission; NGSS-style topics: Structure and Function.

Unit III

— Bioenergetics and Cellular Respiration

- Core thread: Track matter, electrons, and free energy through pathways and ecosystems.
- Instructor move: Launch from a phenomenon, have students model it with Delta G, ATP yield, and electron-carrier accounting, then test the model through data.
- Formative check: Ask students to track carbon, electrons, and ATP across a pathway and then answer: calculate an energy yield or redox consequence and connect it to cellular work.
- Summative product: Transfer energy accounting to exercise, fermentation, hypoxia, and mitochondrial disease.
- Lab/question pair: [Lab — Bioenergetics and Cellular Respiration](#); [Questions — Bioenergetics and Cellular Respiration](#).
- External alignment: Vision & Change: Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems.

— Photosynthesis

- Core thread: Track matter, electrons, and free energy through pathways and ecosystems.
- Instructor move: Launch from a phenomenon, have students model it with Photon, ATP/NADPH, and Calvin-cycle stoichiometry, then test the model through data.
- Formative check: Ask students to interpret light-response and carbon-fixation data and then answer: compute carbon-fixation requirements and explain a limiting factor.
- Summative product: Transfer photosynthetic constraints to crops, algae, climate, or ecosystem productivity.
- Lab/question pair: [Lab — Photosynthesis](#); [Questions — Photosynthesis](#).
- External alignment: Vision & Change: Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems.

— Metabolic Integration and Regulation

- Core thread: Track matter, electrons, and free energy through pathways and ecosystems.
- Instructor move: Launch from a phenomenon, have students model it with Energy charge, control points, and pathway-flux comparisons, then test the model through data.
- Formative check: Ask students to use pathway evidence to infer which metabolic state or tissue is active and then answer: predict how a change in substrate, hormone, or enzyme activity redirects flux.
- Summative product: Apply metabolic network reasoning to diabetes, fasting, exercise, or cancer metabolism.
- Lab/question pair: [Lab — Metabolic Integration and Regulation](#); [Questions — Metabolic Integration and Regulation](#).
- External alignment: Vision & Change: Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Matter and Energy in Organisms and Ecosystems.

Unit IV

— DNA Replication and the Cell Cycle

- Core thread: Connect sequence, regulation, genome integrity, and phenotype through evidence.
- Instructor move: Launch from a phenomenon, have students model it with Replication-fork speed, error-rate, and cell-cycle timing calculations, then test the model through data.
- Formative check: Ask students to interpret replication or cell-cycle data from timing, labeling, or checkpoint perturbations and then answer: calculate replication timing or error burden and infer checkpoint consequences.
- Summative product: Transfer replication logic to cancer, aging, viral replication, or antibiotic targets.
- Lab/question pair: [Lab — DNA Replication and the Cell Cycle](#); [Questions — DNA Replication and the Cell Cycle](#).
- External alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.

— Gene Expression

- Core thread: Connect sequence, regulation, genome integrity, and phenotype through evidence.
- Instructor move: Launch from a phenomenon, have students model it with Reading-frame, codon, and expression-output calculations, then test the model through data.
- Formative check: Ask students to convert DNA/RNA sequence data into predicted molecular products and then answer: translate or annotate a sequence and explain how a regulatory change alters output.

- Summative product: Apply expression logic to mutations, biotechnology, development, and disease diagnostics.
- Lab/question pair: **Lab — Gene Expression; Questions — Gene Expression.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.

— Mutations, CRISPR, and Genomics

- Core thread: Connect sequence, regulation, genome integrity, and phenotype through evidence.
- Instructor move: Launch from a phenomenon, have students model it with Mutation-rate, edit-efficiency, and sequence-comparison calculations, then test the model through data.
- Formative check: Ask students to classify variants and predict likely molecular effect from sequence evidence and then answer: predict the impact of a variant and justify the evidence needed to validate it.
- Summative product: Transfer variant reasoning to cancer genomics, ancestry, gene therapy, or microbial evolution.
- Lab/question pair: **Lab — Mutations, CRISPR, and Genomics; Questions — Mutations, CRISPR, and Genomics.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.

— Chromatin and Epigenetic Mechanisms

- Core thread: Connect sequence, regulation, genome integrity, and phenotype through evidence.
- Instructor move: Launch from a phenomenon, have students model it with Regulatory-state and expression-ratio reasoning, then test the model through data.
- Formative check: Ask students to interpret chromatin or expression evidence from simple regulatory datasets and then answer: explain how a regulatory mark changes accessibility and predict downstream expression.
- Summative product: Apply regulation logic to differentiation, imprinting, cancer, or environmental responses.
- Lab/question pair: **Lab — Chromatin and Epigenetic Mechanisms; Questions — Chromatin and Epigenetic Mechanisms.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.

— Epigenetic Inheritance and Disease

- Core thread: Connect sequence, regulation, genome integrity, and phenotype through evidence.
- Instructor move: Launch from a phenomenon, have students model it with Chromatin-loop, inheritance, and disease-risk reasoning, then test the model through data.
- Formative check: Ask students to interpret Hi-C, imprinting, or transgenerational datasets with causal caution and then answer: explain how 3D organization or inherited marks alter expression and disease risk.
- Summative product: Apply inheritance logic to cancer, developmental disorders, and environmental exposure.
- Lab/question pair: **Lab — Epigenetic Inheritance and Disease; Questions — Epigenetic Inheritance and Disease.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Structure and function; AP Biology: Information Storage and Transmission, Systems Interactions; NGSS-style topics: Inheritance and Variation of Traits, Structure and Function.

Unit V

— Mendelian Principles and Probability

- Core thread: Use probability and population reasoning to connect inheritance to evolution.
- Instructor move: Launch from a phenomenon, have students model it with Punnett, binomial, and chi-square calculations, then test the model through data.
- Formative check: Ask students to use cross data to infer genotype probabilities and then answer: compute a genetic probability or chi-square result and explain the biological assumption.
- Summative product: Transfer Mendelian probability to model organisms and introductory human genetics.
- Lab/question pair: **Lab — Mendelian Principles and Probability; Questions — Mendelian Principles and Probability.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.

— Mendelian Extensions and Human Genetics

- Core thread: Use probability and population reasoning to connect inheritance to evolution.
- Instructor move: Launch from a phenomenon, have students model it with Pedigree, epistasis, and multi-locus probability calculations, then test the model through data.
- Formative check: Ask students to infer inheritance mode and extension mechanism from family or cross data and then answer: use pedigree or extension evidence to justify an inheritance diagnosis.
- Summative product: Transfer extension reasoning to counseling, GWAS interpretation, and breeding.
- Lab/question pair: **Lab — Mendelian Extensions and Human Genetics; Questions — Mendelian Extensions and Human Genetics.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.

— Chromosomal Inheritance and Linkage

- Core thread: Use probability and population reasoning to connect inheritance to evolution.
- Instructor move: Launch from a phenomenon, have students model it with Recombination frequency and three-point mapping, then test the model through data.
- Formative check: Ask students to infer gene order or chromosomal mechanism from offspring counts and then answer: use progeny classes to calculate map distances and infer the most likely gene order.
- Summative product: Transfer linkage reasoning to disease mapping, breeding, and genome assemblies.
- Lab/question pair: **Lab — Chromosomal Inheritance and Linkage; Questions — Chromosomal Inheritance and Linkage.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.

— Population Genetics

- Core thread: Use probability and population reasoning to connect inheritance to evolution.
- Instructor move: Launch from a phenomenon, have students model it with Hardy-Weinberg and allele-frequency recurrence calculations, then test the model through data.
- Formative check: Ask students to estimate genotype or allele frequencies from population data and then answer: calculate expected frequencies and identify which evolutionary force could explain deviations.
- Summative product: Apply population-genetic reasoning to screening, conservation, and pathogen evolution.
- Lab/question pair: **Lab — Population Genetics; Questions — Population Genetics.**
- External alignment: Vision & Change: Information flow, exchange, and storage, Evolution; AP Biology: Information Storage and Transmission, Evolution; NGSS-style topics: Inheritance and Variation of Traits, Natural Selection and Evolution.

Unit VI

— Natural Selection and Adaptation

- Core thread: Return to variation, evidence, and historical inference across evolutionary scales.
- Instructor move: Launch from a phenomenon, have students model it with Selection coefficient and allele-frequency trajectory calculations, then test the model through data.
- Formative check: Ask students to interpret fitness data and distinguish selection from other forces and then answer: estimate selection strength from data and explain why the result is context dependent.
- Summative product: Transfer selection reasoning to antibiotics, pesticide resistance, cancer, or climate adaptation.
- Lab/question pair: **Lab — Natural Selection and Adaptation; Questions — Natural Selection and Adaptation.**
- External alignment: Vision & Change: Evolution, Systems; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Natural Selection and Evolution, Interdependent Relationships in Ecosystems.

— Genetic Drift, Gene Flow, and Speciation

- Core thread: Return to variation, evidence, and historical inference across evolutionary scales.
- Instructor move: Launch from a phenomenon, have students model it with Fixation probability, effective population size, and migration-selection balance, then test the model through data.

- Formative check: Ask students to distinguish stochastic from directional change in allele-frequency data and then answer: predict how population size or isolation changes divergence and fixation risk.
- Summative product: Apply drift reasoning to endangered populations, founder effects, and island radiations.
- Lab/question pair: **Lab — Genetic Drift, Gene Flow, and Speciation; Questions — Genetic Drift, Gene Flow, and Speciation.**
- External alignment: Vision & Change: Evolution, Systems; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Natural Selection and Evolution, Interdependent Relationships in Ecosystems.

— Phylogenetics and the Tree of Life

- Core thread: Return to variation, evidence, and historical inference across evolutionary scales.
- Instructor move: Launch from a phenomenon, have students model it with Tree-distance, parsimony, and molecular-clock calculations, then test the model through data.
- Formative check: Ask students to read trees correctly and map traits or sequences onto branches and then answer: use a tree to infer shared ancestry, character transitions, or divergence time.
- Summative product: Transfer tree thinking to pathogens, conservation units, gene families, and development.
- Lab/question pair: **Lab — Phylogenetics and the Tree of Life; Questions — Phylogenetics and the Tree of Life.**
- External alignment: Vision & Change: Evolution, Systems; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Natural Selection and Evolution, Interdependent Relationships in Ecosystems.

Unit VII

— Bacteria, Archaea, and Viruses

- Core thread: Use microbes to integrate evolution, ecology, host response, and public decisions.
- Instructor move: Launch from a phenomenon, have students model it with Growth-rate, genome-size, and dilution calculations, then test the model through data.
- Formative check: Ask students to interpret microbial observations from growth, sequence, or structural evidence and then answer: classify a microbe or virus from evidence and predict a likely vulnerability.
- Summative product: Apply microbial diversity reasoning to antibiotics, biotechnology, ecology, and outbreaks.
- Lab/question pair: **Lab — Bacteria, Archaea, and Viruses; Questions — Bacteria, Archaea, and Viruses.**
- External alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

— Microbial Ecology and the Microbiome

- Core thread: Use microbes to integrate evolution, ecology, host response, and public decisions.
- Instructor move: Launch from a phenomenon, have students model it with Diversity indices, richness estimates, and interaction-network reasoning, then test the model through data.
- Formative check: Ask students to compute or interpret community metrics from abundance data and then answer: use community data to infer diversity, dominance, and a plausible ecological mechanism.
- Summative product: Transfer microbial ecology to soils, oceans, digestion, disease, and climate feedbacks.
- Lab/question pair: **Lab — Microbial Ecology and the Microbiome; Questions — Microbial Ecology and the Microbiome.**
- External alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

— Host Immunity and Vaccines

- Core thread: Use microbes to integrate evolution, ecology, host response, and public decisions.
- Instructor move: Launch from a phenomenon, have students model it with Herd-immunity threshold and basic immunological reasoning, then test the model through data.
- Formative check: Ask students to interpret antibody, cellular, and vaccine-response evidence and then answer: predict how immunity or vaccination changes individual and population risk.
- Summative product: Transfer immunity reasoning to outbreak response and clinical decision-making.
- Lab/question pair: **Lab — Host Immunity and Vaccines; Questions — Host Immunity and Vaccines.**

- External alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

— Antimicrobial Resistance and Epidemiology

- Core thread: Use microbes to integrate evolution, ecology, host response, and public decisions.
- Instructor move: Launch from a phenomenon, have students model it with R0, resistance-mechanism, and outbreak-trajectory calculations, then test the model through data.
- Formative check: Ask students to interpret resistance assays and outbreak curves and then answer: calculate a threshold or outbreak trajectory and identify the intervention lever.
- Summative product: Transfer resistance and epidemiology reasoning to stewardship and public-health policy.
- Lab/question pair: [Lab — Antimicrobial Resistance and Epidemiology](#); [Questions — Antimicrobial Resistance and Epidemiology](#).
- External alignment: Vision & Change: Evolution, Systems, Structure and function; AP Biology: Evolution, Systems Interactions; NGSS-style topics: Structure and Function, Interdependent Relationships in Ecosystems.

Unit VIII

— Plant Structure and Water Relations

- Core thread: Read plant form as an engineered compromise among transport, energy, and reproduction.
- Instructor move: Launch from a phenomenon, have students model it with Water-potential and transpiration-flux calculations, then test the model through data.
- Formative check: Ask students to interpret plant-water data from pressure, solute, and humidity measurements and then answer: calculate water potential and predict the direction of water movement.
- Summative product: Transfer plant-water reasoning to drought, irrigation, forest physiology, and crop breeding.
- Lab/question pair: [Lab — Plant Structure and Water Relations](#); [Questions — Plant Structure and Water Relations](#).
- External alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Structure and Function, Matter and Energy in Organisms and Ecosystems.

— Plant Reproduction and Development

- Core thread: Read plant form as an engineered compromise among transport, energy, and reproduction.
- Instructor move: Launch from a phenomenon, have students model it with Life-cycle accounting and phyllotaxis/growth-pattern calculations, then test the model through data.
- Formative check: Ask students to track ploidy, tissue origin, and reproductive stage from diagrams or observations and then answer: trace a plant life cycle and predict the consequence of disrupting one stage.
- Summative product: Transfer reproductive reasoning to agriculture, pollination ecology, and plant evolution.
- Lab/question pair: [Lab — Plant Reproduction and Development](#); [Questions — Plant Reproduction and Development](#).
- External alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Structure and Function, Matter and Energy in Organisms and Ecosystems.

— Plant Responses to the Environment

- Core thread: Read plant form as an engineered compromise among transport, energy, and reproduction.
- Instructor move: Launch from a phenomenon, have students model it with Dose-response, water-use-efficiency, and hormone-interaction reasoning, then test the model through data.
- Formative check: Ask students to interpret plant response data across light, gravity, water, and hormone treatments and then answer: predict a plant response from a signal and identify the likely hormone or pathway.
- Summative product: Transfer response logic to shade avoidance, drought, flowering, and crop management.
- Lab/question pair: [Lab — Plant Responses to the Environment](#); [Questions — Plant Responses to the Environment](#).
- External alignment: Vision & Change: Structure and function, Pathways and transformations of energy and matter, Systems; AP Biology: Energetics, Systems Interactions; NGSS-style topics: Structure and Function, Matter and Energy in Organisms and Ecosystems.

Unit IX

— Circulation and Respiration

- Core thread: Spiral homeostasis from organ systems to neural, endocrine, and immune decisions.
- Instructor move: Launch from a phenomenon, have students model it with Cardiac-output, diffusion, oxygen-saturation, and feedback calculations, then test the model through data.
- Formative check: Ask students to interpret physiological data from pressure, flow, saturation, or set-point changes and then answer: calculate a transport or feedback variable and explain the compensatory response.
- Summative product: Transfer homeostatic reasoning to exercise, altitude, hemorrhage, fever, and shock.
- Lab/question pair: **Lab — Circulation and Respiration; Questions — Circulation and Respiration.**
- External alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.

— Nervous System and Neural Signaling

- Core thread: Spiral homeostasis from organ systems to neural, endocrine, and immune decisions.
- Instructor move: Launch from a phenomenon, have students model it with Cable-length, conduction, and simple circuit calculations, then test the model through data.
- Formative check: Ask students to interpret neural data from anatomy, timing, or lesion evidence and then answer: predict behavioral or signal consequences from a circuit or structural perturbation.
- Summative product: Transfer circuit reasoning to reflexes, sensory systems, learning, and disease.
- Lab/question pair: **Lab — Nervous System and Neural Signaling; Questions — Nervous System and Neural Signaling.**
- External alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.

— Action Potentials and Synaptic Transmission

- Core thread: Spiral homeostasis from organ systems to neural, endocrine, and immune decisions.
- Instructor move: Launch from a phenomenon, have students model it with Nernst/Goldman, Hodgkin-Huxley, and synaptic-current reasoning, then test the model through data.
- Formative check: Ask students to interpret voltage traces, conductance changes, and synaptic perturbations and then answer: predict how changing an ion gradient or channel conductance alters excitability.
- Summative product: Transfer excitability reasoning to anesthesia, toxins, epilepsy, and neuromuscular disease.
- Lab/question pair: **Lab — Action Potentials and Synaptic Transmission; Questions — Action Potentials and Synaptic Transmission.**
- External alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.

— Endocrine Signaling and Homeostasis

- Core thread: Spiral homeostasis from organ systems to neural, endocrine, and immune decisions.
- Instructor move: Launch from a phenomenon, have students model it with Hormone feedback and dose-response reasoning, then test the model through data.
- Formative check: Ask students to interpret endocrine time courses, panels, and perturbations and then answer: predict the consequence of changing a hormone, receptor, or axis set-point.
- Summative product: Transfer endocrine reasoning to metabolism, stress, and development.
- Lab/question pair: **Lab — Endocrine Signaling and Homeostasis; Questions — Endocrine Signaling and Homeostasis.**
- External alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.

— Immune System Architecture

- Core thread: Spiral homeostasis from organ systems to neural, endocrine, and immune decisions.
- Instructor move: Launch from a phenomenon, have students model it with Immune-memory, cytokine, and recognition reasoning, then test the model through data.
- Formative check: Ask students to interpret immune titers, cytokine profiles, or perturbation data and then answer: predict the consequence of changing an antigen, cell population, or checkpoint.

- Summative product: Transfer immunity reasoning to vaccination, autoimmunity, infection, and cancer therapy.
- Lab/question pair: **Lab — Immune System Architecture; Questions — Immune System Architecture.**
- External alignment: Vision & Change: Structure and function, Systems; AP Biology: Systems Interactions, Energetics; NGSS-style topics: Structure and Function.

Unit X

— Population Ecology and Growth Models

- Core thread: Use ecological models to connect populations, interactions, matter, climate, and decisions.
- Instructor move: Launch from a phenomenon, have students model it with Exponential/logistic growth, mark-recapture, and matrix projection, then test the model through data.
- Formative check: Ask students to use abundance or age-structure data to estimate growth and risk and then answer: calculate a growth or sampling parameter and interpret its conservation meaning.
- Summative product: Transfer population models to fisheries, invasive species, epidemiology, and endangered species.
- Lab/question pair: **Lab — Population Ecology and Growth Models; Questions — Population Ecology and Growth Models.**
- External alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.

— Community Interactions and Succession

- Core thread: Use ecological models to connect populations, interactions, matter, climate, and decisions.
- Instructor move: Launch from a phenomenon, have students model it with Lotka-Volterra-style interaction reasoning, then test the model through data.
- Formative check: Ask students to interpret abundance, interaction, or disturbance data from communities and then answer: predict how changing one species or resource alters community structure.
- Summative product: Transfer interaction reasoning to restoration, agriculture, and invasion biology.
- Lab/question pair: **Lab — Community Interactions and Succession; Questions — Community Interactions and Succession.**
- External alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.

— Biodiversity and Food Webs

- Core thread: Use ecological models to connect populations, interactions, matter, climate, and decisions.
- Instructor move: Launch from a phenomenon, have students model it with Shannon, species-area, and network connectance reasoning, then test the model through data.
- Formative check: Ask students to interpret food-web, richness, or biogeography datasets and then answer: calculate a diversity or species-area metric and interpret its ecological meaning.
- Summative product: Transfer biodiversity reasoning to conservation planning and habitat fragmentation.
- Lab/question pair: **Lab — Biodiversity and Food Webs; Questions — Biodiversity and Food Webs.**
- External alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.

— Ecosystem Ecology

- Core thread: Use ecological models to connect populations, interactions, matter, climate, and decisions.
- Instructor move: Launch from a phenomenon, have students model it with Energy-flow, productivity, and nutrient-budget calculations, then test the model through data.
- Formative check: Ask students to trace matter and energy through food webs and biogeochemical cycles and then answer: calculate a flux or efficiency and explain which pool or process limits the system.
- Summative product: Transfer ecosystem reasoning to eutrophication, carbon budgets, agriculture, and climate feedback.
- Lab/question pair: **Lab — Ecosystem Ecology; Questions — Ecosystem Ecology.**

- External alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.

— Biomes and Conservation Biology

- Core thread: Use ecological models to connect populations, interactions, matter, climate, and decisions.
- Instructor move: Launch from a phenomenon, have students model it with Species-area, risk, and prioritization calculations, then test the model through data.
- Formative check: Ask students to use maps, trend data, and threat categories to justify conservation priorities and then answer: evaluate a conservation scenario using evidence, tradeoffs, and uncertainty.
- Summative product: Transfer conservation reasoning to land use, climate corridors, restoration, and environmental justice.
- Lab/question pair: **Lab — Biomes and Conservation Biology; Questions — Biomes and Conservation Biology.**
- External alignment: Vision & Change: Systems, Evolution, Pathways and transformations of energy and matter; AP Biology: Systems Interactions, Evolution, Energetics; NGSS-style topics: Interdependent Relationships in Ecosystems, Matter and Energy in Organisms and Ecosystems, Natural Selection and Evolution.

Appendix C — Mathematical Review for Biology

Appendix C — Mathematical Review for Biology · Level 1/3 · 45 min read · Prerequisites: none · Use as reference

This appendix collects the mathematics a reader needs to work through the quantitative chapters of this textbook. It is not a course in mathematics — it is a compact reference for the specific tools used in the chapters. Each section is self-contained; dip in as needed.

C.1 Logarithms and the Natural Log

Definition

$$\log_b(x) = y \iff b^y = x$$

(485)

Biology uses two bases heavily:

- Base 10 (\log_{10}) — pH, sound intensity, earthquake magnitude, powers-of-ten units (nM, μ M, mM).
- Base e (ln, natural log) — most first-order kinetics (exponential growth, decay, enzyme kinetics), where $e \approx 2.71828$.

Conversion: $\log_{10}(x) = \ln(x)/\ln(10) \approx \ln(x)/2.303$.

Key identities

Identity	Biological application
$\log(ab) = \log a + \log b$	Combining probabilities across linked loci
$\log(a/b) = \log a - \log b$	Henderson-Hasselbalch $\text{pH} = \text{p}K_a + \log([\text{A}^-]/[\text{HA}])$
$\log(a^n) = n \log a$	Hill equation — slope in log-log plot
$\log_b(b^x) = x$	Inverting exponential growth: $t = \ln(N/N_0)/r$

Worked example — doubling time

A bacterial culture grows at $r = 0.5 \text{ h}^{-1}$. When does the population double?

$$N(t) = N_0e^{rt} = 2N_0 \implies e^{rt} = 2 \implies t = \frac{\ln 2}{r} = \frac{0.693}{0.5} \approx 1.39 \text{ h}$$

(486)

The “ln 2 trick” recurs throughout biology: half-life $t_{1/2} = \ln 2/k$ (decay); doubling time $t_d = \ln 2/r$ (growth). Memorise $\ln 2 \approx 0.693$.

C.2 Differential and Integral Calculus

Biology rarely requires advanced calculus, but the reader must be comfortable with:

Derivatives as rates

$$\frac{dN}{dt} = \text{rate of change of } N \text{ over time}$$

(487)

In population ecology, $dN/dt > 0$ means the population is growing; $dN/dt = 0$ is equilibrium; $dN/dt < 0$ is decline. In enzyme kinetics, $d[P]/dt =$ reaction velocity v .

Integration as accumulation

$$\int_0^T \frac{dN}{dt} dt = N(T) - N(0)$$

(488)

The integral sums up infinitesimal contributions. Examples:

- Total drug dose delivered by an infusion: $\text{Dose} = \int_0^T (\text{infusion rate}) dt$.

- Net photosynthesis over a day: $\int_0^{24\text{h}} P(t)dt$.

First-order ODE: exponential growth and decay

$$\frac{dN}{dt} = kN \implies N(t) = N_0 e^{kt}$$

(489)

- $k > 0$: growth with doubling time $t_d = \ln 2/k$.
- $k < 0$: decay with half-life $t_{1/2} = \ln 2/|k|$.

Logistic growth (nonlinear)

$$\frac{dN}{dt} = rN \left(1 - \frac{N}{K}\right)$$

(490)

The closed-form solution is:

$$N(t) = \frac{K}{1 + \left(\frac{K-N_0}{N_0}\right)e^{-rt}}$$

(491)

Inflection (maximum rate) at $N = K/2$, giving the sigmoid shape.

C.3 Basic Probability

Independent events

$P(A \cap B) = P(A) \cdot P(B)$ when events are independent. Example: the probability that both parents transmit the recessive allele at a locus ($Aa \times Aa$) is $(1/2)(1/2) = 1/4$.

Conditional probability and Bayes’ theorem

$$P(A \mid B) = \frac{P(A \cap B)}{P(B)}$$

(492)

Bayes’ theorem — central to section 0.3 and to medical testing:

$$P(\text{disease} \mid +) = \frac{P(+ \mid \text{disease}) \cdot P(\text{disease})}{P(+)}$$

(493)

A highly sensitive test can still have a low positive predictive value if the disease is rare — a counterintuitive result with major clinical consequences.

Binomial distribution

Number of successes in n independent trials, each with probability p :

$$P(k \text{ successes}) = \binom{n}{k} p^k (1 - p)^{n-k}$$

(494)

Used for Punnett-square ratios, mark-recapture statistics, and Hardy-Weinberg proportion testing.

Poisson distribution

For rare events at mean rate λ per interval:

$$P(k) = \frac{\lambda^k e^{-\lambda}}{k!}$$

(495)

Used for spontaneous mutation counts per locus, bacterial cell counts in Petri dishes (when plates are not overgrown), rare-disease incidence.

C.4 Dimensional Analysis

Every physical quantity carries units. Units must balance on both sides of every equation — if they don’t, the equation is wrong.

Example — diffusion distance

Fick’s rule for mean diffusion distance:

$$x = \sqrt{2Dt}$$

(496)

Check units: D has units of $\text{m}^2 \text{ s}^{-1}$; t has units of s ; so $\sqrt{2Dt}$ has units of $\sqrt{\text{m}^2} = \text{m}$. ✓

If a student wrote $x = Dt$, units would be $\text{m}^2 \text{ s}^{-1} \cdot \text{s} = \text{m}^2$ — dimensionally wrong.

Standard SI units used in this book

Quantity	Symbol	SI unit	Typical biological magnitude
Length	l	m	cell: 10 μm ; neuron: 1 m
Mass	m	kg	ribosome: 3×10^{-21} kg; cell: 10^{-12} kg
Time	t	s	AP: 1 ms; cell cycle: 24 h
Amount	n	mol	ATP in a cell: 10^{-15} mol
Concentration	$[X]$	$\text{mol L}^{-1} = \text{M}$	cytoplasmic ATP: 5×10^{-3} M
Energy	E	J	ATP hydrolysis: 5×10^{-20} J per molecule, $\approx 30.5 \text{ kJ mol}^{-1}$
Force	F	N	myosin step force: 5×10^{-12} N = 5 pN
Electric potential	V	V	resting membrane: $-0.07 \text{ V} = -70 \text{ mV}$

Non-SI units common in biology

Unit	SI equivalent	Use
mmHg (Torr)	133.322 Pa	blood pressure, gas partial pressures
cal	4.184 J	nutrition (“Calorie” = kcal)
pH unit	$-\log_{10}[\text{H}^+]$ in M	acidity
Da (dalton)	1.661×10^{-27} kg	molecular mass
Kelvin (K)	$^{\circ}\text{C} + 273.15$	thermodynamics requires K, not $^{\circ}\text{C}$

C.5 Linear Algebra Miniature

Primarily trace knowledge is required for this book, but the two ideas below recur.

Matrices as transitions

Allele-frequency change under migration between two populations is a 2×2 matrix multiplication. Markov transition matrices describe stochastic gene expression (lac operon), state transitions in ion channels, and Wright-Fisher drift.

Eigenvalues and equilibrium

The dominant eigenvalue λ_1 of a Leslie matrix equals the long-term finite rate of increase. Eigenvectors give the stable age distribution. This is the formal underpinning of section 36’s demographic analysis.

C.6 Common Pitfalls in Biological Math

1. Confusing concentration and amount. 1 nM is a concentration; 1 nmol is an amount. A picomole of hormone in 5 L of blood is 0.2 pM.
2. Units of rate constants. First-order: s⁻¹. Second-order: M⁻¹ s⁻¹. Third-order: M⁻² s⁻¹. Dimensional analysis typically exposes an order-of-magnitude error.
3. Exponents and prefixes. Milli- (10⁻³), micro- (10⁻⁶), nano- (10⁻⁹), pico- (10⁻¹²), femto- (10⁻¹⁵), atto- (10⁻¹⁸). Shifting by three orders of magnitude is common in biology; single errors are catastrophic.
4. Logarithmic vs linear differences. A tenfold change in [H⁺] is a one-pH-unit change. “Twice the acidity” means 0.3 pH unit down, not 2 pH units.
5. Error propagation. Small errors in input variables compound through multi-step calculations. The textbook flags this at thermodynamics, kinetics, and evolutionary rate estimation in particular.

C.7 Key Equations Quick Reference

These equations recur throughout the textbook. Each entry gives the equation, the variable definitions, and the chapter where it first appears.

Michaelis-Menten equation

$$v = \frac{V_{\max}[S]}{K_m + [S]}$$

(497)

- v = reaction velocity (mol L⁻¹ s⁻¹); V_{\max} = maximum velocity; $[S]$ = substrate concentration; K_m = substrate concentration at half-maximal velocity.
- When $[S] = K_m$, $v = V_{\max}/2$. At $[S] \ll K_m$, $v \approx (V_{\max}/K_m)[S]$ (first-order). At $[S] \gg K_m$, $v \approx V_{\max}$ (zero-order).
- Competitive inhibitor raises apparent K_m by factor $(1 + [I]/K_i)$; V_{\max} unchanged.
- First appears in section 4.

Hill equation (cooperative binding)

$$\theta = \frac{[L]^n}{K_d^n + [L]^n}$$

(498)

- θ = fractional saturation; $[L]$ = ligand concentration; K_d = dissociation constant at half-maximal saturation; n = Hill coefficient (cooperativity).
- $n = 1$: independent (Michaelis-Menten-like, hyperbolic). $n > 1$: positive cooperativity (sigmoidal, switch-like). $n < 1$: negative cooperativity.
- Hemoglobin: $n \approx 2.8$, $K_d \approx 26$ mmHg (P50). Phosphofructokinase-1: $n \approx 4$ for fructose-6-phosphate.
- Switch sharpness: fold-change in θ from $0.1K_d$ to $10K_d$ is 100^n ; for $n = 1$ this is 100-fold; for $n = 4$ it is 10⁸-fold — explaining why cooperative enzymes function as on/off switches.
- First appears in section 4.

Nernst equation

$$E_{ion} = \frac{RT}{zF} \ln \frac{[X]_o}{[X]_i}$$

(499)

- E_{ion} = equilibrium (reversal) potential for the ion; $R = 8.314$ J mol⁻¹ K⁻¹; T = temperature in K; z = ion valence (charge); $F = 96485$ C mol⁻¹; $[X]_o/[X]_i$ = extracellular/intracellular concentration ratio.
- At 37°C: $RT/F \approx 26.7$ mV, so $E_{ion} \approx (26.7/z) \ln([X]_o/[X]_i)$ mV.
- For Na⁺ ($z = +1$, $[Na]_o/[Na]_i \approx 145/12$): $E_{Na} \approx +67$ mV. For K⁺ ($z = +1$, $[K]_o/[K]_i \approx 5/140$): $E_K \approx -90$ mV.
- First appears in section 33.

Goldman-Hodgkin-Katz equation

$$V_m = \frac{RT}{F} \ln \frac{P_K[K]_o + P_{Na}[Na]_o + P_{Cl}[Cl]_i}{P_K[K]_i + P_{Na}[Na]_i + P_{Cl}[Cl]_o}$$

(500)

- Extends the Nernst equation when multiple ions contribute. P_K, P_{Na}, P_{Cl} = membrane permeabilities. At rest: $P_K : P_{Na} : P_{Cl} \approx 1 : 0.04 : 0.45$, giving $V_m \approx -70$ mV.
- During action potential peak: P_{Na} rises 500-fold, shifting V_m toward E_{Na} .
- First appears in section 33.

Henderson-Hasselbalch equation

$$\text{pH} = \text{p}K_a + \log_{10} \frac{[A^-]}{[HA]}$$

(501)

- $[A^-]$ = conjugate base concentration; $[HA]$ = weak acid concentration.
- At $\text{pH} = \text{p}K_a$: $[A^-]/[HA] = 1$ (half-dissociated). Bicarbonate buffer: $\text{p}K_a = 6.1$; at $\text{pH } 7.4$, $[HCO_3^-]/[CO_2] \approx 20$.
- Buffer capacity is greatest within ± 1 pH unit of $\text{p}K_a$.
- First appears in section 1.

Water potential

$$\Psi = \Psi_s + \Psi_p$$

(502)

- Ψ = total water potential (MPa); Ψ_s = solute (osmotic) potential (≤ 0); Ψ_p = pressure potential (turgor; can be positive or negative).
- Water moves from high to low Ψ . Wilted cell: $\Psi_p \approx 0$, $\Psi = \Psi_s < 0$. Turgid cell: $\Psi_p > 0$ partially offsets Ψ_s .
- Xylem tension: $\Psi_p < 0$ (negative pressure) drives cohesion-tension in tall trees.
- First appears in section 28.

Appendix D — Units, Physical Constants, and Biological Ranges

Appendix D — Units, Physical Constants, and Biological Ranges · Level 1/3 · 20 min read · Prerequisites: none · Use as reference

A compact reference for units, constants, and characteristic magnitudes encountered throughout the textbook. Use it during worked problems to sanity-check dimensional analysis, convert between unit systems, and verify that numerical answers fall in biologically plausible ranges.

D.1 SI Base and Derived Units

Quantity	SI unit	Symbol	In base units
Length	meter	m	—
Mass	kilogram	kg	—
Time	second	s	—
Amount of substance	mole	mol	—
Temperature	kelvin	K	—
Electric current	ampere	A	—
Force	newton	N	$\text{kg} \cdot \text{m} \cdot \text{s}^{-2}$
Energy	joule	J	$\text{kg} \cdot \text{m}^2 \cdot \text{s}^{-2}$
Power	watt	W	$\text{J} \cdot \text{s}^{-1}$
Pressure	pascal	Pa	$\text{N} \cdot \text{m}^{-2}$
Electric charge	coulomb	C	$\text{A} \cdot \text{s}$
Electric potential	volt	V	$\text{J} \cdot \text{C}^{-1}$
Electric conductance	siemens	S	Ω^{-1}
Frequency	hertz	Hz	s^{-1}

Metric prefixes

Prefix	Symbol	Factor	Biological use
giga-	G	10^9	Gb base pairs in a genome
mega-	M	10^6	MDa protein complex; Mb DNA fragment
kilo-	k	10^3	kJ mol^{-1} (ΔG); kDa protein mass
centi-	c	10^{-2}	cM genetic map distance
milli-	m	10^{-3}	mM intracellular metabolites; ms AP duration
micro-	μ	10^{-6}	μm cell size; μM low-abundance metabolite
nano-	n	10^{-9}	nm bond length; nM receptor ligand
pico-	p	10^{-12}	pN molecular motor force; pM low-abundance hormone
femto-	f	10^{-15}	fmol amount in a single cell
atto-	a	10^{-18}	amol; approaches single-molecule detection

D.2 Universal Physical Constants

Constant	Symbol	Value
Avogadro’s number	N_A	$6.022 \times 10^{23} \text{ mol}^{-1}$
Boltzmann constant	k_B	$1.381 \times 10^{-23} \text{ J K}^{-1} = 8.617 \times 10^{-5} \text{ eV K}^{-1}$
Gas constant	$R = N_A k_B$	$8.314 \text{ J K}^{-1} \text{ mol}^{-1} = 1.987 \text{ cal K}^{-1} \text{ mol}^{-1}$
Faraday constant	F	$9.649 \times 10^4 \text{ C mol}^{-1}$
Elementary charge	e	$1.602 \times 10^{-19} \text{ C}$

Constant	Symbol	Value
Speed of light in vacuum	c	$2.998 \times 10^8 \text{ m s}^{-1}$
Planck constant	h	$6.626 \times 10^{-34} \text{ J s}$
Permittivity of free space	ϵ_0	$8.854 \times 10^{-12} \text{ F m}^{-1}$
Standard atmospheric pressure	P_{atm}	$101,325 \text{ Pa} = 760 \text{ Torr}$
Body temperature	T_{body}	$310.15 \text{ K} = 37.00 \text{ }^\circ\text{C}$
Thermal energy at body T	$k_B T$	$4.28 \times 10^{-21} \text{ J} \approx 0.027 \text{ eV} = 2.57 \text{ kJ mol}^{-1}$

The rule “ $k_B T \approx \frac{1}{40} \text{ eV} \approx \frac{2.5}{1000} \text{ kJ mol}^{-1}$ at room temperature” is useful: hydrogen bonds (about 20 kJ mol^{-1}) are about $8 k_B T$, so they survive thermal fluctuations; van der Waals contacts (about 1 kJ mol^{-1}) are about $0.4 k_B T$, so each one is barely stable but collectively numerous contacts summate.

D.3 Energy Conversions

From	To	Factor
1 J	cal	0.239
1 cal	J	4.184
1 kcal	kJ	4.184
1 eV	J	1.602×10^{-19}
1 eV	kJ mol ^{−1}	96.485
1 kJ mol ^{−1}	eV	0.01036
1 J	kg·m ² s ^{−2}	1 (definition)
1 $k_B T$ at 37 °C	kJ mol ^{−1}	2.577

ATP hydrolysis benchmarks

- Standard ΔG° for $\text{ATP} \rightarrow \text{ADP} + \text{P}_i$: $-30.5 \text{ kJ mol}^{-1}$.
- Cellular ΔG (physiological $[\text{ATP}]/[\text{ADP}]$): -57 kJ mol^{-1} , roughly $22 k_B T$.
- Number of ATP hydrolyses required to lift a 1 kg mass 1 m: about 300,000 — illustrating why muscle needs 10^8 ATP molecules consumed per second.

D.4 Pressure Conversions

From	To	Factor
1 atm	Pa	101,325
1 atm	mmHg (Torr)	760
1 atm	bar	1.01325
1 mmHg	kPa	0.1333
1 mmHg	Pa	133.322

Blood pressure: systolic 120 mmHg \approx 16 kPa. Arterial O₂: $P_a\text{O}_2 \approx 100 \text{ mmHg} \approx 13.3 \text{ kPa}$. Venous O₂: $P_v\text{O}_2 \approx 40 \text{ mmHg} \approx 5.3 \text{ kPa}$.

D.5 Concentration Conversions

1 molar (M) = 1 mol L^{−1} = 10³ mmol L^{−1} = 10⁶ μmol L^{−1} = 10⁹ nmol L^{−1} = 10¹² pmol L^{−1}.

Concentration	Example
pM (10 ^{−12} M)	Circulating hormones (insulin, oxytocin)

Concentration	Example
nM (10^{-9} M)	Vitamin B ₁₂ , transcription factor at a target site
μ M (10^{-6} M)	Glucose in blood (5×10^{-3} M = 5 mM, upper end)
mM (10^{-3} M)	Major intracellular ions (Na ⁺ , K ⁺), ATP (about 5 mM)
M	Cytoplasm water (55 M); seawater NaCl (0.5 M)

Molarity of water: $M_{H_2O} = 1000 \text{ g L}^{-1} / 18 \text{ g mol}^{-1} = 55.5 \text{ M}$. This is why [H₂O] is treated as constant in biological equilibrium expressions.

D.6 Biological Magnitudes — Quick Reference

Time scales

Event	Time
Bond vibration	10^{-14} s
Enzyme turnover (k_{cat})	$10^{-3} - 10^{-6}$ s
Action potential	10^{-3} s
Synaptic transmission	10^{-3} s
Ribosome peptide-bond formation	0.1 s (5 aa s ⁻¹ per ribosome)
Protein folding	$10^{-3} - 1$ s
Mitosis	1 h
Cell cycle (dividing human cell)	1 d
Hair growth	1 cm month ⁻¹
Human generation time	about 25 yr
Mammalian species lifespan	$10^6 - 10^7$ yr

Length scales

Feature	Size
C–C bond	0.15 nm
Protein (average globular)	3 nm
Ribosome	25 nm
Virus (small RNA)	30 nm
Nuclear pore	100 nm
Bacterium (<i>E. coli</i>)	1 μ m
Mitochondrion	2 μ m
Eukaryotic cell (average)	10–20 μ m
Neuron axon (giraffe recurrent laryngeal)	2 m
Animal (blue whale)	30 m
Redwood tree	100 m

Energy scales

Interaction / event	Energy
Van der Waals contact	about 1 kJ mol ⁻¹
Hydrogen bond	about 20 kJ mol ⁻¹
C–C covalent bond	about 350 kJ mol ⁻¹
ATP hydrolysis (standard)	–30.5 kJ mol ⁻¹

Interaction / event	Energy
ATP hydrolysis (cellular)	−57 kJ mol ^{−1}
Glucose complete oxidation	−2870 kJ mol ^{−1}
Photosynthesis per photon (680 nm)	176 kJ mol ^{−1}
Daily human basal energy	7000 kJ d ^{−1} (≈1700 kcal d ^{−1})

Organismal physiology reference scales

System	Useful scale	Source-backed context
Digestive absorption	Small-intestinal villi and microvilli expand absorptive surface	Nutrient uptake depends on epithelial surface area, enzymes, bile, transporters, and gut motility [National Institute of Diabetes and Digestive and Kidney Diseases, 2024a].
Renal excretion	Adult kidneys filter plasma continuously and adjust urine concentration	Filtration, tubular reabsorption, secretion, and collecting-duct water handling set volume, electrolyte, pH, and nitrogen-waste balance [National Institute of Diabetes and Digestive and Kidney Diseases, 2024b].
Skeletal muscle	Sarcomere force depends on actin-myosin overlap and cross-bridge cycling	Sliding-filament physiology links molecular geometry to organismal movement [Huxley and Hanson, 1954].
Somatosensation	Receptor density sets spatial resolution	Mechanoreceptor subtype, receptive-field size, and cortical magnification jointly shape touch discrimination [Abraira and Ginty, 2013].
Behavior	Four explanatory levels	Mechanism, development, function, and phylogeny answer different questions about the same behavior [Tinbergen, 1963].
Reproduction	Infertility triage starts after 12 months, or 6 months at age 35+	Evaluation separates ovulation, sperm production, anatomy, implantation, endocrine timing, and age-dependent gamete quality [Centers for Disease Control and Prevention, 2024b].

D.7 Fundamental Biological Constants

Parameter	Value	Source / context
Resting cell membrane potential	≈ −70 mV	Neurons, muscle cells
Intracellular [Na ⁺] / [K ⁺]	about 10 / 140 mM	Maintained by Na ⁺ /K ⁺ -ATPase
Extracellular [Na ⁺] / [K ⁺]	about 145 / 5 mM	Plasma
Blood pH	7.35–7.45	Tightly regulated
Arterial pCO ₂	about 40 mmHg	Regulated by respiration
Body-water content	60 % of body mass	Total body water
Hemoglobin O ₂ capacity	1.34 mL O ₂ / g Hb	Full saturation
Blood volume	about 5 L in adult	7 % of body mass
Body surface area (adult)	about 1.8 m ²	DuBois formula
Mitochondrial membrane potential	≈ −180 mV	Drives ATP synthesis
Proton gradient ΔpH across inner mito membrane	about 1 unit	Chemiosmosis
Genome size (human)	3 × 10 ⁹ bp	Haploid
Protein-coding genes (human)	about 20,000	ENCODE estimate
Cells in the adult human body	about 3.7 × 10 ¹³	Bianconi et al. 2013
Bacteria in human gut	about 10 ¹⁴	about equal to human cell count
Species described on Earth	about 2 × 10 ⁶	Estimated 10–30× more undescribed

Appendix E — A Periodic Table for Biology

Appendix E · Level 1/3 · 15 min read · Prerequisites: section 1

Only about 25 of the 118 known elements are biologically essential. This appendix summarizes what each essential element does, what the classic pathologies of deficiency and excess look like, and where to encounter each in the textbook.

E.1 The Six Bulk Elements (CHNOPS)

Together these account for about 99 % of a human’s mass.

Element	Symbol	about % body mass	Where	Biological role
Oxygen	O	65 %	water, organic molecules	Electron acceptor in respiration; H-bond acceptor; part of every major biomolecule
Carbon	C	18 %	organic biomolecules, CO ₂ /HCO ₃ [−] pools	Tetravalent backbone of proteins, carbohydrates, lipids, and nucleic acids (see section 1)
Hydrogen	H	10 %	water and most organic biomolecules	Partner in polar bonds; proton transfer; pH
Nitrogen	N	3 %	amino acids, nucleic acids, ATP	Codes the backbone of DNA/RNA; amide in peptide bond; ring atom in bases
Phosphorus	P	1 %	DNA/RNA backbone, ATP, phospholipids	Phosphodiester bonds; free-energy carrier (ATP); membrane structure
Sulfur	S	0.25 %	cysteine, methionine, CoA, Fe-S	Disulfide bridges in proteins; thioester bonds in metabolism

E.2 Essential Macro-Minerals (Electrolytes + Osteogenics)

Element	Symbol	Common form	Role	Deficiency	Excess
Sodium	Na	Na ⁺	Principal extracellular cation; action potential upstroke	Hyponatraemia → seizures	Hypernatraemia → dehydration
Potassium	K	K ⁺	Principal intracellular cation; resting potential	Hypokalaemia → arrhythmia, muscle weakness	Hyperkalaemia → cardiac arrest
Calcium	Ca	Ca ²⁺	Bone matrix; signaling; coagulation; muscle contraction	Hypocalcaemia → tetany	Hypercalcaemia → stones, constipation

Element	Symbol	Common form	Role	Deficiency	Excess
Magnesium	Mg	Mg ²⁺	ATP co-factor; enzyme cofactor; ribosome structure	Hypomagnesaemia → arrhythmia, tetany	Rare; laxative effect
Chloride	Cl	Cl ⁻	Major anion; gastric HCl; GABA-A/glycine receptors	Loss with vomiting	Acidosis
Phosphate	P	HPO ₄ ²⁻	Energy transfer (ATP); DNA backbone; bone mineralisation	Muscle weakness	Soft tissue calcification (CKD)
Sulfate	S	SO ₄ ²⁻	Sulfated proteoglycans; sulfation of xenobiotics	Rare isolated deficiency	Rare

E.3 Trace Elements (Enzyme Cofactors)

Each is essential at mg day⁻¹ to µg day⁻¹ scale — too much or too little causes specific pathology.

Element	Role	Pathology of deficiency	Pathology of excess
Iron (Fe)	Hemoglobin, cytochromes, Fe-S clusters	Anemia, fatigue	Hereditary haemochromatosis (iron overload)
Copper (Cu)	Cytochrome c oxidase, tyrosinase, lysyl oxidase	Menkes disease (curly hair, neurodegeneration)	Wilson disease (Cu deposition in liver, brain)
Zinc (Zn)	>300 enzymes; zinc finger transcription factors	Impaired growth, taste, immunity	Interferes with Cu absorption
Manganese (Mn)	Superoxide dismutase, glutamine synthetase	Rare; impaired connective tissue	Parkinson-like syndrome (welders)
Cobalt (Co)	Vitamin B ₁₂ core	Megaloblastic anemia, neuropathy	Rare cardiomyopathy (beer cobalt in 1960s)

Element	Role	Pathology of deficiency	Pathology of excess
Molybdenum (Mo)	Xanthine oxidase, sulfite oxidase, nitrate reductase	Rare; sulfite oxidase deficiency	Gout-like syndrome
Selenium (Se)	Glutathione peroxidase (GPX); thyroid deiodinase	Keshan disease (cardiomyopathy)	Selenosis (hair loss, nail brittleness)
Iodine (I)	Thyroid hormones (T3, T4)	Hypothyroidism, goiter, cretinism	Thyrotoxicosis
Chromium (Cr)	Disputed insulin cofactor	Possibly impaired glucose tolerance	Cr(VI) is carcinogenic
Fluorine (F)	Fluoroapatite in enamel	Dental caries	Fluorosis (mottled enamel)

E.4 Ultra-Trace and Context-Dependent Elements

- Nickel (Ni) — cofactor in urease (bacterial, plant) and hydrogenase; suspected but not proven essential in mammals.
- Silicon (Si) — structural in diatoms, horsetails, grasses (silica phytoliths); supports collagen cross-linking in vertebrates.
- Boron (B) — essential in plants (cell-wall cross-linking via borate–rhamnogalacturonan); possibly beneficial in vertebrates.
- Vanadium (V) — sea-squirt blood pigment (vanadocytes); pharmacology for insulin-mimetic effects.
- Tungsten (W) — used instead of molybdenum by hyperthermophilic archaea.

E.5 Life Without an Expected Element

Biology has bent the rules. Examples of organisms that substitute or replace commonly “essential” elements:

- Iron-free bacteria in deep-sea hydrothermal vents — use manganese peroxidases instead.
- Selenocysteine (the “21st amino acid”) — expands the amino-acid alphabet using the rare element Se.
- Pyrrolysine (the “22nd amino acid”) — found in methanogenic archaea; does not require a rare element, but is an unusual 22-atom residue.
- Arsenic-based life controversy (GFAJ-1, 2010) — claim of As replacing P in DNA of a *Halomonas* strain; later retracted.

The periodic table remains under-explored for biological innovations. Astrobiological life may use different element sets entirely.

E.6 Quick Lookup: Which Chapter Covers Each Element?

Element	Primary chapter	Supporting chapter
C, H, N, O	section 1	section 3
P	section 12	section 9
S	section 3	section 9
Na, K	section 7	section 32; section 33
Ca	section 8	section 31; section 35
Mg	section 3	section 9

Module: reference only (no code)

Appendix F — Master Glossary of Biological Terms

Etymology notation: [Gk] = Greek; **L** = Latin; [OFr] = Old French; [Ar] = Arabic. Cross-references use semantic `\cref{...}` links generated from the canonical table of contents.

Maintenance note: glossary terms must use a Pandoc bracketed span, `[**Term**]{#gl:term-slug}` (with `markdown+bracketed_spans`, Pandoc emits a real `LaTeX \label{gl:...}` in PDF). Chapters link with `[**term**](#gl:term-slug)`. After editing terms, run `uv run python scripts/link_glossary.py --check` from the project root and verify `tests/test_build_invariants.py` plus markdown validation.

A

Abiotic [Gk *a* = without + *bios* = life + *-ic* = pertaining to] — Non-living physical and chemical components of an environment (light, temperature, water, minerals). Contrast with biotic. → section [40](#)

Actin [Gk *aktis* = ray or beam] — A 42 kDa globular protein (G-actin) that polymerizes into filaments (F-actin); a major component of the cytoskeleton, sarcomeres, and lamellipodia. → section [6](#)

Action potential [L *actio* = a doing + *potentia* = power] — A transient, all-or-none reversal of membrane potential (about −70 mV to +40 mV) propagated along neuronal axons; gated by voltage-dependent Na⁺ and K⁺ channels. Described mathematically by the Hodgkin-Huxley equations (1952). → section [32](#)

Adaptive immunity [L *adaptare* = to fit + *immunis* = exempt] — Antigen-specific defense mediated by B and T lymphocytes. It is slower than innate immunity during a first exposure but generates immunological memory, enabling faster and stronger secondary responses. → section [35](#)

Adenosine triphosphate (ATP) [Gk *aden* = gland (as in adenine, identified in gland tissue) + *tri* = three + *phosphorus* = light-bearer] — A central phosphoryl-group donor and short-term energy carrier in cells. Hydrolysis to ADP + P_i releases about 30.5 kJ/mol under biochemical standard conditions, while the effective cellular free energy is often larger in magnitude because ATP, ADP, and P_i concentrations are far from equilibrium. → section [9](#)

Aerobic [Gk *aer* = air + *bios* = life] — Requiring molecular oxygen (O₂) as the terminal electron acceptor in cellular respiration. Opposite: anaerobic. → section [9](#)

Allele [Gk *allelon* = of each other; shortened from *allelemorph*] — One of two or more alternative forms of a gene at the same chromosomal locus. Defined by a distinct nucleotide sequence. → section [17](#)

Allostasis [Gk *allos* = other + *stasis* = standing] — Predictive physiological regulation in which the brain adjusts setpoints and resource allocation in anticipation of demand, rather than merely correcting error after disturbance. → section [0.3](#)

Allosteric [Gk *allos* = other + *stereos* = solid/space] — Describing a regulatory site on an enzyme or receptor that is spatially distinct from the active site; ligand binding there changes the macromolecule’s conformation and activity. → section [4](#)

Anaerobic [Gk *an* = without + *aer* = air + *bios* = life] — Occurring without oxygen. Anaerobic respiration uses alternative electron acceptors (nitrate, sulfate); fermentation regenerates NAD⁺ without any external acceptor. → section [9](#)

Anaphase [Gk *ana* = up/apart + *phasis* = appearance] — The stage of mitosis/meiosis in which sister chromatids (mitosis, meiosis II) or homologous chromosomes (meiosis I) are pulled to opposite poles by spindle fibers. → section [12](#)

Angiosperm [Gk *angeion* = vessel/container + *sperma* = seed] — A flowering plant whose seeds are enclosed within a fruit derived from the ovary wall; the dominant plant group (about 300,000 species). Contrast: gymnosperm. → section [28](#)

Anticodon [Gk *anti* = against or opposite + L *codex* = writing block] — The three-nucleotide sequence on a tRNA molecule that base-pairs with the complementary codon on mRNA during translation. → section [13](#)

Apoptosis [Gk *apo* = away + *ptōsis* = a falling] — Programmed, caspase-mediated cell death characterized by chromatin condensation, DNA fragmentation, and membrane blebbing, without inflammatory response. Contrast: necrosis. → section [8](#)

Archaea [Gk *archaios* = ancient] — One of three domains of life; prokaryotes with ether-linked isoprenoid membrane lipids, histone-like proteins, and replication/transcription machinery closer to eukaryotes than to bacteria. Discovered by Woese & Fox (1977). → sections [5](#) and [23](#)

ATP synthase [see ATP + Gk *syn* = together + *thesis* = a placing] — Also Complex V; a rotary F₀F₁ molecular motor driven by the proton-motive force to phosphorylate ADP to ATP. The c-ring rotation of 120° per ATP was directly visualized by Noji et al. (1997). → section [9](#)

Autotroph [Gk *autos* = self + *trophe* = nourishment] — An organism that produces its own organic molecules from inorganic carbon (CO₂); either photoautotroph (energy from light) or chemoautotroph (energy from inorganic chemicals). → sections [5](#), [37](#) and [38](#)

Autonomic nervous system (ANS) [Gk *autonomos* = self-governing] — The visceral motor division of the peripheral nervous system; divided into sympathetic (thoracolumbar; noradrenaline/adrenaline; “fight-or-flight”) and parasympathetic (craniosacral; acetylcholine; “rest-and-digest”) branches. ANS innervates smooth muscle, cardiac muscle, and glands. → section 32

Axon hillock [Gk *axon* = axis + OE *hyll* = small hill] — The region of the neuron where the axon originates from the cell body (soma); the site of action potential initiation due to the high density of voltage-gated Na⁺ channels. EPSPs must summate here to reach threshold (about −55 mV). → section 32

B

Base pair (bp) [Gk *basis* = step, foundation] — A complementary nucleotide pair held by hydrogen bonds in double-stranded nucleic acids: A–T (2 H-bonds in DNA) and G–C (3 H-bonds). One bp ≈ 0.34 nm along the DNA helix. → section 12

Biofilm [Gk *bios* = life + L *filum* = thread] — A structured community of microorganisms attached to a surface and enclosed in a self-produced extracellular polysaccharide matrix; regulated by quorum sensing; often up to 1,000-fold more antibiotic tolerant than planktonic cells because matrix diffusion limits, slow growth, stress responses, and persister cells overlap. → section 24

Biome [Gk *bios* = life + *-ome* = mass/body] — A large-scale terrestrial or aquatic ecosystem characterized by a distinctive climate, vegetation, and fauna. Classified by Whittaker (1975) primarily by mean annual precipitation (MAP) and mean annual temperature (MAT). → section 40

Buffer [OFr *bufer* = to protect from a blow] — A solution containing a weak acid and its conjugate base that resists changes in pH by absorbing added H⁺ or OH[−]. Effective within ±1 pH unit of pK_a (Henderson-Hasselbalch). → section 1

C

Calvin cycle [named for Melvin Calvin, who elucidated it using ¹⁴C radioisotopes, 1950] — The light-independent carbon-fixation reactions of photosynthesis in the chloroplast stroma; not literally dark, because they depend on ATP and NADPH produced by the light reactions. Also called the Calvin-Benson-Bassham cycle. Net: 3 CO₂ + 9 ATP + 6 NADPH → G3P. → section 10

Caspase [L *caspase* = cysteine-containing aspartate protease] — A family of cysteine proteases that execute apoptosis; exists as inactive zymogens; activated by cleavage at specific aspartate residues in a proteolytic cascade. → section 8

Cell cycle [L *cella* = small room + Gk *kyklos* = circle] — The ordered sequence of events by which a cell duplicates its contents and divides: G₁ → S (DNA synthesis) → G₂ → M (mitosis) → cytokinesis. Regulated by cyclin-CDK complexes and checkpoint kinases. → section 12

CaMKII (Calcium/calmodulin-dependent kinase II) [L *calx* = lime (Ca) + *calmodulin* + Gk *kinein* = to move] — A serine/threonine kinase activated by Ca²⁺/calmodulin; autophosphorylation at T286 renders it constitutively active (“molecular memory”). Key effector of NMDA receptor-dependent LTP: phosphorylates AMPA receptors (increased conductance) and drives AMPA receptor exocytosis. → section 33

Cardiac output (CO) [Gk *kardia* = heart + L *emittere* = to send out] — The volume of blood ejected by the heart per minute: CO = heart rate (HR) × stroke volume (SV). Normal resting CO ≈ 5.5 L/min; can reach 20–25 L/min during maximal exercise in athletes. Regulated by the Frank-Starling mechanism and neurohumoral factors. → section 31

cDNA [complementary DNA; L *complementum* = that which fills up] — DNA synthesized from an mRNA template by reverse transcriptase; lacks introns; used in cloning, expression libraries, and RT-PCR diagnostics. → section 13

Centromere [Gk *kentron* = center + *meros* = part] — The specialized chromosomal region where kinetochore proteins assemble and spindle microtubules attach during mitosis and meiosis. Required for accurate chromosome segregation. → section 12

Chemiosmosis [Gk *chemi* = chemistry + *osmos* = push] — The coupling of electron transport to ATP synthesis via a proton electrochemical gradient across a membrane (proton-motive force). Proposed by Peter Mitchell (1961); Nobel Prize 1978. → section 9

Chirality [Gk *cheir* = hand] — The property of a molecule that is non-superimposable on its mirror image, like a hand. Biology is strongly homochiral in its core polymers: proteins mostly use L-amino acids, while nucleic acids and many central metabolites use D-sugars. → section 1

Chlorophyll [Gk *chloros* = green/yellow-green + *phyllon* = leaf] — A porphyrin-ring pigment containing Mg²⁺ at its center; the primary light-harvesting molecule in photosynthesis. Absorbs strongly at 430 nm (violet/blue) and 680–700 nm (red). → section 10

Chromatin [Gk *chroma* = color] — The complex of DNA and proteins (primarily histones) that compacts the genome within the nucleus. Exists in two states: euchromatin (open, transcriptionally active) and heterochromatin (compact, silenced). The fundamental unit is the nucleosome. → section 15

Chromosome [Gk *chroma* = color + *soma* = body] — A linear (eukaryotic) or circular (prokaryotic) DNA molecule associated with proteins (histones in eukaryotes) that carries the cell’s hereditary information. Humans have 46 chromosomes (23 pairs). → section 12

CpG island (C = cytosine; p = phosphodiester bond; G = guanine) — A genomic region (about 500 bp–2 kb) enriched for CG dinucleotides; observed/expected CpG ratio > 0.6; present at about 70% of vertebrate gene promoters. Normally unmethylated; hypermethylation silences the associated promoter in cancer and differentiation. → section 15

CRISPR-Cas [L *crispus* = clustered + *repetitive* + *palindromic* + *Cas* = CRISPR-associated protein] — A prokaryotic adaptive immune system (repeat-spacer arrays + Cas endonucleases) repurposed for programmable genome editing; Cas9 guided by a synthetic sgRNA cleaves DNA at a complementary target. → section 14

Codon [L *codex* = block of writing] — A three-nucleotide sequence in mRNA that specifies one amino acid or a stop signal. The genetic code has 64 codons encoding 20 amino acids (and 3 stop codons); most amino acids have multiple synonymous codons (degeneracy). → section 13

Cortisol [L *cortex* = bark, rind] — The primary glucocorticoid secreted by the adrenal cortex (zona fasciculata) in response to ACTH; mobilizes glucose (gluconeogenesis, protein catabolism), suppresses immunity (reduces IL-2, PGE2, and T cell activation), and regulates the stress response. Circadian peak at 06:00–08:00. Synthetic analogs (prednisone, dexamethasone) are widely used anti-inflammatory agents. → section 35

Cohesion-tension theory [L *cohaerere* = to stick together + Gk *teinein* = to stretch] — The mechanism by which water ascends xylem vessels in plants: evaporation at the leaf surface creates tension (negative pressure) transmitted through the hydrogen-bonded water column via adhesion to cell walls. Proposed by Dixon & Joly (1894). → section 28

Competitive inhibition [L *competere* = to seek together] — Enzyme inhibition in which the inhibitor binds the active site and competes with substrate. Raises apparent K_m without affecting V_{max} ; reversed by increasing **S**. → section 4

Cytoplasm [Gk *kytos* = cell/vessel + *plasma* = something formed] — The collective cell contents between the plasma membrane and the nucleus (or nucleoid); includes cytosol, organelles, ribosomes, and the cytoskeleton. → section 6

Cytoskeleton [Gk *kytos* = vessel + *skeletos* = dried up] — The dynamic network of protein filaments — actin microfilaments (7 nm), intermediate filaments (10 nm), and microtubules (25 nm) — that maintains cell shape, enables motility, and guides intracellular transport. → section 6

D

Diploid (2n) [Gk *diplous* = double + *eidos* = form] — A cell or organism with two complete sets of homologous chromosomes; one set from each parent. Human somatic cells are diploid (2n = 46). Contrast: haploid (n). → section 19

DNA helicase [Gk *helix* = spiral] — An ATP-dependent enzyme that unwinds the DNA double helix at the replication fork by breaking hydrogen bonds between base pairs; the replicative helicase DnaB in bacteria, MCM complex in eukaryotes. → section 12

DNA ligase [L *ligare* = to bind] — An enzyme that forms phosphodiester bonds between adjacent nucleotides; joins Okazaki fragments on the lagging strand; also used in DNA repair and recombinant DNA cloning. → section 12

Dominant [L *dominare* = to rule] — Describing an allele whose phenotypic effect is expressed in both homozygous and heterozygous states. The recessive allele is masked in the heterozygote. Mendel (1866). → section 17

Doubling time (t_d) [OE *dubbel* = twice + L *tempus* = time] — The time required for a population or culture to double in number; $t_d = \ln 2/\mu$ where μ is the specific growth rate. → section 24

E

Electronegativity [Gk *elektron* = amber (as source of static charge) + L *negativus* = denying] — The tendency of an atom to attract bonding electrons. Pauling scale: F = 3.98; O = 3.44; N = 3.04; C = 2.55; H = 2.20. Determines bond polarity. → section 1

Endocytosis [Gk *endon* = within + *kytos* = vessel] — Uptake of extracellular material by inward budding of the plasma membrane to form a vesicle. Subtypes: pinocytosis (fluid/solutes), phagocytosis (large particles), receptor-mediated endocytosis (specific ligands via clathrin-coated pits). Contrast: exocytosis. → section 7

Endosymbiosis [Gk *endon* = within + *sym* = together + *bios* = life] — A relationship in which one organism lives within another over evolutionary time, eventually becoming an organelle. The mitochondrion (about 1.5 Ga ago) and chloroplast (about 1.2 Ga ago) both originated by endosymbiosis of bacterial cells

(Margulis, 1967). → section 5

Entropy (S) [Gk *en* = in + *trope* = transformation] — A thermodynamic state function often described as energy dispersal or the number of accessible microstates. For spontaneous processes in an isolated system, total entropy increases ($\Delta S_{universe} > 0$). Living organisms maintain ordered internal structures by exchanging matter and energy with surroundings. → section 9

Enzyme [Gk *en* = in + *zyme* = leaven/ferment] — A biological catalyst — almost always a protein, sometimes RNA (ribozyme) — that accelerates a reaction by lowering the activation energy without being consumed. Characterized by specificity, saturation kinetics (Michaelis-Menten), and allosteric regulation. → section 4

Epigenetics [Gk *epi* = above/upon + *genet-* = birth; coined by Waddington, 1942] — Heritable changes in gene expression that do not alter the underlying DNA sequence. Molecular carriers: CpG methylation, histone post-translational modifications (acetylation, methylation, phosphorylation), and non-coding RNAs (miRNA, lncRNA, piRNA). → section 15

Epigenome [Gk *epi* = upon + *genos* = origin + *-ome* = total] — The complete set of epigenetic modifications across a cell’s genome; cell-type specific and environmentally modifiable, unlike the genome sequence. Mapped by ENCODE and Roadmap Epigenomics projects. → section 14

Euchromatin [Gk *eu* = true/good + *chroma* = color] — Loosely packed chromatin associated with H3K4me3 and H3K27ac histone marks; transcriptionally permissive. Contrast: heterochromatin. → section 15

Excitotoxicity [L *excitare* = to rouse + Gk *toxikon* = poison] — Neuronal death caused by excessive glutamate receptor activation (especially NMDA), leading to massive Ca^{2+} influx, mitochondrial dysfunction, caspase activation, and necrosis/apoptosis. The primary mechanism of neuronal death in ischemic stroke. Target of neuroprotective strategies. → section 33

Eukaryote [Gk *eu* = true + *karyon* = nucleus] — An organism whose cells contain a membrane-enclosed nucleus and membrane-bound organelles. Includes protists, fungi, plants, and animals. Contrast: prokaryote. → section 5

Exon [Gk *exo* = outside; coined by Gilbert, 1978] — A coding sequence in a eukaryotic gene that is retained in the mature mRNA after splicing and is translated into protein. Contrast: intron. → section 13

F

FEV₁/FVC [forced expiratory volume/forced vital capacity] — The fraction of vital capacity exhaled in the first second of a forced expiration; obstruction is best interpreted against the age-dependent lower limit of normal, with a fixed 0.70 threshold used as a simple COPD screening convention. Restrictive patterns usually preserve or raise the ratio while reducing absolute lung volumes. → section 31

Fatty acid [ME *fat* + Gk *oxys* = acid/sharp] — A carboxylic acid with a hydrocarbon chain. Saturated fatty acids pack tightly; unsaturated *cis* double bonds introduce bends that increase membrane fluidity. → section 3

Fisheries [OE *fisc* = fish] — Human-managed harvest systems for aquatic populations; modern stock assessment uses age structure, recruitment, mortality, and maximum sustainable yield models to avoid collapse. → sections 36 and 40

Frank-Starling law [named for Otto Frank (1895) and Ernest Starling (1914)] — The intrinsic property of cardiac muscle whereby stroke volume increases with end-diastolic volume (preload): greater stretch of sarcomeres increases Ca^{2+} sensitivity of troponin C, increasing force generation. Operates up to an optimal sarcomere length (about 2.2 μm); beyond this, overlap of thick and thin filaments decreases. → section 31

Facilitated diffusion [L *facilis* = easy + *diffundere* = to pour out] — Passive transport of molecules down their concentration gradient via membrane proteins (channels or carriers); no energy required. Contrast: active transport. → section 7

Fitness (w) [OE *gefittan* = to be suitable] — In evolutionary biology, the relative contribution of a genotype to the next generation; often expressed as $w = 1 - s$ where *s* is the selection coefficient. → section 20

Free energy (ΔG) [Gk *eleutheros* = free] — Gibbs free energy; the energy available to do work at constant temperature and pressure: $\Delta G = \Delta H - T\Delta S$. Spontaneous reactions have $\Delta G < 0$ (exergonic). → section 9

G

GLP-1 (glucagon-like peptide-1) [L *glucos* = sweet + *lysis* = splitting] — An incretin hormone secreted by intestinal L cells in response to nutrient ingestion; potentiates glucose-dependent insulin secretion (GSI) from beta cells; suppresses glucagon; delays gastric emptying; reduces appetite via hypothalamic signaling.

GLP-1 receptor agonists (semaglutide, tirzepatide) are transformative in treating type 2 diabetes and obesity. → section 35

GLUT4 [glucose transporter type 4] — The insulin-sensitive glucose transporter expressed in muscle and adipose tissue; stored in intracellular vesicles; translocated to the plasma membrane within minutes of insulin receptor activation (PI3K–Akt–AS160 cascade). Responsible for up to 90% of post-prandial muscle glucose uptake. Impaired GLUT4 trafficking underlies insulin resistance in type 2 diabetes. → section 35

Gamete [Gk *gamete* = wife; *gametes* = husband; from *gamein* = to marry] — A haploid reproductive cell (sperm or egg) that fuses with another gamete during fertilization to restore the diploid number. → section 19

Gene [Gk *genos* = birth/origin; coined by Johannsen, 1909] — A heritable unit of information encoded in DNA that typically specifies the sequence of a protein or functional RNA; operationally defined as a sequence occupying a defined chromosomal locus. → section 15

Genetic code [Gk *genos* = birth + L *codex* = writing block] — The mapping from 64 mRNA codons to 20 amino acids and stop signals. It is nearly universal, degenerate, and read by tRNA anticodons during translation. → section 13

Genome [Gk *genos* = birth + *-ome* = total body of] — The complete set of genetic information in an organism, including nuclear chromosomes, mitochondrial DNA, and in plants, chloroplast DNA. Human haploid genome: about 3.2 Gb, about 20,000 protein-coding genes. → section 14

Genome-wide association study (GWAS) [Eng *genome* + *wide* + *association*] — A population scan correlating millions of SNP genotypes with a trait or disease; identifies tag loci (not always causal genes); requires large samples and correction for multiple testing. → section 14

Glycolysis [Gk *glykys* = sweet + *lysis* = splitting] — The 10-step cytosolic pathway that converts glucose (6C) to 2 pyruvate (3C), yielding a net 2 ATP and 2 NADH per glucose under standard textbook accounting. It does not require oxygen directly and is among the most ancient and widespread central metabolic pathways, though some organisms use modified glycolytic routes. → section 9

Gram stain [named for Hans Christian Gram, Danish bacteriologist, 1884] — A differential microbiological stain that distinguishes thick-peptidoglycan bacteria (Gram-positive: retain crystal violet, purple) from thin-peptidoglycan + outer membrane bacteria (Gram-negative: lose crystal violet, pink after safranin counterstain). → section 5

H

HPA axis (hypothalamic–pituitary–adrenal axis) [Gk *hypo* = under + *thalamos* = inner chamber] — The neuroendocrine stress axis: CRH (hypothalamus) → ACTH (anterior pituitary) → cortisol (adrenal cortex). Regulated by negative feedback at hypothalamus and pituitary. Dysregulation implicated in depression, PTSD, and Cushing’s syndrome. → section 35

HPG axis (hypothalamic–pituitary–gonadal axis) — GnRH (hypothalamus) → FSH + LH (anterior pituitary) → sex steroids + gametes (gonads). Pulsatile GnRH (every 90 min) is required for normal FSH/LH secretion; continuous GnRH causes receptor downregulation and gonadotropin suppression. → section 35

HPT axis (hypothalamic–pituitary–thyroid axis) — TRH (hypothalamus) → TSH (anterior pituitary) → T4/T3 (thyroid gland). T3 is the active form; acts on nuclear receptors to increase metabolic rate, thermogenesis, and cardiac output. Hypothyroidism: TSH ↑; hyperthyroidism: TSH ↓. → section 35

Haploidy (n) [Gk *haplous* = single + *eidos* = form] — Condition of having one complete set of chromosomes; characteristic of gametes and the gametophyte generation of plants. → section 19

Hardy-Weinberg equilibrium [named for Godfrey Hardy, mathematician, and Wilhelm Weinberg, physician, 1908] — The principle that allele and genotype frequencies remain constant in a population absent of evolutionary forces (no selection, drift, mutation, migration, non-random mating). Genotype frequencies: $p^2 + 2pq + q^2 = 1$. → section 20

Heterozygous [Gk *heteros* = different + *zygotos* = yoked] — Possessing two different alleles at a given locus (e.g., *Aa*). Contrast: homozygous (*AA* or *aa*). → section 17

Hill coefficient (n) [named for Archibald Hill, 1910] — A measure of cooperativity in ligand binding. $n = 1$ = no cooperativity; $n > 1$ = positive cooperativity (sigmoidal binding curve). Hemoglobin: $n \approx 2.8$. → section 4

Homeostasis [Gk *homoios* = similar + *stasis* = standing/state] — The maintenance of a relatively stable internal environment despite external fluctuations; achieved by negative feedback loops with a sensor, comparator (integrator), and effector. Coined by Walter Cannon (1926, building on Claude Bernard). → section 32

Heterochromatin [Gk *heteros* = different + *chroma* = color] — Densely compacted chromatin bearing repressive histone marks (H3K9me3, H3K27me3) and high DNA methylation; transcriptionally silent. Constitutive heterochromatin (centromeres, telomeres) is permanent; facultative heterochromatin (e.g., the inactive X chromosome) is cell-type specific. → section 15

Histone [Gk *histos* = loom/web] — One of five abundant nuclear proteins (H1, H2A, H2B, H3, H4) that form the nucleosome core and linker. Tails are post-translationally modified by acetylation, methylation, phosphorylation, and ubiquitination to regulate gene expression (histone code). → section 15

Histone code [Gk *histos* = loom; L *codex* = writing block] — The hypothesis (Strahl & Allis, 2000) that combinations of histone post-translational modifications specify unique chromatin states; ‘written’ by HATs/HMTs, ‘read’ by bromodomains/chromodomains, ‘erased’ by HDACs/KDMs. → section 15

Holobiont [Gk *holos* = whole + *bios* = life] — The host plus its persistent associated microbiota (and sometimes viruses) treated as an integrated biological system; useful for analyzing nutrition, immunity, and niche construction. → sections 24 and 25

Hydrogen bond [Gk *hydor* = water + *genes* = born from (as in generated with water)] — A weak electrostatic attraction (2–40 kJ/mol) between a hydrogen atom covalently bonded to an electronegative atom (N, O, or F) and another electronegative atom. Critical for DNA base-pairing, protein secondary structure, and water’s unique properties. → section 1

Hydrolysis [Gk *hydor* = water + *lysis* = loosening] — Cleavage of a chemical bond by addition of water; central to digestion, ATP turnover, polymer breakdown, and many enzyme-catalysed reaction mechanisms. → sections 3 and 4

Hydrophobic effect [Gk *hydor* = water + *phobos* = fear] — The entropy-driven clustering of nonpolar surfaces in water as ordered water cages are released. It drives membrane assembly, protein folding, and ligand binding. → sections 2 and 3

I

Insulin receptor [L *insula* = island, as in islets of Langerhans] — A receptor tyrosine kinase (RTK) composed of two α and two β subunits; insulin binding activates RTK, triggering autophosphorylation and IRS-1/2 phosphorylation; downstream: PI3K–Akt (GLUT4 translocation, glycogen synthesis) and MAPK (gene expression, cell growth). Type 2 diabetes involves insulin receptor signaling resistance. → section 35

Independent assortment [L *independens* = not hanging upon] — Mendel’s second law: genes on non-homologous chromosomes are inherited independently of each other, producing 9:3:3:1 ratios in dihybrid crosses. Applies only to genes on different chromosomes or far apart on the same chromosome. → section 17

Intron [L *intra* = within; coined by Sharp & Roberts, 1977] — A non-coding intervening sequence within a eukaryotic gene that is transcribed but removed from the pre-mRNA by the spliceosome before translation. Nobel Prize 1993 (Sharp & Roberts). → section 13

K

Keystone species [L *lapis* = stone; *clavus* = key] — A species with a disproportionately large effect on its ecosystem relative to its biomass; its removal causes dramatic shifts in community structure. Term coined by Robert Paine (1966) based on sea-star (*Pisaster*) removal experiments. → section 37

Km (Michaelis constant) [after Leonor Michaelis] — The substrate concentration at which an enzyme operates at half its maximum velocity ($V_{\max}/2$); reflects enzyme-substrate affinity (lower K_m = higher affinity). Units: mol/L (M). → section 4

L

LTP (long-term potentiation) [L *longum* = long + *tempus* = time + *potentia* = power] — A persistent (hours to days) increase in synaptic efficacy following high-frequency stimulation; requires NMDA receptor activation → Ca^{2+} influx → CaMKII autophosphorylation → AMPA receptor insertion; the cellular model of learning and memory (Bløndell, Lømo 1973). → section 33

LTD (long-term depression) [L *deprimere* = to press down] — A persistent decrease in synaptic efficacy; induced by low-frequency stimulation (1 Hz) or by mGluR/endocannabinoid signaling (“endocannabinoid-mediated LTD”); involves PP1/PP2A phosphatase activation and AMPA receptor internalization via dynamin-clathrin endocytosis. → section 33

Linkage [ON *hlenkr* = chain link] — The tendency of genes located on the same chromosome to be inherited together; the closer the genes, the stronger the linkage (lower recombination frequency). → section 19

Locus (plural: loci) [L *locus* = place] — The fixed chromosomal position occupied by a particular gene; defined by its physical map coordinates (base pair position) or genetic map position (centimorgans from a reference marker). → section 19

Lotka-Volterra equations [named for Alfred Lotka (1925) and Vito Volterra (1926)] — A pair of coupled nonlinear ODEs describing predator-prey population cycles: $dN/dt = \alpha N - \beta NP$ (prey) and $dP/dt = \delta NP - \gamma P$ (predator). Produce neutrally stable oscillatory dynamics. → section 37

M

mRNA (messenger RNA) [L *nuntius* = messenger] — An RNA molecule transcribed from a gene’s template strand; carries the codon sequence from the nucleus to the ribosome for translation into protein. Processed in eukaryotes by 5’ capping, 3’ polyadenylation, and splicing. → section 13

Meiosis [Gk *meiosis* = lessening] — Two successive cell divisions — Meiosis I (reductional; homologue separation) and Meiosis II (equational; sister chromatid separation) — that produce four haploid gametes from one diploid cell. Sources of genetic diversity: crossing-over and independent assortment. → section 19

Membrane potential (Vm) [L *membrana* = thin skin + *potentia* = power] — The electric potential difference across a biological membrane; in neurons at rest, approximately –70 mV (inside negative). Governed by the Goldman equation for multiple ion species. → section 31

Michaelis-Menten kinetics [after Leonor Michaelis & Maud Menten, 1913] — The standard kinetic model for enzyme catalysis: $v = V_{max}[S]/(K_m + [S])$. Assumes rapid equilibrium or steady-state complex formation and one substrate. → section 4

Microbiome [Gk *mikros* + *bios* + *-ome*] — The full complement of microorganisms (bacteria, archaea, fungi, viruses) and their genes in a defined environment (e.g., gut, rhizosphere); often profiled by metagenomic sequencing. → section 24

Microbiota [Gk *mikros* + *bios* + *-ota* collective] — The assemblage of microorganisms themselves (contrast microbiome, which often denotes genes and functions as well). → section 24

MicroRNA (miRNA) [Gk *mikros* = small] — A about 22 nt single-stranded RNA that directs post-transcriptional gene silencing; biogenesis: Drosha (nuclear) → pre-miRNA → Dicer (cytoplasmic) → AGO2/RISC; partial 3’UTR complementarity causes translational repression and mRNA decay. > 2,000 human miRNAs regulate about 60% of protein-coding genes. → section 15

Mitosis [Gk *mitos* = thread] — Cell division in which one diploid cell produces two genetically identical diploid daughter cells; consists of prophase, metaphase, anaphase, and telophase followed by cytokinesis. → section 12

Mutation [L *mutare* = to change] — A heritable change in genetic sequence, including substitutions, insertions, deletions, inversions, duplications, and translocations. Mutation creates new sequence variants; recombination, segregation, gene flow, and selection then reshape how those variants are combined and distributed in populations. → section 14

5-Methylcytosine (5mC) — The “fifth base” of DNA; cytosine methylated at C5 by DNMT enzymes using S-adenosylmethionine as methyl donor. Silences promoters via MBD protein recruitment; oxidised to 5-hydroxymethylcytosine (5hmC) by TET enzymes for active demethylation. → section 15

N

Natural selection [L *natura* = nature; *selectio* = choosing] — The process by which heritable variations that increase survival or reproduction become more common in a population over generations. Proposed by Darwin & Wallace (1858). → section 20

Niche [OFr *nicher* = to nest] — The totality of an organism’s role in its environment, including physical conditions (temperature, pH, resources) it can use and interactions with other species. Fundamental niche: possible without competition. Realized niche: actual range when competitors are present. → section 37

Nucleosome [L *nucleus* = nut kernel + Gk *soma* = body] — The fundamental repeating unit of chromatin: 147 bp of DNA wound about 1.65 turns around a histone octamer (H2A, H2B, H3, H4 × 2); diameter 11 nm. First visualized by electron microscopy (Kornberg, 1974; Nobel Prize 2006). → section 15

Nucleotide [Gk *nucleus* = kernel + L *nucleus* = nut kernel] — The monomer of nucleic acids: a nitrogenous base + pentose sugar + one to three phosphate groups. Adenine, guanine (purines); cytosine, thymine, uracil (pyrimidines). → section 12

O

Organelle [Gk *organon* = tool/instrument + *ella* = diminutive suffix] — A membrane-bound (or in some definitions, functionally discrete) structure within a eukaryotic cell, performing a specialized function. Examples: nucleus, mitochondrion, chloroplast, Golgi apparatus, lysosome. → section 6

Osmosis [Gk *osmos* = pushing] — The movement of water across a selectively permeable membrane from a region of lower solute concentration (higher water potential) to a region of higher solute concentration (lower water potential). Van ’t Hoff equation: $\pi = iCRT$. → section 7

Oxidative phosphorylation [L *oxidare* = to oxidise + Gk *phosphoros* = light-bearer] — The ATP-generating process driven by electron transfer from NADH/FADH₂ to O₂ via the electron transport chain, producing the proton-motive force used by ATP synthase. Yields about 28 of the about 30–32 ATP per glucose. → section 9

P

P₅₀ [partial pressure at which hemoglobin is 50% saturated] — A measure of hemoglobin-O₂ affinity; normal P₅₀ = 26–27 mmHg. Rightward shifts (increased P₅₀) = decreased affinity: caused by increased PCO₂, H⁺, temperature, 2,3-BPG (Bohr effect). Leftward shifts = increased affinity: caused by decreased PCO₂, alkalosis, hypothermia, foetal Hb. → section 31

Pan-genome [Gk *pan* = all + *genome*] — The union of the collective genes found across a species or clade when many strains are sequenced; comprises a core genome (shared) and accessory genes (variable). Explains strain-specific virulence and metabolic capabilities in bacteria. → section 14

Poiseuille’s law [named for Jean Léonard Marie Poiseuille, 1840] — Laminar flow of a viscous fluid in a cylindrical tube: $Q = \pi r^4 \Delta P / 8 \eta L$, where r = radius, ΔP = pressure gradient, η = viscosity, L = length. The r^4 dependence explains why small changes in vessel radius (e.g., arteriolar vasodilation) produce large changes in flow and vascular resistance. → section 31

Peptide bond [Gk *pepsis* = digestion; peptides were initially thought to be digestion products] — The covalent bond (–CO–NH–) formed by condensation between the carboxyl group of one amino acid and the amino group of another during translation. Has partial double-bond character (resonance; about 40% double bond), conferring planarity. → section 3

pH [Danish *potenz* = power + Gk *hydro* = water; coined by Sørensen, 1909] — The negative common logarithm of hydrogen ion activity: $pH = -\log_{10}[H^+]$. Physiological range: blood plasma 7.35–7.45; lysosomes 4.5–5.0; mitochondrial matrix 7.8–8.0. → section 1

Phenotype [Gk *phainein* = to show + *typos* = impression] — The observable characteristics of an organism, determined by the interaction of genotype with environment. Contrast: genotype. → section 17

Phospholipid bilayer [Gk *phosphoros* = light-bearer + L *lipidus* = fat] — A self-assembled membrane structure in which amphipathic lipids orient hydrophilic heads toward aqueous environments and hydrophobic tails inward; typical thickness is about 7–8 nm. It is the dominant membrane architecture in bacteria and eukaryotes, while archaeal membranes often use ether-linked isoprenoid lipids and can form monolayers. → section 7

Photosynthesis [Gk *phos/photos* = light + *synthesis* = putting together] — The process by which photosynthetic organisms use light energy to produce organic compounds from CO₂ and H₂O; in plants: light reactions (thylakoids; produce ATP + NADPH) + Calvin cycle (stroma; fix CO₂ into G3P). → section 10

Plasmid [Gk *plasma* = formed thing] — A small, circular, double-stranded DNA molecule in bacteria (and some eukaryotes) that replicates independently of the chromosome; often carries genes for antibiotic resistance or virulence. → section 5

Polymerase chain reaction (PCR) [Gk *polys* = many + L *merus* = part; Gk *kyklos* = circle; coined by Kary Mullis, 1983] — An *in vitro* method for amplifying a specific DNA sequence using repeated cycles of denaturation, primer annealing, and extension by Taq polymerase. Transformed molecular biology; Nobel Prize 1993. → section 14

Promoter [L *promovere* = to move forward] — A DNA sequence upstream of a gene where RNA polymerase and transcription factors bind to initiate transcription. In prokaryotes: –10 (Pribnow box) and –35 elements; in eukaryotes: TATA box, initiator, and Pol II general transcription factors. → section 13

Protein [Gk *proteios* = of the first quality; coined by Mulder & Berzelius, 1838] — A polymer of L-amino acids linked by peptide bonds; encoded by the gene sequence; functional form depends on primary (1°), secondary (2°), tertiary (3°), and quaternary (4°) structure. → section 3

R

RAAS (renin–angiotensin–aldosterone system) [L *ren* = kidney] — The hormonal blood pressure and volume regulatory cascade: low renal perfusion → juxtaglomerular cells release renin → cleaves angiotensinogen to angiotensin I → ACE (lung) converts to angiotensin II → vasoconstriction + aldosterone release (Na⁺/H₂O retention). ACE inhibitors (enalapril) and ARBs (losartan) are first-line antihypertensive drugs. → section 31

Recombination [L *re* = again + *combinare* = to combine] — The process of generating new combinations of alleles through crossing-over between homologous chromosomes during meiosis I. Frequency (θ) is proportional to genetic map distance (1 cM = 1% recombination). → section 19

Reduction potential (E°) [L *reducere* = to lead back] — The tendency of a molecule to accept electrons, measured in volts under standard biochemical conditions (pH 7, 25°C). O₂/H₂O: +0.816 V; NAD⁺/NADH: –0.320 V. Electrons flow from lower to higher E°. → section 1

Ribonucleic acid (RNA) [L *nucleus* + suffix *ic*] — A single-stranded nucleic acid using ribose and uracil (instead of deoxyribose and thymine); roles include mRNA (messenger), tRNA (transfer), rRNA (ribosomal), and regulatory (miRNA, siRNA, snRNA). → section 13

Ribosome [named for ribose + Gk *soma* = body] — The ribonucleoprotein complex (about 2.5 MDa in eukaryotes; 80S = 40S + 60S subunits) that catalyses peptide bond formation during translation; catalytic activity resides in rRNA (a ribozyme). Nobel Prize 2009 (Ramakrishnan, Steitz, Yonath). → section 13

S

Saltatory conduction [L *saltare* = to jump] — The rapid propagation of action potentials in myelinated axons by jumping from one node of Ranvier to the next; velocity proportional to internodal distance; 5–70 m/s vs 0.5–2 m/s in unmyelinated C fibers. Enabled by high Na⁺ channel density at nodes and insulation by myelin between nodes. → section 33

SNARE complex [acronym: Soluble N-ethylmaleimide-sensitive factor Attachment protein REceptors] — The core vesicle fusion machinery: v-SNARE (synaptobrevin/VAMP-2, on vesicle) + t-SNAREs (syntaxin-1A and SNAP-25, on target membrane) zipper together in a four-helix bundle providing the energy for membrane fusion. Cleaved by clostridial neurotoxins (botulinum toxin cleaves SNAP-25/VAMP; tetanus toxin cleaves VAMP in spinal inhibitory interneurons). → section 33

Surfactant [L *superficies* = surface + *activus* = active] — A complex mixture of phospholipids (primarily DPPC) and proteins (SP-A, SP-B, SP-C, SP-D) secreted by alveolar type II pneumocytes; reduces alveolar surface tension according to Laplace’s law ($P = 2T/r$), preventing alveolar collapse (atelectasis) during expiration and reducing the work of breathing. Deficiency causes neonatal respiratory distress syndrome (RDS). → section 31

Synaptotagmin [Gk *synapsis* = junction + *tagma* = arrangement] — The Ca²⁺ sensor for fast neurotransmitter release; C2A and C2B domains bind 3–5 Ca²⁺ ions cooperatively (Hill coefficient $n \approx 4$), explaining Ca²⁺ cooperativity of neurotransmitter release. Synaptotagmin-1 drives synchronous fast release; synaptotagmin-7 drives asynchronous release and facilitatory plasticity. → section 33

Selection coefficient (s) [see *natural selection*] — A quantitative measure of the fitness disadvantage (or advantage) conferred by an allele; $s = 1 - w$ where w is relative fitness. Dominant lethal: $s = 1$; neutral: $s = 0$. → section 20

Speciation [L *species* = appearance/kind] — The evolutionary process by which one ancestral population diverges into two or more reproductively isolated species. Mechanisms: allopatric (geographic isolation), sympatric (within a range; polyploidy, disruptive selection). → section 22

Species-area relationship [L *species* = kind + *area* = open space] — The empirical relationship $S = cA^z$ between species richness (S) and area (A); exponent $z \approx 0.25$ for continental habitats, $z \approx 0.30$ for island habitats. MacArthur & Wilson (1967). → section 40

Surface-area-to-volume ratio (A/V) [L *superficies* = surface] — For a sphere: $A/V = 3/r$. As cell radius increases, A/V decreases, limiting diffusion-based nutrient exchange; this constraint accounts for why cells are microscopically small. → section 5

T

Thermodynamics [Gk *therme* = heat + *dynamis* = power] — The branch of physical science concerned with heat, work, and energy transformations. First Law: energy is conserved. Second Law: entropy increases in any spontaneous process. → section 9

Transcription [L *transcribere* = to copy] — The synthesis of an RNA molecule from a DNA template by RNA polymerase; proceeds 5’ to 3’ reading the template strand 3’ to 5’; regulated by transcription factors, promoters, and enhancers. → section 13

Translation [L *translatio* = carrying across] — The ribosome-mediated synthesis of a polypeptide from an mRNA template; proceeds from 5’ to 3’ (mRNA), adding amino acids from N- to C-terminus at about 15 residues/second (eukaryotes). → section 13

Transpiration [L *trans* = across + *spirare* = to breathe] — The evaporation of water from leaf mesophyll cells and its diffusion through stomata; drives the transpiration stream (cohesion-tension mechanism) and enables mineral transport in xylem. → section 28

Trophic level [Gk *trophe* = nourishment] — A functional tier in a food web defined by the number of energy-transfer steps from primary producers; approximately 10% of energy passes between levels (Lindeman’s trophic-dynamic theory, 1942). → section 39

V

Van der Waals forces [named for Johannes Diderik van der Waals, 1873] — Weak, short-range intermolecular attractions (0.1–10 kJ/mol) arising from transient (London dispersion), permanent-induced (Debye), or permanent-permanent (Keesom) dipole interactions. Important for packing of hydrophobic molecules and protein-ligand recognition. → section 1

Virulence [L *virulentus* = full of poison] — The capacity of a pathogen to cause disease; quantified as the proportion of infected hosts that develop disease or die. Virulence factors include toxins, adhesins, capsules, and immune evasion mechanisms. → section 24

W

Water potential (Ψ) [named analogy to electrical potential] — A measure of the free energy of water in a system relative to pure water: $\Psi = \Psi_s + \Psi_p$ (solute + pressure components). Water moves from high Ψ to low Ψ (down the gradient). Units: megapascals (MPa). → section 28

X

Xylem [Gk *xylon* = wood] — The vascular tissue that conducts water and dissolved minerals from roots to aerial organs; composed of non-living tracheids and vessel members (dead at maturity) plus parenchyma and fibers. Water moves by cohesion-tension mechanism. → section 28

Z

Zygote [Gk *zygotos* = yoked] — The diploid cell formed by the fusion of two haploid gametes during fertilization; the first cell of a new organism; undergoes mitotic divisions to form the embryo. → section 17

This glossary covers about 120 core terms. Chapter-specific key terms are listed in each chapter’s Key Terms section. For full index, see the combined PDF output.

Additional Terms

C (continued)

Carrying capacity (K) [L *capax* = able to hold] — The maximum number of individuals an environment can support indefinitely, determined by resource availability; the equilibrium of the logistic growth model $dN/dt = rN(1 - N/K)$. → section 36

Chloroplast [Gk *chloros* = green + *plastos* = formed] — A double-membrane plant organelle derived from a cyanobacterial endosymbiont; contains the thylakoid membranes (light reactions) and stroma (Calvin cycle); its own circular genome encodes about 80 proteins. → section 10

Coevolution [L *co*- = together + *evolutio* = unrolling] — The reciprocal evolutionary change in two or more species exerting strong selective pressure on each other; classic examples: plant-pollinator mutualism, host-parasite arms races, flowering plant-butterfly chemical coevolution (Ehrlich & Raven, 1964). → section 37

Competitive exclusion [L *competere* = to strive together + *excludere* = to shut out] — Gause’s competitive exclusion principle (1934): two species competing for identical limiting resources cannot coexist indefinitely at equilibrium; one will be excluded. → section 37

Copepod [Gk *kope* = oar + *pous/podos* = foot] — A crustacean subclass of small aquatic organisms forming a major component of marine and freshwater zooplankton; primary consumers linking phytoplankton to larger predators in ocean food webs. → section 39

D (continued)

Decomposer [L *de* = down + *componere* = put together] — An organism (primarily bacteria and fungi) that breaks dead organic matter into inorganic nutrients through enzymatic digestion; drives nutrient cycling in every ecosystem. → section 39

Density-dependent regulation [L *densus* = thick] — A population regulatory mechanism whose effect (per-capita birth or death rate) changes as a function of population density; resource competition, disease, and predation are density-dependent. Contrast: density-independent factors (e.g., floods, fires). → section 36

Depolarization [L *de* = away from + Gk *polos* = pivot] — A decrease in magnitude of membrane potential (movement toward zero or positive values); in neurons, caused by Na^+ influx through voltage-gated channels during the rising phase of an action potential. Contrast: repolarization, hyperpolarization. → section 32

E (continued)

Effective population size (N_e) [Gk *effectivus* = productive] — An idealised census number equivalent to the actual population in terms of rate of genetic drift; typically much smaller than the census size due to unequal sex ratios, variance in reproductive success, and population size fluctuations. $\sigma^2(\Delta p) = pq/2N_e$. → section 22

Eusociality [Gk *eu* = good/true + L *socialis* = allied] — Social organization with cooperative brood care, overlapping generations, and reproductive division of labor, including sterile or weakly reproductive worker castes in ants, many bees and wasps, and termites. → sections 21 and 23

Epiphyte [Gk *epi* = upon + *phyton* = plant] — A plant that grows on another plant for physical support without parasitising it; absorbs water and nutrients from rain and air; orchids, bromeliads, and ferns are prominent epiphytes. → section 40

Eutrophication [Gk *eutrophos* = well-nourished] — Nutrient enrichment of an aquatic body (typically N and P from agricultural runoff) triggering algal blooms; subsequent decomposition of algal biomass depletes dissolved oxygen, causing hypoxic dead zones. → section 39

F (continued)

Fermentation [L *fermentum* = leaven] — Anaerobic metabolic process regenerating NAD⁺ by reducing pyruvate to lactate (lactic acid fermentation) or to ethanol + CO₂ (alcoholic fermentation); net gain: 2 ATP/glucose. → section 9

Founder effect [OE *funden* = to establish] — A form of genetic drift in which allele frequencies in a new population established from a small group of founders differ from the source population by chance; can lead to high prevalence of otherwise rare alleles. → section 22

Frond [L *frons/frondis* = leafy branch] — The large leaf of a fern or other pteridophyte; bears sporangia on its underside (in a sorus); anatomically equivalent to a compound leaf. → section 28

G (continued)

Genetic drift [ON *drift* = a driving of snow] — Random, chance changes in allele frequencies in a population from generation to generation due to sampling error in finite populations; stronger effect in small populations. → section 22

GPP (gross primary productivity) [Gk *ge* = earth + *protos* = first + L *producere*] — The total rate of photosynthetic carbon fixation by producers; GPP – R_a (autotrophic respiration) = NPP (net primary productivity). → section 39

Guard cell [ME *garde* = protection + L *cella* = small room] — One of two kidney-shaped epidermal cells flanking a stoma; changes in turgor pressure (driven by K⁺ and water movement) open or close the stomatal pore to regulate gas exchange and water loss. → section 28

H (continued)

Haplodiploidy [Gk *haploos* = single + *diploos* = double] — Sex-determination system in which haploid males develop from unfertilised eggs and diploid females from fertilized eggs; important in many Hymenoptera but not sufficient by itself to explain eusociality. → section 21

Herd immunity [ME *herd* = flock + L *immunis* = exempt] — Indirect protection of susceptible individuals when a sufficiently large proportion of the population is immune (vaccinated or recovered), reducing pathogen transmission; threshold: p_c = 1 – 1/R₀. → section 24

Herbivory [L *herba* = grass + *vorare* = to devour] — Consumption of plant or algal tissue by an animal or other organism; herbivores occupy the second trophic level; plant defenses (thorns, secondary metabolites, trichomes) and herbivore counter-adaptations drive coevolution. → section 37

Hormone [Gk *hormaein* = to set in motion] — A chemical signal produced in one part of an organism that travels (via blood in animals, phloem in plants) to act on distant target cells bearing specific receptors; plant hormones (phytohormones) include auxin, gibberellin, cytokinin, abscisic acid, and ethylene. → sections 29, 34 and 35

I (continued)

Innate immunity [L *innatus* = inborn] — The non-specific, evolutionarily ancient first-line defense against pathogens; includes physical barriers (skin, mucous membranes), phagocytes (neutrophils, macrophages), complement, and pattern recognition receptors (TLRs detecting PAMPs). Acts within minutes to hours. → section 35

Inclusive fitness [L *includere* = to enclose + OE *fit* = suitable] — Total genetic contribution to future generations through both direct reproduction and indirect effects on relatives' reproduction, weighted by relatedness. → section 21

Intrinsic rate of increase (r) [L *intrinsecus* = inward] — The per-capita growth rate of a population under ideal (unlimited) conditions; r = ln(λ) where λ is the per-generation finite rate of increase; positive r = growing population; r = 0 at K. → section 36

Island biogeography [OE *ealand* = island + Gk *ge* = earth + *graphein* = to write] — The study of factors affecting species richness of islands (or habitat patches); key model: species richness at equilibrium = balance between immigration rate and extinction rate; species-area law $S = cA^z$ (MacArthur & Wilson, 1967). → section 40

K (continued)

K-strategist [see *carrying capacity* + Gk *strategia* = strategy] — An organism with a life history strategy maximizing competitive success near carrying capacity: slow growth, long lifespan, large body, few offspring with high parental investment. Contrast: r-strategist. → section 36

L (continued)

Life table [ME *lyf* + L *tabula* = flat board] — A tabular display of age-specific survival (*lx*) and fecundity (*mx*) values for a cohort; used to calculate net reproductive rate ($R_0 = \sum lx \cdot mx$) and intrinsic rate of increase (*r*). → section 36

Logistic growth [Gk *logistikos* = skilled in reckoning] — Population growth model $dN/dt = rN(1 - N/K)$, producing a sigmoidal S-shaped curve; growth decelerates as population approaches carrying capacity *K*; introduced by Verhulst (1838). → section 36

M (continued)

Minimum viable population (MVP) [L *minus* = smallest + *vita* = life] — The smallest population size with a specified probability (e.g., 99%) of persisting for a given period (e.g., 1,000 years); accounts for demographic stochasticity, environmental stochasticity, and genetic factors; used in conservation planning. → section 40

Molecular clock [Gk *molecula* + OE *clocke*] — The approximate constancy of the rate of neutral nucleotide substitution in lineages; enables dating of evolutionary divergence events: $t = d/(2\mu)$ where *d* = sequence divergence, μ = substitution rate per year. Calibrated using the fossil record. → section 22

Mutualism [L *mutuus* = mutual, reciprocal] — A symbiotic relationship benefiting both participating species (+/+); examples: mycorrhizal fungi increasing plant phosphorus uptake, nitrogen-fixing *Rhizobium* in legume root nodules, cleaner fish and reef fish. → section 37

Mycorrhiza [Gk *mykes* = fungus + *rhiza* = root] — A mutualistic association between soil fungi (Glomeromycota for arbuscular type; Basidiomycota/Ascomycota for ectomycorrhizal type) and plant roots; fungi receive photosynthate, plant receives water and phosphorus; present in about 80% of land plants. → section 28

Myrmecochory [Gk *myrmex* = ant + *choreia* = movement/dance] — Seed dispersal by ants, often mediated by lipid-rich elaiosomes that reward ants for carrying seeds to nests or nutrient-enriched refuse sites. → sections 29, 37 and 38

N (continued)

Neuron [Gk *neuron* = nerve, sinew] — The basic signaling unit of the nervous system; consists of a cell body (soma), dendrites (input), and an axon (output); classified by function (sensory, motor, interneuron) or morphology; communicates via electrical (action potentials) or chemical (synaptic) signals. → section 32

Neutral theory [L *neutralis* = neither + Gk *theoria* = view] — Kimura’s (1968) theory that the majority of molecular evolutionary change is selectively neutral (neither advantageous nor deleterious); neutral mutations drift to fixation at a rate equal to the mutation rate (*u*), independent of population size. → section 22

Nitrification [L *nitrum* = saltpetre + *facere* = to make] — The aerobic microbial oxidation of ammonium (NH₄⁺) to nitrite (NO₂⁻) by *Nitrosomonas*, then nitrite to nitrate (NO₃⁻) by *Nitrobacter*; a key step in the nitrogen cycle making nitrogen available to most plants. → section 39

Nitrogen fixation [L *nitrum* + *fixatio* = making firm] — The enzymatic reduction of atmospheric N₂ to NH₃ by nitrogenase; performed by free-living bacteria (*Azotobacter*, cyanobacteria) and symbionts (*Rhizobium*, *Frankia*); rate about 120 Tg N/yr globally. → section 24

O (continued)

Operon [L *opus* = work] — A prokaryotic gene cluster transcribed as a polycistronic mRNA from a single promoter; regulated by operator/repressor interactions; the *lac* operon (Jacob & Monod, 1961) was the first characterized gene regulatory system; Nobel Prize 1965. → section 13

P (continued)

Parasite [Gk *parasitos* = one who eats beside another] — An organism that benefits from living in or on a host organism at the host’s expense (+/-); parasites reduce host fitness without immediately killing the host (unlike predators); include worms (helminths), protozoa, and many bacteria and fungi. → section 24

Photoperiodism [Gk *photos* = light + L *periodus* = cycle] — The response of an organism to the relative duration of day and night (photoperiod); controls flowering (long-day vs. short-day vs. day-neutral plants) via phytochrome, a red/far-red reversible photoreceptor. → section 30

Phytochrome [Gk *phyton* = plant + *chroma* = color] — A plant photoreceptor protein interconvertible between a red-light-absorbing form (Pr, 660 nm) and a far-red-light-absorbing form (Pfr, 730 nm); Pfr is the biologically active form; governs seed germination, shade avoidance, and flowering. → section 30

Phytoplankton [Gk *phyton* = plant + *planktos* = wandering] — Microscopic photosynthetic organisms (cyanobacteria, diatoms, dinoflagellates) drifting in the photic zone of aquatic ecosystems; responsible for about 50% of Earth’s net primary productivity. → section 39

Population genetics [L *populus* = people + Gk *genos* = birth + *statistike* = statecraft] — The study of allele and genotype frequency distributions and their changes in populations; mathematical foundation provided by Hardy, Weinberg (1908), Fisher, Wright, and Haldane (1930s). → section 20

Primary succession [L *primus* = first + *successio* = following] — Ecological succession on a surface not previously colonised (e.g., bare rock after a lava flow or retreating glacier); begins with pioneer species (lichenised fungi, mosses) and proceeds through intermediate stages to a climax community. → section 37

Proton-motive force (Δp) [Gk *proton* = first + L *movere* = to move] — The electrochemical driving force for proton movement across a membrane, composed of a chemical gradient ($\Delta p H$) and an electrical gradient ($\Delta \Psi$); Δp (mV) = $\Delta \Psi - 59 \Delta p H$; drives ATP synthase rotation. → section 9

R (continued)

Reflex arc [L *reflectere* = to bend back] — The neural pathway of a reflex response: stimulus → sensory neuron → integration center (interneuron in spinal cord or brain) → motor neuron → effector; characterized by Sherrington (1906). → section 32

Reproductive isolation [L *reproducere* = to produce again + *isolatus* = set apart] — The existence of biological barriers (prezygotic or postzygotic) preventing interbreeding between populations; the operational criterion for separate species status in the Biological Species Concept (Mayr). → section 22

r-strategist [see *r*, rate of increase + Gk *strategia*] — An organism with a life history strategy maximizing reproductive rate (*r*): small body, rapid maturation, large clutch sizes, little parental investment; thrives in unstable, unpredictable environments. Contrast: K-strategist. → section 36

Resting potential [ME *resten* + L *potentialis*] — The stable membrane potential of a non-stimulated neuron (about −70 mV inside relative to outside); maintained by the sodium-potassium pump (3 Na⁺ out, 2 K⁺ in per ATP) and selective membrane permeability. → section 32

S (continued)

Saprophyte [Gk *sapros* = rotten + *phyton* = plant] — An organism that obtains nutrients by absorbing dissolved organic compounds from dead or decaying matter; now more precisely called saprotrophic or decomposer; includes most fungi and many bacteria. → section 39

Secondary succession [L *secundus* = following + *successio*] — Ecological succession in an area where a previous community has been disrupted (fire, flood, deforestation) but soil and seed bank remain; faster than primary succession; classic example: forest regeneration after clear-cutting. → section 37

Self-organization [OE *self* + Gk *organon* = tool/instrument] — The emergence of ordered pattern from local interactions without central control; examples include biofilms, morphogen gradients, flocking, and vegetation patching in drylands. → sections 2 and 36

Shannon diversity index (*H'*) [after Claude Shannon’s information entropy, 1948] — A measure of species diversity: $H' = -\sum p_i \ln p_i$ where p_i is the relative abundance of species *i*; higher *H'* = greater diversity; *H'* = 0 for a monoculture; simultaneously measures species richness and evenness. → section 38

Signal transduction [L *signum* = mark + *transducere* = to lead across] — The process by which a receptor converts an extracellular signal (ligand, light, mechanical force) into an intracellular biochemical response via cascades of protein-protein interactions and phosphorylation events. → section 8

SNP (single-nucleotide polymorphism) [genetics abbreviation] — A common single-base genomic variant, usually defined by minor allele frequency of at least 1% in a population; used as a marker in GWAS, ancestry inference, and risk prediction. → sections 14, 17 and 18

Stigmergy [Gk *stigma* = mark + *ergon* = work] — Coordination by environmental traces, such as pheromone trails or construction cues, through which individual actions modify the environment and guide later actions by others. → section 0.2

Stomata (sing. stoma) [Gk *stoma* = mouth] — Microscopic pores in the leaf epidermis flanked by guard cells; regulate CO₂ entry for photosynthesis and water vapor exit (transpiration); respond to light, CO₂ concentration, and ABA. → section 28

Succession [L *successio* = a following] — The directional, predictable change in species composition of a community over time from initial colonization to a relatively stable climax community; driven by facilitation, inhibition, or tolerance mechanisms. → section 37

Superorganism [L *super* = above + Gk *organon* = instrument] — A colony-level analogy for tightly integrated societies, especially social insects, in which individuals function like differentiated parts of a larger reproductive and regulatory unit. → sections 0.2 and 21

Survivorship curve [L *super* = beyond + *vivere* = to live] — A graph of the proportion of a cohort surviving to each age; Type I (most survive to old age; humans, large mammals); Type II (constant mortality rate; many birds); Type III (high early mortality; marine invertebrates, most plants). → section 36

Sympatric speciation [Gk *sym* = together + L *patria* = homeland] — Speciation occurring within a single geographic area without physical barriers; common in plants via allopolyploidy; also documented in cichlids and apple maggot flies. → section 22

T (continued)

T helper cell (Th) [L *thymus* + ME *helpen*] — A CD4+ T lymphocyte that coordinates adaptive immunity; Th1 cells activate cytotoxic T cells and macrophages (intracellular pathogens); Th2 cells activate B cells (antibody production, extracellular pathogens); regulatory T cells (Treg) suppress autoimmunity. → section 35

Telomere [Gk *telos* = end + *meros* = part] — Repetitive non-coding DNA sequences (TTAGGG)_n capping eukaryotic chromosome ends; protect against exonuclease degradation, end-to-end chromosome fusions, and loss of information-carrying DNA; shortened with each S phase (end-replication problem) unless telomerase is expressed. Nobel Prize 2009 (Blackburn, Greider, Szostak). → section 12

Thermoregulation [Gk *therme* = heat + L *regulare* = to rule] — Maintenance of body temperature within a physiological range; endotherms (birds, mammals) generate heat metabolically; ectotherms (reptiles, fish) rely on behavioral and environmental sources; homeostatic mechanism with hypothalamic ‘thermostat’. → section 32

Toll-like receptor (TLR) [*Toll* = German interjection of amazement; Toll pathway discovered in *Drosophila* by Christiane Nüsslein-Volhard] — A family of pattern-recognition receptors (TLR1–10 in humans, with additional functional TLRs in other mammals) expressed on innate immune cells; recognize conserved PAMPs and signal via MyD88 and TRIF adaptors to activate NF-κB and IRF3. Dysregulation linked to sepsis and autoimmune disease. Nobel Prize 2011 (Hoffmann, Beutler). → section 35

Totipotency [L *totus* = whole + *potens* = powerful] — The ability of a single cell to develop into a complete organism; characterizes fertilized eggs and early-cleavage blastomeres; plant cells frequently retain totipotency (basis of tissue culture propagation). → section 28

Transpiration stream [L *trans* + *spirare* = breathe] — The continuous movement of water from soil through roots, stem, and leaves to the atmosphere; driven by evaporation from mesophyll cell walls; responsible for transport of dissolved minerals throughout the plant. → section 28

Trophic cascade [Gk *trophe* = nourishment + L *cascata* = waterfall] — Indirect predator effects on non-prey species, transmitted down the food chain; top-down cascade: predator suppresses herbivore → vegetation recovers; bottom-up cascade: primary productivity determines higher trophic levels. Documented in Yellowstone (wolves → elk → willows → beaver → hydrology). → section 37

Turgor pressure [L *turgere* = to swell] — The pressure exerted by the contents of a plant cell against its cell wall when the vacuole is filled with water; drives cell expansion during growth and maintains tissue rigidity (wilting = loss of turgor). → section 28

V (continued)

Vaccine [L *vacca* = cow; from Jenner’s cowpox inoculation against smallpox, 1796] — A biological preparation conferring immunity against a specific pathogen; types include live-attenuated (MMR), inactivated (IPV), subunit (HepB), mRNA (SARS-CoV-2 mRNA-1273, BNT162b2), and viral vector vaccines. → section 24

Viviparity [L *vivus* = alive + *parere* = to beget] — Giving birth to live young rather than laying eggs; characteristic of most mammals and some fish, reptiles, and invertebrates; requires placentation (in eutherian mammals) for gas and nutrient exchange. → section 32

W (continued)

Watershed [OE *wæter* + OE *scēad* = divide] — The land area draining into a common body of water (stream, lake, or estuary); the ecological unit for studying nutrient export, hydrology, and land-use impacts on aquatic ecosystems; Hubbard Brook watershed experiments (Bormann & Likens, 1967) pioneered biogeochemical cycle measurement at watershed scale. → section 39

Expanded glossary now covers about 200 terms across all 10 units. Etymologies sourced from Oxford Latin Dictionary, Liddell-Scott-Jones Greek-English Lexicon, and Online Etymology Dictionary (etymonline.com).

Appendix G — Index of Key Terms

Appendix G · Level 1/3 · Use as reference

An index of the 225 glossary terms, each with the chapter(s) where the term is introduced, bolded, or discussed at length. Terms marked in bold appear as section headings somewhere in the textbook; the glossary entry carries the full definition.

Each entry follows the pattern:

Term (`#gl:slug`) with semantic chapter links

The `#gl:slug` anchor is the canonical location defined in the master glossary (`manuscript/glossary.md`). Full-text search for the slug string finds every cross-reference.

Note on maintenance. This index is maintained by `scripts/link_glossary.py` from the glossary file and canonical ToC labels. To verify after editing `glossary.md`, run `uv run python scripts/link_glossary.py --check`.

5-Methylcytosine (5mC) (`#gl:5-methylcytosine`) → section 15

A

Abiotic (`#gl:abiotic`) → section 40 Actin (`#gl:actin`) → section 6 Action potential (`#gl:action-potential`) → section 32 Adaptive immunity (`#gl:adaptive-immunity`) → section 35 Adenosine triphosphate(ATP) (`#gl:adenosine-triphosphate`) → section 9 Aerobic (`#gl:aerobic`) → section 9 Allele (`#gl:allele`) → section 17 Allostasis (`#gl:allostasis`) → section 0.3 Allosteric (`#gl:allosteric`) → section 4 Anaerobic (`#gl:anaerobic`) → section 9 Anaphase (`#gl:anaphase`) → section 12 Angiosperm (`#gl:angiosperm`) → section 28 Anticodon (`#gl:anticodon`) → section 13 Apoptosis (`#gl:apoptosis`) → section 8 Archaea (`#gl:archaea`) → sections 5 and 23 ATP synthase (`#gl:atp-synthase`) → section 9 Autonomic nervous system (ANS) (`#gl:autonomic-nervous-system`) → section 32 Autotroph (`#gl:autotroph`) → sections 5, 37 and 38 Axon hillock (`#gl:axon-hillock`) → section 32

B

Base pair (bp) (`#gl:base-pair`) → section 12 Biofilm (`#gl:biofilm`) → section 24 Biome (`#gl:biome`) → section 40 Buffer (`#gl:buffer`) → section 1

C

Calvin cycle (`#gl:calvin-cycle`) → section 10 CaMKII (Calcium/calmodulin-dependent kinase II) (`#gl:camkii`) → section 33 Cardiac output (CO) (`#gl:cardiac-output`) → section 31 Carrying capacity (K) (`#gl:carrying-capacity`) → section 36 Caspase (`#gl:caspase`) → section 8 cDNA (`#gl:cdna`) → section 13 Cell cycle (`#gl:cell-cycle`) → section 12 Centromere (`#gl:centromere`) → section 12 Chemiosmosis (`#gl:chemiosmosis`) → section 9 Chirality (`#gl:chirality`) → section 1 Chlorophyll (`#gl:chlorophyll`) → section 10 Chloroplast (`#gl:chloroplast`) → section 10 Chromatin (`#gl:chromatin`) → section 15 Chromosome (`#gl:chromosome`) → section 12 Codon (`#gl:codon`) → section 13 Coevolution (`#gl:coevolution`) → section 37 Cohesion-tension theory (`#gl:cohesion-tension-theory`) → section 28 Competitive exclusion (`#gl:competitive-exclusion`) → section 37 Competitive inhibition (`#gl:competitive-inhibition`) → section 4 Copepod (`#gl:copepod`) → section 39 Cortisol (`#gl:cortisol`) → section 35 CpG island (`#gl:cpg-island`) → section 15 CRISPR-Cas (`#gl:crispr-cas`) → section 14 Cytoplasm (`#gl:cytoplasm`) → section 6 Cytoskeleton (`#gl:cytoskeleton`) → section 6

D

Decomposer (`#gl:decomposer`) → section 39 Density-dependent regulation (`#gl:density-dependent-regulation`) → section 36 Depolarization (`#gl:depolarization`) → section 32 Diploid (2n) (`#gl:diploid`) → section 19 DNA helicase (`#gl:dna-helicase`) → section 12 DNA ligase (`#gl:dna-ligase`) → section 12 Dominant (`#gl:dominant`) → section 17 Doubling time (`td`) (`#gl:doubling-time`) → section 24

E

Effective population size (N_e) (`#gl:effective-population-size`) → section 22 Electronegativity (`#gl:electronegativity`) → section 1 Endocytosis (`#gl:endocytosis`) → section 7 Endosymbiosis (`#gl:endosymbiosis`) → section 5 Entropy (S) (`#gl:entropy`) → section 9 Enzyme (`#gl:enzyme`) → section 4 Epigenetics (`#gl:epigenetics`) → section 15 Epigenome (`#gl:epigenome`) → section 14 Epiphyte (`#gl:epiphyte`) → section 40 Euchromatin (`#gl:euchromatin`) → section 15 Eukaryote (`#gl:eukaryote`) → section 5 Eusociality (`#gl:eusociality`) → sections 21 and 23 Eutrophication (`#gl:eutrophication`) → section 39 Excitotoxicity (`#gl:excitotoxicity`) → section 33 Exon (`#gl:exon`) → section 13

F

Facilitated diffusion (#gl:facilitated-diffusion) → section 7 Fatty acid (#gl:fatty-acid) → section 3 Fermentation (#gl:fermentation) → section 9 FEV₁/FVC (#gl:fev-fvc) → section 31 Fisheries (#gl:fisheries) → sections 36 and 40 Fitness (w) (#gl:fitness) → section 20 Founder effect (#gl:founder-effect) → section 22 Frank-Starling law (#gl:frank-starling-law) → section 31 Free energy (ΔG) (#gl:free-energy) → section 9 Frond (#gl:frond) → section 28

G

Gamete (#gl:gamete) → section 19 Gene (#gl:gene) → section 15 Genetic code (#gl:genetic-code) → section 13 Genetic drift (#gl:genetic-drift) → section 22 Genome (#gl:genome) → section 14 Genome-wide association study (GWAS) (#gl:genome-wide-association-study) → section 14 GLP-1 (glucagon-like peptide-1) (#gl:glp-1) → section 35 GLUT4 (#gl:glut4) → section 35 Glycolysis (#gl:glycolysis) → section 9 GPP (gross primary productivity) (#gl:gpp) → section 39 Gram stain (#gl:gram-stain) → section 5 Guard cell (#gl:guard-cell) → section 28

H

Haplodiploidy (#gl:haplodiploidy) → section 21 Haploidy (n) (#gl:haploidy) → section 19 Hardy-Weinberg equilibrium (#gl:hardy-weinberg-equilibrium) → section 20 Herbivory (#gl:herbivory) → section 37 Herd immunity (#gl:herd-immunity) → section 24 Heterochromatin (#gl:heterochromatin) → section 15 Heterozygous (#gl:heterozygous) → section 17 Hill coefficient (n) (#gl:hill-coefficient) → section 4 Histone (#gl:histone) → section 15 Histone code (#gl:histone-code) → section 15 Holobiont (#gl:holobiont) → sections 24 and 25 Homeostasis (#gl:homeostasis) → section 32 Hormone (#gl:hormone) → sections 29, 34 and 35 HPA axis (hypothalamic-pituitary-adrenal axis) (#gl:hpa-axis) → section 35 HPG axis (hypothalamic-pituitary-gonadal axis) (#gl:hpg-axis) → section 35 HPT axis (hypothalamic-pituitary-thyroid axis) (#gl:hpt-axis) → section 35 Hydrogen bond (#gl:hydrogen-bond) → section 1 Hydrolysis (#gl:hydrolysis) → sections 3 and 4 Hydrophobic effect (#gl:hydrophobic-effect) → sections 2 and 3

I

Inclusive fitness (#gl:inclusive-fitness) → section 21 Independent assortment (#gl:independent-assortment) → section 17 Innate immunity (#gl:innate-immunity) → section 35 Insulin receptor (#gl:insulin-receptor) → section 35 Intrinsic rate of increase (r) (#gl:intrinsic-rate-of-increase) → section 36 Intron (#gl:intron) → section 13 Island biogeography (#gl:island-biogeography) → section 40

K

K-strategist (#gl:k-strategist) → section 36 Keystone species (#gl:keystone-species) → section 37 Km (Michaelis constant) (#gl:km) → section 4

L

Life table (#gl:life-table) → section 36 Linkage (#gl:linkage) → section 19 Locus (plural: loci) (#gl:locus) → section 19 Logistic growth (#gl:logistic-growth) → section 36 Lotka-Volterra equations (#gl:lotka-volterra-equations) → section 37 LTD (long-term depression) (#gl:ltd) → section 33 LTP (long-term potentiation) (#gl:ltп) → section 33

M

Meiosis (#gl:meiosis) → section 19 Membrane potential (Vm) (#gl:membrane-potential) → section 31 Michaelis-Menten kinetics (#gl:michaelis-menten-kinetics) → section 4 Microbiome (#gl:microbiome) → section 24 Microbiota (#gl:microbiota) → section 24 MicroRNA (miRNA) (#gl:microrna) → section 15 Minimum viable population (MVP) (#gl:minimum-viable-population) → section 40 Mitosis (#gl:mitosis) → section 12 Molecular clock (#gl:molecular-clock) → section 22 mRNA (messenger RNA) (#gl:mrna) → section 13 Mutation (#gl:mutation) → section 14 Mutualism (#gl:mutualism) → section 37 Mycorrhiza (#gl:mycorrhiza) → section 28 Myrmecochory (#gl:myrmecochory) → sections 29, 37 and 38

N

Natural selection (#gl:natural-selection) → section 20 Neuron (#gl:neuron) → section 32 Neutral theory (#gl:neutral-theory) → section 22 Niche (#gl:niche) → section 37 Nitrification (#gl:nitrification) → section 39 Nitrogen fixation (#gl:nitrogen-fixation) → section 24 Nucleosome (#gl:nucleosome) → section 15 Nucleotide (#gl:nucleotide) → section 12

O

Operon (#gl:operon) → section 13 Organelle (#gl:organelle) → section 6 Osmosis (#gl:osmosis) → section 7 Oxidative phosphorylation (#gl:oxidative-phosphorylation) → section 9

P

Pan-genome (#gl:pan-genome) → section 14 Parasite (#gl:parasite) → section 24 Peptide bond (#gl:peptide-bond) → section 3 pH (#gl:ph) → section 1 Phenotype (#gl:phenotype) → section 17 Phospholipid bilayer (#gl:phospholipid-bilayer) → section 7 Photoperiodism (#gl:photoperiodism) → section 30 Photosynthesis (#gl:photosynthesis) → section 10 Phytochrome (#gl:phytochrome) → section 30 Phytoplankton (#gl:phytoplankton) → section 39 Plasmid

(#gl:plasmid) → section 5 Poiseuille’s law (#gl:poiseuille-s-law) → section 31 Polymerase chain reaction (PCR) (#gl:polymerase-chain-reaction) → section 14 Population genetics (#gl:population-genetics) → section 20 Primary succession (#gl:primary-succession) → section 37 Promoter (#gl:promoter) → section 13 Protein (#gl:protein) → section 3 Proton-motive force (Δp) (#gl:proton-motive-force) → section 9 P_{50} (#gl:p) → section 31

R

r-strategist (#gl:r-strategist) → section 36 RAAS (renin-angiotensin-aldosterone system) (#gl:raas) → section 31 Recombination (#gl:recombination) → section 19 Reduction potential (E°) (#gl:reduction-potential) → section 1 Reflex arc (#gl:reflex-arc) → section 32 Reproductive isolation (#gl:reproductive-isolation) → section 22 Resting potential (#gl:resting-potential) → section 32 Ribonucleic acid (RNA) (#gl:ribonucleic-acid) → section 13 Ribosome (#gl:ribosome) → section 13

S

Saltatory conduction (#gl:saltatory-conduction) → section 33 Saprophyte (#gl:saprophyte) → section 39 Secondary succession (#gl:secondary-succession) → section 37 Selection coefficient (s) (#gl:selection-coefficient) → section 20 Self-organization (#gl:self-organization) → sections 2 and 36 Shannon diversity index (H') (#gl:shannon-diversity-index) → section 38 Signal transduction (#gl:signal-transduction) → section 8 SNARE complex (#gl:snare-complex) → section 33 SNP (single-nucleotide polymorphism) (#gl:snp) → sections 14, 17 and 18 Speciation (#gl:speciation) → section 22 Species-area relationship (#gl:species-area-relationship) → section 40 Stigmergy (#gl:stigmergy) → section 0.2 Stomata (#gl:stomata) → section 28 Succession (#gl:succession) → section 37 Superorganism (#gl:superorganism) → sections 0.2 and 21 Surface-area-to-volume ratio (A/V) (#gl:surface-area-to-volume-ratio) → section 5 Surfactant (#gl:surfactant) → section 31 Survivorship curve (#gl:survivorship-curve) → section 36 Sympatric speciation (#gl:sympatric-speciation) → section 22 Synaptotagmin (#gl:synaptotagmin) → section 33

T

T helper cell (Th) (#gl:t-helper-cell) → section 35 Telomere (#gl:telomere) → section 12 Thermodynamics (#gl:thermodynamics) → section 9 Thermoregulation (#gl:thermoregulation) → section 32 Toll-like receptor (TLR) (#gl:toll-like-receptor) → section 35 Totipotency (#gl:totipotency) → section 28 Transcription (#gl:transcription) → section 13 Translation (#gl:translation) → section 13 Transpiration (#gl:transpiration) → section 28 Transpiration stream (#gl:transpiration-stream) → section 28 Trophic cascade (#gl:trophic-cascade) → section 37 Trophic level (#gl:trophic-level) → section 39 Turgor pressure (#gl:turgor-pressure) → section 28

V

Vaccine (#gl:vaccine) → section 24 Van der Waals forces (#gl:van-der-waals-forces) → section 1 Virulence (#gl:virulence) → section 24 Viviparity (#gl:viviparity) → section 32

W

Water potential (Ψ) (#gl:water-potential) → section 28 Watershed (#gl:watershed) → section 39

X

Xylem (#gl:xylem) → section 28

Z

Zygote (#gl:zygote) → section 17

Using the index. When a term appears as a bolded, #gl:-linked first use in a chapter (see **Unit I — Chemistry of Life: Introduction** onward), clicking the term jumps to the canonical entry in the master glossary. This appendix provides an author- and instructor-facing overview of which chapter establishes each concept first, useful for lecture planning and term-by-term syllabus design.
