

24th International Society for Music Information Retrieval Conference

November 5-9, 2023
Milan, Italy

Proceedings

ISMIR 2023 was organized by Politecnico di Milano, Fondazione Politecnico di Milano, the International Society for Music Information Retrieval, and a diverse international committee of organizers.

Preface

Welcome to ISMIR 2023, the 24th International Society for Music Information Retrieval Conference. ISMIR is the world’s leading research forum on processing, searching, organizing, and accessing music-related data. Our community reflects a diversity of scientific disciplines, seniority levels, professional affiliations, and cultural backgrounds. We aim to foster and stimulate this diversity, leading to better science and better music services. The organizing team, who came together from all over the world to ensure the success of this event, welcomes you to ISMIR 2023.

Scientific Program

The ISMIR 2023 scientific program comprised three keynote talks, six tutorials and 103 papers. A total of 272 abstracts were registered on the submission system, of which 229 were submitted as complete papers eligible for review. In keeping with the practices of the previous years, a two-tier double-blind review process was conducted involving a total of 211 reviewers and 63 meta-reviewers. Each paper was assigned to a single meta-reviewer and three reviewers, and replacement reviewers were found when the originally assigned reviewer was unable to complete their review. Meta-reviewers were also instructed to complete a full review of each of their assigned papers, in addition to the final meta-review summarizing the individual reviews. Each meta-reviewer and reviewer was responsible for no more than 4 papers, in order that the reviewing load would be manageable, thus promoting careful and thorough reviews. The initial reviewing phase was followed by a discussion period, in which reviewers and meta-reviewers could discuss and revise their assessments of each paper. Meta-reviewers were then instructed to summarize the discussion and reviews in the final report. The Scientific Program Chairs (SPC) made the final decisions on each paper, based on the recommendations of metareviewers and reviewers. 104 papers were accepted (one of which was later withdrawn by the authors), giving an **acceptance rate of 45.4%** (or 38.2% if incomplete submissions are included). The SPC would like to express their thanks to the ISMIR community of reviewers and metareviewers for their wholehearted support of this critical aspect of a successful ISMIR technical program.

Table 1 summarizes the number of submitted and accepted papers in each subject area (as selected by authors during the submission process) together with the corresponding proportion of papers in the program. Table 2 summarizes the publication statistics over the 24-year history of the conference.

Table 1: Papers submitted and accepted by subject area

Subject Area	Submitted	Accepted	Accepted %
MIR tasks	77	21	20.2%
Musical features and properties	42	17	16.3%
Knowledge-driven approaches to MIR	37	18	17.3%
Applications	35	11	10.6%
MIR fundamentals and methodology	22	10	9.6%
Evaluation, datasets, reproducibility	19	7	6.7%
Human-centered MIR	19	8	7.7%
Computational musicology	12	6	5.8%
MIR and ML for musical acoustics	5	3	2.9%
Philosophical and ethical discussions	4	3	2.9%
Total	272	104	

Table 2: Summary of publication statistics over the 24-year-history of the ISMIR conference

Year	Location	Oral	Poster	Total	Authors	Unique Authors	<u>Authors Paper</u>	<u>Unique Authors Paper</u>
2000	Plymouth	19	16	35	68	63	1.9	1.8
2001	Indiana	25	16	41	100	86	2.4	2.1

2014	Taipei	33	73	106	343	271	3.2	2.6
2015	Málaga	24	90	114	370	296	3.2	2.6
2016	New York	25	88	113	341	270	3.0	2.4
2017	Suzhou	24	73	97	324	248	3.3	2.6
2018	Paris			104	337	265	3.2	2.5
2019	Delft			114	390	315	3.4	2.8
2020	Virtual			115	426	343	3.7	3.0
2021	Virtual			104	334	269	3.2	2.6
2022	Bengaluru			113	423	355	3.8	3.0
2023	Milan			103	374	311	3.6	3.0

Best Paper Awards

Awards for the best paper and best student paper were given at ISMIR 2023. Best paper candidates were selected from the 104 accepted papers. The SPC selected six candidate papers based on reviewers’ and meta-reviewers’ nominations as well as the paper review scores and comments. The final selections were made by specially appointed judges drawn from experienced MIR researchers who had no conflict of interest with any of the award candidates. In addition, judges from Universal Music Group selected one paper from a longer list of highly ranked papers on the basis of its contribution to responsible MIR research, for a special Responsible Research Award, sponsored by UMG.

The following papers were nominated for consideration for the Best Paper Awards (in order of paper number):

- *Exploring the Correspondence of Melodic Contour with Gesture in Raga Alap Singing*, Shreyas M Nadkarni, Sujoy Roychowdhury, Preeti Rao and Martin Clayton
- *CLaMP: Contrastive Language-Music Pre-training for Cross-Modal Symbolic Music Information Retrieval*, Shangda Wu, Dingyao Yu, Xu Tan and Maosong Sun
- *BPS-Motif: A Dataset for Repeated Pattern Discovery of Polyphonic Symbolic Music*, Yo-Wei Hsiao, Tzu-Yun Hung, Tsung-Ping Chen and Li Su
- *PESTO: Pitch Estimation with Self-Supervised Transposition-Equivariant Objective*, Alain Riou, Stefan Lattner, Gaëtan Hadjeres and Geoffroy Peeters
- *LP-MusicCaps: LLM-Based Pseudo Music Captioning*, Seunghoon Doh, Keunwoo Choi, Jongpil Lee and Juhan Nam
- *Singing Voice Synthesis Using Differentiable LPC and Glottal-Flow-Inspired Wavetables*, Chin-Yun Yu and George Fazekas

Each of the Best Paper candidates will be invited to publish an extended version of their paper in the Transactions of the International Society for Music Information Retrieval (TISMIR), the open access journal of the Society. The Society will cover the article processing charges of these publications. The following three awards were given:

Best Paper Award *PESTO: Pitch Estimation with Self-Supervised Transposition-Equivariant Objective*, Alain Riou, Stefan Lattner, Gaëtan Hadjeres and Geoffroy Peeters

Best Student Paper Award *CLaMP: Contrastive Language-Music Pre-training for Cross-Modal Symbolic Music Information Retrieval*, Shangda Wu, Dingyao Yu, Xu Tan and Maosong Sun

UMG Award for Responsible Research *Data Collection in Music Generation Training Sets: A Critical Analysis*, Fabio Morreale, Megha Sharma and I-Chieh Wei

Diversity & Inclusion

The ISMIR 2023 conference took a broad view of Diversity, Equity, and Inclusion (DEI). We considered two “sides” of DEI: on the one hand, the diversity and equity in the musical objects we study or create, as well as the musical artists, technological approaches, and content that we work with; and the diversity, equity, and inclusion of the people doing the research in MIR. From this standpoint, the DEI Chairs, in consultation with the organizing committee, coordinated a variety of initiatives with the aim of bringing together (and widening) the range of perspectives, traditions, and people across our MIR community. Notably, thanks to the Board and the generous support of our sponsors, we were able to support an unprecedented level of financial support covering travel, accommodation, registration, and childcare costs. Waivers and fee reductions for the above-mentioned categories were prioritized for underrepresented individuals including women, ethnic minorities, members of the LGBTQIA community, and attendees from low-income countries. In addition, priority was also given to unaffiliated attendees, “new-to-ISMIR” presenters, and students. All attendees were eligible to apply for childcare grants.

Inclusion Panel The aim of the DEI panel was to foster discussion, both between panelists, and between the audience and the panelists, relating to not only the diversity of people who work in MIR, but also diversity in topics, approaches, and data. Panelists were selected based on their excellent track records of commitment to diversity in MIR. After a brief overview of their research and how it has been influenced by, or relates to, DEI, our panelists contributed to a rich discussion of both the content and the people in MIR, and the ways in which we, as a community, can improve. Discussion topics included: bias in music access, consumption, and recommender systems; barriers and issues of DEI in MIR scholarship and how to overcome them; the relation of DEI and “ethical AI”; and how to increase the number of women and minorities in our field.

Moderator: Claire Arthur, Georgia Institute of Technology

Panelists: Anja Volk, Utrecht University; Jin Ha Lee, University of Washington; Christine Bauer, University of Salzburg; Lorenzo Pocarano, European Commission Joint Research Center (Milan)

Inclusion Meetup A DEI meetup session was planned with the aim of designing a social event that would encourage the intermingling of people from different backgrounds, levels of scholarship, and communities. Several interactive activities were organized to encourage movement, mingling, discussion, and entertainment. According to those who were in attendance (over 100 people!), the event was a success.

Host: Riccardo Giampiccolo

Women in Music Information Retrieval (WiMIR)

Women in Music Information Retrieval (WiMIR) is a group of people dedicated to promoting the role of, and increasing opportunities for, women in the MIR field. WiMIR’s initiatives started as informal gatherings around breakfast or lunch during ISMIR conferences (2011–2014), and moved to formal WiMIR events included in the conference program (2015–today) garnering a high turnout of both women and allies. These events provide occasions for people to network and to discuss several important issues ranging from mentorship and conference support, to improving the representation of women and, more broadly, diversity in the community. In 2018, WiMIR started hosting its own workshop as a satellite event, in which attendees of all genders participated. These workshops aim to offer participants an opportunity for networking, put the spotlight on technical work done by women in the field, and foster collaboration between women and allies by proposing group work led by project guides to try to solve small research problems or to undertake new

research projects that could lead to longer-term collaborations. In 2023, due to the decline (and rotation) in volunteers, the WiMIR workshop initiative was suspended. However, the aim is to resume these very popular and successful workshops again in 2024. The ISMIR 2023 DEI Chairs gratefully acknowledge the support of this year's WiMIR sponsors, whose contributions support women in the field as well as the broader DEI efforts of this year's conference.

Newcomer Initiative

A mentoring program was offered in 2023 for prospective authors who are new to ISMIR. They were given feedback on their ideas and drafts of their ISMIR submissions. We would like to thank the following people who volunteered to be mentors for this initiative:

- Emmanouil Benetos
- Geoffroy Peeters
- Brian McFee
- Juhan Nam
- Chris Donahue
- Cheng-i Wang
- Cory McKay
- Jin Ha Lee
- Gus Xia
- Mitsunori Ogihara
- Andre Holzapfel

Special Sessions

The Scientific Program Chairs organized two special sessions. Brief introductions and session information are provided below:

Panel session: Hybrid deep learning for MIR

In MIR, as in many other domains, there is a significant trend towards purely data-driven approaches aimed at directly solving the machine learning problem at hand, while only crudely considering the nature and structure of the data being processed. In the music domain, prior knowledge can relate to the production of sound (using an acoustic model), the way music is perceived (based on a perceptual model), or how music is composed (using a musicological model).

These models can usually be encoded with only a few parameters, leading to controllable and interpretable systems that can be exploited in modern neural-based machine learning frameworks, resulting in so-called hybrid deep learning models.

The aim of this panel was to illustrate the concept of hybrid deep learning with some specific examples in MIR, and to discuss its limits, merits and potential for future machine learning based music applications.

Moderator: Gaël Richard, Télécom Paris

Panelists: George Fazekas, Queen Mary University of London; Changhong Wang, Télécom Paris, Zhiyao Duan, University of Rochester; Gus Xia, NYU Shanghai/MBZUAI

Industry Panel

The industrial panel aimed to facilitate a high-level discussion, providing conference participants with insights into MIR efforts by ISMIR's sponsoring companies. This initiative aimed to foster collaborations among participants, be they from the industry or academic realm. The primary focus was on delving into the future of multi-modal AI in music research – a burgeoning paradigm that leverages diverse data types like audio, image, text, and speech to enhance outcomes. Each panelist briefly presented their perspective on the topic, leading to an open discussion. Notably, the discourse also explored the relevance of existing Large Language Models and their impact on the field of music.

Moderator: Xavier Serra, Director of the Music Technology Group of the Universitat Pompeu Fabra.

Panelists: Justin Salamon, Senior Research Scientist at Adobe; Elio Quinton, VP, Artificial Intelligence at Universal Music Group; Akira Maezawa, Senior Engineer at Yamaha; Fabien Gouyon, Senior Director of Research at Pandora – SiriusXM; Romain Hennequin, Head of Research at Deezer; Maria Stella Tavella, Senior AI Engineer and Manager at Musixmatch; Filip Korzeniowski, Lead Data Scientist at Moises.AI

Late Breaking/Demo Session

The Late Breaking/Demo (LBD) Session is where we showcase cool works that are still in the making — prototypes, early ideas and results that generate excitement in the MIR community. This year we received more submissions than expected. To handle the demand, we split the session into two parts and papers were presented in-person as well as using the virtual platform. Following a light review process by the LBD chairs, we accepted 40 papers for live, in-person presentation, while another 8 papers were accepted for virtual presentation, ensuring broader accessibility to the valuable insights shared within the LBD Session. This decision allowed us to accommodate the diverse preferences and circumstances of our contributors and attendees. Following previous years' practice, LBD contributions are not part of the official ISMIR proceedings and should be seen as non-refereed works — think of them as fresh works in progress and exciting fun demos that led to an exceptionally lively session contributing to this year's edition of ISMIR.

Unconference

ISMIR 2023 reintroduced the “Unconference” session, where participants team up into small groups to engage in discussions on Music Information Retrieval (MIR) topics of their specific interest. Two weeks prior to the session, participants were invited to propose their preferred topics. The session then started with a brief plenary in which session topics of greatest interest were selected. The session gathered around 80 participants, including both students and senior researchers from academia and industry. Four topics, namely "MIR + music education," "Open review for MIR," "Human-centered AI," and "Evaluation of generative AI," were chosen for the initial round of discussions. Subsequently, participants were divided into four groups, engaging in impromptu discussions for 30 minutes. Although it is customary in the Unconference to choose new topics every 30 minutes, the participants in each group were so engrossed in their discussions that they extended the conversation into a second and even a third round, all centered around the same topics. The session concluded with a plenary session, during which one representative from each group was invited to provide a summary of their discussions for the benefit of the other groups. Following this, participants were encouraged to continue their conversations beyond the session and explore opportunities for potential collaborations on the discussed topics.

Music Session

The ISMIR 2023 Music Session received nine submissions, six of which were accepted for presentation. Half of the contributions were performed live, whereas the remaining ones were pre-recorded and reproduced during the session. All the pre-recorded contributions included video content. Overall, the selected submissions showed a high degree of variety, ranging from AI-assisted performances to improvisations with augmented instruments and combinations with visual arts.

Here is the complete list of music pieces that were presented at ISMIR 2023:

Conversations with our Digital Selves: the development of an autonomous music improviser Matthew Yee-King, Mark d'Inverno

“confluyo yo, el ambiente me sigue” Hugo Flores Garcia

Sliogán: a performance composed for the HITar Andrea Martelloni, Andrew McPherson, Mathieu Barthet

The Words I Tried to Say Angela Weihang Ng

Nor Hope Wenbin Lyu

AI Pianist Performance: Collaboration with Soprano Sumi Jo Taegyun Kwon, Joonhyung Bae, Jiyun Park, Jaeran Choi, Hyeyoon Cho, Yonghyun Kim, Dasaem Jeong, Juhan Nam

Satellite Events

In addition to the main conference, four satellite events took place immediately before or after ISMIR, and were attended by many ISMIR delegates:

- Sound Demixing Workshop, November 4, 2023
- Workshop on Reading Music Systems (WoRMS), November 4, 2023
- Workshop on Human-Centric Music Information Research (HCMIR), November, 10, 2023
- 10th International Conference on Digital Libraries for Musicology (DLfM), November, 10, 2023

Acknowledgements

We are happy to present to you the proceedings of ISMIR 2023. The conference program was made possible thanks to the hard work of many people, including the ISMIR 2023 conference chairs, ISMIR Board members, volunteers, and the many reviewers and meta-reviewers from the program committee.

We would also like to thank our sponsors, whose contributions made this conference possible:

Platinum sponsors

- Moises

Gold sponsors

- Yamaha
- MusixMatch
- Algoriddim
- Deezer
- Adobe
- Google Research
- Universal Music Group

Silver sponsors

- ACRCLOUD
- Steinberg
- Native Instruments
- SiriusXM

We would like to thank the sponsors that explicitly chose to sponsor WiMIR, its grants, and its initiatives:

Patron

- Deezer

Contributors

- Moises
- Google Research
- Native Instruments
- SiriusXM

Supporters

- Steinberg

ISMIR 2023 would not have been possible without the exceptional contributions of our community in response to our call for participation. The biggest acknowledgment goes to you, the researchers, presenters and participants.

Table of Contents

Keynote Talks	1
Help! - Bridging the Gap Between Music Technology and Diverse Stakeholder Needs <i>Christine Bauer</i>	3
Building & Launching MIR Systems at Industry Scale <i>Rachel Bittner</i>	4
Seeing the Light Through Music, a Blind Man’s Journey of Discovery Through Audio and How to Navigate Making Music That Speaks to the World in the Age of the Screen Driven Universe <i>Joey Stuckey</i>	5
Tutorials	7
Analysing Physiological Data Collected During Music Listening: An Introduction <i>Laura Bishop, Geoffray Bonnin and Jérémy Frey</i>	9
Introduction to Differentiable Audio Synthesizer Programming <i>Ben Hayes, Jordie Shier, Chin-Yun Yu, David Südholt and Rodrigo Diaz</i>	10
Transformer-Based Symbolic Music Generation: Fundamentals to Advanced Concepts, Stylistic Considerations, Conditioning Mechanisms and Large Language Models <i>Berker Banar, Pedro Sarmiento and Sara Adkins</i>	12
Computer-Assisted Music-Making Systems: Taxonomy, Review, and Coding <i>Christodoulos Benetatos, Zhiyao Duan and Philippe Pasquier</i>	14
Learning With Music Signals: Technology Meets Education <i>Meinard Müller</i>	15
Kymatio: Deep Learning Meets Wavelet Theory for Music Signal Processing <i>Cyrus Vahidi, Christopher Mitcheltree, Vincent Lostanlen</i>	16
Papers – Session I	19
Exploring the Correspondence of Melodic Contour With Gesture in Raga Alap Singing <i>Shreyas Nadkarni, Sujoy Roychowdhury, Preeti Rao, Martin Clayton</i>	21
TriAD: Capturing Harmonics With 3D Convolutions <i>Miguel Perez, Holger Kirchhoff, Xavier Serra</i>	29
Data Collection in Music Generation Training Sets: A Critical Analysis <i>Fabio Morreale, Megha Sharma, I-Chieh Wei</i>	37

A Review of Validity and Its Relationship to Music Information Research <i>Bob L. T. Sturm, Arthur Flexer</i>	47
Segmentation and Analysis of Taniavartanam in Carnatic Music Concerts <i>Gowriprasad R, Srikrishnan Sridharan, R Aravind, Hema A. Murthy</i>	56
Transfer Learning and Bias Correction With Pre-Trained Audio Embeddings <i>Changhong Wang, Gaël Richard, Brian McFee</i>	64
Collaborative Song Dataset (CoSoD): An Annotated Dataset of Multi-Artist Collaborations in Popular Music <i>Michèle Duguay, Kate Mancey, Johanna Devaney</i>	71
Human-AI Music Creation: Understanding the Perceptions and Experiences of Music Creators for Ethical and Productive Collaboration <i>Michele Newman, Lidia Morris, Jin Ha Lee</i>	80
Impact of Time and Note Duration Tokenizations on Deep Learning Symbolic Music Modeling <i>Nathan Fradet, Nicolas Gutowski, Fabien Chhel, Jean-Pierre Briot</i>	89
Musical Micro-Timing for Live Coding <i>Max Johnson, Mark R. H. Gotham</i>	98
A Few-Shot Neural Approach for Layout Analysis of Music Score Images <i>Francisco J. Castellanos, Antonio Javier Gallego, Ichiro Fujinaga</i>	106
TapTamDrum: A Dataset for Dualized Drum Patterns <i>Behzad Haki, Błażej Kotowski, Cheuk Lun Isaac Lee, Sergi Jordà</i>	114
Real-Time Percussive Technique Recognition and Embedding Learning for the Acoustic Guitar <i>Andrea Martelloni, Andrew P. McPherson, Mathieu Barthelet</i>	121
IteraTTA: An Interface for Exploring Both Text Prompts and Audio Priors in Generating Music With Text-to-Audio Models <i>Hiromu Yakura, Masataka Goto</i>	129
Similarity Evaluation of Violin Directivity Patterns for Musical Instrument Retrieval <i>Mirco Pezzoli, Raffaele Malvermi, Fabio Antonacci, Augusto Sarti</i>	138
Polyrhythmic Modelling of Non-Isochronous and Microtiming Patterns <i>George Sioros</i>	146
Papers – Session II	155
CLaMP: Contrastive Language-Music Pre-Training for Cross-Modal Symbolic Music Information Retrieval <i>Shangda Wu, Dingyao Yu, Xu Tan, Maosong Sun</i>	157
Gender-Coded Sound: Analysing the Gendering of Music in Toy Commercials via Multi-Task Learning <i>Luca Marinelli, György Fazekas, Charalampos Saitis</i>	166
A Dataset and Baselines for Measuring and Predicting the Music Piece Memorability <i>Li-Yang Tseng, Tzu-Ling Lin, Hong-Han Shuai, Jen-Wei Huang, Wen-Whei Chang</i>	174
Efficient Notation Assembly in Optical Music Recognition <i>Carlos Peñarrubia, Carlos Garrido-Munoz, Jose J. Valero-Mas, Jorge Calvo-Zaragoza</i>	182
White Box Search Over Audio Synthesizer Parameters <i>Yuting Yang, Zeyu Jin, Connelly Barnes, Adam Finkelstein</i>	190

Decoding Drums, Instrumentals, Vocals, and Mixed Sources in Music Using Human Brain Activity With fMRI <i>Vincent K. M. Cheung, Lana Okuma, Kazuhisa Shibata, Kosetsu Tsukuda, Masataka Goto, Shinichi Furuya</i>	197
Dual Attention-Based Multi-Scale Feature Fusion Approach for Dynamic Music Emotion Recognition <i>Liyue Zhang, Xinyu Yang, Yichi Zhang, Jing Luo</i>	207
Automatic Piano Transcription With Hierarchical Frequency-Time Transformer <i>Keisuke Toyama, Taketo Akama, Yukara Ikemiya, Yuhta Takida, Wei-Hsiang Liao, Yuki Mitsufuji</i>	215
High-Resolution Violin Transcription Using Weak Labels <i>Nazif Can Tamer, Yigitcan Özer, Meinard Müller, Xavier Serra</i>	223
Polyffusion: A Diffusion Model for Polyphonic Score Generation With Internal and External Controls <i>Lejun Min, Junyan Jiang, Gus Xia, Jingwei Zhao</i>	231
The Coordinated Corpus of Popular Musics (CoCoPops): A Meta-Corpus of Melodic and Harmonic Transcriptions <i>Claire Arthur, Nathaniel Condit-Schultz</i>	239
Towards Computational Music Analysis for Music Therapy <i>Anja Volk, Tinka Veldhuis, Katrien Foubert, Jos De Backer</i>	247
Timbre Transfer Using Image-to-Image Denoising Diffusion Implicit Models <i>Luca Comanducci, Fabio Antonacci, Augusto Sarti</i>	257
Correlation of EEG Responses Reflects Structural Similarity of Choruses in Popular Music <i>Neha Rajagopalan, Blair Kaneshiro</i>	264
Chromatic Chords in Theory and Practice <i>Mark R. H. Gotham</i>	272
Papers – Session III	279
BPS-Motif: A Dataset for Repeated Pattern Discovery of Polyphonic Symbolic Music <i>Yo-Wei Hsiao, Tzu-Yun Hung, Tsung-Ping Chen, Li Su</i>	281
Weakly Supervised Multi-Pitch Estimation Using Cross-Version Alignment <i>Michael Krause, Sebastian Strahl, Meinard Müller</i>	289
The Batik-Plays-Mozart Corpus: Linking Performance to Score to Musicological Annotations <i>Patricia Hu, Gerhard Widmer</i>	297
Mono-to-Stereo Through Parametric Stereo Generation <i>Joan Serrà, Davide Scaini, Santiago Pascual, Daniel Arteaga, Jordi Pons, Jeroen Breebaart, Giulio Cengarle</i>	304
From West to East: Who Can Understand the Music of the Others Better? <i>Charilaos Papaioannou, Emmanouil Benetos, Alexandros Potamianos</i>	311
On the Performance of Optical Music Recognition in the Absence of Specific Training Data <i>Juan C. Martinez-Sevilla, Adrián Roselló, David Rizo, Jorge Calvo-Zaragoza</i>	319
Composer’s Assistant: An Interactive Transformer for Multi-Track MIDI Infilling <i>Martin E. Malandro</i>	327
The FAV Corpus: An Audio Dataset of Favorite Pieces and Excerpts, With Formal Analyses and Music Theory Descriptors <i>Ethan Lustig, David Temperley</i>	335

LyricWhiz: Robust Multilingual Zero-Shot Lyrics Transcription by Whispering to ChatGPT <i>Le Zhuo, Ruibin Yuan, Jiahao Pan, Yinghao Ma, Yizhi Li, Ge Zhang, Si Liu, Roger B. Dannenberg, Jie Fu, Chenghua Lin, Emmanouil Benetos, Wenhui Chen, Wei Xue, Yike Guo</i>	343
Sounds Out of Place? Score-Independent Detection of Conspicuous Mistakes in Piano Performances <i>Alia Morsi, Kana Tatsumi, Akira Maezawa, Takuya Fujishima, Xavier Serra</i>	352
VampNet: Music Generation via Masked Acoustic Token Modeling <i>Hugo Flores García, Prem Seetharaman, Rithesh Kumar, Bryan Pardo</i>	359
Expert and Novice Evaluations of Piano Performances: Criteria for Computer-Aided Feedback <i>Yucong Jiang</i>	367
Contrastive Learning for Cross-Modal Artist Retrieval <i>Andres Ferraro, Jaehun Kim, Sergio Oramas, Andreas Ehmann, Fabien Gouyon</i>	375
Repetition-Structure Inference With Formal Prototypes <i>Christoph Finkensiep, Matthieu Haerberle, Friedrich Eisenbrand, Markus Neuwirth, Martin Rohrmeier</i>	383
Algorithmic Harmonization of Tonal Melodies Using Weighted Pitch Context Vectors <i>Peter van Kranenburg, Eoin J. Kearns</i>	391
Text-to-Lyrics Generation With Image-Based Semantics and Reduced Risk of Plagiarism <i>Kento Watanabe, Masataka Goto</i>	398
Papers – Session IV	407
LP-MusicCaps: LLM-Based Pseudo Music Captioning <i>SeungHeon Doh, Keunwoo Choi, Jongpil Lee, Juhan Nam</i>	409
A Repetition-Based Triplet Mining Approach for Music Segmentation <i>Morgan Buisson, Brian McFee, Slim Essid, Helene C. Crayencour</i>	417
Predicting Music Hierarchies With a Graph-Based Neural Decoder <i>Francesco Foscarin, Daniel Harasim, Gerhard Widmer</i>	425
Stabilizing Training With Soft Dynamic Time Warping: A Case Study for Pitch Class Estimation With Weakly Aligned Targets <i>Johannes Zeidler, Simon Deniffel, Michael Krause, Meinard Müller</i>	433
Finding Tori: Self-Supervised Learning for Analyzing Korean Folk Song <i>Danbinaerin Han, Rafael Caro Repetto, Dasaem Jeong</i>	440
Singer Identity Representation Learning Using Self-Supervised Techniques <i>Bernardo Torres, Stefan Latner, Gaël Richard</i>	448
On the Effectiveness of Speech Self-Supervised Learning for Music <i>Yinghao Ma, Ruibin Yuan, Yizhi Li, Ge Zhang, Chenghua Lin, Xingran Chen, Anton Ragni, Hanzhi Yin, Emmanouil Benetos, Norbert Gyenge, Ruibo Liu, Gus Xia, Roger B. Dannenberg, Yike Guo, Jie Fu</i>	457
Transformer-Based Beat Tracking With Low-Resolution Encoder and High-Resolution Decoder <i>Tian Cheng, Masataka Goto</i>	466
Adding Descriptors to Melodies Improves Pattern Matching: A Study on Slovenian Folk Songs <i>Vanessa Nina Borsan, Mathieu Giraud, Richard Groult, Thierry Lecroq</i>	474
How Control and Transparency for Users Could Improve Artist Fairness in Music Recommender Systems <i>Karlijn Dinnissen, Christine Bauer</i>	482

Towards a New Interface for Music Listening: A User Experience Study on YouTube <i>Ahyeon Choi, Eunsik Shin, Haesun Joung, Joongseek Lee, Kyogu Lee</i>	492
FiloBass: A Dataset and Corpus Based Study of Jazz Basslines <i>Xavier Riley, Simon Dixon</i>	500
Comparing Texture in Piano Scores <i>Louis Couturier, Louis Bigo, Florence Levé</i>	508
Introducing DiMCAT for Processing and Analyzing Notated Music on a Very Large Scale <i>Johannes Hentschel, Andrew McLeod, Yannis Rammos, Martin Rohrmeier</i>	516
Sequence-to-Sequence Network Training Methods for Automatic Guitar Transcription With Tokenized Outputs <i>Sehun Kim, Kazuya Takeda, Tomoki Toda</i>	524
Papers – Session V	533
PESTO: Pitch Estimation With Self-Supervised Transposition-Equivariant Objective <i>Alain Riou, Stefan Lattner, Gaëtan Hadjeres, Geoffroy Peeters</i>	535
The Games We Play: Exploring the Impact of ISMIR on Musicology <i>Vanessa Nina Borsan, Mathieu Giraud, Richard Groult</i>	545
Carnatic Singing Voice Separation Using Cold Diffusion on Training Data With Bleeding <i>Genís Plaja-Roglans, Marius Miron, Adithi Shankar, Xavier Serra</i>	553
Unveiling the Impact of Musical Factors in Judging a Song on First Listen: Insights From a User Survey <i>Kosetsu Tsukuda, Tomoyasu Nakano, Masahiro Hamasaki, Masataka Goto</i>	561
Towards Building a Phylogeny of Gregorian Chant Melodies <i>Jan Hajič jr., Gustavo A. Ballen, Klára Hedvika Mühlová, Hana Vlhová-Wörner</i>	571
Audio Embeddings as Teachers for Music Classification <i>Yiwei Ding, Alexander Lerch</i>	579
ScorePerformer: Expressive Piano Performance Rendering With Fine-Grained Control <i>Ilya Borovik, Vladimir Viro</i>	588
Roman Numeral Analysis With Graph Neural Networks: Onset-Wise Predictions From Note-Wise Features <i>Emmanouil Karystinaios, Gerhard Widmer</i>	597
Semi-Automated Music Catalog Curation Using Audio and Metadata <i>Brian Regan, Desislava Hristova, Mariano Beguerisse-Díaz</i>	605
Crowd’s Performance on Temporal Activity Detection of Musical Instruments in Polyphonic Music <i>Ioannis Petros Samiotis, Christoph Lofi, Alessandro Bozzon</i>	612
MoisesDB: A Dataset for Source Separation Beyond 4-Stems <i>Igor Pereira, Felipe Araújo, Filip Korzeniowski, Richard Vogl</i>	619
Music as Flow: A Formal Representation of Hierarchical Processes in Music <i>Zeng Ren, Wulfram Gerstner, Martin Rohrmeier</i>	627
Online Symbolic Music Alignment With Offline Reinforcement Learning <i>Silvan David Peter</i>	634
Inversynth II: Sound Matching via Self-Supervised Synthesizer-Proxy and Inference-Time Finetuning <i>Oren Barkan, Shlomi Shvartzman, Noy Uzrad, Moshe Laufer, Almog Elharar, Noam Koenigstein</i>	642

A Semi-Supervised Deep Learning Approach to Dataset Collection for Query-by-Humming Task <i>Amantur Amatov, Dmitry Lamanov, Maksim Titov, Ivan Vovk, Ilya Makarov, Mikhail Kudinov</i>	649
Towards Improving Harmonic Sensitivity and Prediction Stability for Singing Melody Extraction <i>Keren Shao, Ke Chen, Taylor Berg-Kirkpatrick, Shlomo Dubnov</i>	657
Papers – Session VI	665
Singing Voice Synthesis Using Differentiable LPC and Glottal-Flow-Inspired Wavetables <i>Chin-Yun Yu, György Fazekas</i>	667
Harmonic Analysis With Neural Semi-CRF <i>Qiaoyu Yang, Frank Cwitkowitz, Zhiyao Duan</i>	676
A Dataset and Baseline for Automated Assessment of Timbre Quality in Trumpet Sound <i>Alberto Acquilino, Ninad Puranik, Ichiro Fujinaga, Gary Scavone</i>	684
Visual Overviews for Sheet Music Structure <i>Frank Heyen, Quynh Quang Ngo, Michael Sedlmair</i>	692
Passage Summarization With Recurrent Models for Audio – Sheet Music Retrieval <i>Luís Carvalho, Gerhard Widmer</i>	700
Predicting Performance Difficulty From Piano Sheet Music Images <i>Pedro Ramoneda, Jose J. Valero-Mas, Dasaem Jeong, Xavier Serra</i>	708
Self-Refining of Pseudo Labels for Music Source Separation With Noisy Labeled Data <i>Junghyun Koo, Yunkee Chae, Chang-Bin Jeon, Kyogu Lee</i>	716
Quantifying the Ease of Playing Song Chords on the Guitar <i>Marcel A. Vélez Vásquez, Mariëlle Baelemans, Jonathan Driedger, Willem Zuidema, John Ashley Burgoyne</i>	725
FlexDTW: Dynamic Time Warping With Flexible Boundary Conditions <i>Irmak Bükey, Jason Zhang, TJ Tsai</i>	733
Modeling Bends in Popular Music Guitar Tablatures <i>Alexandre D’Hooge, Louis Bigo, Ken Déguernel</i>	741
Self-Similarity-Based and Novelty-Based Loss for Music Structure Analysis <i>Geoffroy Peeters</i>	749
Modeling Harmonic Similarity for Jazz Using Co-occurrence Vectors and the Membrane Area <i>Carey Bunks, Tillman Weyde, Simon Dixon, Bruno Di Giorgi</i>	757
SingStyle111: A Multilingual Singing Dataset With Style Transfer <i>Shuqi Dai, Yuxuan Wu, Siqu Chen, Roy Huang, Roger B. Dannenberg</i>	765
A Computational Evaluation Framework for Singable Lyric Translation <i>Haven Kim, Kento Watanabe, Masataka Goto, Juhan Nam</i>	774
Chorus-Playlist: Exploring the Impact of Listening to Only Choruses in a Playlist <i>Kosetsu Tsukuda, Masahiro Hamasaki, Masataka Goto</i>	782
Papers – Session VII	793
Supporting Musicological Investigations With Information Retrieval Tools: An Iterative Approach to Data Col- lection <i>David Lewis, Elisabete Shibata, Andrew Hankinson, Johannes Kepper, Kevin R. Page, Lisa Rosendahl, Mark Saccomano, Christine Siegert</i>	795

Optimizing Feature Extraction for Symbolic Music <i>Federico Simonetta, Ana Llorens, Martín Serrano, Eduardo García-Portugués, Álvaro Torrente</i>	802
Exploring Sampling Techniques for Generating Melodies With a Transformer Language Model <i>Mathias Rose Bjare, Stefan Lattner, Gerhard Widmer</i>	810
Measuring the Eurovision Song Contest: A Living Dataset for Real-World MIR <i>John Ashley Burgoyne, Janne Spijkervet, David John Baker</i>	817
Efficient Supervised Training of Audio Transformers for Music Representation Learning <i>Pablo Alonso-Jiménez, Xavier Serra, Dmitry Bogdanov</i>	824
A Cross-Version Approach to Audio Representation Learning for Orchestral Music <i>Michael Krause, Christof Weiß, Meinard Müller</i>	832
Music Source Separation With MLP Mixing of Time, Frequency, and Channel <i>Tomoyasu Nakano, Masataka Goto</i>	840
Symbolic Music Representations for Classification Tasks: A Systematic Evaluation <i>Huan Zhang, Emmanouil Karystinaios, Simon Dixon, Gerhard Widmer, Carlos Eduardo Cancino-Chacón</i>	848
The Music Meta Ontology: A Flexible Semantic Model for the Interoperability of Music Metadata <i>Jacopo de Berardinis, Valentina Anita Carriero, Albert Meroño-Peñuela, Andrea Poltronieri, Valentina Presutti</i>	859
Polar Manhattan Displacement: Measuring Tonal Distances Between Chords Based on Intervallic Content <i>Jeff Miller, Johan Pauwels, Mark Sandler</i>	868

Help! – Bridging the Gap Between Music Technology and Diverse Stakeholder Needs

Christine Bauer

Professor of Interactive Intelligent Systems
Paris Lodron University Salzburg

Abstract

Music information retrieval (MIR) has become an indispensable asset in the music industry. It powers music recommendations for listeners and supports artists in mastering their crafts. While MIR has made remarkable progress, we need to improve in serving the multifaceted needs of stakeholders who rely on these technologies. Taking examples from music recommender systems, I will demonstrate the potential risks of neglecting artists' needs and provide strategies for mitigation.

Biography

Christine Bauer is EXDIGIT Professor of Interactive Intelligent Systems at the Department of Artificial Intelligence and Human Interfaces (AIHI) at the Paris Lodron University Salzburg, Austria.

Her research centers on interactive intelligent systems, where she integrates research on intelligent technologies, the interaction of humans with an intelligent system, and their interplay. She takes a human-centered perspective, where technology follows humans' and society's needs. In recent years, she worked on context-aware recommender systems in the music and media domains. The core interests in her research activities are fairness and multi-method evaluations.

She has authored more than 100 papers and holds several best paper awards and many awards for her reviewing activities. She received the prestigious Elise Richter career research grant (2017–2020), funded by the Austrian Science Fund (FWF). She is on the Editorial Board of ACM Transactions on Recommender Systems (TORS) and co-organizes the Workshop series "Perspectives on the Evaluation of Recommender Systems (PERSPECTIVES)".

She advocates for equal opportunities and engages in initiatives such as Women in Music Information Retrieval (WiMIR) and the Allyship program at CHI.

Further information can be found at <https://christinebauer.eu>.

Keynote Talk – 2

Building & Launching MIR Systems at Industry Scale

Rachel Bittner

Research Manager
Spotify

Abstract

There is a considerable gap in the research and engineering methods we use to build MIR systems for academic research and the way we build them for industry-scale systems. This keynote covers some of the many differences and challenges faced when building MIR systems for industry applications. We first discuss the way we define problems in the first place, and why the academic definition of problems is often ill-suited for a particular application. There are also substantial differences in engineering workflows – in particular when multiple researchers and engineers build a single system. We explore differences in academic datasets which are usually “small and clean” to real-world datasets which are “large and noisy”. Academic metrics are useful for us scientists, but they often either don’t match a product use case or mean nothing to product teams. Finally, we dig into deployment considerations including how to run inference flexibly, considering cost and speed, and where the system needs to run. We will explore numerous real-world examples throughout and provide insight into how to build MIR systems within industry.

Biography

Rachel is a Research Manager at Spotify in Paris. Before Spotify, she worked at NASA Ames Research Center in the Human Factors division. She received her Ph.D. degree in music technology and digital signal processing from New York University. Before that, she did a Master’s degree in Mathematics at New York University, and a joint Bachelor’s degree in Music Performance and Math at UC Irvine. Her research interests include automatic music transcription, musical source separation, metrics, and dataset creation.

Keynote Talk – 3

Seeing the Light Through Music, a Blind Man’s Journey of Discovery Through Audio and How to Navigate Making Music That Speaks to the World in the Age of the Screen Driven Universe

Joey Stuckey

Professor of Music Technology
Mercer University

Abstract

This presentation will encompass:

- Diversity, Equity, Inclusion and Accessibility issues and best practices for a truly vibrant and equitable community in the audio industry and music business.
- Getting back to fundamentals, critical listening in the age of the “Screen Driven Universe”.
- Important elements of music making and the recording sciences
- How to live a successful life of intention despite obstacles

Biography

Joey Stuckey is the Official Music Ambassador of his hometown of Macon, Georgia. Joey spends every moment living life to the fullest and sharing his story and inspirational spirit through his musical performances and speaking engagements. As a toddler, Joey was diagnosed with a brain tumor and underwent surgery with little hope of survival. Though the tumor left Joey blind and with other health challenges, today, he continues to live a successful life of intention in his chosen field of music. Joey is professor of music technology at Mercer University, the music technology consultant for Middle Georgia State University, and an official music mentor for the Recording, Radio and Film Connection in Los Angeles as well as an active voting member of the Grammys. He is the owner and senior engineer at Shadow Sound Studio which is a destination recording facility with state-of-the-art analog and digital technology. He has spoken and performed all over the world including at the University College of London, the Georgia Music Hall of Fame, and the Audio Engineering Society in New York City, just to name a few. In his roles as producer, engineer, recording artist and journalist, he has worked with many musical legends including Trisha Yearwood, Clarence Carter, James Brown, Alan Parsons, Gene Simmons (KISS), Al Chez (Tower of Power), Jimmy Hall (Wet Willie), Danny Seraphin (Chicago), Kevin Kenney (Drivin’ and Cryin’), and many, many more.

Tutorials

Tutorial 1

Analysing Physiological Data Collected During Music Listening: An Introduction

Laura Bishop, Geoffray Bonnin and Jérémy Frey

Abstract

Music has diverse effects on listeners, including inducing emotions, triggering movement or dancing, and prompting changes in visual attention. These effects are often associated with psychophysiological responses like changes in heart activity, respiratory rate, and pupil size, which can themselves be influenced by the cognitive effort exerted during music listening, e.g., when engaging with unfamiliar tracks on a web radio for music discovery.

This tutorial aims to introduce psychophysiological data analysis for a broad MIR audience, with a particular focus on the analysis of heart rate, electrodermal activity and pupillometry data. It will be structured in three parts. The first part will provide a presentation of psychophysiological data that we collected in the context of a preliminary study related to music discovery. The second part will be a hands-on tutorial during which we will guide the participants to remake two of our data analyses. In the third part, we will assist participants in undertaking their own data analysis of our data. These analyses will be demonstrated using R and Python.

Our aim with this tutorial is twofold: to promote underrepresented topics in the MIR community, especially the recognition of induced emotions from physiological data and discovery-oriented music recommendation; and to encourage researchers from those domains to interact with the MIR community. The audience we target is therefore relatively large. Participants should, however, possess sufficient knowledge of R and/or Python and standard statistical analysis methods to participate in the hands-on parts of the tutorial.

Biographies of the Presenters

Laura Bishop is a researcher at the RITMO Centre for Interdisciplinary Studies in Rhythm, Time and Motion and the Department of Musicology at the University of Oslo. She specialises in pupillometry, eye-tracking, and motion capture using approaches mainly grounded in psychology. She completed her PhD in music psychology at the MARCS Institute, Western Sydney University, Australia, in 2013. She currently co-leads the Austrian Science Fund project “Achieving togetherness in music ensembles” in collaboration with the University for Music and Performing Arts Vienna (mdw), which investigates physiological and body motion coordination in ensemble playing.

Geoffray Bonnin is an Associate Professor at the Lorraine Research Laboratory in Computer Science and its Applications (Loria), Université de Lorraine. He obtained his Ph.D. in 2010 and joined the Loria lab in 2014 as an Associate Professor. His research topics are related to artificial intelligence for music and for education. He is currently in charge of the Music-Mouv’ project, which is a collaboration with researchers in the domain of psychology that started in October 2021. The project aims at helping individuals with Parkinson’s disease to walk by triggering relevant emotions through physiology-based music recommendations.

Jérémy Frey is the CTO and co-founder of Ullo. After a master degree in cognitive sciences, he obtained his PhD degree in computer science in 2015 from the University of Bordeaux, France. During his work within the Inria research team Potioc, he had been studying how passive brain-computer interfaces could contribute to the evaluation of user experience, using for example EEG to infer a continuous index of cognitive load. His current research interests revolve around increasing introspection and social presence, by displaying inner states through tangible interfaces or wearables, with applications ranging from well-being to education.

Tutorial 2

Introduction to Differentiable Audio Synthesizer Programming

Ben Hayes, Jordie Shier, Chin-Yun Yu, David Sūdholt and Rodrigo Diaz

Abstract

Differentiable digital signal processing is a technique in which signal processing algorithms are implemented as differentiable programs used in combination with deep neural networks. The advantages of this methodology include a reduction in model complexity, lower data requirements, and an inherently interpretable intermediate representation. In recent years, differentiable audio synthesizers have been applied to a variety of tasks, including voice and instrument modelling, synthesizer control, pitch estimation, source separation, and parameter estimation. Yet despite the growing popularity of such methods, the implementation of differentiable audio synthesizers remains poorly documented, and the simple formulation of many synthesizers belies their complex optimization behaviour. To address this gap, this tutorial offers an introduction to the fundamentals of differentiable synthesizer programming.

The tutorial will centre around practical demonstrations, which participants can follow using an accompanying suite of Jupyter notebooks. All tutorial content will be documented in an accompanying web book, and all tutorial materials and dependencies will be fully open source and accessible for free online. Prior experience with writing Python 3 code is assumed, and a basic knowledge of PyTorch is beneficial though not strictly required. The tutorial is targeted at music and audio researchers and engineers with a grounding in the basics of digital signal processing and machine learning. Our aim is to equip participants to apply these techniques in their own research, whilst enabling those with prior knowledge to sharpen their skills.

Biographies of the Presenters

Ben Hayes is a third year PhD student at the Centre for Digital Music's CDT in Artificial Intelligence and Music, based at Queen Mary University of London, under the supervision of Dr György Fazekas and Dr Charalampos Saitis. His research focuses on expanding the capabilities of differentiable digital signal processing by enabling control over non-convex operations. His work has been accepted to leading conferences in the field, including ISMIR, ICASSP, ICA, and the AES Convention, and published in the Journal of the Audio Engineering Society. He also holds an MSc with Distinction in Sound and Music Computing from QMUL and a first class BMus(Hons) in Electronic Music from the Guildhall School of Music and Drama, where he is now a member of teaching faculty. He is a founding member of the Special Interest Group on Neural Audio Synthesis at C4DM, and is the organizer of the international Neural Audio Synthesis Hackathon. Previously he was a Research intern at ByteDance, music lead at the award-winning generative music startup Jukedeck, and an internationally touring musician signed to R&S Records.

Jordie Shier is a first year PhD student in the Artificial Intelligence and Music (AIM) programme based at Queen Mary University of London (QMUL), studying under the supervision of Prof. Andrew McPherson and Dr. Charalampos Saitis. His research is focused on the development of novel methods for synthesizing audio and the creation of new interaction paradigms for music synthesizers. His current PhD project is on real-time timbral mapping for synthesized percussive performance and is being conducted in collaboration with Ableton. He was a co-organizer of the 2021 Holistic Evaluation of Audio Representations (HEAR) NeurIPS challenge and his work has been published in PMLR, DAFx, and the JAES. Previously, he completed an MSc in Computer Science and Music under the supervision of Prof. George Tzanetakis and Assoc. Prof. Kirck McNally.

Chin-Yun Yu is a first year PhD student in the Artificial Intelligence and Music (AIM) programme based at Queen Mary University of London (QMUL), under the supervision of Dr György Fazekas. His current research theme is on leveraging signal processing and deep generative models for controllable, expressive vocal synthesis. In addition, he is dedicated to open science and reproducible research by developing open-source packages and contributing to public research projects. He received a BSc in Computer Science from National Chiao Tung University in 2018 and was a research assistant at the Institute of Information Science, Academia Sinica, supervised by Prof. Li Su. His recent work has been published at ICASSP.

David Südholt is a first year PhD student in the Artificial Intelligence and Music (AIM) programme based at Queen Mary University of London (QMUL). Supervised by Prof. Joshua Reiss, he is researching parameter estimation for physical modelling synthesis, focussing on the synthesis and expressive transformation of the human voice. He received an MSc degree in Sound and Music Computing from Aalborg University Copenhagen in 2022, where he was supervised by Prof. Stefania Serafin and Assoc. Prof. Cumhuri Erku. His work has been published at the SMC conference and in the IEEE/ACM Transactions on Audio, Speech and Language Processing.

Rodrigo Diaz is a PhD candidate in Artificial Intelligence and Music at Queen Mary University in London, under the supervision of Prof. Mark Sandler and Dr. Charalampos Saitis. Rodrigo's work has been published in leading computer vision and audio conferences, including CVPR, ICASSP, IC3D, and the AES Conference on Headphone Technology. Before starting his PhD studies, he worked as a researcher at the Immersive Communications group at the Fraunhofer HHI Institute in Berlin, where he investigated volumetric reconstruction from images using neural networks. His current research focuses on real-time audio synthesis using neural networks for 3D objects and drums. Rodrigo's interdisciplinary background includes a Master's degree in Media Arts and Design from Bauhaus University in Weimar and a Bachelor of Music from Texas Christian University.

Tutorial 3

Transformer-Based Symbolic Music Generation: Fundamentals to Advanced Concepts, Stylistic Considerations, Conditioning Mechanisms and Large Language Models

Berker Banar, Pedro Sarmiento and Sara Adkins

Abstract

With the rise of the attention mechanism and the success of auto-regressive generative modelling and large language models, the Transformer architecture has arguably been the most promising technology for symbolic music generation. While audio-based methods have shown promise, symbolic music generation offers distinct advantages in terms of control, long-term coherence and computational efficiency. This tutorial explores the potential of the Transformer architecture in symbolic music generation and aims to provide (1) a thorough understanding of the vanilla Transformer architecture (emphasising the reasoning behind its design choices) and the utilisation of large language models for symbolic music generation. Additionally, it offers (2) a comprehensive overview of the field, including a taxonomy and a curated list of valuable datasets. The tutorial delves into (3) an in-depth analysis of Transformer variants and large language models specifically tailored for symbolic music generation. Also, it examines (4) examples and advanced considerations such as style, musical conditioning, and real-time performance. Furthermore, the tutorial offers (5) two hands-on exercises using Google Colab Notebooks, enabling participants to apply the concepts covered. Overall, this tutorial equips participants with the theoretical knowledge and practical skills necessary to explore the power of the Transformer architecture in symbolic music generation.

Biographies of the Presenters

Berker Banar is a PhD Researcher (Comp. Sci.) at the Centre for Doctoral Training in AI and Music (AIM CDT) and the Centre for Digital Music (C4DM) at Queen Mary University of London (QMUL), and also an Enrichment Student at the Alan Turing Institute. His PhD focuses on ‘Composing Contemporary Classical Music using Generative Deep Learning’ under supervision of Simon Colton to enhance human creativity and enable new aesthetics. Berker’s research interests include transformer-based generative modelling, optimisation, self-supervised representation learning for audio and music, explainable AI, quality-diversity analysis of generative model and out-of-distribution generation. He has worked at Sony and Bose as a research intern, and at Northwestern University Metamaterials and Nanophotonic Devices Lab as a nanophotonics researcher. Berker holds a BS in Electrical and Electronics Engineering from Bilkent University, Ankara, Turkey and a BM in Electronic Production and Design from Berklee College of Music, Boston, MA. His awards include Enrichment Community Award (The Alan Turing Institute), Exceptional Great Work Award (Bose), Outstanding Students of 2022 (EvoMUSART), Roland Award Endowed Scholarship (Berklee) and Outstanding Success Scholarship (Turkish Educational Foundation, upon ranking 17th in 1.5 million people in national university entrance exam). As a musician (drums and electronics), Berker has performed at venues such as the Museum of Fine Arts Boston, Harvard University Holden Chapel & Carpenter Center for Visual Arts (an original piece premiered as part of Berklee Interdisciplinary Arts Institute), Berklee Performance Center, Wally’s Jazz Club Boston, Nardis Jazz Club Istanbul and Istanbul Jazz Festival.

Pedro Sarmiento is a PhD researcher at the Centre for Digital Music (C4DM), Queen Mary University of London (QMUL), working under the supervision of Mathieu Barthet within the UKRI Centre for Doctoral Training in Artificial Intelligence and Music (AIM). His research focuses on guitar-focused symbolic music generation with deep learning. This concerns the exploration of techniques for the creation of novel music that is represented in a digital tablature format, in which additional information about how to play specific music passages is provided. He holds an Integrated MSc degree in Electrical Engineering from Faculdade de Engenharia da Universidade do Porto (FEUP), a degree in Classical Guitar from the Conservatory of Music of Porto, and a second MSc degree in Multimedia and Interactive Sound from FEUP. He has an ongoing collaboration with Orquestra de Jazz de Matosinhos (OJM) where he leads sessions that foster an approach to STEM via musical concepts for young students. He volunteers for an online music magazine, writing album reviews and conducting interviews with artists from the Metal scene.

Sara Adkins is a music technologist, machine learning engineer, and performer who is enthusiastic about promoting the use of machine learning and AI in the creative arts. Currently, she works as a Generative Music and Audio Developer at Infinite Album, developing a real-time, interactive, and copyright-safe music engine for Twitch streamers. Sara holds a Master of Science in Sound and Music Computing from Queen Mary University of London where she was funded through a US-UK Fulbright grant. Her master's thesis focused on developing a Transformer model capable of generating loopable musical phrases for live coding and algorave performances, and received an Outstanding Student Mention at EvoMUSART 2023. Before moving to London, Sara spent three years in Boston where she worked as a machine learning engineer at Bose and played as a freelance classical guitarist. At Bose, she worked on deep learning models for speech enhancement that were optimized to run live on a hearing aid micro-controller. She also led a research project that developed generative audio algorithms that adapt to biofeedback signals to induce sleep using soothing music. Sara graduated from Carnegie Mellon University with an interdisciplinary bachelor's degree in music technology and computer science. Her senior capstone project, "Creating with the Machine," combined algorithmic and traditional methods of composition into live performances to explore how interactive generative algorithms can influence creativity in musical improvisation. "Creating with the Machine" was premiered by the Carnegie Mellon Exploded Ensemble in the spring of 2018 and was awarded the Henry Armero Memorial Award for Inclusive Creativity.

Tutorial 4

Computer-Assisted Music-Making Systems: Taxonomy, Review, and Coding

Christodoulos Benetatos, Zhiyao Duan and Philippe Pasquier

Abstract

Computer-Assisted Music-Making (CAMM) systems, are software-based tools designed to assist and augment the musical creativity of composers, performers, and music enthusiasts. CAMM systems encompass a wide range of systems that can be broadly categorized into two main types according to their design purposes: to assist music performance and to assist music composition. This tutorial offers a comprehensive review of the design principles, practical applications, taxonomy, and the state-of-the-art research of CAMM systems, with an emphasis on systems assisting music performance, which are also called “interactive music systems” or “musical agents” in the literature. Research on CAMMs is interdisciplinary in its nature, combining fields such as Music Information Retrieval (MIR), Artificial Intelligence (AI) and Human-Computer Interaction (HCI). Participants will gain an understanding of how these fields converge to create innovative and interactive musical experiences. This tutorial will also feature a coding session for participants to build a real-time musical agent, under the framework of Euterpe, a prototyping framework for creating music interactions on the Web. The tutorial will examine existing systems built using Euterpe, provide insights into the development process, and guide participants through the creation of their own musical agents. Participants in the coding part should bring a laptop with Chrome and Node.js (<https://nodejs.org/en/download>) installed, as well as have some coding experience. Familiarity with JavaScript will be helpful, but not necessary.

Biographies of the Presenters

Christodoulos Benetatos is a 5th year Ph.D student in the Department of Electrical and Computer Engineering at the University of Rochester. He received his B.S and M.Eng in Electrical Engineering from National Technical University of Athens in 2018. His research interests are focused primarily on automatic music generation as well as the design and development of computer-assisted music-making systems. During his research internships at Kwai and TikTok, he worked on audio digital signal processing and music generation algorithms. As a classical guitarist, he has won several prizes in international guitar competitions and is a regular performer both as a soloist and as part of ensembles.

Philippe Pasquier is a professor at Simon Fraser University’s School of Interactive Arts and Technology, where he directs the Metacreation Lab for Creative AI. He leads a research-creation program around generative systems for creative tasks. As such, he is a scientist specialized in artificial intelligence, a software designer, a multidisciplinary media artist, an educator, and a community builder. Pursuing a multidisciplinary research-creation program, his contributions bridge fundamental research on generative systems, machine learning, affective computing and computer-assisted creativity, applied research in the creative software industry, and artistic practice in interactive and generative art.

Zhiyao Duan is an associate professor in Electrical and Computer Engineering, Computer Science and Data Science at the University of Rochester. He received his B.S. in Automation and M.S. in Control Science and Engineering from Tsinghua University, China, in 2004 and 2008, respectively, and received his Ph.D. in Computer Science from Northwestern University in 2013. His research interest is in computer audition and its connections with computer vision, natural language processing, and augmented and virtual reality. He received a best paper award at the Sound and Music Computing (SMC) conference in 2017, a best paper nomination at the International Society for Music Information Retrieval (ISMIR) conference in 2017, and a CAREER award from the National Science Foundation (NSF). He served as a Scientific Program Co-Chair of ISMIR 2021, and is serving as an associate editor for IEEE Open Journal of Signal Processing, a guest editor for Transactions of the International Society for Music Information Retrieval, and a guest editor for Frontiers in Signal Processing. He is the President-Elect of ISMIR.

Tutorial 5

Learning With Music Signals: Technology Meets Education

Meinard Müller

Abstract

Music information retrieval (MIR) is an exciting and challenging research area that aims to develop techniques and tools for organizing, analyzing, retrieving, and presenting music-related data. Being at the intersection of engineering and humanities, MIR relates to different research disciplines, including signal processing, machine learning, information retrieval, musicology, and the digital humanities. In this tutorial, using music as a tangible and concrete application domain, we approach the concept of learning from different angles, addressing technological and educational aspects. In this way, the tutorial serves several purposes: we give a gentle introduction to MIR, highlight avenues for developing explainable machine-learning models, discuss how recent technology can be applied and communicated in interdisciplinary research and education, and introduce a new software package for teaching and learning music processing.

Our primary goal is to give an exciting tutorial that builds a bridge from basic to advanced techniques in MIR while highlighting technological and educational aspects. This tutorial should appeal to a broad audience, including students, educators, non-experts, and researchers new to the field, by covering concrete MIR tasks while providing many illustrative audio examples.

Biography of the Presenter

Meinard Müller received the Diploma degree (1997) in mathematics and the Ph.D. degree (2001) in computer science from the University of Bonn, Germany. Since 2012, he has held a professorship for Semantic Audio Signal Processing at the International Audio Laboratories Erlangen, a joint institute of the Friedrich-Alexander-Universität and the Fraunhofer Institute for Integrated Circuits IIS. His recent research interests include music processing, music information retrieval, audio signal processing, and motion processing. He was a member of the IEEE Audio and Acoustic Signal Processing Technical Committee from 2010 to 2015, a member of the Senior Editorial Board of the IEEE Signal Processing Magazine (2018-2022), and a member of the Board of Directors of the International Society for Music Information Retrieval (2009-2021, being its president in 2020/2021). In 2020, he was elevated to IEEE Fellow for contributions to music signal processing.

Besides his scientific research, Meinard Müller has been very active in teaching music and audio processing. He gave numerous tutorials at major conferences, including ISMIR (2007, 2010, 2011, 2014, 2017, 2019), ICASSP (2009, 2011, 2019), Deep Learning IndabaX (2021), GI Jahrestagung (2017), Eurographics (2009, 2023), and ICME (2008). Furthermore, he wrote a monograph titled “Information Retrieval for Music and Motion” (Springer, 2007) as well as a textbook titled “Fundamentals of Music Processing” (Springer, 2015, www.music-processing.de). Recently, he released a comprehensive collection of educational Python notebooks designed for teaching and learning audio signal processing using music as an instructive application domain (<https://www.audiolabs-erlangen.de/FMP>).

Tutorial 6

Kymatio: Deep Learning Meets Wavelet Theory for Music Signal Processing

Cyrus Vahidi, Christopher Mitcheltree, Vincent Lostanlen

Abstract

We present a tutorial on MIR with the open-source Kymatio (Andreux et al., 2020) toolkit for analysis and synthesis of music signals and timbre with differentiable computing. Kymatio is a Python package for applications at the intersection of deep learning and wavelet scattering. Its latest release (v0.4) provides an implementation of the joint time–frequency scattering transform (JTFS), which is an idealisation of a neurophysiological model that is commonly known in musical timbre perception research: the spectrotemporal receptive field (STRF) (Patil et al., 2012). In the MIR research, scattering transforms have demonstrated effectiveness in musical instrument classification (Vahidi et al., 2022), neural audio synthesis (Andreux et al., 2018), playing technique recognition and similarity (Lostanlen et al., 2021), acoustic modelling (Lostanlen et al., 2020), synthesizer parameter estimation and objective audio similarity (Vahidi et al., 2023, Lostanlen et al., 2023).

The Kymatio ecosystem will be introduced with examples in MIR:

- Wavelet transform and scattering introduction (including constant-Q transform, scattering transforms, joint time–frequency scattering transforms, and visualizations)
- MIR with scattering: music classification and segmentation
- A perceptual distance objective for gradient descent
- Generative evaluation of audio representations (GEAR) (Lostanlen et al., 2023)

A comprehensive overview of Kymatio’s frontend user interface will be given, with examples of extensibility of the core routines and filterbank construction.

We ask our participants to have some prior knowledge in:

- Python and NumPy programming (familiarity with Pytorch is a bonus, but not essential)
- Spectrogram visualization
- Computer-generated sounds

No prior knowledge of wavelet or scattering transforms is expected.

EXPLORING THE CORRESPONDENCE OF MELODIC CONTOUR WITH GESTURE IN RAGA ALAP SINGING

Shreyas Nadkarni¹ Sujoy Roychowdhury¹ Preeti Rao¹ Martin Clayton²

¹Department of Electrical Engineering, Indian Institute of Technology Bombay, India

²Department of Music, Durham University, United Kingdom

prao@ee.iitb.ac.in, martin.clayton@durham.ac.uk

ABSTRACT

Musicology research suggests a correspondence between manual gesture and melodic contour in raga performance. Computational tools such as pose estimation from video and time series pattern matching potentially facilitate larger-scale studies of gesture and audio correspondence. We present a dataset of audiovisual recordings of Hindustani vocal music comprising 9 ragas sung by 11 expert performers. With the automatic segmentation of the audiovisual time series based on analyses of the extracted F0 contour, we study whether melodic similarity implies gesture similarity. Our results indicate that specific representations of gesture kinematics can predict high-level melodic features such as held notes and raga-characteristic motifs significantly better than chance.

1. INTRODUCTION

Manual gesturing by singers is an integral part of vocal music performances in the Indian classical traditions. Previous work has demonstrated that singers’ gestures have several different referents and functions: for example, they may relate to the rhythmic structure of the music (marking a steady beat or tala cycle) or play a role in signalling to co-performers or audience members, as well as appearing to accompany or illustrate aspects of the melody being sung. In the latter case, hand movements sometimes appear to correspond to pitch height (i.e. ascending pitch co-occurs with one or both hands rising and/or moving to one side); at other times they relate to other aspects of melody, such as the tension felt while sustaining certain notes, or the image or abstract design visualised by the performer [1–5].

Little computational work has been carried out on gesture-to-audio correspondence in Hindustani vocal music. Paschalidou [6] carried out research on a motion capture dataset of solo alap recordings in the dhrupad genre, looking at a range of movement and audio features in relation to the concept of ‘effort’: although she found cor-

Dataset	Singers	Ragas	Pakad	Alap	Dur(min)
Study in [7]	3 (1M,2F)	9	37	55	193
Current Work	11(5M,6F)	9	109	199	664

Table 1: A summary of the newly augmented audiovisual dataset compared with that of closest previous work [7].

respondences, generalising across performers proved challenging.

Clayton et al [7] explored the use of movement data to classify 12-sec excerpts drawn from a corpus comprising 3 singers performing 9 common Hindustani ragas in the khyal genre. The use of solo alap meant the gestures cannot refer to either metric structure or interaction with co-performers, and thus relate predominantly to the melody of the ragas being presented. An inception block preceded by independently trained convolution layers for each of audio and gesture time series classification provided the best performance in the context of singer-dependent raga classification, especially reducing the confusion between melodically similar ragas with respect to the otherwise high-performing audio-only classification. While the work demonstrated the complementarity of gesture and melodic profiles in relation to raga identity, we are more interested in the present work in understanding which characteristics of gesture correlate with specific melodic characteristics. Further, given that the dataset of [8] was limited to 3 singers and therefore not suited to cross-singer studies, we present here a considerably enlarged corpus with 8 additional performers, collected following a similar methodology, as summarised in Table 1.

In the related Karnatak tradition, Pearson’s research has looked at the role of gesture in vocal teaching [9]. The relation between the acoustics and the kinematics was studied in recent work by Pearson & Pouw using the tracking of left and right wrist positions [10]. They manually segmented the gesture tracks and studied the correspondence of various kinematic extrema with the temporally aligned changes in the acoustics (fundamental frequency, or F0, and amplitude envelope). A correspondence was established between the magnitudes of local peaks in acceleration and changes in F0, in line with previous work in co-speech gesturing [11].

In this work, we study the newly expanded corpus of

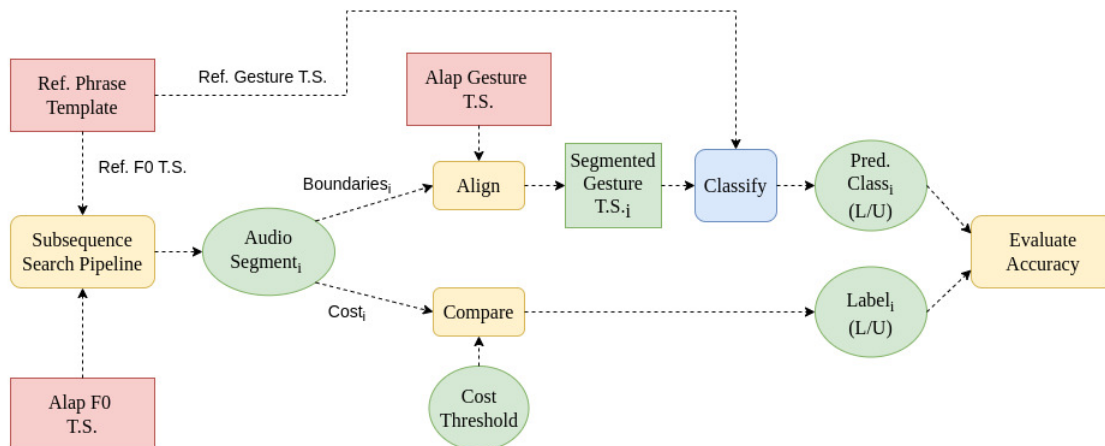

Figure 1: The overall testing and evaluation framework for the raga phrase-based segmentation. The audio and visual components of a candidate AV segment (i -th segment from an alap) are separately compared with the respective audio and visual components of a reference phrase segment (from a pakad) to see whether they are together consistent in their estimation of similarity with the reference phrase. We note that the gesture T.S. (time series) is multidimensional while the audio T.S. is a unidimensional sequence of F0 samples.

solo alap recordings. Since the same set of 9 ragas is performed by all the singers (11 in this case), we can explore commonalities in the gestures used by different singers for particular raga-specific melodic movements. That is, in contrast to the body of previous work, we use musically motivated units, implied by the raga melodic structure, to group the representations of melody and gesture. The aim of the study is to investigate correspondences between the singers’ movements (captured in the time series for x - and y -coordinates of their wrist positions) and the melodies they sing (represented as F0 contours).

Figure 1 depicts our overall framework. The melodic phrase segments are obtained for each alap audio via a subsequence search using a reference audio template (such as a manually labeled phrase segment). The audio segment start and end times are then used to identify the corresponding time-synchronised video segment. The audio and video segments are individually processed to compute audio-based similarity and video-based similarity with respect to the corresponding components of the AV (audio-visual) reference template. We now seek to quantify the extent to which video-based similarity predicts audio similarity. We simplify the evaluation task to comparing, across the two modalities, the following binary labels: L (i.e. close to, or Like, the reference) or U (Unlike the reference).

In the next section, we provide the details of our dataset. This is followed by a discussion of the audiovisual segmentation methods. The experiments and results are presented in the final two sections of the paper.

2. DATASET AND PREPROCESSING

We consider our dataset of vocal alap performances by 11 professional musicians performing 2 alaps each of 9 ragas. Each alap is about 3 minutes long. The singers also contributed shorter ‘pakad’ recordings, rendering some of the

key phrases of each raga in a brief format of a few seconds. The total duration of this newly expanded dataset (summarised in Table 1) is about 11 hours. Each piece was recorded using three video cameras and separate microphone; only the central camera is used in the current analyses. While each alap is labeled only by singer and raga, we carry out further manual annotation of the pakad audio files for selected raga phrases as used in this study. That is, all the pakads of a given raga across the 11 singers are searched for instances of the desired phrase (e.g. gmD in raga Bageshree). This task, carried out by a musician, is facilitated by the fact that the pakad is almost always sung with solfege (unlike the alap).

Our audio and video processing pipelines closely follow those of [7]. An initial stage of audio suppression of the background drone is obtained via source separation [12]. The suppression, while not complete, is adequate for the reliable estimation voicing and pitch at 10 ms intervals using monophonic pitch detection based on short-time autocorrelation analysis [13]. Brief unvoiced regions (less than 400 ms) arising from short breath pauses and consonant utterances are filled in via cubic spline interpolation to obtain the continuous pitch contours associated with melodic movements that are bounded by silence (>400 ms) on both ends. These are termed ‘Silence-Delimited Segments’ (SDS). The pitch contour is tonic-normalised using an automatically detected (and manually verified) tonic to obtain the F0 (cents) contour [14].

In order to extract the movement data, the central video view of each piece is processed using the OpenPose pose estimation algorithm, which generates x - and y -coordinates for 11 upper body joints [15]. We select the right and left wrist coordinates. Any missing data are interpolated and each of the time series is low-pass filtered to remove jitter. The position time-series, originally sampled at 25 fps is interpolated to 100 samples/sec to synchronise

it with the sampled F0 contour. Other important low-level human motion descriptors include velocity (rate of change of the 2d position) and acceleration (rate of change of the velocity) [16]. We derive velocity and acceleration profiles from the 2d position time-series of each joint by computing derivatives. A robust estimate of the derivative is obtained via a differencing kernel such as a biphasic filter with its controllable smoothing parameters [17, 18]. We find that a 101-point filter achieves a lowpass filtering of about 2 Hz, giving a sufficiently smooth and physiologically plausible movement acceleration profile [19]. We eventually obtain the 8-dim gesture time series of position (x and y), velocity and acceleration for each of the left and right wrists for each of the singer-alap and pakad recordings. In this, we include the synchronized F0 contour to get the complete audiovisual time series for an alap, now in the form of a sequence of SDS. A detailed review of the data collection and processing appears in the supplementary material.

3. SEGMENTATION METHODS

The first stage of segmentation of the synchronised AV time series comprises the silence-delimited segments (SDS) obtained in the previous section. We discard segments of duration less than 500 ms as too limited for our further analyses. The retained SDS, numbering approximately 30 per alap, have a mean duration of 5.2 s with less than 1% (of the total count of 6012) exceeding 20 s. As discussed next, we apply melodic segmentation principles to each SDS to obtain stable note and raga-characteristic melodic movements or phrases that can help us explore the links between specific musical expressions and the corresponding gestures.

In a top-down approach, the alap can be segmented into its phrases. A raga phrase, although notated simply by its solfege sequence, has a melodic-rhythmic realisation comprising specific intonations and durations of its constituent svaras, together with the transitions to/from neighbouring svaras [20]. On the other hand, in a bottom-up approach, the melodic contour can be viewed as comprising the following broad categories of segments: stable notes, and the transitions between the notes which can include distinctive melodic ornaments such as glides (meend) and oscillatory movements (andolan) apart from steep changes of pitch or pauses [21]. Figure 2 presents an example of an SDS that comprises a variety of stable and transitional sub-segments. It is therefore of interest to examine audio-visual correspondences in the context of the distinct types of melodic movements. The two different audio-based segmentation procedures are detailed next.

3.1 Stable note segmentation

To identify occurrences of stable or sustained tones, the continuous F0 contour corresponding to an SDS is searched for instances in which the same raga note (svara) is sustained for > 250 ms. That is, a stable note is defined as a region where the F0 lies within a 25 cent interval of the mean intonation of the raga note. This is based on

Figure 2: A sample SDS with identified steady notes (shaded regions of blue F0 contour) and pitch salience distribution (on the left) computed from the entire alap audio with detected svara locations highlighted.

past work that associated the similar duration and intonation parameters with a listener’s percept of a held note [22]. Further, given that a svara may not be realised on the equitempered grid but rather with a raga-specific intonation, we use a finely binned pitch salience distribution computed across the alap to establish the svara locations [22]. Stable note regions corresponding to the same svara that are separated by less than 100 ms are next merged. The boundaries of the so detected stable notes are shown in the example of Figure 2. Across our alap dataset, stable notes were found to range from 0.25 s to 9.9 s with a mean of 0.73 s.

In a similar vein, we considered the segmentation of another characteristic melodic movement, the glide (or slide). This has been attempted previously via the quality of a linear fit to the F0 contour for Indian popular vocal music [23]. However we found that the variety and complexity of glide movements in raga music make it challenging to develop a universal glide detection algorithm. We therefore resort to template-based phrase detection for the purpose, as explained next.

3.2 Phrase-based segmentation

As depicted in Table 2, the raga motifs selected for our exploration include a distinctive upward slide of an augmented fourth in Shree, a falling slide of a fourth in Nand, and a three-note ascending phrase in Bageshree. The chosen phrases are highly characteristic of the corresponding raga and occur in the raga alap with relatively unchanged melodic shape, prompting the question about whether their gesture executions also bear some measurable similarity. The corresponding pakad phrases serve as templates for the segmentation of the alaps for the chosen raga across the 11 singers. We obtain a number of templates of the given phrase from across the 11 singers’ pakads. The set of templates represents the diversity in the realization of the phrase across and within singers. This is manually reduced to a set of 6 templates per phrase while retaining the diversity. Figure 3 shows a few examples for each of the phrases chosen for the current study. We observe that the simple notation used to represent the up or down slide (/,

Raga	Svara (Notes)	Phrase
Bageshree	S R g m P D n	gmD
Shree	S r G M P d N	r/P
Nand	S R G m M P D N	P\R

Table 2: The ragas and phrases used in this study. The svaras S r R g G m M P d D n N correspond to the 12 notes of the Western chromatic scale with S representing the tonic. The symbols / and \ denote the upward and downward slide respectively [24], [25].

\) belies the complexity of contour shapes defined by raga grammar. Also clear are the essential shape features that point to the need for dynamic time warping (DTW) based comparisons [26]. Next, the following steps (also visualised in Figure 4) lead to the desired segmentation of the alap audio files for each selected raga phrase.

1. The six phrase templates from the pakads are warped to the same target length (that of the 3rd template in increasing length order in the set) using a penalty parameter that discourages large deviations from the diagonal path. This helps to ensure that the subsequence DTW matching costs can be meaningfully compared across the templates.

2. As shown in the middle panel of Figure 4, constrained DTW based subsequence search is executed on each SDS with each of the 6 warped audio templates (WAT) to obtain for each WAT the lowest cost match that satisfies a duration criterion ($> 0.5s$) in order to avoid cases of pathological warping [27]. Such matches are accepted as valid and stored with the cost, temporal boundaries and WAT index. In case no valid match is returned (in the top 20 retrieved responses) for a particular template, that SDS-template is not considered further. This step leaves us with between 1 to 6 best matched segments per SDS along with the associated DTW costs.

3. Next, we pick the single lowest cost for each SDS and use this value to cluster the entire set of SDS, across 22 alaps of the raga, into 2 clusters by fitting a kernel density estimate (KDE) to the distribution of costs as shown in Figure 5 [28]. The cost value coinciding with the lowest point in the valley between the peaks is used as a cost threshold to label each SDS as one of the two classes: ‘Like’ (i.e. similar to the raga motif) and ‘Unlike’ (different from the raga motif). These are the labels we would like to predict from the corresponding gesture time series segments in the context of our investigation of audiovisual correspondence.

4. In order to increase the number of examples for the gesture-based prediction task, we club all the different template matches obtained in Step 2 for the same SDS under the same label. This was justified by our observation that the SDS labeled Like (L) in Step 3 typically exhibited similar low cost matches across all templates of the same phrase. The SDS marked Unlike (U), on the other hand, exhibited a relative wide spread in cost values above the threshold, similar to that depicted in Figure 5.

Finally, with the audio segments computed in this section, we extract the corresponding temporally synchro-

Figure 3: Sample templates for each of the three phrases: gmD (purple), r/P (blue) and P\R (violet).

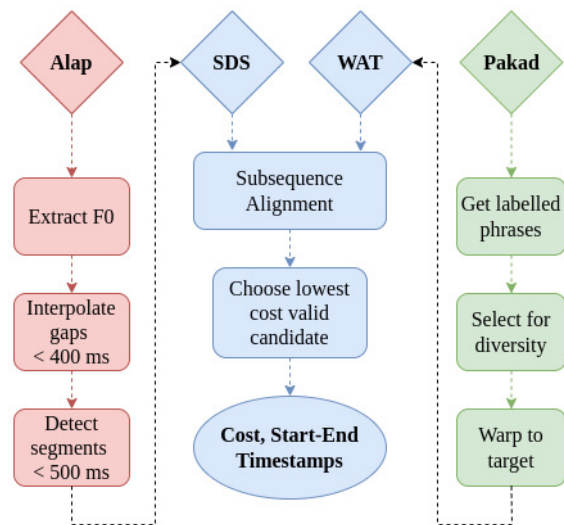

Figure 4: The pipeline for phrase-based segmentation using alap and pakad audio data. For warping the pakad phrase templates, a window size of 100 and a penalty of 200 was chosen, while for the subsequence alignment, $K = 20$ and $penalty = 0.1$ were chosen [27].

nised gesture time series for each SDS and WAT pair. In the next section, we report our experiments on testing various kinematic features for the prediction of the corresponding audio-derived labels in our two distinct tasks.

4. EXPERIMENTS

Past work on gesture kinematics in the context of speech and singing co-gesturing has considered velocity and acceleration parameters rather than the raw position time series with these parameters relating more directly to human effort or force [10, 29–31]. We therefore include the (x,y) position of each wrist as well as the corresponding velocity and acceleration profiles across the segment as input features for our two classification tasks. Summarising the previous section, the gesture time series is segmented based on the previously obtained audio segment boundaries giving us a time-aligned multidimensional time series

Figure 5: Distribution of the DTW subsequence cost across the SDS of all singer alaps for the best matched audio phrase template for PAR of raga Nand. The dashed vertical line shows the threshold derived from the KDE fit (dashed contour), using which the SDS are labeled as Like and Unlike with reference to the template phrase.

for (i) each stable-note and non-stable segment across all the alaps in the dataset, and (ii) each pakad phrase gesture template and its audio-matched gesture segment from the SDS. We consider supervised classification for each task with the different features as discussed next.

4.1 Stable-note prediction

Stable note segments were labeled as such based on the F0 variation across the segment as discussed in Section 3.1. We would like to investigate whether there is any consistency in the gesture kinematics corresponding to stable note regions. We implement a binary classifier trained and tested on the dataset of labeled stable notes and the (complementary) non-stable regions where the training and test data are both drawn from across singers and ragas. Although 250 ms regions of stable pitch qualified as stable notes, we restricted the examples of both categories used in this experiment to those with a minimum duration of 0.5 s in order to ensure that the training dataset was relatively balanced. When the segment duration was constrained to the range 0.5 s to 5 s, the stable notes constituted 39% of the total examples, with across-singer variability as captured in row 2 of Table 3.

Postulating that gesture kinematics are relatively more subdued during the stable note events, we investigate a simple set of explicit features using a Support Vector Machine (SVM) classifier. We compute the statistical aggregates of each of the velocity and acceleration in the form of the mean and variance across the duration of the corresponding time series segment. We thus have 4 features per wrist (i.e. 8 features in all) for the binary classification of segments into stable and non-stable pitch events. We carry out 10-fold cross-validation on the dataset and report the F1 score for the detection of stable notes with the SVM hyperparameters tuned to maximise the average performance across the folds. This exercise is carried out on the entire dataset as well as on singer-specific datasets, where the corresponding counts of examples are provided in Table 3.

4.2 Raga phrase detection

Our goal is to determine whether the L and U labels (that were assigned based on audio proximity) can be predicted by gesture alone at better than chance (i.e. based only on the priors) and, if so, which kinematic features are most useful in this task. Our measure of similarity is the DTW distance computed between the template and test (i.e. the alap SDS subsequence) time series. In the context of our alap gesture time series, already segmented based on the audio phrase matching, we now compute DTW distance between the multidimensional reference and candidate under test.

Multidimensional time series present us with some distinct options for the distance computation. Two obvious approaches are DTW_I and DTW_D depending on whether the individual time series are each warped independently or whether they are all forced into a single warping path [32]. The use of DTW_D appears meaningful for the incorporation of the velocity and acceleration contours derived from the corresponding position time series of the wrists. However, it is interesting also to test with independent DTW costs across the separate time series (to get an 8-dim feature vector of costs) to see if this helps reduce the effect of the less informative features, if any. We term this DTW_{IND} . Further, decoupling the left and right wrists to obtained two differently warped sets of time series (DTW_{LR}) is also perfectly meaningful in the current task.

With $DTW\ cost(s)$ as the input features, we create 5 train-test splits with the uniform distribution of singers across the splits. Thus every example appears once in the test set. We train a logistic regression classifier with L2 regularizer and use 3-fold cross-validation within the train set to learn the best set of parameters.

5. RESULTS AND DISCUSSION

5.1 Stable-note detection

Table 3 presents classifier performance in terms of the F1 score for the retrieval of stable notes. We restrict ourselves to the set of labeled segments of duration between 0.5 s and 5 s, with 20897 examples in all. With 38.9% of these corresponding to stable notes, we find that the obtained F1 score is 65.7% when considering the overall dataset across singers and ragas. Given the known high singer-dependence of gesturing, we also evaluate singer-specific classification with the same kinematic features, now restricted to training and validation (10-fold CV as before) on the smaller dataset of each singer’s alaps across ragas.

As anticipated, we note a large variation in the F1 scores across singers in Table 3 but with all values considerably above chance (which equals the corresponding % Stable entry in row 2). While some of the variation could be attributed to the differences in distributions of labels across the singers’ datasets, we observe variation even across singers with similar distribution characteristics (such as AP and SM, for instance).

As for the singers with F1 scores well below the across-singers stable note detection F1 score (such as the case of

Singer	All	AG	AK	AP	CC	MG	MP	NM	RV	SCh	SM	SS
Count	20897	1242	1987	2382	2274	1822	2111	1769	1563	2069	2083	1595
% Stable	38.9	53.6	36.7	44.1	34.0	51.5	47.3	32.8	34.7	22.5	43.6	30.1
F1 Score (%)	65.7	81.1	63.6	69.5	68.2	72.5	71.6	65.8	65.2	60.5	75.1	49.2

Table 3: Overall and singer-specific performances for stable note detection from segmented gesture time series across the set of instances in the duration range [0.5, 5] s. Count indicates the number of instances in each singer (or overall) dataset. The F1 scores in the final row may be compared with the values in the row 2 that correspond to the chance-level F1 score.

Phrase	Like	Unlike	Chance Accuracy	DTW _D (1)	DTW _I (1)	DTW _{Ind} (8)	DTW _{LR} (2)
gmD	944	827	50.2	52.2	48.6	51.8	52.4
r/P	1035	1268	50.5	55.3	47.1	56.1	55.1
P\R	817	1340	53.0	65.0	45.7	65.2	65.1

Table 4: Classification accuracy (%) for Like and Unlike phrase detection with gesture time series and different DTW distance measures. Feature dimensionality (i.e. DTW path costs) appears in parantheses. Bold font indicates that the model performance is significantly better ($p < 0.005$) than chance, with the chance accuracy (%) also mentioned in the table.

SCh and SS), we note the relatively low proportions of stable notes in their data. Such behaviour can arise, for example, when the singer makes a choice to focus more on melodic movements in their alap rather than long periods of held notes. With a relatively low representation of their stable note examples in the training data, it is probable that idiosyncratic aspects of their stable note gestures, if any, were not learned by the classifier. We did not find much of raga dependence in stable note detection performance. We also did an analysis of tonic versus other stable notes to find that the tonic notes (fewer in number overall) were harder to detect; this observation needs more data for a better understanding.

5.2 Raga-phrase detection

Table 4 displays the Like/Unlike classification of raga phrases across the alaps of all singers. We see a roughly equal proportion of L and U examples and therefore chance baseline accuracies close to 50%. Both P\R and r/P exhibit gesture classification accuracies that are statistically better than chance for all versions of DTW distance except the DTW_I which is the simple summing of independent path costs across the 8 different series. In the case of the gmD phrase, we see a relatively small increase over chance with the only significant difference provided by the DTW_{LR} that combines left and right wrist paths, each computed independently of the other. A singer-based breakdown of the overall accuracy showed relatively uniform behaviour across singers for all the phrases except for one outlier (out of the 11) for each of P\R and r/P phrases.

We would also like to comment on the equal proportion of L and U examples in our data for this task. Although there is a far larger number of U instances (that is alap segments that probably do not contain the phrase of interest and therefore expected to return a high cost in the DTW subsequence search of the audio), we found that many of

these actually led to invalid paths from pathological warping and thus were unusable candidates for this study.

6. CONCLUSION

This work proposed a new approach to examining melodic similarity captured in co-singing gestures by analysing audiovisual recordings. With a new dataset of 11 singers, raga-characteristic phrases were proposed as a proxy for similar melodic movements within and across singers. As in previous work, wrist movements that accompanied the solo alap singing were represented as kinematics time series. In the absence of ground-truth phrase labels for the alap data, we developed a pipeline for achieving the AV segmentation for the chosen phrases via DTW-based audio template matching using a small set of hand-labeled segments. We also considered the classification task for more generic AV segments defined in a bottom-up manner such as stable-note regions. Overall, our experimental results indicate that there is significant kinematic information linked to the selected melodic events, and confirm the importance of computed velocity and acceleration profiles in the gesture representation.

A useful contribution of this work is the musicological questions it encourages. Apart from the aspects already mentioned in the discussion of the results, we note that the use of multiple phrase templates can facilitate larger experimental validation of hypotheses, such as that of Rahaim [5], that gestures could function to draw attention to *what is different* between two semantically close melodic patterns. Finally, several enhancements to the presented methods are possible including better-motivated movement features, more keypoints (elbow and hand joints) and using all 3 camera views to include depth movement.

ABSTRACT

Thanks to advancements in deep learning (DL), automatic music transcription (AMT) systems recently outperformed previous ones fully based on manual feature design. Many of these highly capable DL models, however, are computationally expensive. Researchers are moving towards smaller models capable of maintaining state-of-the-art (SOTA) results by embedding musical knowledge in the network architecture. Existing approaches employ convolutional blocks specifically designed to capture the harmonic structure. These approaches, however, require either large kernels or multiple kernels, with each kernel aiming to capture a different harmonic. We present TriAD, a convolutional block that achieves an unequally distanced dilation over the frequency axis. This allows our method to capture multiple harmonics with a single yet small kernel. We compare TriAD with other methods of capturing harmonics, and we observe that our approach maintains SOTA results while reducing the number of parameters required. We also conduct an ablation study showing that our proposed method effectively relies on harmonic information.

1. INTRODUCTION

When a note is played, a set of strongly related frequencies start to sound leading to a pitch sensation for the listener. These strongly related frequencies are what we call the *harmonic spectrum*, in which we distinguish two parts: the fundamental frequency (f_0) and the harmonics. The fundamental is the frequency associated with the pitch, and the harmonics are integer multiples of f_0 . Different instruments reinforce different harmonics, achieving different timbres; but the underlying structure created by f_0 and its harmonics remain present.

Traditional Automatic music transcription (AMT) systems based on manual feature design employed this property to look for harmonic patterns given an observed spectrogram [1]. When DL became more popular, many researchers refrained from incorporating expert knowledge into their model architectures, but relied on generic models in combination with large amounts of task-specific training data. Even though these systems significantly outper-

formed traditional approaches, models utilized large numbers of parameters. [2, 3].

The number of parameters plays an important role, as more parameters can help capture the harmonic pattern better; in exchange, larger models require more computing resources as the number of operations grows. Many DL practitioners do not always have access to large GPU clusters, and might not be able to train such large models. Moreover, many portable devices such as phones have limited battery and memory, and such large models in those devices will either quickly drain their battery or be directly impossible to employ. Part of the research focused on reducing the number of models' parameters without harming the transcription's accuracy. This was achieved in many cases through the incorporation of pitch expert knowledge within the architecture neural network (NN) [4–9].

The main challenge resides in the unequal distances between harmonics in the spectrum, so previous approaches employ either large kernels or several ones running in parallel. This paper introduces a *tridimensional* kernel *harmonically dilated* (TriAD), a neural block that captures music intervals and is capable of observing multiple harmonics while using a single yet small kernel.

The rest of the paper is divided into the following sections: Section 2 gives more details about prior work capturing harmonics from the spectrum. Section 3 describes our method, including the processing of the signal and the design of the kernels. The experimental setting is described in Section 4. We present the results for these experiments as well as an ablation study in Section 5. Finally, Section 6 contains our conclusions for this paper and future work.

2. RELATED WORK

As mentioned in Section 1, harmonics played an important role in the first AMT systems. For example, [1] creates a dictionary of sets of expected harmonics for each fundamental. These ideal patterns were then matched to the spectrograms used as input for the system using the non-negative least squares (NNLS) algorithm. The result is an estimation of fundamental frequencies that along with their respective harmonics, would resemble the input's spectrogram.

For AMT systems using DL, prior work has incorporated domain-specific knowledge in two ways: 1. by choosing a custom input representation that allows the model to detect harmonic structures [4, 10, 11]; 2. by employing specific network architectures to search for pat-

terns in a given feature map obtained at any point of the network [6–8, 12]. Within the first category, one of the most popular approaches is the harmonic constant Q transform (HCQT) [4], a feature that extends the constant Q transform (CQT) [13]. The standard CQT returns a log-frequency representation of the spectrum, where the n^{th} bin is associated with the frequency $f_n = f_{min} \cdot 2^{n/p}$ where f_{min} is the minimum frequency to be considered, and p is the number of bins per octave. The magnitude of CQT spectrogram is a representation containing a single channel, F_{bins} frequency bins, for T frames; its shape is $[1, F_{bins}, T]$. The HCQT extends the CQT the channel dimension, where now H harmonics are aligned, resulting in a tensor with dimensions $[H, F_{bins}, T]$. This extension is done by stacking a number of H CQTs through the channel dimension. Each one of these H CQTs is a regular one whose f_{min} has been scaled by a harmonic factor h : $f_n = h \cdot f_{min}$; the CQTs with $h = 1$ will refer to the fundamental, $h = 2$ will refer to the first harmonic, $h = 3$ to the third harmonic, etc. up to H different values. Similarly, sub-harmonics can be added by making $h = 0.5, 0.25$, etc. In a nutshell, the HCQT facilitates information about the fundamentals directly at the network’s input.

As mentioned, other works incorporated the harmonic knowledge within the architecture of NNs, e.g. [6] extended the idea of frequency-shifted representations, for the internal feature maps obtained inside NNs. The authors named this method multiple rates dilated harmonic causal convolution (MRDC-Conv). Let \mathcal{X} denote a feature map, with shape $[C_{in}, F_{bins}, T]$ at an arbitrary point of the network. The number of channels for that map is C_{in} . In a CQT spectrum, the distance d_n between the fundamental frequency and the n^{th} harmonic is given by:

$$d_n = \text{round}(p \cdot \log_2(n)) \tag{1}$$

Where p is a parameter that determines the number of bins per octave in the CQT spectra. To capture k harmonics with MRDC-Conv, the feature map \mathcal{X} is convolved with k different kernels in parallel, resulting in k outputs. Each of the outputs is shifted following the harmonic factors given by Equation 1. E.g. to capture the first three harmonics, three different kernels are required, thus, producing three different outputs. In the case of $p = 12$ and following Equation 1, the shifts associated with the 2^{nd} , 3^{rd} and 4^{th} harmonics are 12, 19, and 24. The sum across the k outputs is taken, leading to a single final output of shape $[C_{out}, F_{bins}, T]$, where C_{out} is the number of output channels. This method is illustrated in Figure 1a. MRDC-Conv achieves a convolution able to observe the input at the precise position of the harmonics; its drawback is that for each of the harmonics, a different kernel is needed, thus requiring a different feature map stored in memory for each of the k harmonics before they can be aggregated.

Some other authors embedded harmonic knowledge within the convolutional kernels rather than in the manipulation of their inputs/outputs. In [12] the authors use sparse convolutions so that only relevant parts of the spectrum are considered. Sparse convolutions allow the kernels to “ignore” certain parts of the input, so they do not contribute

Harmonics	Music Interval	pitc class distance
2, 4, 8, 16	octave	$b \cdot 12$
17	minor second	$b \cdot 1$
9, 18	major second	$b \cdot 2$
19	minor third	$b \cdot 3$
5, 10, 20	major third	$b \cdot 4$
21	perfect fourth	$b \cdot 5$
11, 22	augmented fourth	$b \cdot 6$
3, 6, 12, 24	perfect fifth	$b \cdot 7$
25	minor sixth	$b \cdot 8$
27	major sixth	$b \cdot 9$
7, 14, 28	minor seventh	$b \cdot 10$
15, 30	major seventh	$b \cdot 11$

Table 1: The harmonics of the first 3 octaves, and their associated music intervals. The rightmost column indicates the distance in bins associated with each interval, where b is the number of bins per semitone.

either to the output or to backpropagation during training [14]. According to [15], the harmonics are *positive* indicators that a certain pitch is present, but some frequencies indicate that the pitch might not be present at all. The latter are called *negative* indicators. The sparse convolutions from [12] are used in such a way that only *positive* and *negative* indicators defined in [15] are taken into account. Sparse convolutions require nonetheless using large kernels to cover relevant parts of the spectrum, i.e. [12] resulted in around 650k parameters exclusively for harmonic processing, accounting for the major portion of the model’s parameters.

In [8], dilated convolutions are used to capture the harmonics from the spectrum, with a method named harmonic dilated convolution (HD-Conv). Dilated convolutions are a special kind of convolution, where the kernels’ inputs are spaced by a fixed amount. An example of dilated convolutions can be seen in Figure 1b. By controlling the dilation size, the authors space the kernels’ inputs, so each kernel obtains a specific harmonic. The outputs of the different kernels are aggregated by summing across the kernels’ outputs as shown in Figure 1b. The size of the dilations is given by Equation (1). E.g. for $p = 12$, the second harmonic is separated from the fundamental by $d_2 = 12$ bins, the third one by $d_3 = 19$; to capture both the second and the third harmonic, we would need to create two convolutional kernels with a dilation size of 12 and 19 at the frequency dimension. This method has the same drawback as MRDC-Conv, as different harmonics also require a different kernel.

3. OUR METHOD

Similarly to [8], our method uses dilated convolutions to capture the harmonics of the spectrum. As mentioned before, a constant dilation can not capture multiple harmonics given the logarithmic nature of these. If it was possible to use different dilations for the same kernel, this problem

Figure 1: Figure (a) An example of MRDC-Conv [6]. Two kernels are applied to the same input. The fundamental f is separated from the harmonic n by d_n bins. One output gets shifted by d_n , and so f and n get aligned. Figure (b) An example of HD-Conv [8], with two kernels applied to the same input, each one with a different dilation (3, and 2 respectively).

would have been already solved, but currently, DL frameworks support only dilations with constant spacing. Our method is able to partially overcome this technical limitation and achieve a convolution at the frequency axis with different dilation rates; thanks to this, our proposed method captures multiple harmonics by just using a single kernel.

We named our method *TriAD*, and it involves a series of steps. The first step is to split the frequency dimension into two new ones, each representing different octaves and pitch classes. We call this representation the *pitch/octave* spectrogram. Next, we create the kernels for our method. Previous works used kernels spanning 2 dimensions: frequency and time; our method’s kernels however span 3 dimensions: octave, pitch class, and time. An arbitrary number of m different kernels can be created, each one capturing a different music interval. The m kernels are convolved with the previously described pitch/octave spectrogram, resulting in m different outputs. Finally, these outputs are aggregated by taking the sum across them. The consecutive steps are illustrated in Figure 2.

Subsection 3.1 details the procedure followed to convert a log-frequency spectrogram onto a pitch/octave spectrogram. Subsection 3.2 explains how our convolutional kernels are created and the difference they have with the method described in [8]. At the end of that subsection, we describe a special kind of padding used in our technique, the octave-circular padding.

3.1 The pitch/octave spectrogram

Let $\mathcal{X}^{C_{in} \times F_{bins} \times T}$ be a feature map, with F_{bins} logarithmically spaced frequency bins, T frames, and C_{in} channels. Our goal is to separate octave and pitch class information. We split the F_{bins} bins into two dimensions representing the octave (o) and pitch class (p) information. The number of pitch classes is simply the number of bins per octave used, and the number of octaves can be obtained by $o = \frac{F_{bins}}{p}$. Note that o must be an integer, and so when this condition is not met, we pad the upper part of \mathcal{X} ’s frequency dimension with the minimum amount of zeros that satisfies the condition. The result is the pitch/octave spectrogram $\mathcal{Y}^{C_{in} \times o \times p \times T}$, a view of \mathcal{X} where F_{bins} has been separated into its octave and pitch class information.

3.2 The harmonic convolutions

Our aim is to compare two pitch classes across multiple octaves to capture harmonically related information. As shown in Table 1, harmonics and music intervals are closely related. Comparing two pitch classes separated by a certain interval at multiple octaves simultaneously will effectively obtain the harmonics associated with that music interval.

As previously mentioned, our kernels have 3 dimensions: $K^{k_o \times k_p \times k_t}$, related to the octaves (k_o), pitch classes (k_p), and frames (k_t) of the pitch/octave spectrogram; this means that our method uses 3D convolutions¹. By changing the convolution dilation at the pitch class dimension we control which interval we capture, and consequently its associated harmonics. Since our goal is to compare the same two pitch classes, our method has a fixed $k_p = 2$, but the sizes of k_o and k_t can be varied, spanning many octaves and timesteps. The effect of dilation exclusively on pitch classes is what achieves the aforementioned non-constant dilation at the frequency dimension. E.g. Let $p = 12$ and a kernel K with $k_o = 3$ and a perfect fifth dilation at the pitch class dimension, in a certain position, this kernel would see $C_1, G_1, C_2, G_2, C_3, G_3$ simultaneously. The distance from each C to the next G is 7 bins, but the distance from each G to the next C is 5 bins. Our method is to the best of our knowledge, the only one capable of achieving that effect in dilation. In the same scenario using linear dilations [8], a kernel with the same size and dilation of a perfect fifth would see instead $C_1, G_1, D_2, A_2, E_3, B_3$. Using our method, a single kernel with $k_o = 3$ and a dilation of perfect fifths at the k_p dimension capture 5 of the first 7 harmonics (see Table 1).

As can be observed in Figure 2, the inputs and outputs of the convolutions have the same size, which is achieved by padding the pitch/octave spectrogram. The values used to pad follow the values of the continuous log-frequency spectrogram. E.g. given $p = 12$, to pad above B_1 , we use the values of the bins $C_2, C\sharp_2, etc.$ In contrast, values above the highest octave of the pitch/octave spectrogram will be padded with zeros. We call this method *circular-octave padding*.

¹ When $k_t = 1$, our method can be implemented with 2D convolutions by stacking frames across the batch dimension. 3D is just the general case for an arbitrary k_t

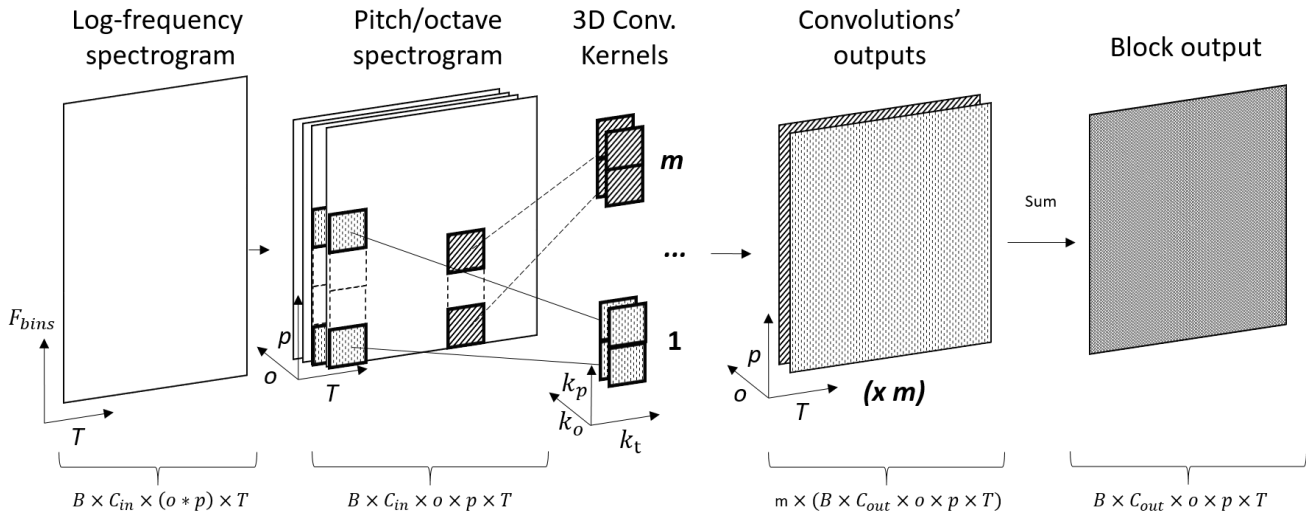

Figure 2: An overview of TriAD. The channel dimension has been omitted in the image. The first stage converts a log-frequency spectrogram onto a pitch/octave one. We apply m of our harmonically motivated kernels to the pitch/octave spectrogram. Each kernel captures different harmonics, depending on the dilation at the p dimension. The kernels’ outputs are aggregated by summing the m outputs. B stands for the batch dimension.

4. EXPERIMENTS

We test the performance of our method on AMT for the subtask of piano transcription. Our method is compared with other SOTA approaches of capturing the harmonic spectrum within the architecture itself; concretely, we used the harmonic blocks MRDC-Conv [6], and HD-Conv [8]. We do not include input manipulations such as the HCQT, since these are input manipulations rather than network-internal musically motivated convolutional operations, and a fair comparison is not straightforward.

4.1 Datasets

We used two datasets in our experiments: *MIDI and audio edited for synchronous track and organization* (MAESTRO) [16], and *MIDI aligned piano sounds* (MAPS) [17]. MAESTRO contains about 200 hours of audio for complex piano performances precisely aligned to note labels. Some compositions appear multiple times, each played by a different interpreter. In the paper where MAESTRO is presented, an official train/validation/test configuration was also proposed so that compositions played by different interpreters are in the same split group. We use the latest version of this dataset, version 3, in our experiments. MAPS is another popular dataset used in piano transcription. In contrast to MAESTRO that contains only complete piano pieces, this dataset also contains isolated notes and chords.

Following the practice used in previous works [7, 8, 16], we use the train and validation splits from MAESTRO to train our NNs, and the test sets of MAESTRO and MAPS for testing the trained models. Chunks of audio of 20 seconds and a sample rate of 16.000Hz were used and transformed into a CQT spectrogram, with 352 bins, $f_{min} = 32.070Hz$, and a resolution of 4 bins per semitone. A hop size of 320 samples is employed, resulting in a time resolution of 20 milliseconds.

4.2 The model

We use the HPPNet-base model from [8] for our experiments. This model consists of a backbone and 4 different heads; each head is in charge respectively of predicting which notes are present in each frame, its velocity and whether there is an onset or offset happening. Figure 3 shows an overview of the network. The backbone consists of multiple convolutional layers, and it is divided into three main sections. The first section consists of 3 blocks with 2D convolutions, whose kernels are squarely shaped (7×7) and perform initial processing of the CQT spectrogram. The second section is in charge of doing the backbone’s harmonic processing; this is where either HD-Conv, MRDC-Conv, or TriAD will be placed. The last block consists of 5 2D convolutional layers with filter shape (1×5), spanning across the time dimension ².

The output of the backbone is then used as input for the four heads. Each head consists of a bidirectional long short-term memory (LSTM) [18] and a dense layer. LSTMs model sequential data, which are the features associated with each output bin in this case. The dense layer takes the features outputted by the LSTM and produces a single value for each of the 88 notes of a piano. Details about the design choices of HPPNet can be found in [8].

We run our experiments by comparing the model’s performance when the backbone’s harmonic processing is done either by our method (TriAD), MRDC-Conv [6], or HD-Conv [8]. We use those methods as employed in their respective papers: 12 kernels of shape (1×1) in the case of [6], and 8 kernels with shape (3×1) in the case of [8]. For our method, we use just two kernels, one dilated for perfect fifths, and another one for major thirds; these are

² The third block differs from the original paper description; following their description, that block of the backbone alone has 983.040 parameters, whereas the paper specifies that the backbone contains 421K parameters. We used the network as implemented in the official repo, which matches the number of parameters and replicates their reported results

the intervals with the most associated harmonics. Our kernels span 3 octaves ($k_o = 3$) and a single frame ($k_t = 1$). The code for MRDC-Conv and HD-Conv can be found in their official repositories^{3 4}. We do not train a version of the model with a “harmonically agnostic” block, as [8] already shows in an ablation study that the model’s performance drops significantly in that case.

As optimizer, ADAM [19] with a learning rate of $6 \cdot 10^{-3}$ was used. We trained all the models for 200.000 steps, where each step consists of a batch size of 4 chunks of audio. The evaluation was done on MAESTRO’s evaluation dataset every 500 steps, to check for possible cases of overfitting. The models were trained 3 times, each one with a random weight initialization. All the harmonic blocks take a similar time to train, around 24h to complete in a V100 GPU.

The employed loss is the same one as in HPPNet’s paper [8], a combination of individual losses for the frame, onset, offset, and velocity heads. Weighted binary cross entropy (see Equation 2) was used as loss for the frame, onset and offset heads. This loss is used since there are few positive onset labels, yet predicting onsets is necessary to distinguish consecutive notes. The parameter w controls the relevance of positive labels in the loss and is chosen as $w = 1$ for offsets and frames, and $w = 2$ for onsets. The loss for the velocity head is the mean squared error between the expected and estimated velocities of each individual note.

$$l_{bce}(y, \hat{y}) = -wy \cdot \log(\hat{y}) - (1 - y) \cdot \log(1 - \hat{y}) \quad (2)$$

5. RESULTS

The metrics reported follow the convention described in [20]. These metrics report different aspects of the transcription. The *frame* metric operates at the frame level, while the other three operate at the *note* level. Within the note level, three different metrics exist, considering offsets and/or velocity. This is due to the partially subjective nature of this task. The onset (referred to as the moment when a certain note starts to sound) is not very subjective given the sharp attack of the piano [21]. In contrast, offset (the moment when a certain note stops sounding) and velocity are less objective aspects of the transcription. An estimate of a note is assumed to be correct if its onset is within ± 50 ms of the reference, and its pitch is correct. When contemplating offsets, in addition to the previous requisites, the estimation’s offset should also be within a certain range; this range is either ± 50 ms or 20% of the reference note’s duration, whatever is larger.

Velocity estimation is more intricate, as depending on the microphone position a note played with a certain velocity can sound louder or quieter. We use the procedure described in [2], which involves rescaling velocities and using linear regression to account for the aforementioned

Figure 3: A diagram of HPPNet. The brackets’ numbers represent the sizes of the channel, frequency, and frame dimensions. Letter d indicates the dilation rate.

difference in loudness. All the metrics were calculated using *mir_eval* [22].

The scores for Section 4 experiments are in Table 2. We also report the results of some larger models of the SOTA as reference. Onsets & Frames [2] is among the most well-known DL models for piano transcription. Semi-CRFs [3] is a method designed to improve the predictions made about the offsets. These are large and capable models, but the ones using harmonic knowledge also manage to achieve similar results with notably fewer parameters. Both TriAD and HD-Conv blocks achieve similar results, in pair with large models. The MRDC-Conv block uses fewer parameters than HD-Conv, but in exchange drops in performance. Noticeably, the model using TriAD has the same number of parameters as the one MRDC-Conv, yet it does not drop in performance.

5.1 Kernel dilation relevance

In music theory, some intervals are more important than others. Equally, some music intervals have more harmonics associated with them than others, as shown in Table 1. It could be expected, that using a kernel dilated with a highly relevant interval yields better results than a kernel associated with a less relevant interval. We tested whether this assumption held or not in our method; instead of using multiple kernels as previously described, our block consists of a single kernel for these experiments. We used 2 relevant intervals (perfect fifth, major third), and 2 lesser relevant intervals (minor second, major seventh) to test the aforementioned assumption. These kernels span 3 octaves ($k_o = 3$) and a single frame ($k_t = 1$), as in the previous ex-

HPPNet + TriAD	90.14% (± 0.02)	71.58% (± 0.01)	90.23% (± 0.02)	71.98% (± 0.01)	83.16% (± 0.01)	68.53% (± 0.01)	83.36% (± 0.01)	69.19% (± 0.02)
HPPNet + HD-Conv	84.89% (± 0.01)	69.96% (± 0.02)	85.98% (± 0.02)	70.50% (± 0.03)	84.23% (± 0.03)	67.86% (± 0.03)	84.79% (± 0.01)	68.69% (± 0.02)

Table 3: F1 framewise results for the single kernel experiments described at section 5.1. Our method obtains worse results if a “less relevant” music interval is chosen. HD-Conv achieves more similar results regardless of the dilation, with just a small improvement for the case of the perfect fifth (where it employs two kernels).

periment. We also used the method with constant dilations i.e. HD-Conv from [8], equally using single kernels except for the case of the perfect fifth. There are two harmonics associated with the perfect fifth within the first 3 octaves, so we employ two rather than a single kernel. The constant dilations capture in this case major third: 5th harmonic; perfect fifths, 3rd and 6th harmonics; minor second, 17th harmonic; and major seventh 30th harmonic. We noticed that after 50.000 steps, the speed at which the loss diminished slowed down sensibly, and therefore, we reduced the number of training steps for this experiment and trained for 70.000 steps in each run.

The results can be seen in Table 3. HD-Conv [8] obtains slightly better results for the perfect fifth kernels, but similar results for other cases. Our method (TriAD) has a distinguishable performance gap depending on the interval. Results are worse for minor second and major seventh intervals, compared to the cases of the major third and the perfect fifth. Moreover, in those two cases, our method achieves notably better results than HD-Conv.

6. CONCLUSIONS

In this paper, we presented TriAD, a novel convolutional block for NNs capable of capturing the harmonics related to music intervals. To obtain such information, we separate octave and pitch class dimensions from log-frequency spectrograms and create convolutional kernels specifically designed to process this disentangled representation. We tested and compared our method with other ones designed to capture harmonic information, in the task of piano-AMT. We also compared how our model performed when only a single kernel was employed. To the best of our knowledge, our method is the only one capable of achieving dilated convolutions which are not “equally spaced”

along the frequency axis, allowing our model to capture multiple harmonics using a small kernel. To achieve this effect, other approaches require applying different convolutional layers to the same input [6, 8] or using large kernels [12].

Our method is still capable of reaching the performance achieved by other harmonic blocks while making use of fewer parameters, showing the effectiveness of our approach. Furthermore, the results from the experiment described in Subsection 5.1 show that our method’s performance highly depends on the dilation choice, thus hinting that our method is indeed using the harmonics to determine which pitches are present. Moreover, with an appropriate dilation choice our model outperforms other methods also using a single kernel.

Harmonic series are relevant for other tasks beyond AMT, for example, instrument recognition. Some works have found that the harmonics and their respective amplitudes are crucial to correctly classifying instruments [23, 24]. Our method could be employed to capture the amplitude of different harmonics and learn specific patterns for each instrument. In future work, we will use “harmonically designed” networks in other AMT related tasks. Recent advances in AMT such MT3 [25] demonstrate that with the current DL techniques is possible to transcribe an arbitrary number of instruments from a piece of music audio instead of just piano as shown here. Since the harmonics are relevant for instrument recognition, we hypothesize using harmonic blocks such as the ones presented here, the accuracy with which notes are assigned to each instrument in systems like MT3 could improve. We release code for reproducibility experimentation⁵.

ABSTRACT

The practices of data collection in training sets for Automatic Music Generation (AMG) tasks are opaque and overlooked. In this paper, we aimed to identify these practices and surface the values they embed. We systematically identified all datasets used to train AMG models presented at the last ten editions of ISMIR. For each dataset, we checked how it was populated and the extent to which musicians wittingly contributed to its creation. Almost half of the datasets (42.6%) were indiscriminately populated by accumulating music data available online without seeking any sort of permission. We discuss the ideologies that underlie this practice and propose a number of suggestions AMG dataset creators might follow. Overall, this paper contributes to the emerging self-critical corpus of work of the ISMIR community, reflecting on the ethical considerations and the social responsibility of our work.

1. INTRODUCTION

The quest to generate music with AI (Automatic Music Generation, AMG) is undergoing crucial but overlooked ontological, artistic, and political transformations. Originally confined to academic labs and employed in niche music genres, this quest is gaining traction mostly among commercial companies¹ aiming at automatically generating music in all genres. These transformations are enabled by a combination of socio-technical novelties, including i) the growing influx of money in the field [2, 3]; ii) advanced in Deep-Learning (DL) techniques, such as Transformers [4]; and iii) the increase of cheap computational power. While, from a purely musical perspective, the quality of the music created with AI is undoubtedly rising, from a socio-political perspective, a new gold rush resulting from efforts to outperform competitors and make the best AMG model is following the typical blueprint of capitalist innovation [5–7]: corners are being cut; critical

questions have not been asked; short-term gains are prioritised; *permission* is not being sought.

These ethically questionable practices are causing increased concerns. A group of artists² recently released a manifesto that identifies one of the most urgent ethical issues arising from AI-generated art: the exploitation of artists’ work in training AI generation systems. Similarly, Holly Herndon, a musician famous for popularising AI-generated music, recently criticised OpenAI for not asking living performers’ permission to use their music in their AI model, JukeBox [8]. Most systems that generate artistic content using Machine Learning (ML) indeed often indiscriminately populate their training datasets by accumulating original material that is available online [9–12].

Within the ISMIR community, occasional fiery calls requested the community to reflect on the ethical implications [13–15] of, and demanded accountability [2] for the work we produce. However, no specific work investigated the potentially exploitative nature of the datasets we use, and no ethical consideration has been given to how data has been generated. We argue that such investigation is long overdue, especially as the publication of AMG models proceeds undisturbed - and actually, as we will show in the paper, is steadily increasing.

To fill this gap, we aimed to assess the extent to which training sets used in ISMIR papers that propose new AMG models are affected by this issue. We first identified all papers presented at the last ten editions of the conference, from 2013 to 2022, that introduced a new music generation model or a pertinent dataset. Then we identified all dataset(s) that have been used in these papers. Finally, we surveyed information for each dataset, including how data was populated and the extent to which musicians wittingly contributed to its creation.

The contribution of this paper is threefold. First, we provide descriptive statistics about the datasets that are mostly used at ISMIR in AMG applications and how they are populated. Second, we report the ideologies that are embedded in them and outline a lack of adequate engagement with musicians and carelessness on ethical matters. Third, we offer suggestions for dataset creators interested in following responsible practices in their work.

The rest of the paper is structured as follows. We first review literature in Critical Data set Studies and report discussions on ethical issues within MIR. We then describe

² The European Guild for Artificial Intelligence Regulation, <https://www.egair.eu/>

the research process, report the results, identify the values that are inscribed in the datasets, and offer suggestions for dataset creators. We conclude the paper with a summary of the study and directions for future work.

2. BACKGROUND

Deep-learning (DL), which nowadays is the most commonly adopted method to generate music automatically [16–19], significantly relies on the quality and volume of vast training data. Despite this reliance, dataset development remains an underappreciated element in DL practice.

2.1 Critical Data Set Studies

A growing literature on *critical data set studies* [20] aims at identifying the ethical issues and hegemonic power structures of datasets, in particular when used to train ML models [10, 12, 21]. One of the most urgent issues concerns the exploitation of user labour in AI systems: datasets are populated with data generated by “unwitting labourers” [9] and scraped from the Internet “without context and without consent” [11]. The question around consent is particularly convoluted: consent may have been given unwittingly, for a specific use only, and “some people may never have been given the chance to offer their consent at all” [20]. This concern is not limited to the ivory tower of academia. Musicians are gaining awareness of this issue, and an increasing number of complaints arise from the unfair or unconsented use of original material in AI-generated art.³

Most critical work on dataset creation addressed Computer Vision (CV) sets [11, 24, 25] like ImageNet and MS-Celeb, which contain tens of millions of digital images uploaded by platform users. [25] identified the values embedded into these datasets and their formation: evaluating *model work* is prioritised to the detriment of careful *data work*. Another case study that received attention is that of reCAPTCHA [26–28]. Disguised as a *human authentication tool*, reCAPTCHA can be seen as a capture-machine that exploits unpaid individuals’ perceptual abilities and micro-labour to train AI datasets [27, 29].

The very way in which most datasets are created embeds specific neoliberal values, like extractivism and deregulation, as exemplified by OpenAI’s argument that “IP should be free to use for AI, with training constituting fair use” [30, p. 54]. The all-you-can-scrap ideology dismisses individuals’ contributions to dataset creation, which can be met by their creators with a *laissez-faire* attitude [31] that overlooks the ethical implication and liability of scraping the whole Internet [21, 25]. In fact, when concerns are voiced, they are specifically aligned with libertarian values and related to how data privacy and data ownership are barriers to collecting data [25].

The practices and routines of data accumulation are not secret. The opposite is true. Among dataset creators, they have become widely accepted, unquestioned, and unchallenged following a process of *dataset naturalisation*: “the

contingencies of dataset creation are eroded in a manner that ultimately renders the constitutive elements of their formation invisible” [24]. Notably, the values and ideologies are not only inscribed in how technology is used but also in how it is taught. The lack of interest in how datasets are constructed can indeed be found in the lack of guidance in typical ML textbooks or syllabi [24, 32].

While many dataset creators do not consciously attempt to hide their data accumulation practices, they do not try to fully disclose them either. Dataset naturalisation is indeed exacerbated by ill documentary practices: as reported by [33], ML communities pay little attention to documenting data creation and use. [24] proposes that the lack of information on dataset creation (e.g. how datasets have been created, and whether and how much annotators have been paid) is *structural* - thus ideological - rather than accidental. Every decision and every step in dataset development that is left unaccounted and unarticulated from documentary practices has a political meaning as these steps and decisions are related as “not important” [25]. We will return to this point in the discussions.

2.2 Critical turn in MIR and AIM

Several technology communities are undergoing a *critical turn* [34–37] that challenges existing knowledge production methods and political positions as well as ethical and political thoughts within a field. This turn is ethico-onto-epistemological [38, 39] insofar as it questions what kinds of work, knowledge, and social commitment is pursued within and by the community.

While most criticisms of MIR research come from outside the community [3, 40–42], recent academic production within MIR [2, 3, 14, 43–45] and the development of a workshop series on Human-Centric MIR [46] testify that we might be close to a *Critical MIR* - i.e. MIR scholarship devoted to critically analysing the work produced in the field. However, the sort of work that is (not) published at ISMIR (less than 0.5% of the ISMIR submissions engage with any sort of ethical discussions [2]) indicates that the response of the field on ethical issues is still inadequate.

With respect to AMG, the ethical issues that have been identified include copyright issues [15, 47], a narrow and Western-centered understanding to music [43, 45], the risk of *musician redundancy* [2, 14] or the *crisis of proliferation* [44, 48], diversity issues [49], colonialist and extractive practices [2], and assumptions and bias that are embedded in the AI systems [13–15]. To the best of our knowledge, the potentially exploitative nature of AMG datasets remains uncharted territory.

3. METHODOLOGY

3.1 Researcher Positionality and Motivation

Positionality statements are common in critical studies and serve as a foundation for critical work to understand the research context and the authors’ interpretation of the results. Since the outset of the research process, we have

³ Notable cases include GettyImages suing Stable Diffusion’s creators [22] and audiobook narrators complaining against Apple for using their voices to train AI [23].

strived to maintain objectivity and reflexivity by acknowledging our unique positions and backgrounds. All three authors are actively involved in MIR. The first author is formally trained in computer science and is expert in critical theory and technology studies; the second author has a background in computer science; and the third author has a background in electronic engineering and is specialised in machine learning algorithms.

The motivation for undertaking this study is twofold. First, we aimed to support the growth of ISMIR community by contributing to the corpus of self-reflective work, identifying ideologies that might be latent but, once surfaced, can be considered problematic by community members. Second, the development of the suggestions for dataset creation derived from the personal experience of one of the authors, who was involved in dataset creation for AMGs and acknowledged the importance of community guidance on the best ethical practices to adhere to.

3.2 Analysis of ISMIR publications

We conducted a systematic review of the last ten editions of ISMIR (2013-2022). A total of 1078 publications were sourced from the conference proceedings. Two of the authors manually filtered the papers adopting two inclusion criteria. First, we included all papers presenting a new music generation model. We included all models that generate new compositions or performances, including in-painting, style transfer, and improvisation. Second, we included all papers that introduced a new dataset that could potentially be utilised as training material for AMG models but rejected works that did not contain symbolic or raw audio music files. For example, we did not include the NSynth Dataset [50], which contains sampled notes from different instruments, but we included MedleyDB [51], which contains annotated multitrack audio.

The analysis proceeded in two phases. First, for each paper, we identified whether authors employed existing datasets (i.e. datasets released or introduced before the publication of the ISMIR paper) or created new ones (i.e. datasets created or introduced as part of the original research reported in the paper). We also examined the presence of any discussions of ethics and permission for using data entries training data for AMG models.

In the second phase, we examined the datasets identified in the first phase. For papers that used an existing dataset, we retrieved dataset information from the original paper (whether or not it was published at ISMIR) in which it was introduced. When we could not find sufficient information in the paper, we checked dataset release links, which were found either in the original paper or by a web search of the dataset name. The information we collected included i) data format (symbolic or audio), ii) how datasets were populated; iii) whether data contained original performances, compositions, or arrangements; iv) the data type; v) the extent to which musicians were involved in the dataset creation and whether they were aware of the intended purposes for the dataset; and vi) whether ethical concerns were discussed.

Figure 1: Distribution of selected papers and datasets over the years (only papers after 2003 were considered).

Dataset Name	Format	Occurrence
POP909	Symbolic	11
Nottingham	Symbolic	9
Lakh MIDI	Symbolic	5
HTPD3	Symbolic	3
Yamaha e-Competition	Symbolic	3
Lakh Pianoroll	Symbolic	3
MusicNet	Both	3
URMP	Both	3
AILABS17k	Both	3
Bach Music21	Symbolic	3
Bach Chorales	Symbolic	3
RWC	Both	3

Table 1: The most popular datasets and their occurrences. Each dataset comprises data in symbolic form, but three of them also include audio files.

From a methodological point of view, most of these investigations involved checking the aspect under scrutiny (e.g. whether ethics was discussed) from the dataset sources. The task of identifying how datasets were populated was not as straightforward. In order to streamline the analysis and facilitate the report of the findings, we aimed to cluster datasets into categories that reflected different ways of populating datasets. Two of the authors performed this categorisation following a deductive approach. As they analysed more datasets, they introduced new categories and deleted or merged existing ones. The analysis spreadsheet is available at <https://github.com/Sma1033/amgdatasetethics>.

4. FINDINGS

A total of 121 papers survived the filtering. Fig. 1 shows the significant rise of interest in AMG in recent years. Three fourth of the articles (82) introduced a new model, which was either introduced on its own or with a new dataset (Fig. 2a). From this list of papers, we identified 115 datasets (Fig. 2b). When only considering the 82 papers that introduced a new model, most (62 papers, 75.6%) ISMIR researchers use, at least in part, existing datasets to train their AMG models. Tab. 1 shows the 12 most frequently used datasets in our survey, along with data format and their occurrence in our survey. The remaining 104 datasets were only used in one or two papers.

Figure 2: (a) **What is introduced:** new model (73 papers), new dataset (39), both (9). (b) **Dataset Originality:** new datasets (58), existing datasets (53), both (12).

4.1 Dataset Creation

We clustered datasets into nine categories to reflect the different ways in which entries were collected (Tab. 2). The categories are non-orthogonal: datasets could be associated with more than one category. In most cases, datasets were populated without creators incurring any costs. Only five datasets used paid online sources or compensated the involved musicians. With the exception of those belonging to the ‘Involved musicians’ and ‘Synthesised music’ categories, all datasets were populated with existing music data. New music data accounted for 16.5% of all datasets. We found evidence of poor documentary practices for 18 datasets (15.7%): in 10 cases, there was no information on how data was collected; in 8 cases, we could not find any documentation reporting how datasets were created.

4.2 Musicians’ involvement

Only 17 datasets (14.8%) involved musicians in any capacity (category ‘Involved musicians’). In 11 cases, musicians performed or arranged existing compositions. Three of these datasets (ASF-4, HP-10, and AIST) were entirely created from novel compositions. The remaining three datasets from this category did not contain compositions or performances created specifically for the dataset, or at least, it was not explicitly mentioned. The Irish Traditional Dance Music dataset [61] used the recordings of one of the authors’ own performances. For the remaining two datasets [51, 62], the creators mentioned that professional musicians had created those recordings. However, it is unclear whether these recordings are specifically created for the dataset. The other two datasets that included new music belonged to the ‘Synthesised music’ category and algorithmically generated monophonic melodies [59] or polyphonic MIDI sequences [63].

4.3 Musicians’ permission and awareness

We checked whether explicit permission was sought from musicians to use their creations to train an AMG model. Only three datasets creators reported having asked such permission. The authors of ASF-4 and HP-10 datasets [64] explicitly mentioned that the musicians involved were made aware of the purpose of the dataset for AMG. Jazz players participating in the creation of the FILOSAX

dataset [54] signed a document that provided explanations about the goals of the dataset. However, it is not clear whether these goals included AMG: whereas the authors mention “music generation” in the Abstract, AMG was not included in the list of potential applications of the dataset. In the Mozart Piano Music Dataset [65], pianists gave permission to use their performances for the intended use of the dataset (music analysis), but they were probably not aware and did not consent to have their performances used to train the AMG model introduced in [66].

Two cases were particularly problematic. The MAST Dataset [67], which was introduced for automatic rhythm assessment, was sourced from student entrance exams without seeking consent from the students. Another popular dataset, the Yamaha e-Competition dataset⁴ features MIDI files of piano performances obtained from the entries of the piano competition. Although Yamaha claims ownership over all data generated during the event, competitors are unlikely aware their performances are used to train AMG models, as seen in [68]. The lack of permission sought from the musicians clashes with the several comments offered by dataset creators that often acknowledged the valuable contributions made by these musicians, which allows the dataset to exist in the first place.

4.4 Discussions on Ethical Issues

Our analysis revealed a lack of engagement with ethical issues, corroborating findings from [25] in their analysis of CV datasets. Only four datasets included any ethical considerations, and only two of them contained an explicit ethics statement. The authors of [69], which presented a new GuitarPro dataset, listed several questions, some of which are particularly relevant to this paper: “How to acknowledge, reward and remunerate artists whose music has been used to train models?” and “What if an artist does not want to be part of a dataset?”. While their spontaneous engagement with these issues is commendable, it is not clear to which extent the authors used these questions in the development of their dataset.

In [70], the authors raised concerns about the impact of AMG for “human musicians of the future”. They also stated “care have (*sic*) to be given regarding the fair use of existing musical material for model training” but did not further explain what sort of care and what constitutes unfair use. [57] included an analysis concerning plagiarism issues and observed that their model demonstrated a potential tendency for plagiarism. This issue was also recently highlighted in [47], similar to the level exhibited by a human musician.

5. DISCUSSIONS

By leveraging our findings, this section first reports and discusses the values embedded in the datasets used at ISMIR for AMG models. Then, we move to offer practical suggestions to AMG dataset creators.

⁴ <https://www.piano-e-competition.com/>

Category	Description	Occurrence
Scraped online	Existing music data collected online from websites [52] or databases [53]	49
Existing datasets	Existing music data collected from existing datasets [16]	26
Involved musicians	New music data was created by involving musicians in some capacity [54]	17
Private data	Existing music data was collected from private databases [55]	5
Book collection	Existing music data collected from printed books [56]	5
Online store	Existing music data collected from an online commercial website [57]	4
CD collection	Existing music data collected from published CD recordings [58]	3
Synthesised music	New music synthesised using rule-based heuristics or other methods [59]	2
Not mentioned	No explicit information about how data was obtained [60]	18

Table 2: Categorisation of how data was collected in the datasets. For each category, we included exemplary references.

5.1 The Values Embedded in Our Datasets

Our analysis extends what [24, 25, 33] have suggested for other ML applications areas: *data work* and data collection practices are de-prioritised and de-valued in AMG datasets used at ISMIR. Most datasets (~60%) had been populated either by scraping songs from the Internet or by accumulating data from existing ones. Considering original music as a *terra nullius* that is free for the taking means addressing dataset creation with expediency. This approach follows the hegemonic narrative that compares *data* to *oil*. This comparison is highly ideological [71–73] as it disguises the origin (and ends) of data [11], and de-penalises and justifies extractive practices using neo-colonial rhetoric that data is something waiting to be discovered [71, 73].

This narrative underestimates or blatantly neglects the human labour necessary for its development - which includes writing, performing, transcribing, and recording music. The majority of datasets were created by amassing musical compositions initially intended for purposes other than AMG. In these cases, the original labour that was put into the creative acts of composition or performance is simply neglected. Relatively few datasets included original material, and in only two cases, specific permission was asked to use musicians’ work to train datasets for AMG purposes. This discussion point resonates with objections to the unfair and exploitative practices of capturing individuals’ labour and *humanness* [9] when creating data for digital platforms [6, 74–76] and training AI systems [10–12]. As proposed by [77], human labour is *structurally obfuscated* in ML applications to the benefit of profit and innovation. Similarly, [78] proposes that hiding the labour in this context is crucial to attracting capital investments.

Our direct knowledge and lived experience of MIR offers us a vantage point that we can employ in our reflexive inquiry. We propose that dataset creators might have prioritised safety over criticality and followed common, albeit questionable, procedures simply because these are the procedures that are typically employed in AMG research. This comment is not intended to absolve dataset creators from the responsibilities that come with their work. Rather, it is an invitation to self-assess one’s alignment with the exploitative ideologies we surfaced in this section. Yet, we unequivocally found a lack of *data work* - including a limited interest in creating one’s own data, exploitation of the

labour of unwitting musicians (e.g. in the e-piano competition) and students [67] in dataset curation, and poor documentary practices regarding the source of data [60, 79]. We argue that this lack is ideological. What we leave unaccounted for or unspoken in dataset creation and documentation signs what we consider important or irrelevant [25].

Our findings indicate that the rights and demands of musicians are not prioritised by dataset creators and that the degree to which new models and datasets advance or curb a fair model for musicians is largely ignored. This comment resonates with a note from [80], who explained that streaming services overlook “the rights of musicians or users because their decisions are made based on wholly other problems”. It is thus essential that ISMIR researchers and practitioners reflect on the *problems* they drive their decisions on and the *agendas* they implicitly or explicitly follow. Answering questions like “what is the agenda we are following and who benefits from it?” [81] requires community discussions that are difficult, uncomfortable, and controversial but nevertheless necessary. Avoiding engaging with these questions is not a political absence but rather a political tacit acceptance of the status quo [36, 37] as datasets do not exist in a political void [20, 82].

5.2 Suggestions

In this section, we offer suggestions to the broader community and to individual authors interested in creating new datasets or using existing ones to train AMG models. We developed these suggestions by integrating results from our analysis with findings from other academic contributions, including ethical CV datasets recommendations [25]. These suggestions are not intended to be meticulously followed as a recipe book. Rather, we devised them as probes, navigation tools, or structured conversations whose development should continue in a participatory way with the rest of the community.

Develop one’s own dataset. While exploiting musicians’ labour in AI dataset creation is a questionable practice [9], expecting dataset creators to seek and obtain consent from all humans involved in AMG datasets is unrealistic [30]. Thus, we recommend creating, whenever possible, one’s own dataset and hire musicians for as many tasks as possible (i.e. composing, performing, arranging songs). A small but important amount of datasets in our

investigation followed this practice. We acknowledge that this suggestion might lead to equity issues. If it were to be enforced, only big companies and top university labs would have the economic means to develop such datasets. However, rather than dismissing this issue as unsolvable and continuing business as usual, we propose that the community interrogates itself and finds strategies to tackle it. As an alternative, efforts might be made to develop models that are trainable on small or procedurally-generated datasets following recent successful examples like [30,83].

Receive consent from musicians and remunerate them. Dataset creators should inform musicians about the specific goals of the dataset. It is possible that musicians would willingly consent to train a dataset for several MIR tasks but not for training AMG. When possible, dataset creators should consider paying musicians for their labour and disclose the amount [24], as found in [54]. Given the equity problem discussed above, when paying musicians is not feasible, that should be reported [25], and musicians should be at least acknowledged. When AMG systems are integrated into commercial products, a technical infrastructure might be implemented to distribute royalties to dataset contributors. This suggestion shares Holly Herndon’s vision for a novel IP framework “compensates me for my likeness when (and only when) money is made from it” [8].

Document the process of dataset development. Our analysis revealed a general lack of care not only in *doing* but also in *documenting* data work. For instance, POP909 dataset’s creators did not mention the source or selection process of the “909 popular songs” used to generate piano arrangements [84] and the Lakh dataset’s creators simply mentioned that they extracted songs from “publicly-available sources on the internet”⁵ website. Careless documentary practices, which we believe were mostly involuntary and caused by an undervaluing of this process in the field [24, 25], implicitly reveal that *how a dataset is developed* and *whose labour goes in it* is not important. We suggest the community develop protocols, guidelines, or templates offering *fair practice* suggestions for dataset creators to follow.

Report the intended use of the dataset. Our findings indicate that it is a common practice among AMG dataset creators to reuse existing datasets. We suggest that dataset creators should report the original intended use of their dataset and list the potential ‘allowed’ applications, following the example of [54]. This practice would prevent, or at least dissuade, future dataset creators from using that data for purposes other than the ones envisioned by the creators and that musicians agreed on. This suggestion is grounded on the observation that technologies are often interpreted, used, and appropriated in ways that their creators cannot foresee or control (what [85] terms *designer’s fallacy*). As new applications of datasets are discovered, measures should be taken to ensure that permission from involved musicians is obtained to use their work for uses other than the ones they agreed on.

When borrowing data, maintain the purpose of the

original datasets. Connected to the above suggestion, creators should maintain their original purpose when borrowing entries for new datasets and avoid misappropriation. This is particularly important when dealing with culturally relevant and sensitive music. This is, for instance, the case of the dataset on the Australian Aboriginal language used by [86]. The author reported: “These datasets were public domain and encouraged for use by the creator as a way to share the sound of the language. Even so, it is not clear that the creators of the dataset from the late nineties could predict this (AI generation) ‘future use’ case” [30].

Volunteer ethical considerations. Our analysis revealed that almost the entirety of the papers did not engage in any form of ethical considerations. Authors can show commitment to advancing more just practices in dataset creation by reflecting on potential ethical limitations in their datasets. Preferably, they should also include documents approved by an Ethics board, if applicable, that were given and signed by the participating musicians.

6. CONCLUSIONS AND FUTURE WORK

We identified the dominant approaches to dataset creation within ISMIR and analysed them with critical lenses to understand their ideological substrate. Most authors seem to handle dataset creation with neoliberal attitudes and expediency. However, a small - yet significant - number of dataset creators showed that other attitudes and values are at play within ISMIR when creating datasets for AMG. Our analysis did not explain the motivations for dataset creators to engage, or not engage, with ethical issues in their work, and this investigation is left for future work. Finally, we aim to extend the analysis to papers other than the ones published at ISMIR and to conduct an ethnographic study with AMG dataset creators to give voice to their perspectives on the topic. To conclude, ISMIR has been playing a significant role in the growth of ML models for AMGs but the lack of an ethical infrastructure may facilitate an exploitative industry. It is our responsibility as the main academic hub of AMG to recognise the need to engage in discussions around the matters raised in the article and to establish ISMIR as the home of this debate.

7. ETHICAL STATEMENT

In this study, we only used secondary data (desk research) that is publicly available online. We reflect that analysing existing information does not incur ethical issues.

8. CONFLICTS OF INTEREST

We have no relevant financial or non-financial interests to disclose and no financial or proprietary interests in anything discussed in this paper.

9. DATA AVAILABILITY

The spreadsheet with our analysis is available at <https://github.com/Sma1033/amgdatasetethics>.

ABSTRACT

Validity is the truth of an inference made from evidence and is a central concern in scientific work. Given the maturity of the domain of music information research (MIR), validity in our opinion should be discussed and considered much more than it has been so far. Puzzling MIR phenomena like adversarial attacks, horses, and performance glass ceilings become less mysterious through the lens of validity. In this paper, we review the subject of validity as presented in a key reference of causal inference: Shadish et al., *Experimental and Quasi-experimental Designs for Generalised Causal Inference* [1]. We discuss the four types of validity and threats to each one. We consider them in relationship to MIR experiments grounded with a practical demonstration using a typical MIR experiment.

1. INTRODUCTION

The multi-disciplinary field of Music Information Research (MIR) is focused on making music and information about music accessible to a variety of users. This ranges from systems for search and retrieval, to recommendation, and even to more creative applications like music generation. The effectiveness and reliability of MIR systems are of prime importance to the MIR researcher, not to mention other stakeholders. The researcher thus performs experiments to compare approaches for modeling and retrieving music data. A principal focus is on users, but the cost of performing experiments with users is high, and the replicability of such studies is difficult. This has motivated the *Cranfield Paradigm* [2]: computer-based experiments where “test collections” serve as proxies for human users. While such an approach is inexpensive and replicable, its relevance and reliability for MIR, and information retrieval in general, have been questioned [3, 4].

Under the Cranfield Paradigm, state-of-the-art MIR systems perform exceptionally well in reproducing the ground truth of some datasets, e.g., inferring rhythm, genre or emotion from audio data. This leads to conclusions that the

systems are actually learning to perform the task believed necessary to recover the ground truth from audio data. However, slight and irrelevant transformations of the audio, e.g., “adversarial attacks”, can suddenly render these systems ineffectual [5–9]. Such attacks can reveal what an MIR system is relying on for its success. In one case, a “genre recognition” system relies on infrasonic signatures that are imperceptible and irrelevant for human listeners [8]. In another, a “rhythm recognition” system is recognising tempo instead of rhythm, a confounding originating from the data collection [6]. Systems relying on such “tricks” have been called “horses” [5]. A related topic in MIR is “glass ceilings” [10, 11], i.e., that an observed barrier to improving system performance to perfect or human level is claimed as coming from psychophysical and cultural factors of music missing from features extracted from audio recordings [12].

In order to better understand the problems described above it is necessary to consider what lies at the heart of any experiment: the relationship between conclusions drawn from its results and their *validity*, or “truth value” [1]. Ideally, an experiment will be carefully designed and implemented to answer a well-defined hypothesis. Its components – units, treatments, design, observations, and settings – should be carefully operationalised (translated from theory into practice) to maximize quality and minimize cost (e.g., money and time). This is the purview of the discipline *Design of Experiments*: how can one get the strongest evidence for the least cost?

Despite a small chorus of calls to improve validity of conclusions in MIR, e.g., [4–6, 13–19], there has yet to be published a systematic and critical engagement of what validity means in the context of MIR, and how to consider it when designing, implementing and analyzing experiments. In this paper, we focus on the four principal types of validity in Shadish et al. [1], an authoritative resource about validity in causal inference and experimental science. Other typologies exist, e.g., [20], but we use that of Shadish et al. [1] because it is an established point of reference, and has already been mentioned in the context of MIR, e.g., in [4]. We review the four types of validity and present actionable questions that can help MIR researchers to scrutinize the conclusions they draw from their experiments. We ground our general discussion of validity in this paper by a practical demonstration,¹ which presents a typical MIR experiment

9NN	0.700	0.681	0.664	0.668
unif	0.12 ± 0.02	0.13 ± 0.03	0.12 ± 0.02	0.12 ± 0.02
freq	0.13 ± 0.02	0.13 ± 0.03	0.13 ± 0.02	0.13 ± 0.02
maj	0.16	0.02	0.12	0.03

Table 1. Accuracy, and macro-averaged precision, recall and f1-score observed for several models in a testing partition of BALLROOM [21]. The performance of two models selecting labels randomly (with standard deviation) are shown in the rows labeled: *unif* samples labels uniformly; *freq* samples labels according to training data label frequency. The last row *maj* shows the performance of a model choosing the label most frequent in the training data.

that exemplifies a considerable amount of MIR research: music classification using machine learning (ML) and a benchmark dataset. We use the BALLROOM dataset [21], which has appeared in dozens of studies seeking to build MIR systems sensitive to rhythm [6]. We partition the dataset into training and testing sets, extract features and train ML models, then label test set recordings and count coincident ground truth labels, and finally compute figures of merit for the different ML models. Table 1 presents the results from which we wish to draw valid conclusions.

A less abridged version of this paper [22] integrates the supplementary material in more detail. We hope that these materials will help MIR researchers to design, implement and analyze experiments in MIR and draw valid conclusions, but also convince them that the language of validity is reason. Creative thinking is necessary when examining the truth value of any conclusion drawn from an experiment.

2. COMPONENTS OF EXPERIMENTS

Before discussing the validity of conclusions drawn from an experiment, we must identify its components: units, treatments, design, observations, and settings. *Treatments* are the things applied to units in order to cause an effect (or not in the case of a *control*), *units* are the things that are treated, and *observations* are what is measured on a unit. The *design* specifies which treatment is applied to which unit, and *settings* involve time, place, and condition. To make this more concrete, consider a medical experiment in which the effect of a treatment on blood pressure is being studied. A number of people are sampled from a population, some of whom will receive the treatment while the others receive a placebo (control). The design describes which people get the treatment, and which do not. The observation is the blood pressure of a person after one month. The setting can include particulars of the population (rural or urban), place of treatment (hospital or home), and so on. The experimentalist contrasts blood pressure observations across groups to conclude, e.g., the effect of the treatment (causes a decrease in blood pressure).

Our typical MIR experiment measures the effectiveness of different ML models in predicting the labels of a test recording dataset. There are two ways to see its components. We can see the treatments as the ten models and the units as replicates of the entire testing dataset, or we can see the entire testing dataset as the one treatment and the units as the ten models. Since Table 1 reports figures of merit (observations) of each model on the entire test dataset, the latter interpretation motivates conclusions about the effectiveness of particular models. In this case, the design is simple: each unit (ML model) is given the same treatment (dataset). The setting involves the dataset partitioning, the extracted features, random seeds, software libraries, etc.

3. STATISTICAL CONCLUSION VALIDITY

Statistical conclusion validity is “the validity of inferences about covariation between two variables” [1]. This includes concluding that a covariation exists, and perhaps its strength as well. This is the level at which one is concerned with *statistical significance*, i.e., that an observed covariation between treatment and effect is not likely to arise by chance. As a concrete example, an experiment measuring the effects of two different medicines on lowering blood pressure seeks to determine which of the medicines has the greatest effect, if at all. The statistical conclusion validity of a conclusion resulting from this experiment relies on its power, but can be threatened in other ways. Shadish et al. [1] (p. 45) includes a table of nine different threats to statistical conclusion validity. Four threats relevant to computer-based experiments are: violated assumptions about the statistics underlying the observations (and the use of the wrong statistical test, a *type III error* [23]); a sample size too small to reliably detect covariation (lack of power); the purposeful search for significant results by trying multiple analyses and data selections (“p-hacking” [24]); and increased variance in observations due to the heterogeneity of units.

Are my results statistically significant? Null hypothesis statistical testing (NHST) quantifies whether the observed effects of the treatments on the responses arise by mere chance, as well as the direction of effect and its size. This answers the question: are the results statistically significant? Fundamentals about statistical testing in MIR have already been discussed [25], also for Artificial Intelligence in general [26], and for ML [27]. One must take care in selecting a statistical test to use; each one makes strong assumptions that could be violated. NHST is most straightforwardly applicable to completely randomized experimental designs [28], thereby reducing the possibility of structure in units and treatments interfering with the responses (which results in confounding). Most MIR experiments cannot use complete randomisation because the target population from which samples come is unclear (what is a random sample of “sad” music, with the term “sad” being quite ill-defined?), and so the kinds of conclusions that can be made with NHST in MIR are limited.²

² Experimental designs that cannot be completely randomised are called *quasi-experimental designs*, another major topic of Shadish et al. [1].

Is the observed statistical significance relevant for a user? In MIR, even if one finds statistical significance, this may not generalise to a perceivable difference for actual users interacting with the “improved” MIR system. As an example from MIR, a crowd-sourced user evaluation [29] demonstrates that there is an upper bound of user satisfaction with music recommendation systems of about 80%, since this was the highest percentage of users agreeing that two systems “are equally good.” In addition, for the MIREX task of *Audio Music Similarity and Retrieval* it has been demonstrated [29] that statistically significant differences between algorithms can be so small that they make no practical difference for users.

Let us now consider the typical MIR experiment and reason about what conclusions we can draw from it that have statistical conclusion validity. Table 1 clearly shows that each response of model to the dataset is greater than the random approaches *unif*, *freq* and *maj*. How likely is it that any of the responses of models is due to chance, i.e., that any of the models is actually no better than one of the random approaches? Since we have the empirical distributions for *unif* and *freq*, we can estimate the probability of either of them resulting in, e.g., a macro-average recall at least as large as 0.6: $p < e^{-200}$.³ Hence, a valid statistical conclusion is that we observe a significant covariation between the use of a machine learning model with these particular features and the responses measured on a specific partition of BALLROOM.

One might consider statistical conclusions relating to the type of ML, i.e., Gaussian modeling (LDA and QDA) vs. nearest neighbour modeling (KNN), or LDA vs. QDA. If we conclude from Table 1 that Gaussian modeling performs better than nearest neighbour modeling with these features on 70/30 partitions of BALLROOM, we would be wrong. This is a “type I error”, which is concluding there to be a significant difference when in fact there is none. When we perform this experiment 1000 times with random 70/30 partitions we observe that the difference between the best response of a Gaussian model and the best response of a nearest neighbour model is distributed Gaussian, and that the probability of observing zero difference or less is $p > 0.41$ for any of the figures of merit.

The most general statistical conclusion we can make from Table 1 is that the responses we observe from ML models are highly inconsistent with the responses of choosing randomly. Each ML model knows *something* about BALLROOM linking the features computed from a music recording with its ground truth label. Because we do not know the amount of variation in any response due to partitioning, we cannot make any valid statistical conclusion about which type of ML model is the best for this particular dataset. In order to go further, we must run the experiment multiple times to obtain distributions of the contrasts. Even then, however, we cannot say anything about the *cause* of significant differences yet. This is where the notion of internal validity becomes relevant.

4. INTERNAL VALIDITY

Internal validity is “the validity of inferences about whether the observed covariation between two variables is causal” [1]. While statistical conclusion validity is concerned only with the strength of covariation between treatment and responses, internal validity is focused on the *cause* of a particular response to the treatment. Shadish et al. [1] (p. 55) includes a table of nine different threats to causal conclusions. Several of these involve *confounding*, which is the confusion of the treatment with other factors arising from poor operationalisation in an experiment. As a concrete example, consider an experiment measuring the effects of two different medicines on lowering blood pressure, but where one medicine is given to young patients and the other is given to elderly patients. This experimental design confounds the two medicines and patient age, and so the effects caused by the two factors cannot be disambiguated. Any conclusion from this experiment about the effects of the medicines lacks internal validity.

Does my data collection introduce confounds? One’s methodology for collecting data might unintentionally introduce structure. For instance, it has been discussed that BALLROOM was assembled by downloading excerpts of music CDs sold at a website selling music for ballroom dance competitions [6]. Ballroom dance competitions are regulated by organisations, e.g., World DanceSport Federation (WDSF),⁴ to ensure uniformity of events for competitors around the world. These organisations set strict requirements of tempo of each dance such that high skill is required of the dancers. Hence, the labels of BALLROOM can reflect any of the following: 1) the rhythm of the music; 2) the type of dance performed to the music; 3) the strict tempo requirements of the dance in the context of competition. As a result, good performance in BALLROOM can be due to rhythm detection and/or tempo estimation. Tempo and rhythm are related musical characteristics, but they are not the same thing [30].

Does my data partitioning introduce confounds? Dataset partitioning can also introduce confounds, e.g., “bleeding ground truth.” An example is to first segment recordings into short (e.g., 40ms) time frames and then partition these frames into training and testing sets, thus spreading highly correlated features across these sets. In the context of audio-based genre classification, the presence of songs from the same artists or albums in both training and test data has been shown to artificially inflate performance [31, 32]. Audio-based genre classification using very direct representations of spectral content has been shown [33] to degrade more when employing artist/album filters than classification based on more abstract kind of features like rhythmic content (fluctuation patterns). This insight that problems of data partitioning can affect MIR systems in quite different ways and hence change performance rankings has been confirmed in another meta-study [34].

Returning to our typical MIR experiment, of interest is *what* it is in our trained ML models causing their response to be inconsistent with random selection. Knowing how

³ See the supplementary material for an explanation.

⁴ <https://www.worlddancesport.org/>

Gaussian models used in LDA and QDA are built – mean and covariance parameters are estimated from training data – an internally valid conclusion is that these models work well in BALLROOM because likelihood distributions estimated from the training data also fit the testing data well. Another internally valid conclusion is that the high performances of these ML models in BALLROOM are caused by the features together with the expressivity of the models capturing information related to the labels in BALLROOM.

With reference to the aims of MIR research, we want to conclude something more specific, e.g., our ML models have learned to recognize the rhythms in BALLROOM. This is certainly one explanation consistent with our observations, but is it the only one? The internal validity of this conclusion relies on a key assumption: inferring the labels of BALLROOM can *only* be the result of learning to discriminate between and identify its rhythms. In other words, we must assume that there is no other way to infer labels in BALLROOM than by perceiving rhythm.

Since we know tempo is highly correlated with rhythm in BALLROOM, we thus perform an experiment to test the sensitivity of our trained ML models to tempo: we alter all test recordings by some amount of pitch-preserving time dilation, and then measure the responses of the models to these new treatments. We see that the responses of all ML models decay to being not significantly different from random selection with dilations in the range of $\pm 15\%$. We see this intervention clearly reveals the extent to which the ML models we test rely on the tempi in the test data.

The experimental design of the typical MIR experiment does not account for the structure present in the dataset; we do not control for other ways of inferring the labels of BALLROOM, which are guaranteed to exist by its very construction. From Table 1 and our experimental design, we thus cannot be any more specific in our causal inference than this: the responses of our ML models are caused by their having learned *something* about BALLROOM. This then calls into question how comparing predictions with ground truth in BALLROOM relates to the ability we might actually want to measure, that is the recognition of rhythm. This is where the notion of construct validity becomes relevant.

5. CONSTRUCT VALIDITY

Construct validity is “the validity of inferences about the higher order constructs that represent sampling particulars” [1]. This involves the relationship between what is meant to be inferred by the experimentalist from an experiment and what is actually measured, i.e., the *operationalisation* of the experimentalist’s intention. For instance, directly measuring the blood pressure of a person involves an invasive procedure inserting a measuring device in their veins. Blood pressure can be measured less invasively but indirectly by externally applying known pressure to a vein and listening for when blood flow ceases. Knowledge about the incompressibility of liquids in closed systems makes the measurement of pressure in the balloon a relevant measure of blood pressure. Shadish et al. [1] (p. 73) includes a table of fourteen different threats to construct validity, but several

of these are irrelevant to computer-based experiments. The main threat is a questionable relationship between what is being measured and what is intended to be measured. Selecting a measure by convenience but not relevance, sampling from convenient populations, and a lack of definition of what is intended to be measured, are threats to construct validity. Construct validity involves more than just how something is measured; it also involves what is measured and in what settings.

How is classification accuracy, or any figure of merit, in a labeled music dataset related to X? Two examples in MIR are the use of “genre” classification accuracy as an indirect measure of music similarity [11], or user satisfaction (see, e.g., [14] for a discussion). The relationship between these is very tenuous, especially so considering that accuracy itself is an unreliable measure of whether or not a system has learned anything relevant to music [5, 15]. A key reference in this respect is that of Pfungst [35] describing a series of experiments in trying to reliably measure the arithmetic acumen of a horse that was only able to tap out answers. Counting the number of correct answers tapped out by the horse, no matter how many questions are asked, is irrelevant without considering how each question is posed (the setting). The key to Pfungst discovering the cause of the horse’s apparent arithmetic acumen involved changing the setting: the questions remained the same, and accuracy of correct response was measured, but how the questions were posed was changed in order to control for different factors of the experiment. The same is true for MIR.

What is the “use case” of the system to be tested? To counter threats to construct validity the MIR experimentalist must operationalise as much as possible the use case of the system to be built and tested. One attempt to do so for music description [36] emphasises the need to define success criteria. The experimentalist must determine how their method of measurement relates to the success criteria, e.g., relating accuracy in genre classification to the satisfaction of a specific type of user.

How can we test the construct validity of a conclusion? One possibility is to assess the outcomes of different experiments which are supposed to measure the same higher order constructs. An example in MIR is to study correlations of different genre classifiers when given identical inputs [18]. Low correlations between classifiers point to problems of construct validity. A related topic is that of adversarial examples, which casts doubt on the conclusion that the high accuracy of an MIR system in some dataset reflects its “perception” of the music in the waveform. Adversarial examples have first been described in image analysis [37], where imperceptible perturbations of input data significantly degraded classification accuracy. For music genre classification systems, imperceptible audio filtering transformations of music signals have been used [5] to both deflate and inflate classification accuracy to be no better than chance level or perfect 100%. Following these so-called untargeted attacks which try to change a prediction to an arbitrary target, targeted attacks aiming at changing predictions to specific classes have been explored. A targeted

attack on genre recognition has been reported [7], where magnitude spectral frames computed from audio are treated as images and attacked using approaches from image object recognition. For music instrument classification a targeted attack allowing to add perturbations directly to audio waveforms instead of spectrograms has also been presented [9]. The attacks were able to reduce the accuracy close to a random baseline and produce misclassifications to any desired instrument. The authors also artificially boosted playcounts via an attack on a real-world music recommender, thereby demonstrating that such attacks can be a security issue in MIR. Follow-up work presented lines of defence against such malicious attacks [38].

Returning to our typical MIR experiment, we are interested in making construct inferences around the latent ability of rhythm recognition we are supposedly measuring in our ML models. For instance, one construct inference is that our features measure relevant aspects of rhythm in recorded music. In some sense, by their definition from basic signal processing components, our features come from temporal aspects that are certainly relevant to rhythm. Our features are also reliant on acoustic information, and in particular there being high-contrast differences in onsets captured by spectral flux – hence limiting their relationship to rhythms played by particular kinds of instruments with sharp attacks. However, we have seen above that the features are also indicative of tempo, and that tempo is another path an ML model can use to infer the rhythm label. Hence we are left to question the relationship of our features to the concept we are trying to operationalise, i.e., rhythm.

Having a system label any partition of the BALLROOM dataset provides no reliable measure of a system’s ability to recognise rhythm without changing the setting to control for other factors. It is not as simple as choosing a different feature, measure, cross-validation method, or using a particular statistical test. One must change the experiment itself such that *rhythm recognition* is what is actually being measured. This means that BALLROOM can still be useful to measuring the rhythm recognition of an ML model. Indeed, in the previous section we used it to disprove the causal claim that the good performance of the ML systems of Table 1 is caused by their ability to recognize rhythm. Might performance in BALLROOM also be an indication of performance in other datasets focused on rhythm? This is where the notion of external validity becomes relevant.

6. EXTERNAL VALIDITY

External validity is “the validity of inferences about the extent to which a causal relationship holds over variations in experimental units, settings, treatment variables and measurement variables” [1]. More generally, external validity is the truth of a generalised causal inference drawn from an experiment. An example is inferring that medicine found to lower blood pressure in patients living in Germany will also lower blood pressure in people living in Mexico – a conclusion that can lack validity due to differences in diet, living and working conditions, and so on. Another example is that increasing the dose of the medicine will cause blood

pressure to lower further in the studied population. If a causal inference we draw from an experiment lacks internal validity, then generalising that inference to include variations not tested will not have external validity. Shadish et al. [1] (p. 87) includes a table of five different threats to external validity, which are in addition to the threats to internal validity. The main threat is that variation of the components of the experiment might destroy the causal inference that holds in the experiment. For instance, a medication may work for the type of illness tested, but that type of illness may not be generalisable to other closely related illnesses.

Does my model generalize to out-of-sample data? The standard approach in evaluating MIR classification systems is to use separate train and test sets in cross-validation experiments to obtain seemingly unbiased estimates of performance. However, if such MIR systems are exposed to independent out-of-sample data often severe loss of performance is observed. One example are experiments on genre recognition where accuracy results do not hold when evaluated across different collections that are not part of the training sets [39, 40]. The results do not generalize to supposedly identical genre labels in different collections, which reflects a lack of external validity. Genre labels like ‘Rock’ will be used differently by different annotators working on these collections – which is also a threat to construct validity. Another example are how different audio encodings affect subsequent computation of descriptors and classification results [41], or how in general differences in software implementations diminish replicability [42].

Do different raters agree on a ground truth? Human perception of music is highly subjective resulting in possible low inter-rater agreement. Therefore only a certain amount of agreement can be expected if several human subjects are asked to rate the same song pairs according to their perceived similarity, depending on a number of subjective factors [14, 43] like personal taste, listening history, familiarity with the music, current mood, etc. Concerning annotation of music, it has been shown [44] that the performance of humans classifying songs into 19 genres ranges from modest 26% to 71%. Audio-based grounding of everyday musical terms shows the same problematic results [45]. It has even been argued [12] that no such thing as an immovable ‘ground’ exists in the context of music, because music itself is subjective, highly context-dependent and dynamic.

The lack of inter-rater agreement presents a problem of external validity because inferences from the experiment do not generalize from users or annotators in the experiment to the intended target population of arbitrary users/annotators. It is also a problem of reliability, since different groups of users or annotators with their differing subjective opinions will impede repeatability of experimental results. This lack of inter-rater agreement presents an upper bound for MIR approaches, since it is not meaningful to have computational models going beyond the level of human agreement. Such upper bounds have been reported [14, 43, 46] for the MIREX tasks of ‘Audio Music Similarity and Retrieval’ (AMS) and ‘Music Structural Segmentation’ (MSS). For AMS the upper

	Accuracy	Precision	Recall	f1-score
LDA	0.659	0.647	0.643	0.643

unif	0.12 ± 0.01	0.13 ± 0.01	0.12 ± 0.01	0.12 ± 0.01
freq	0.13 ± 0.01	0.13 ± 0.01	0.12 ± 0.01	0.12 ± 0.01
maj	0.13	0.02	0.12	0.03

Table 2. As in Table 1, models trained in BALLROOM and tested in all of X-BALLROOM [51].

bound has already been reached in 2009, while for MSS the upper bound is within reach for at least some genres of music. Comparable results exist concerning music structure analysis [47] and chord estimation [48, 49].

Do raters agree with themselves at different points in time? Going beyond the question of whether different annotators agree on a ground truth one can also access what the level of agreement within one person is when faced with identical annotation tasks at different points in time. A high intra-rater agreement would help to overcome the problem of upper bounds in MIR systems since it would make personalization of models meaningful, i.e. to have separate models for individual persons. However, at least for the task of general music similarity it has been shown that intra-rater agreement is only slightly higher than inter-rater agreement [19], with the absolute level also depending on music material and mood of raters at test time. An approach to personalize chord labels for individual annotators via deep learning was more successful [50].

Returning to the typical MIR experiment, we cannot validly conclude that any of our models is recognizing rhythm in general because we do not know if they are recognizing rhythm in BALLROOM. Our dilation intervention experiment in Sec. 4 reveals that all of the models lose their supposed ability to recognize rhythm in BALLROOM, so there is no reason to infer they will recognize rhythm elsewhere. One causal conclusion we might make is that our models perform well in BALLROOM because they have learned something about BALLROOM – a curated set of recordings downloaded from a specific website in 2004. Might they have learned something about other recordings from that same website, but collected many years later?

The extended BALLROOM dataset (X-BALLROOM) [51] consists of 3,484 audio recordings in the same eight dance styles or music rhythms as BALLROOM, but downloaded from the same website over a decade later. This gives us a chance to test our conclusion. The figures of merit measured from our models trained in BALLROOM but applied to all of X-BALLROOM are shown in Table 2. We still see significant covariation between response and the use of ML with our features. By and large, whatever concepts our ML models have learned about BALLROOM carry over to X-BALLROOM – but we still do not know whether or not those concepts have to do with rhythm.

7. CONCLUSION

This paper provides a review of the notion of validity based on the typology given in Shadish et al. [1]. It brings together the few sources in MIR that mention validity, and several sources that do not but are related. This paper does not aim to prescribe how to design and perform experiments such that valid conclusions can be drawn from them. Instead, it aims to bring within the realm of MIR what validity means, why it is important, and how it can be threatened. One thing to reiterate is that one does not talk about the “validity of an experiment”. An experiment does not possess “truth value”. Validity is a property of a conclusion made given evidence collected from an experiment. The components of an experiment – units, treatments, design, observations, and setting – have major consequences for the validity of conclusions drawn from it, whether it is statistical conclusion validity, internal validity, construct validity, or external validity.

In MIR the predominant experimental methodology is the Cranfield Paradigm: train a model on a partition of a dataset and count the number of correct answers on another partition. This kind of experiment is inexpensive, and provides numbers that can be compared in ways that convince peer reviewers that progress has been accomplished [52]. Despite various appeals [14, 53] and beseechings [4, 5, 15, 16, 19, 29, 43], such an experimental approach is still standard in the field and its serious flaws are ignored. Any conclusion from this experiment that is more general than “the system has learned something about the dataset” lacks internal, construct and external validity. This does not mean that all such inferences are false, just that they cannot follow from the experiment as designed and implemented. Reproducing the ground truth of a dataset represents a beginning and must be followed by a search for the causes of the observed behavior.

Shadish et al. [1] provides an established starting point for MIR, but there exist other types of validity. For instance, Lund [20] revises the typology of [1] to address ambiguities between causes and treatments, to better define aspects of settings, and to establish a hierarchical ordering of five types of validity: statistical conclusion, causal, construct, generalization and theoretical. Other kinds of validity include ecological, convergent, and criterion [13], but these still deal with the kind of conclusion one is drawing from evidence collected in some way.

As a final note, a frustration when encountering Shadish et al. [1] as an engineer is that of its 623 pages there are only five pages with at least one equation on them. Instead, Shadish et al. [1] describe experiments and how each type of validity manifests in the conclusions drawn, with specific threats to the reasoning of those conclusions. Experiments, not to mention experimentalists, are such complex assemblages that expressing them in formal ways that appear to permit the computation of numbers that relate to each type of validity would probably have very limited applicability, and then only be understood by a limited audience. The language of validity is *reason*, and we hope this article will inspire MIR researchers to think creatively about the phenomena they observe to discover their causes.

ABSTRACT

In Carnatic music concerts, taniāvartanam is a solo percussion segment that showcases intricate and elaborate extempore rhythmic evolution through a series of homogeneous sections with shared rhythmic characteristics. While taniāvartanam segments have been segmented from concerts earlier, no effort has been made to analyze these percussion segments. This paper attempts to further segment the taniāvartanam portion into musically meaningful segments. A taniāvartanam segment consists of an abhiprāya, where artists show their prowess at extempore enunciation of percussion stroke segments, followed by an optional korapu, where each artist challenges the other, and concluding with mohra and korvai, each with its own nuances. This work helps obtain a comprehensive musical description of the taniāvartanam in Carnatic concerts. However, analysis is complicated owing to a plethora of tāla and naḍe. The segmentation of a taniāvartanam section can be used for further analysis, such as stroke sequence recognition, and help find relations between different learning schools. The study uses 12 hours of taniāvartanam segments consisting of four tāla-s and five naḍe-s for analysis and achieves 0.85 F1-score in the segmentation task.

1. INTRODUCTION

Carnatic music (CM) is a South Indian music tradition considered an ancient form of Indian art music (IAM). A typical CM concert features a lead artist, typically a vocalist, accompanied by a violinist and percussion instrument artists. The lead percussion instrument in this ensemble is usually the *mridangam*, while additional percussion instruments like the *ghatam*, *khanjira*, and *morsing* may also be present. A CM concert includes a solo percussion performance known as *taniāvartanam*, or *tani* for short. Tani is a structured sequence of rhythmic elaborations performed at a fixed metric tempo and bound to a metric cycle (*tāla*). This study attempts to study the elaborations in tani, segment them using a culture-specific approach, and assigns semantically meaningful labels.

Audio recordings of concert performances available online often lack detailed metadata and annotations regarding section boundaries and other information, particularly in the context of IAM. With the increasing availability of music collections and digital devices, there is growing interest in accessing music based on its characteristics. The paucity of editorial metadata has necessitated the development of music information retrieval (MIR) techniques to extract music's characteristic properties from audio recordings automatically. The paper is organized as follows. The taniāvartanam structure is described, followed by the task objectives, challenges, and dataset description. Domain-specific feature engineering is done, and the task is addressed for different cases. The experimental results are analyzed and discussed with culture-specific explanations.

1.1 Taniāvartanam Description

The tani is a highly structured and elaborate percussion performance that is a prominent feature of CM, showcasing the rhythmic skills and creativity of the percussionist. The main percussion instrument is the mridangam, occasionally accompanied by ghatam (clay pot), khanjira, and morsing (Jew's Harp). Since tani is part of a main item, it is performed in the same tāla, and metrical tempo as the main item. The intricacies are based on the precise mathematical calculations of the metric cycle.

The duration of the tani is divided among the mridangam and accompanying percussion to showcase individual artistry, e.g., if mridangam and ghatam are present, the structural framework of the tani is typically as follows: The mridangam always starts first by playing *sarvalaghu* (SV) patterns (indicators of basic tāla structure), and the complex patterns are introduced gradually. These elaborations are performed in a particular rhythm structure called *naḍe* (usually in *chaturaśra* at first) for a few rhythm cycles. These elaborations on a particular rhythmic theme are termed as *abhiprāya*. The literal meaning is "opinion", i.e., the artists' viewpoint of that particular rhythm structure. Ghatam follows and tries to keep the same theme built by the mridangam in the first cycle by playing in the same naḍe [1]. In the second cycle, the mridangist usually may change the naḍe (to *tiśra*, for example) and elaborates. The ghatam usually follows in the same naḍe or switches to a different naḍe (*khaṇḍa*). These may or may not continue for more than two cycles, usually owing to time constraints. Each abhiprāya ends with a pattern called *korvai*, which is repeated thrice to arrive at downbeat.

Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

Figure 1. Spectral Illustration of a few Carnatic Percussion Strokes. D: Damped Strokes, R: Resonant Strokes

These abhiprāya-s are followed by the *korapu*, usually seen as a question-answer between mridangam and ghatam. Here it starts with multiple cycles of rhythmic patterns by the mridangam followed by ghatam, where each artist challenges the other. The duration of the rhythm patterns in korapu keeps reducing progressively from full cycle, half cycle, quarter cycle until it finally reduces to a single beat. It can be translated as “rhythmic descent” or “step-by-step reduction”. The artist(s) then start playing together playing faster with crisp strokes (*farans*), building up the necessary momentum for playing the last parts of the tani called *mohra* and longer *korvai* [1]. Each of these has a specific composition structure upon which the artist builds. This structure holds even if only the mridangam is present, except that the korapu part might be absent. Summarizing the sequence of sections in a *tani* segment can be listed as sarvalaghu patterns abhiprāya in a specific naḍe → change of naḍe → back to starting naḍe → korapu → farans → mohra → final korvai [2].

1.1.1 Aspects of timbre and spectral differences among the Carnatic percussion

In Indian music tradition, accompanying instruments are relatively tuned according to the main melodic instrument or voice. The percussion instruments are also categorized on the sonic aspect. Figure 1 illustrates the damped (D) strokes and resonant (R) strokes of Carnatic percussion instruments. Two-sided percussion, mridangam has both the low-frequency and mid-frequency spectra covered. The ghatam occupies a little over the mid-frequency band, and morsing predominantly spreads over the high-mid frequency spectrum and has a larger resonance. Khanjira occupies a low-frequency spectrum a bit less than the left side of the mridangam. This explains the aesthetic quality of the percussion instruments that have been traditionally in use for CM concerts. The tonal nature also enhances the entire concert when played harmoniously.

1.2 Problem Objective and Challenges

This work addresses three primary tasks: (1) Diarization of the audio into mridangam, khanjira, and ghatam sections when multiple instruments are present, (2) Estimation of section boundaries using musical attributes, and (3) Classification of segments into broad categories such as abhiprāya, korapu, farans, mohra, and korvai. To achieve these goals, the paper applies techniques from well-researched music genres while also considering the culture-specific characteristics of tani. To improve readability and clarity, several terms are defined in Table 1.

Identifying and understanding the segments in tani is difficult for most CM audiences, except for professionally

Segment	Audio fragment between any two adjacent detected boundaries that may or may not cover a complete section.
Section	A primary portion of the taniāvartanam. A section can contain multiple compositions and multiple segments.
Naḍe	A modifier to tāla that decides the number of strokes per beat, The subdivision structure within a beat in CM Chaturaśra, Tīśra, Khaṇḍa are different kinds of naḍe-s
Abhipraya (AB)	A rhythmic elaboration in a particular naḍe during tani.
Korapu (KP)	A musical dialogue between the musicians during performance.
Farans (FA)	The first part of the conclusion in tani where the percussionists play fast to gain momentum toward the end.
Mohra (MO)	Popular rhythmic structure played after the farans hinting the climax of taniāvartanam.
Korvai (KO)	Stroke patterns that are played three times, concluding the tani.

Table 1. Definitions of terms relevant to this paper

trained and practicing percussionists. However, this challenge can be addressed if we have a reliable system that can classify the primary segments in tani from audio recordings. Such a system would not only aid in appreciating the art form for a broader audience, but also serve as a valuable learning tool for beginner-level percussion students.

Coming to the challenges, tani is very diverse and extempore. The number of percussions may vary across the concerts. The duration of the tani also varies, influencing the number of possible segments. Additionally, the presence of the korapu section is contingent on the number of percussions, which is rare when only mridangam is played. Each rhythmic structure is presented at multiple speeds. This is reflected in the boundary within a single abhiprāya due to sudden tempo changes. The rendition also has small pauses, which may be part of the rhythmic elaboration or due to the artist’s presentation style. As a result, the tani segmentation task presents unique challenges to existing audio segmentation methods. Listening to the entire audio carefully to mark the segment boundaries is time-consuming. This underscores the need to develop systems for automatic segmentation and annotations.

1.3 Dataset Description

Experimenting with various shades of tani requires a diverse collection of annotated audio data. As there is no properly annotated dataset available for this task, we collected diverse recordings of tani and labeled them. All the audio data used in this work is a subset of the Charsur Carnatic [3,4], Sangeethapriya [5] datasets along with two audios from [6]. The tani part from the main concerts is extracted by marking the start and end points. Professional performers listened and annotated the boundaries of primary sections in the tani. By doing so, we collected around 12 hours of annotated tani audio. The duration of each tani in the dataset ranges from 6 minutes to 29 minutes, with 11 minutes of mean duration.

The dataset details are described in Table 2. The considered audios comprises of tani played in four major tāla-s of CM [7, 8], namely ādi, miśra chāpu, khaṇḍa chāpu, and rupaka. The annotations consist of tāla labels, boundary instances, and labels of primary sections of tani. The multiple percussion audios considered in this work have only two instruments along with additional labelings of the instrument name for their respective segments. The dataset is heterogeneous with artist variability (22 mridangam, >12 ghatam, >8 khanjira), tonic, and tempo variability.

	No. of Abhiprāya	No. of Concerts	Duration ~ (hrs:mins)
Mridangam	51	16	02:24
Mrid + Ghat	86	18	04:56
Mrid + Khanj	94	21	05:47
Total	231	55	12:08

Table 2. Dataset Description.

1.4 Related Work

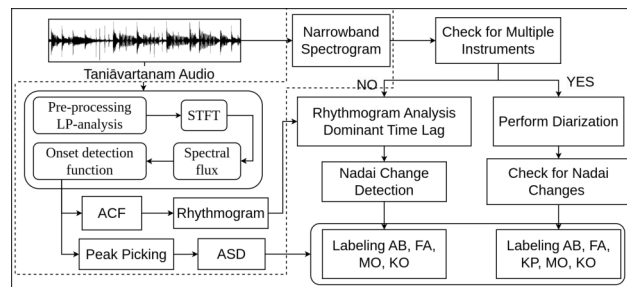

Segmentation and metadata labeling of a music recording have a fairly good research history both in Western [9–11] and IAM traditions [12, 13]. Various acoustic and temporal parameters were used for the segmentation task [9, 14]. Foote et al. [15] proposed a self-distance matrix method to determine the boundary between contrasting musical characteristics. The changes in musical features in Pop and Rock music were used to train the boosted decision stump [16]. Lately, [17] explored neural networks for structural segmentation, spanning various genres [18].

In the context of IAM, different approaches were explored for segmenting the main concert audios in the Dhrupad [13, 19, 20], Hindustani [21, 22], and Carnatic [12, 23–25] music traditions. For instrumental concerts, Vinutha et al. [22] considered the segmentation of sitar and sarod concerts using reliable tempo detection [26]. The analysis of rhythm/percussion in IAM has primarily focused on stroke onset detection [27, 28], stroke recognition [6, 29–33], and sequence modeling [34, 35] percussion pattern identification [36]. Ajay Srinivasamurthy [37] worked on tracking the "downbeat," provided the tāla is known. Tani diarization was also attempted in [4]. Further, mridangam artist identification from tani audio was attempted [38]. Parallel to [38], tabla gharānā recognition from the tabla solo was addressed in [39, 40].

Nevertheless, no attempts have been reported on the structural analysis of Indian solo percussion. This paper attempts to include additional meta-information to the tani portion of a concert, where the audio is segmented based on musical attributes. This can help identify the tāla and enable the association of the cycle of strokes with that of the lyrics of the main composition in CM. The outcomes can help in the concert summarization task and for further MIR studies in the field of percussion, which is crucial as it can give insights into the rhythm of the main item of the concert. Combined with works on meter tracking [7], percussion source separation [41], and stroke recognition [6], this could lead to additional metadata that could be important to an ardent listener or performer.

2. AUDIO FEATURE ENGINEERING

The raw concert audios have to be pre-processed for further analysis. Since each concert is unique in the choice of metric tempo, tonic, and compositional structure, the features used should be based on concert-specific characteristics. At the same time, it should scale inter-concert. We address the tasks by computing relevant features considering the culture-specific musicological perspectives. Initially, the raw audio is pre-processed by computing the Hilbert envelope of the linear prediction (LP) residual on the raw audio [27]. Then the onset detection function (ODF) is computed

Figure 2. Flow Diagram for Segmentation and Labeling

using the spectral flux method [42]. It is shown to perform on par with state-of-the-art machine learning-based onset detection algorithms on percussion instruments [27]. The computed onset locations are considered for further rhythm analysis. While we have used LP analysis, any onset detection technique could have been used.

2.1 Rhythm and Tempo Features

The change in the rhythm structure or the tempo is a prominent indicator of the section transitions. In the case of percussion instruments, rhythm pattern refers to the aspects of stroke patterns. A rhythm representation can be obtained by considering the stroke ODF (sampled at 10 ms) over a suitably long window and computing the auto-correlation function (ACF). The periodicity analysis using the ACF of the ODF represents the audio in terms of rhythm called rhythmogram [43–45], where rhythm/tempo alone is emphasized.

The ACF of the ODF is computed frame-wise with a frame length of 4 seconds and a frameshift of 0.5 seconds up to a lag of 1 second. The dimension of each frame of the rhythmogram is $p = 100$, corresponding to a 1-second lag. The window length must be large enough to contain sufficient strokes for computing the ACF. Even while playing a slower tempo, we observe at least more than 8-10 strokes (sufficient to calculate the periodicity) in a window length of 4-5 seconds. A uniform window size of 4s is chosen to accommodate variability in rhythm. The peaks along the lag axis of the rhythmogram depict the periodicity of the surface rhythm, indicating surface tempo [22].

The tempo estimation using the product of ACF-DFT [46] is often prone to tempo octave errors due to uneven stroke distribution. We compute the number of strokes in each 4 seconds frame and divide by 4 to get the stroke density at every frame instance. The feature is named average stroke density (ASD), as the averaging is done over 4 seconds frame. The ASD is robust to tempo octave errors and is representative of surface tempo [13]. The mean and std. deviation of strokes per second, as obtained in the entire dataset, are 8.6 and 3.8, respectively. The variance of ASD depicts the tempo diversity in the dataset. Figure 4(c) shows the evolution of ASD over time.

2.2 Spectral Feature

From Section 1.1.1, it is clear that each of the Carnatic percussion instruments has distinct spectral properties, and the spectral features can serve as potential features for instru-

Figure 3. Self-Similarity Matrices on Different Features

ment classification. In this work, we need to localize the segments as coming from one of the percussion. To get the complete spectral aspects of a particular instrument, the spectrum must be computed over a window with almost all kinds of strokes. Thus we computed a narrow band spectrogram (NBS) with a window size of 4s and a hop size of 0.5s. From Section 2.1, we know that the mean ASD is eight strokes per second. Thus in a four-second frame, we can expect at least one resonant stroke. We can clearly distinguish mridangam and ghatam segments from NBS in Figure 4(a).

2.3 Spectral and Rhythm Posteriors

The high-dimensional NBS and ACF rhythmogram represent the spectral and rhythmic-tempo homogeneity within the segment and the changes between the adjacent segments. This allows us to use Gaussian mixture models (GMM) to model the instrument’s spectral and temporal homogeneity. The NBS and ACF vectors are converted to spectral and rhythm posteriors (NBS-P, ACF-P), representing class conditional probabilities.

We use two mixtures GMM to represent NBS feature vectors with the intuition that each instrument property is modeled by one mixture. Interestingly we find that each mixture corresponds to a different timbre. We also tried a third mixture to represent the portion where both the instruments play together (FA, MO, KO). This failed due to the volume dominance of mridangam and gave false alarms. The posterior feature computed on NBS is depicted in Figure 4(d). The posteriors from the rhythmogram are computed with five mixture components, each representing a particular speed. The GMM is fit only on the NBS and ACF vectors from a particular concert. The number of Gaussians is determined by the different speeds and μ -s expected in a concert.

3. TANI SEGMENTATION AND LABELING

Since tani may contain only mridangam or multiple instruments, we first need to detect if a particular tani audio has multiple instrument or not. The abhiprāya region segmentation task is slightly different in both cases. Locating the abhiprāya boundaries is based on detecting a change in the instrument itself (in case of multiple instrument) and the local rhythmic structure of segments at the highest timescale (in case of solo mridangam). Figure 2 shows the overall steps involved in the task. Each of the segmentation and labeling steps is described here.

3.1 Multiple Instrument Detection

From Sections 1.1.1, we know that different Carnatic percussion instruments differ in their sonic and timbral aspects

Figure 4. Eg: Multiple Instrument Tani: Segment labels on top (a) NBS feature (b) ACF Rhythmogram with NF-ACF+P overlay-ed (c) ASD evolution over time (d) Posteriors computed on NBS (e) NF-NBS-P (red) obtained from $(15s \times 15s)$ kernel, NF-NBS (blue) from $(3s \times 3s)$ kernel (f) NF-NBS-P replaced with NF-ACF+P in last 2.5 min indicating FA, MO, KO boundaries, and ground truth

and occupy different frequency bins in the spectrum. We use the NBS extracted in Section 2.2 from all the available audios. We built a Gaussian Mixture Model (GMM) on NBS with five mixtures, one for each class – mridangam, ghatam, khanjira, mrid-ghat, mrid-khan. If the ratio of the number of frames from any two classes to the total number of frames in a concert is greater than 20%, then that concert is classified as having multiple instruments. Otherwise, we verify if most frames are from mridangam (at least 80%) and classify it as single instrument mridangam. We performed GMM classification on MFCC features as well. Both methods gave 100% classification accuracy in detecting multiple percussion instruments in a recording.

3.2 Novelty Function Computation

The aim is to get an NF whose peaks indicate the desired segment boundaries. Given the ACF, ACF-P, NBS, and NBS-P feature vectors, the Self-Similarity Matrices (SSM) are computed on each of them using L_2 distance measure [10]. The SSM obtained on the ACF, ACF-P, NBS, and NBS-P are displayed in Figure 3. The homogeneous segments of length L frames possibly appear as $(L \times L)$ blocks. The section change points with high contrast in SSM are captured by convolving a checker-board kernel along the diagonal of SSM [15]. The 1D output obtained is called a novelty function (NF). The peaks of the NF indicate the segment boundary instances having high contrast in SSM. The obtained NFs are (1) the average of NF-ACF, NF-ACF-P (Figure 4(b), Figure 5(a)), (2) NF-NBS, and NF-NBS-P (Figure 4(e)).

NFs are computed by convolving $(15s \times 15s)$ kernel with SSM of different features. Peak picking is performed by maintaining a minimum distance between adjacent peaks as 5s. We experimented with smaller kernel sizes such as $(3s \times 3s)$, and $(5s \times 5s)$, resulting in noisy NFs. This decreased the precision due to a lot of false positives. Though much larger kernel sizes, such as $(50s \times 50s)$, made the NFs smoother, they compromised in

Figure 5. Eg: Solo Mridangam Tani, (a) ACF Rhythmogram with NF-ACF+P overlay-ed along with detected peaks (b) First Dominant peak along the Lag axis FDL (yellow), and its 1st diff. FDL-1D highlighting the discontinuities (c) FDL computed on the Gaussian smoothed ACF (yellow) and its 1st diff. FDL-1D (white) (d) NF-FDL-ACF (black) is a point-wise product of NF-ACF+P (red) and FDL-1D (blue) (e) NF-FDL-ACF replaced with NF-ACF+P in last 2.5 min indicating FA, MO, KO boundaries along with ground truth, and the segment labels below resolving the closer boundaries. All the features and NFs in this work are computed at the resolution of 0.5 seconds.

3.3 Case1: Multiple Instrument Tani

In the case of multiple instrument tani, each round of individual percussion elaboration is considered one abhiprāya (one thematic development). Thus instrument change point detection is necessary and sufficient for getting the abhiprāya boundaries. Since the instrument change points are visually evident from the NBS, we used NF-NBS and NF-NBS-P to get the boundaries. A NF obtained from a smaller kernel enhances the rapid instrument change in the KP section, useful in localizing the KP section but creating false positives during segmentation. The first portion of the KP section is fairly large. A larger kernel emphasizes only the start instance of KP by suppressing the rapid instrument change. Thus we used NF obtained from a larger ($15s \times 15s$) kernel for the segmentation task and the smaller ($3s \times 3s$) kernel NF for localizing the KP section.

The FA, MO, and KO are always played toward the end of the tani and the FA has a higher ASD. As we see in the Figure 4(e), NF-NBS and NF-NBS-P do not capture these change points. Thus we replace the last two and a half minutes of NF-NBS-P with the average of NF-ACF and NF-ACF-P (NF-ACF+P). This gives the final NF ('red' curve in Figure 4(g)) in the case of multiple instrument tani. We empirically choose the last 2.5 mins as the FA, MO, KO are always found in the last 2.5 mins in the entire dataset.

3.4 Case2: Solo Mridangam Tani

Computing the AB boundaries on solo mridangam tani is a tough task, as the AB change needs to be detected based on the rhythm (naḍe) change. Naḍe change detection is

pivotal in getting the AB boundaries, especially in the case of solo mridangam tani. Relying only on the raw rhythmogram features (NF-ACF+P) creates false alarms due to multiple tempo changes and irregularities within a single AB segment. This necessitates the computation of a robust function to tempo octave changes but also captures the non-octave tempo changes that indicate the naḍe changes.

We initially set to track the first peak along the lag axis of the rhythmogram over time, and the change in the peak lag apart from doubling and halving is expected to indicate the naḍe change. But this is also found to be noisy ('yellow' curve in Figure 5(b)). Thus, we perform horizontal Gaussian smoothing on the rhythmogram to mask the irregularities, then pick the first dominant lag peak (FDL). This fetched a smoother curve ('yellow' curve in Figure 5(c)) having discontinuities around the naḍe change with less tempo octave errors. The peaks on the first difference of this curve (FDL-1D) gave fairly good naḍe change estimates, along with a few false positives. We can observe that the peaks of both NF-ACF+P and FDL-1D (Figure 5(d)-E1) coincide around the naḍe change instances but not elsewhere. Thus we perform "AND" operation by multiplying NF-ACF+P and FDL-1D to get a NF which is an indicator of naḍe change. We can observe that the false positives are considerably reduced. Again we can see that towards the last FA-MO-KO portion, this NF is not indicating FA-MO-KO boundaries. Thus, we replace the last two and a half minutes of NF-FDL-ACF with NF-ACF+P, similar to Case1. This gives the final NF in the case of solo mridangam tani ('black' curve in Figure 5(e)).

3.5 Section Classification and Labeling

Given the hypothesized segment boundaries, the task is to classify each segment with appropriate labels. Each section, AB, KP, FA, MO, and KO, has unique structural, positional, and duration characteristics common across the concerts. We use the characteristic musical cues to classify and label the segments. For the multiple instrument tani, a NF obtained from a smaller kernel ($3s \times 3s$) gives multiple peaks in the KP portion. The hypothesized segment having multiple peaks is labeled as KP [Figure 4(e)(E-2)]. The segments before the KP are classified broadly as AB. We compute the mean of ASD in each segment. As the ASD is high during FA-MO, the segment after KP having the highest mean-ASD is labeled FA [Figure 4(c)(E-1)], followed by KO at last. Labeling of FA, MO, and KO is the same for solo mridangam concerts as well. Korapu is not present if only mridangam is present. All the segments before FA are broadly labeled as AB for solo mridangam concerts. Thus the algorithm with a set of rules based on the structure of tani and the domain knowledge performs classification and labeling. Implementation, annotations, and dataset details are shared for research purposes¹.

4. ANALYSIS OF RESULTS AND DISCUSSION

The tani structural segmentation task is approached as a boundary detection task, where the presence or absence of

¹ <https://bit.ly/3XIJfMa>

Case	Section	Precision	Recall	F1-Score
Multiple Percussion	AB	0.92	0.99	0.96
	KP-FA-MO-KO	0.82	0.89	0.86
	Overall	0.87	0.94	0.91±0.03
Single Percussion	AB	0.7	0.82	0.74
	FA-MO-KO	0.82	0.86	0.83
	Overall	0.75	0.84	0.79±0.05

Table 3. Segmentation Results

a boundary is examined in uniformly spaced feature frames of 0.5 seconds. Unlike stroke onset detection, the task is addressed at a larger time scale and thus has a tolerance duration in "seconds" rather than milliseconds [27, 47]. A true-positive detection is one where the prediction boundary falls within ± 3 seconds of the ground truth boundary, while a false-positive detection is one where it does not. Precision, recall, and F1-scores are used for evaluation. Evaluation is performed on the entire dataset, as the proposed method is unsupervised, and no model training is done.

The segmentation evaluation scores for each case and individual sections are tabulated in Table 3. The recall is good in all cases, indicating that the system successfully detects the desired boundaries considerably. We can observe that the precision is consistently less than recall, indicating false positives. The change in local rhythm structure, which may be both gradual and abrupt, causes peaks in the NFs. The gradual change in rhythm structure can be seen often in the AB section as it is extempore.

In Case 1, the AB boundaries are identical to the instrument switching instances, and the NF-NBS/NF-NBS-P captured it well with a 0.96 F1-score. The KP-FA-MO-KO section performance is slightly lower, as the rapid instrument switching caused false positives. The end of the KP section is not always evident as the cycle duration reduces to one beat. A small SV pattern may also exist after KP while moving towards FA, making boundary detection challenging. Since MO is played along with or immediately follows the FA, the FA-MO boundary is often missed, reducing recall.

In Case 2, the AB boundaries are not straightforward. The local variations, tempo doubling and halving cause false positives when the NF-ACF and NF-ACF-P are used. These local variations also cause the first dominant lag on the ACF to be noisy. The horizontal averaging of the rhythmogram aided in noise-free first dominant lag tracing and considerably reduced false positives, but still, the false alarms persisted. The $\text{na}\ddot{d}\text{e}$ changes are also very gradual in many cases, which are not evident with tempo-related ACF analysis. For example, while transiting from 6 to 5 strokes per beat, the change is hardly noticeable when the metric tempo is fast. A few of the AB boundaries are also missed during smoothing. The performance on the FA-MO-KO is similar to Case:1, as the NF-ACF+P is used in the last 2.5 mins for both cases. Case 2 has more variance in F1-Score than Case 1. The average F1-score for both cases combined is 0.83.

We also experimented with $\pm 5s$ and $\pm 1s$ tolerance windows. The overall recall increased by 0.2 with a marginal increment in precision for the $\pm 5s$ case. The $\pm 1s$ case re-

ported a drop of precision and recall by 0.4 and 0.3, respectively. This is evident as 1s corresponds to only two feature frames in this work, and many boundaries are missed.

Section classification performance is evaluated by considering the ground truth markings. We quantify the performance of calculating the ratio of correctly classified frames to the total number of frames in a tani. The weighted average of correctly classified frames in the entire dataset considering the lengths of each tani is 92%. That is, given 10m of segmented tani, around 9m-15s of the frames are correctly labeled as AB, KP, FA, MO, KO.

5. CONCLUSIONS

This work has addressed an unexplored problem, structural segmentation, and labeling of tani audios. We motivate the problem and present different facets and challenges in the task. From the experiments performed, it is clear that individual features alone are inadequate for segmentation. A culture-specific approach is clearly required, both in feature choice and modeling. Timbre is used when it is required to detect if multiple instruments are present in the tani, and MFCC features were found to be adequate. On the other hand, detecting AB sections required analysis of both timbre and rhythmogram to detect boundaries. Identifying AB sections when two percussion instruments are present is quite easy. In contrast, determining AB sections in a solo percussion instrument is difficult as $\text{na}\ddot{d}\text{e}$ changes/speed changes are difficult to determine. The hope is that such a task will aid in including additional meta-data w.r.t a concert.

The major contributions of this work are as follows: (i) curating a diverse dataset of tani recordings of around 12 hours having section boundary information along with primary section labels, (ii) evaluating the existing MIR techniques with culture-specific adaptation for a musicologically important task, segmentation and labeling of tani, (iii) formulating average stroke density (ASD) feature (a representative of surface tempo), which is robust to tempo octave errors, (iv) formulating the class-conditional probability features from the rhythmogram, and spectral features, and (v) exploring the combination of different NFs obtained from different features to achieve the task. Finally, this work provides an example of adapting available MIR methods to genre-specific problems by performing appropriate feature engineering.

6. ACKNOWLEDGMENTS

The authors are grateful to the percussion maestros V Selvaganesh, Patri Satish Kumar and Giridhar Udupa for their support and help. We are thankful to Ajay Srinivasamurthy for his support and timely guidance. We thank Jom Kurikose for sharing the dataset audios.

ABSTRACT

Deep neural network models have become the dominant approach to a large variety of tasks within music information retrieval (MIR). These models generally require large amounts of (annotated) training data to achieve high accuracy. Because not all applications in MIR have sufficient quantities of training data, it is becoming increasingly common to transfer models across domains. This approach allows representations derived for one task to be applied to another, and can result in high accuracy with less stringent training data requirements for the downstream task. However, the properties of pre-trained audio embeddings are not fully understood. Specifically, and unlike traditionally engineered features, the representations extracted from pre-trained deep networks may embed and propagate biases from the model’s training regime.

This work investigates the phenomenon of bias propagation in the context of pre-trained audio representations for the task of instrument recognition. We first demonstrate that three different pre-trained representations (VGGish, OpenL3, and YAMNet) exhibit comparable performance when constrained to a single dataset, but differ in their ability to generalize across datasets (OpenMIC and IRMAS). We then investigate dataset identity and genre distribution as potential sources of bias. Finally, we propose and evaluate post-processing countermeasures to mitigate the effects of bias, and improve generalization across datasets.

1. INTRODUCTION

Transfer learning generally refers to the concept of adapting a model for one task to solve another task. Often, this is achieved by extracting the internal representation (an *embedding*) of input data from a pre-trained neural network, and providing it as input features to some (often simpler) *downstream* model for the target task. While this approach is increasingly common and effective, pre-trained embedding models may encode and propagate implicit biases which can have detrimental and disparate population-

dependent effects. Biases have caught wide attention from research fields such as natural language processing (NLP) [1–3], cognitive science [4], and computer vision [5], while in music information retrieval (MIR), bias of pre-trained audio embeddings, is under-explored.

In this paper, we identify and address the bias of different pre-trained audio embeddings for transfer learning on the task of instrument recognition. We summarize the contributions as following. (1) We study the within- and cross-domain performance of three pre-trained audio embeddings (VGGish, OpenL3, YAMNet) on two instrument datasets (IRMAS and OpenMIC-2018). (2) We demonstrate that this approach can propagate bias by producing classifiers which are sensitive to the source domain (dataset). (3) Based on the performance variation in cross-domain generalization, we investigate dataset identity and genre distribution as potential sources of bias. (4) We propose a post-processing countermeasure to mitigate unwanted bias in the representation. We experiment different bias correction strategies, and analyze the robustness of each pre-trained audio embedding. The proposed strategies make use of relatively little additional information, and generally produce a modest improvement to cross-domain accuracy for the instrument recognition task. Our code for all experiments is publicly available¹.

2. RELATED WORK

Pre-trained embeddings are becoming increasingly used in transfer learning for audio-related tasks. Choi et al. [6] presented a transfer learning approach for music classification and regression tasks using the internal activations of a pre-trained convolutional network as features. The network was trained on the source task of music tagging, and the learned representation was then transferred to five target tasks, including genre classification, vocal/non-vocal classification, emotion prediction, speech/music classification, and acoustic event classification. Other well-known audio embedding models include OpenL3 [7], VGGish [8], and YAMNet². The OpenL3 is a 512-dimensional embedding model that results from self-supervised training of the look-listen-learn (L3)-Net for audiovisual correlations. VGGish (128-dimensional) and YAMNet (1024-

² <https://github.com/tensorflow/models/tree/master/research/audioset/yamnet>

dimensional) are both embeddings derived from classification models trained on AudioSet [8]. Although these embedding models differ in the architecture of the network, source data, and training regime, they have each demonstrated good and comparable generalization performance for a variety of tasks.

Despite that embedding models are normally trained on large amounts of data, it inevitably encodes biases due to the limitation of collected data. This problem can be especially prevalent in models trained via unsupervised or self-supervised strategies, where there may be no incentive for the model to learn invariances or equivalencies in the data beyond what is required for by the training objective. As a result, pre-trained embeddings may propagate unwanted biases to downstream tasks. Different types of biases and bias correction methods are explored in the NLP literature, such as gender [9], race and religion [10]. A general approach for addressing gender bias in word embedding was proposed by Bolukbasi et al., following three steps: identify bias direction, remove bias by projecting out the bias direction, and equalize pairs [9].

Besides field-specific biases, dataset bias is a general type of bias that could happen in any application domain. Tommasi et al. [5] investigated dataset bias in visual recognition with a cross-dataset testbed comprising 12 different datasets. Ganin et al. [11] proposed adversarial training for domain adaptation to reduce sensitivity to data drawn from similar but different distributions. When detecting depression, a mental health disorder, from speech, Bailey and Plumbley [12] found that biases in dataset could result in skewed classification performance.

The approach we take in this paper is most similar to those of Bolukbasi et al. [9] and Ganin et al. [11]. While Bolukbasi et al.’s method requires numerous paired examples to identify a subspace which encodes undesirable bias, our proposed method works at the level of collection statistics rather than individual correspondence, and may be easier to apply for audio applications. Similarly, Ganin et al.’s method requires adversarial training of the initial model to produce a representation which cannot discriminate well between subsets of data that should be treated equivalently. Our approach is implemented as a post-processing step, and can be applied to any pre-trained model. While we focus in this work on dataset identity as a concrete source of bias, we emphasize that the method should be generally applicable to other scenarios in which audio representations exhibit unwanted sensitivity to identifiable attributes.

3. METHODS

We consider embedding bias from the perspective of *domain adaptation*. Unlike transfer learning, which relates to the *output* of the model, domain adaptation refers to the behavior of a model (classifier, regressor, etc.) under changes to the distribution of *input data*. This is closely related to *representation bias*, which is one among many forms of bias known to impact machine learning systems as enumerated by Mehrabi et al. [13]. If a classifier is trained on a sample of (labeled) data which is not representative of

the target population, then we expect the model to generalize poorly. The degree to which a pre-trained audio embedding is sensitive to differences between populations of interest—e.g., between a dataset annotated for instrumentation, compared to other collections of music—is therefore of principal interest [14].

3.1 Domain sensitivity

We investigate the domain sensitivity of three pre-trained embeddings (OpenL3, VGGish, and YAMNet) in transfer learning for the downstream task of instrument recognition. Each embedding is evaluated in both within-domain and cross-domain setting. For within-domain evaluation, we train and test the embedding in a single dataset; while for cross-domain case, we investigate the domain adaptation capability of the embedding models across datasets, i.e. training and testing the downstream classifier using data from different datasets. As a study case, we consider two well-known datasets for instrument recognition, i.e. IRMAS [15] and OpenMIC-2018 [16] (see Section 4.1 for dataset details).

Fig. 1 (a) and (d) visualize the within-domain (IRMAS–IRMAS and OpenMIC–OpenMIC) recognition results in terms of area under the receiver operating characteristic curve (ROC-AUC) using the three embeddings above for each of the ten instrument classes.³ All three embeddings achieve comparable results, although there is a loose performance ranking of YAMNet > OpenL3 > VGGish for most instrument classes.

When generalizing across domains, performance degradation happens for both cross-dataset pairs, as shown in Fig. 1 (b) IRMAS–OpenMIC and (c) OpenMIC–IRMAS. The performance ranking of the three embedding does not persist either. Comparing the results when testing on OpenMIC, i.e. (b) and (d), only *voice*, *piano*, and *guitar* retain close results. For the remaining instrument classes, all three embeddings exhibit diminished performance. Similar trends take place in the comparison between (a) and (c) where the test set is IRMAS.

Surprisingly, a dramatic performance drop happens for the *organ* class. Examining this class in both datasets, we notice a large distribution difference on genre, as shown in Fig. 2. Organ in IRMAS is confined to *pop/rock* and *jazz/blue* genres, suggesting that examples mostly contain electric organ sounds (e.g. Hammond B3). The distribution of organ in OpenMIC is more balanced, but dominated by classical recordings which are more likely to contain pipe organ than electric. These differences aside, we generally expect the instrument labels to refer to similar sounds across domains.

3.2 Quantifying domain bias

To quantify the effect of domain bias, we first obtain the domain separation direction vector $w \in \mathbb{R}^D$ by fitting a linear discriminant analysis (LDA) model to discriminate

³ We report AUC because it is invariant to overall class proportions and decision thresholds—which vary between datasets—and thereby allows us to focus on the separating directions identified for each class.

Figure 1. Within-domain (a, d) and cross-domain (b, c) performance of pre-trained audio embeddings (VGGish, OpenL3, and YAMNet) on instrument recognition in the IRMAS and OpenMIC datasets. ROC-AUC refers to area under the receiver operating characteristic curve.

between the OpenMIC and IRMAS datasets in each representation (VGGish, OpenL3, and YAMNet). $v_k \in \mathbb{R}^D$ is the instrument separation direction vector, i.e. the coefficient vector of the trained downstream classifier, for the k -th instrument. $k = 1, 2, \dots, K$ is the instrument class index and D is the dimension of pre-trained embedding. We measure the correlation between the domain separation and downstream classification using the cosine similarity between w and v_k :

$$c_k(w, v) = \frac{\langle w, v_k \rangle}{\|w\| \times \|v_k\|} \quad (1)$$

Large (in magnitude) c_k indicates that the instrument classifier is sensitive to dataset identity.

Fig. 3 top shows the absolute correlation value for each instrument class, when the classifier is trained on the training set of (a) IRMAS and (b) OpenMIC dataset, respectively. The mean correlation value over all instruments for each embedding is displayed in the legend. It clearly shows that YAMNet is the least sensitive to dataset bias; OpenL3 is also relatively stable while VGGish is the most sensitive to dataset bias. The relatively large correlation value for the organ class matches our analysis in Section 3.1 that genre distribution might be also a potential source of bias (see Fig. 2). Although the sensitivity of different embeddings to dataset bias are different, bias cannot generally be removed by simply using different pre-trained embeddings. As we will demonstrate, explicitly correcting for dataset bias can potentially improve domain adaptation

performance for each choice of embedding.

3.3 Bias correction

To mitigate domain bias, we propose a post-processing countermeasure on the pre-trained embeddings which does not interact with the training process of embeddings. Importantly, the proposed method requires only samples of data which should behave similarly for the downstream task, but it does not require these samples to be *labeled* for the downstream task.

Continuing our instrument classification example, given that both datasets contain examples from each of the instrument categories of interest, we should expect that a well-formed linear classifier should behave independently of the domain from which data is drawn. Concretely, this means that the separating direction v_k should be orthogonal to any direction w which separates the two datasets in the embedding space, resulting in $c_k(w, v_k) = 0$. While Ganin et al. [11] use this intuition to adversarially train the representation, this approach is impractical when using pre-trained embeddings which are presumed to be fixed in advance. Instead, we approach this problem by post-processing the embedding to project out the direction w which separates domains that should be indistinguishable for the downstream task.

Concretely, if $w \in \mathbb{R}^D$ is the domain-separating direction (normalized to unit length, $\|w\| = 1$), we project this dimension out of the space by applying the following transformation to input data $x \in \mathbb{R}^D$:

$$x_P := (\mathbf{I} - ww^T) x \quad (2)$$

where \mathbf{I} is the $D \times D$ identity matrix. The new embedding x_P is the input to the classifier.

3.4 Multiple bias correction

While the above strategy is defined for binary bias correction, e.g. where there are two domains to be reconciled, it does generalize to more complex settings. In the instrument recognition example, we may also consider differences between genres across datasets as a source of bias. Even if two datasets both consist of examples in the same genre categories, this does not necessarily mean that the genre terms are used consistently between datasets.

To consider the influence of genre distribution, we propose also *multiple bias correction*, where we extract the dataset separation direction in the genre subspace. That is, for each pair of matched genre labels, e.g. pop/rock in IRMAS and pop/rock in OpenMIC, we fit a binary LDA to separate them. Then for each genre category $g = 1, 2, \dots, G$ (for $G \geq 1$ genres), we obtain a dataset separation direction vector w_g which depends only on examples from genre g . Collecting all w_g into a matrix $W \in \mathbb{R}^{D \times G}$ defines a basis for a subspace of the embedding of dimension at most G . Note that W may not be an orthogonal basis, as different w_g may correlate with each other.

Figure 2. Number of genre examples for each instrument in the training set of IRMAS and OpenMIC datasets. We align the genre labels according to those in the IRMAS dataset: pop/rock, jazz/blue, classical, and country/folk.

We therefore derive an orthogonal basis by factorizing W via the reduced singular vector decomposition (SVD):

$$W = U\Sigma V^T \quad (3)$$

where Σ is a $G \times G$ diagonal matrix of singular values, and $U \in \mathbb{R}^{D \times G}$ and $V \in \mathbb{R}^{D \times G}$ are the left- and right-singular vectors. We use the right singular vectors as an orthogonal basis for the domain-separating subspace, resulting in the following generalization of Eq. (2):

$$\mathbf{x}_P := (\mathbf{I} - VV^T) \mathbf{x} \quad (4)$$

In applying Eq. (4), it is important to verify that W is full rank (G), e.g. by verifying that all singular values Σ are sufficiently large, as Eq. (4) would otherwise remove a larger than necessary subspace from the representation. In all cases studied in this work, W was full rank.

3.5 Nonlinear bias correction

The above methods are based on two assumptions: 1) that the downstream model will be linear, and 2) that the domains are linearly separable. These assumptions may be restrictive in practice, so we generalize the method above by transforming the embeddings to a higher dimensional space using kernel methods. While both logistic regression and linear discriminant analysis support kernel generalizations [17], the subspace projection method described above is less directly adaptable.⁴

Instead of using implicit kernel representations, we will use approximate, i.e. explicit kernel approximation. That is, instead of replacing inner products $\langle \mathbf{w}, \mathbf{v} \rangle$ by nonlinear kernel function calculations $k(\mathbf{w}, \mathbf{v})$, we apply an explicit nonlinear transformation $f : \mathbb{R}^D \rightarrow \mathbb{R}^{D'}$ such that

$$\langle f(\mathbf{w}), f(\mathbf{v}) \rangle \approx k(\mathbf{w}, \mathbf{v}) \quad (5)$$

We then apply the previously defined bias correction methods on the transformed data $f(\mathbf{w})$, which results in projecting out the dataset-separating direction(s) after applying f but prior to fitting the downstream (instrument) classifiers.

There are several choices to be made here when selecting the kernel k and the approximating map f . In this work, we use a standard radial basis function (Gaussian)

⁴One could achieve a similar effect by adding a linear constraint $\langle \mathbf{w}, \mathbf{v} \rangle = 0$ to the logistic regression problem, but this would require a custom solver and limit the general utility of the approach.

kernel and the “random Fourier features” approximation method [18]. However, we note that other choices (e.g., the Nyström method) are readily available in scikit-learn [19], and may work just as well.

In total, we have four bias-correction strategies: linear bias correction (*LDA*), linear multiple bias correction (*mLDA*), nonlinear bias correction in the kernelized embedding space (*KLDA*), nonlinear multiple bias correction in the kernelized embedding space (*mKLDA*).

4. EXPERIMENTS

4.1 Datasets and experimental details

The datasets we use are two well-known datasets with instrument annotations, IRMAS [15] and OpenMIC-2018 [16]. The former comprises 20,000 examples of 10-second excerpts, partially labeled for the presence or absence of 20 instrument classes; and the latter contains 6705 audio files of 3-second clips, of which only the predominant instrument were annotated. Since there are 20 instrument classes in the OpenMIC dataset and 11 in the IRMAS, we focus only on the 10 mutual classes: *cello*, *clarinet*, *flute*, *guitar*, *organ*, *piano*, *saxophone*, *trumpet*, *violin*, and *voice*. For the sake of consistency, *electric guitar* and *acoustic guitar* in the IRMAS dataset have been merged into a single class: *guitar*.

To investigate the impact of genre, we also align the genres in the two datasets. Each audio sample in the IRMAS dataset is labeled with one of the five genres: *pop/rock*, *jazz/blue*, *classical*, *country/folk*, and *latin/soul*; while samples in the OpenMIC dataset has multiple labels from around 130 genres. We consider four genres (pop/rock, jazz/blue, classical, country/folk) as the latin/soul genre has few examples in both datasets. The genre labels of the OpenMIC dataset are merged into those of IRMAS with name intersections. For example, we merge the genres—*Rock*, *Loud-Rock*, *Noise-Rock*, *Psych-Rock*, et. al.—in OpenMIC into one genre label: *pop/rock*. Multiple genre labels in the OpenMIC dataset are reduced to a single label by the first activation from the four considered genres or the first of the original labels otherwise.

With the embedding features extracted using pre-trained VGGish, OpenL3, and YAMNet models, we train a logistic regression classifier for each instrument class using IRMAS and OpenMIC training data. The input to the

Figure 3. Correlation between domain separation and instrument classification for each instrument in the IRMAS and OpenMIC training set. (*Top*): correlation in the original embedding space with domain separation direction extracted using only dataset identity; (*middle*): correlation in the original embedding space with domain separation direction extracted class-wise; (*bottom*): same as middle but in the kernelized embedding space. Mean value is given in parentheses.

classifier is the mean frame embedding of each audio example. For OpenMIC dataset, we follow the train-test split in [16], with a ratio of 3:1. For fair comparisons, we create a new partition with the same train-test ratio on IRMAS dataset which takes into account of the class-balance and non-track overlap between training and test sets. To focus only on distribution shift, we use the same number of samples per class for both datasets during training, following the lower one.

For the nonlinear method, we first standardize the embedding features using z-score normalization with the training-set statistics. Then we approximate the kernels for the embeddings with a fixed dimension D' of four times the dimension (D) of the original embeddings. Finally, we tune the hyper-parameter for the logistic regression classifier, i.e. the inverse of regularization strength C , by cross-validation with a grid of $10^{-8:1:4}$.

4.2 Results

Table. 1 lists the instrument classification performance of the debiasing methods discussed in Section 3 in terms of mean ROC-AUC over the 10 instrument classes. To compare the performance of using only dataset identity as additional information and that uses also class-labels, we present two sets of results: *global bias correction* and *class-wise bias correction*. We first present some observations that are common to both cases and then discuss the comparison. For the original embeddings (in *italic*), large performance drop shows for all cross-domain cases. OpenL3 is most sensitive to distribution shift, with a drop of 12.7% and 7% when testing on IRMAS and OpenMIC

dataset, respectively. Yet, from the cosine similarity values in Fig. 3 top and middle, OpenL3 does not embed the most domain bias. This may indicate that for the task at hand, other more significant distribution shifts that OpenL3 is sensitive to may exist. For all embeddings, projecting to the higher dimensional space (debiasing methods with “K”) almost never substantially hurts the within-domain performance and sometimes improves the performance.

Interestingly, when comparing linear debiasing (“-LDA” and “-mLDA”) with nonlinear debiasing (“-KLDA” and “-mKLDA”) for all embeddings, we find that kernelization does not help for VGGish while YAMNet only works in the kernelized embedding space. This explains the relative increase of cosine similarity values for YAMNet after kernelization as compared to the other two embeddings (see Fig. 3 bottom). Both linear and nonlinear debiasing exhibit performance improvement for OpenL3. In terms of global bias correction, almost no improvement for VGGish except LDA for OpenMIC->IRMAS; OpenL3 yields some boost for both cross-domain cases. YAMNet improves the results only for OpenMIC->IRMAS. It is expected that the class-wise bias correction achieves better performance as we extract the domain bias for the target instrument exactly. This is also verified by the more noticeable cosine similarity values in the middle subfigure as compared to the top of Fig. 3. VGGish and OpenL3 yields slight improvement for most linear debiasing. All nonlinear debiasing improves the results of OpenL3 for IRMAS->OpenMIC and YAMNet for OpenMIC->IRMAS. Although the overall improvement is not significant, we observe large improvements for some instrument classes.

Table 1. Mean ROC-AUC (%) of global bias correction and class-wise bias correction on instrument classification in IRMAS (IR) and OpenMIC (OP) datasets. VGGish, OpenL3, and YAMNet (in *italic*) refers to the original embedding; the other cases, i.e. with -LDA, -mLDA, -LDA, and -mKLDA, correspond to linear, linear-multiple, nonlinear, and nonlinear-multiple debiasing strategies; cases with -K are the kernelized embeddings. Values in parenthesis are the performance boost (>0.1 are **bolded**) or degradation as compared to the original embedding (the closest underlined above).

5. DISCUSSION

We notice two important factors for transfer learning with pre-trained audio embeddings: the training regime of the embeddings, and the class vocabulary alignment between the source task and downstream task.

The better generalization performance of YAMNet and VGGish in a transfer setting may be attributed to their training regime. YAMNet and VGGish are derived from supervised training while OpenL3 is from self-supervised training and more prone to overfitting a domain. As a result, YAMNet and VGGish have both been incentivized to learn invariances within specific categories (including musical instrumentation), while OpenL3 has no such incentive as it is only designed to predict audio-visual correspondence. Moreover, YAMNet was specifically trained for sound classification using a vocabulary that broadly subsumes that of our downstream task (instrumentation). This likely contributes to its high performance and cross-domain stability overall.

The class vocabulary alignment is related to *label shift*, an under-explored type of distribution shift in the domain-adaptation field [20]. The labelling scheme difference between the two datasets complicates the debiasing as the IRMAS dataset only contains labels for the predominant instrument while all active instruments are annotated in the OpenMIC dataset. Aligning these two datasets is nontrivial as it involves label shift besides *covariate shift*. We propose multiple-bias correction, i.e. debiasing in the genre subspace, to deal with this problem. Yet, it does not resolve the conditional probability shift that happens due to unbalanced relationships between instrumentation and genre, e.g. the strong dependence between organ and pop/jazz

in IRMAS, and in this specific case an argument could be made that the classification task is closer to transfer learning than domain adaptation.

A notable limitation of the presented experiments is the small amount of functional data. Although OpenMIC dataset is relatively large with 14915 samples for training, only a small portion is actually used in the binary classification of each instrument. After equalizing the number of samples per class in both datasets, there are only 288, 221, 177, 578, 290, 551, 476, 427, 385, and 358 samples for the 10 instrument classes in the binary classification. Most classes have number of samples less than the dimension of OpenL3 (512) and all of them are below that of YAMNet (1024).

6. CONCLUSION

The method proposed in this work addresses one specific form of bias that can arise in transfer learning scenarios. Correctly applying this method requires identifying subsets of data that should be treated equivalently, i.e., be indistinguishable under the chosen representation. We stress that this notion of equivalence ultimately depends on the choice of the downstream task, and caution should be exercised when identifying populations to treat as equivalent. For the case study presented here—domain adaptation and instrument recognition—we argue that the downstream task ought to be generally independent of the source domain, though we recognize that this will not always be true in practice. We therefore urge practitioners to critically investigate all assumptions of equivalence and independence when applying bias correction methods.

ABSTRACT

The Collaborative Song Dataset (CoSoD) is a corpus of 331 multi-artist collaborations from the 2010–2019 *Billboard* “Hot 100” year-end charts. The corpus is annotated with formal sections, aspects of vocal production (including reverberation, layering, panning, and gender of the performers), and relevant metadata. CoSoD complements other popular music datasets by focusing exclusively on musical collaborations between independent acts. In addition to facilitating the study of song form and vocal production, CoSoD allows for the in-depth study of gender as it relates to various timbral, pitch, and formal parameters in musical collaborations. In this paper, we detail the contents of the dataset and outline the annotation process. We also present an experiment using CoSoD that examines how the use of reverberation, layering, and panning are related to the gender of the artist. In this experiment, we find that men’s voices are on average treated with less reverberation and occupy a more narrow position in the stereo mix than women’s voices.

1. INTRODUCTION

As far back as the 1960s, *Billboard* charts have featured collaborations between independent acts. In recent years, however, the number of songs featuring a collaboration between artists has skyrocketed [1]. Part of this is due to the rising popularity of hip-hop in the 1980s, in which collaboration between different artists is a fixture. The 1986 version of “Walk This Way” by Aerosmith and Run DMC is an oft-cited example of such a collaboration. As Rose notes, the success of a collaboration between a hip-hop group (Run DMC) and a rock group (Aerosmith) “brought [hip-hop’s] strategies of intertextuality into the commercial spotlight” [2, p. 51–52]. The 1990 success of “She Ain’t Worth It” by Glenn Medeiros ft. Bobby Brown marked the first time a sung and rapped collaboration reached #1 on

Billboard’s “Hot 100.” Molanphy notes that during this period, multi-artist collaborations crystallized into two different frameworks: the “featured bridge rapper,” and the “featured hook singer” [3]. Subsequently, tracks with one or more guest artist(s) have become a mainstay on the charts.

By 2021, over a third (39%) of the songs in *Billboard*’s “Hot 100” year-end chart credited more than one artist. Consider for instance “Save Your Tears,” by singers The Weeknd & Ariana Grande, which occupied second place on the chart. A solo version of the song originally appeared on The Weeknd’s album *After Hours* (2020). While this version achieved commercial success, the remix with Ariana Grande became a #1 single on the *Billboard* “Top 100” in May 2021 and became the longest-charting collaboration in *Billboard* “Hot 100” history. In the remix, Grande performs approximately half of the vocals, transforming the solo song into a dialogue between two characters. The collaboration between the two artists is responsible for the popularity of the remix, inviting both Grande’s and The Weeknd’s fans to stream, buy, and otherwise engage with the song. Several musicological studies have examined this relationship between collaborative songs and commercial success [4–6]. Other work has provided in-depth explorations of the musical characteristics of collaborative songs, with a particular focus on hip-hop [7–9].

Given the popularity of multi-artist collaborations, a more systematic exploration of their musical features is warranted. In this paper, we introduce the Collaborative Song Dataset (CoSoD), an annotated dataset that facilitates the study of various musical features in multi-artist collaborations. CoSoD provides metadata and analytical data for 331 multi-artist collaborations appearing on the *Billboard* “Hot 100” year-end charts between 2010 and 2019. The dataset also provides timed annotations on the song’s formal structure, artists’ gender, vocal delivery and pitch, and vocal production (reverberation, panning, and layering). As detailed in Section 2, the range of features included in the dataset makes it more broadly applicable for MIR research tasks. These include structural segmentation, vocal mixing, automatic music production, and examinations of gender in popular music. After outlining the contents of the dataset and the annotation methodology in Section 3, we present an experiment in Section 4 that examines the relationship between vocal production parameters and the gender of the performer in a subset of CoSoD.

Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

2. RELATED WORK

CoSoD complements the growing list of annotated datasets that provide information on song structure in various popular music genres, e.g., [10–17], and is the first dataset to exclusively contain data on collaborative songs between independent acts. It can thus be used for training and evaluating structural segmentation tasks and for studying the specific structural characteristics of collaborative songs. CoSoD also complements existing datasets for multi-track mixing/analysis [18–23] and vocal analysis [24–26] by providing analytical annotations on the treatment of the voice in a mix.

In recent years, several studies have proposed tools and methods to automate the mixing of multi-track recordings [27,28]. Such automatic production methods have various artistic and creative applications. One framework has been suggested to remix early jazz recordings, which are pre-processed using source separation then remixed with automatic production tools [29]. [30] proposes a prototype for an automatic DJ mixing system allowing for cross-fading via beat and tempo adjustment between songs. Studies on automatic mixing can be enhanced by knowledge of common mixing practices for specific instruments or sound sources. For instance, one study uses mixing practices that are consistent between mixing engineers to create a model that automatically mixes multiple drum tracks [31]. By focusing on vocals, which are a salient component of the mix in popular music [32], CoSoD provides a complementary approach to these studies on automated production. By providing annotations based on close listening of specific vocal mixing parameters in the different formal sections of a song, the dataset allows for the identification of trends in panning, layering, and use of artificial reverberation as they are applied to vocals in commercially successful post-2010 popular music. It enables the direct comparison of how various mixing parameters are applied to individual artists’ voices within and across songs. In addition to facilitating the modeling of voice mixing, CoSoD also allows musicologists to ask questions about the way different voice types and individuals are mixed.

Finally, CoSoD facilitates the study of the relationship between gender and popular music. A number of previous studies have examined music programming and streaming services, exploring for instance how listeners tend to stream male artists more than women and mixed-gender groups [33]. Watson discusses gender inequality and low programming of women’s music in country music radio [34]. Other work addresses how a listener’s declared gender impacts automatic music recommendation [35] and musical preferences [36]. Additionally, various studies have addressed race and gender, along with sexist and racist discourses and practices, as they impact the music industry in general and the *Billboard* charts in particular [37–43]. By providing data on musical features, gender, and the role of these parameters within the formal structure of a song, CoSoD offers a new and complementary angle for the study of gender as it directly relates to the musical content of post-2010 popular collaborations.

3. COLLABORATIVE SONG DATASET (COSOD)

CoSoD¹ consists of metadata and analytical data of a 331-song corpus comprising all multi-artist collaborations on the *Billboard* “Hot 100” year-end charts published between 2010 and 2019. Each song in the dataset is associated with two CSV files: one for metadata and one for analytical data. We assembled the corpus by identifying every song on the charts that featured collaborations between two or more artists who usually perform independently from one another.

3.1 Annotation of Musical Features

The following analytical data is provided for each song in the dataset:

1. **Index number:** 1 to 33
2. **Time stamps:** In seconds (start of new section)
3. **Formal section label:** *Introduction, Verse, Pre-chorus, Chorus, Hook, Dance Chorus [44], Link, Post-chorus, Bridge, Outro, Refrain* or *Other*
4. **Name of artist(s):** Full name of the artist performing in each section. If all artists credited on the *Billboard* listing perform in a section, the label *both* or *all* is used.

Songs were assigned at random to one of two annotators, who generated time stamps at the onset of each formal section with Sonic Visualiser.² The annotators provided formal labels according to their analysis of the song. In case of ambiguity in the formal sections, both annotators discussed the analysis and agreed upon an interpretation.

For each formal section performed by *one artist only*, the following analytical data on the voice is provided:

1. **Gender of artist:** *M* (Man), *W* (Woman), *NB* (Non-binary)
2. **Function of artist:** *Feat* (Featured artist), *Main* (Main artist), *Neither, Uncredited*
3. **Style of vocal delivery:** *R* (Rapped vocals), *S* (Sung vocals), *Spoken*
4. **Minimum pitch value:** In Hz
5. **First quartile pitch value:** In Hz
6. **Median pitch value:** In Hz
7. **Third quartile pitch value:** In Hz
8. **Maximum pitch value:** In Hz
9. **Environment value:** On a scale of E1 to E5
10. **Layering value:** On a scale of L1 to L5
11. **Width (panning) value:** On a scale of W1 to W5

¹ <https://github.com/duguay-michele/CoSoD>

² The first annotator (first author) has a doctorate in music theory, while the second (second author) is a doctoral candidate in the same field.

The annotators determined the name of the artist(s) performing in each section by ear, and using song lyric website Genius.com to validate their hearing. In cases where an artist only provides minimal background vocals (a few words) in a particular formal section, their name is not included. One annotator then provided analytical data on each formal section performed by one artist only. Data on gender was gathered from media interviews and social media statements from the artists, and matches the artist's gender identity at the time of the dataset creation. This methodology yielded three categories: man, non-binary, and woman. We understand these labels as umbrella terms that encompass a variety of lived experiences that intersect with race, sexuality, and other power structures. The style of vocal delivery was determined by ear. The distinction between rapping and singing is porous, with many vocalists adopting ambiguous modes of vocal delivery. We consider any formal section containing a melodic line performed with sustained pitches as sung.

The pitch data was obtained by first isolating the vocals from the full mix using Open-Unmix [45] and then running the pYIN Smoothed Pitch Track transform [46] on the isolated vocal file. The minimum, first quartile, median, third quartile, and maximum pitch points in each formal section were calculated and recorded in the dataset.³

The Environment, Layering, and Width values were determined by the first annotator to ensure consistency. Rather than attempting to reconstruct the mixing process itself, the annotations for these parameters represent the way a listener might perceive the final mix upon listening to it on stereo speakers. The Environment of a voice is the space in which the voice reverberates. Environment values were determined via an aural analysis of the full track by using the following scale⁴:

- E1: The voice's environment sounds flat. There might be minimal ambiance added to the voice, but there is no audible echo or reverberation.
- E2: The last word or syllable of most musical phrases is repeated through an echo or reverberation effect.
- E3: The vocal line is repeated in one clear layer of echo. This added layer may be dry or slightly reverberant and has a lower amplitude than the main voice.
- E4: The main voice is accompanied by a noticeable amount of reverberation. There is no clear echo layer, but rather a sense that the main voice is being reverberated across a large space.
- E5: The main voice is accompanied by two or more layers of echo. The echo layers may be noticeably reverberant, similar in amplitude to the main voice, and difficult to differentiate from one another.

³ The accuracy of the F_0 estimates used to calculate this feature is impacted by the quality of the vocal source separation. A more accurate isolated vocal file would allow for more precise pitch data. Additionally, since pYIN Smoothed Pitch Track can only track a single melodic line, the accuracy of the pitch data is lessened in sections that feature multiple vocal layers with different pitch content.

⁴ The scales were initially published in [9].

The Layering of a voice refers to the additional vocal tracks that are dubbed over a single voice. Layering values were determined via an aural analysis of the full track by using the following scale:

- L1: The voice is presented as solo. Occasionally, a few words may be doubled with another vocal track for emphasis. Double-tracking is often used in the mixing process to create a fuller sound, with a final result sounding like a single vocal layer. Such cases fall into this category.
- L2: The voice is presented as solo, but additional vocal layers are added at the end of musical phrases for emphasis.
- L3: The main voice is accompanied by one or two layers. Layers might provide minimal harmonies or double the main voice. The layers have a noticeably lower amplitude than the main voice.
- L4: The main voice is accompanied by two or more layers. These layers are close copies of the main voice, sharing the same pitch and similar amplitude.
- L5: The main voice is accompanied by two or more layers. These layers add harmonies to the main voice, creating a thick and multi-voiced texture.

The Width of a voice refers to the breadth it occupies on the stereo stage. The Width was analyzed aurally with the aid of panning visualisation tool MarPanning [47]. The annotator simultaneously listened to the isolated vocal audio and observed the MarPanning visualization generated from the isolated vocals to determine the Width value. Since Open-Unmix occasionally omits reverberated components of the voice from the isolated file, the analyst then listened to the full track to confirm the Width value. Width values were determined according to the following scale:

- W1: The voice occupies a narrow position in the center of the stereo stage.
- W2: The voice occupies a slightly more diffuse position in the center of the stereo stage.
- W3: The main voice occupies a narrow position in the center of the stereo stage, but some of its components (echo, reverberation, and/or additional vocal tracks) are panned toward the sides. These wider components have a lower amplitude than the main voice.
- W4: The main voice occupies a slightly more diffuse position in the center of the stereo stage, and some of its components (echo, reverberation, and/or additional vocal tracks) are panned toward the sides. These wider components have a lower amplitude than the main voice.
- W5: The main voice and its associated components (echo, reverberation, and/or additional vocal tracks) are panned across the stereo stage. All components have a similar amplitude.

3.2 Metadata

The following metadata is provided for each song in the dataset:

1. **Index number:** From 1 to 331
2. **Year of first appearance on *Billboard* “Hot 100” year-end charts**
3. **Chart position:** As it appears on the *Billboard* “Hot 100” year-end charts
4. **Song title:** As it appears on the *Billboard* “Hot 100” year-end charts
5. **Name of artists:** As it appears on the *Billboard* “Hot 100” year-end charts
6. **Collaboration type:**
 - *Lead/featured:* Collab. with lead artist(s) and featured artist(s)
 - *No lead/featured:* Collab. with no determined lead
 - *DJ/vocals:* Collab. between a DJ and vocalist(s)
7. **Gender of artists:**
 - *Men:* Collab. between two or more men
 - *Women:* Collab. between two or more women
 - *Mixed:* Collab. between two or more artists of different genders
8. **Collaboration type + gender:**
 - *Collab M:* Collab. between men, no determined lead
 - *Collab M and W:* Collab. between men and women, no determined lead
 - *Collab NB and W:* Collab. between women and non-binary artists, no determined lead
 - *Collab W:* Collab. between women, no determined lead
 - *DJ with M:* Collab. between male DJ and male vocalist
 - *DJ with Mix:* Collab. between male DJ and mixed-gender vocalists
 - *DJ with NB:* Collab. between male DJ and non-binary vocalist
 - *DJ with W:* Collab. between male DJ and female vocalist
 - *M ft. M:* Men featuring men
 - *M ft. W:* Men featuring non-binary artist(s)
 - *W ft. M:* Women featuring men
 - *W ft. W:* Women featuring women
9. **MusicBrainz URL:** Link to the song on open music encyclopedia MusicBrainz

Each song in the dataset is labeled with an index number from 1 to 331. Songs are numbered in reverse chronological order, beginning with the 2019 charts and ending with 2010. One annotator obtained the metadata on year, chart

Figure 1. Summary of the gender distribution across different types of multi-artist collaborations. Subplot (i) shows gender counts for collaborations with lead and featured artists, subplot (ii) shows collaborations with no determined lead or featured artist, and subplot (iii) shows collaborations between DJs and vocalist(s).

position, title, and artists from the information available on the *Billboard* charts. Within years, songs are organized according to their position on the chart, from highest to lowest. Some songs appear on the charts two years in a row. In such cases, we only include the data for the earliest appearance.

3.3 Corpus Statistics

The dataset can be divided into three categories (shown in Figure 1): (i) collaborations between the lead artist(s) and featured artist(s), which account for 221, or 66.7% of the tracks, (ii) collaborations with no determined lead or featured artist, which account for 59, or 17.8%, of the tracks, and (iii) collaborations between a DJ and a vocalist, which account for 51, or 15.4% of the tracks. In category (i), the lead artist usually performs the majority of vocals. For example, in “No Limit” (2018) by G-Eazy ft. A\$AP Rocky & Cardi B, G-Eazy performs most of the vocals. A\$AP

Figure 2. Number of formal sections performed by a single artist (main, featured, or neither), categorized according to formal section type

Rocky accompanies him in the chorus and Cardi B raps the second verse. In category (ii), the performance of the vocals is often more equally distributed. Such collaborations are often billed as “duets,” and the artists’ names are separated by a “+”, a “&”, or a comma on the *Billboard* charts. For example, “Something’ Bad” (2014) is labeled as a “Miranda Lambert Duet With Carrie Underwood.” Both vocalists perform approximately equal portions of the song. In category (iii), the DJ does not provide vocals. In “Sweet Nothing” (2012), for instance, only the featured Florence Welch sings. The voice of DJ Calvin Harris is not heard.

Mixed-gender collaborations (including any combination of non-binary, women, and men artists) frequently appear on the *Billboard* charts and account for 162, or 49%, of the tracks in the dataset. Collaborations between two or more men account for 159 tracks, or 48% of the dataset. Finally, collaborations between women account for 10, or 3%, of the tracks. In six of the ten years under study—2011, 2012, 2015, 2017, 2018, and 2019—no collaborations between women reached the *Billboard* “Hot 100” year-end chart. Conversely, songs with two or more male vocalists were a consistent fixture on the charts. Mixed-gender collaborations, with any combination of men, women, and non-binary artists within the same track, also frequently appear on the charts.

Figure 2 shows the number and type of sections performed by individual artists in the corpus, categorized according to gender. This figure includes identical sections (such as choruses) that are repeated within a song. Sections in which more than one artist performs are not included. More sections are performed by men than by women and non-binary artists, which is to be expected given the over-representation of men in the dataset as a whole (Figure 1). Figure 3 displays the number and type of sections performed by *featured* artists only.

Figure 3. Number of formal sections performed by featured artists, categorized according to formal section type

4. EXPERIMENT: VOCAL PRODUCTION FEATURES AND GENDER

This section examines the relationship between the gender of an artist and the treatment of their voice, as characterized by three of the annotated musical features in the dataset: Environment, Layering, and Width. For the purposes of statistical power in the experiment, only songs with men and/or women artists were included. We only included tracks that contained verse and chorus sections to remove section types that occur in only a few tracks. In order to avoid over-representations of tracks with repeated sections (i.e., several instances of the same chorus), we sampled the first verse and chorus performed by a single artist from each track.⁵ This method resulted in the inclusion of two sections from 287 of the 331 dataset tracks in the experiment.

We analyzed the data with three separate logistic regressions—one for each feature—using the `statsmodels` package in Python. We encoded the different levels of the parameter scales (defined in Section 3.1) with one-hot encoding in order to allow us to examine whether there is a correspondence between specific parameter scale levels and gender.

Of the three logistic regressions, Environment ($R^2_{\text{McFadden}}(4, N = 574) = 0.028, p < 0.0001$) and Width ($R^2_{\text{McFadden}}(4, N = 574) = 0.035, p < 0.0001$) were statistically significant, while Layering ($R^2_{\text{McFadden}}(4, N = 574) = 0.0036, p = 0.64$) was not. The McFadden R^2 values for both Environment and Width were very low. This was not surprising since we did not anticipate that these features, particularly in isolation, would be explanatory. We were instead interested in exploring whether there is a significance between these features with respect to the man/woman gender binary in these collaborations.

For Environment, there were significant effects ($p <$

⁵ If the first verse of a song was performed by two artists simultaneously, while the second verse was only performed by one, we sampled the second verse.

0.0001) for E1 ($\beta=-1.18$, 95%CI [-1.49, -0.87]), E2 ($\beta=-1.12$, 95%CI [-1.56, -0.69]), and E3 ($\beta=-0.78$, 95%CI [-1.14, -0.42]). There was a significant negative effect for the lower/mid-level environment values and gender, meaning that men’s voices are more likely to be set in less reverberant spaces than women’s voices. For Width, there were significant effects at all of the levels: W1 ($\beta=-1.84$, 95%CI [-2.50, -1.17]), W2 ($\beta=-1.58$, 95%CI [-2.39, -0.77]), W3 ($\beta=-1.13$, 95%CI [-1.51, -0.75]), W4 ($\beta=-0.47$, 95%CI [-0.77, -0.17]), and W5 ($\beta=-0.60$, 95%CI [-0.95, -0.25]).

The Width results are harder to interpret than the Environment ones because the coefficient values are smaller and all negative. This is likely due to the imbalance between men and women in featured artist roles, both in the dataset (see Figure 1) overall and in the sample used in this experiment (404 of the included sections featured men while only of 170 featured women). However, the overall trend is similar to the one in the Environment experiment: lower-level values are more common for men than women. Men’s voices are more likely to occupy a narrow, centered position on the stereo stage, while women’s voices are more likely to occupy a wider space. These results were expected given that high Environment values tend to be associated with high Width values, as the reverberated components of a voice are generally panned across the stereo stage.

The lack of significant results for Layering indicates that there are no differences in the ways in which this parameter is applied to men’s and women’s voices. Since textural variation (such as the addition of vocal layers) is a standard feature of verse-chorus form, it is possible that Layering is linked to the type of formal section rather than to the gender of the vocalist. The significant results for the Environment and Width parameters can be interpreted in light of Brøvig-Hanssen’s and Danielsen’s work on technological mediation [48]. The authors establish a distinction between transparent and opaque technological mediation in recorded music. Transparent mediation, on one hand, is meant to create a recorded product that sounds natural and unaltered. Low Environment and Width values, for instance, are closer to transparent mediation because they sound closer to a real-life performance that is unmediated with artificial reverb or panning. Opaque mediation, on the other hand, highlights the use of technology by making it obvious to the listener. High Width and Environment values, with their clearly audible artificial reverberation and wide panning, are examples of opaque mediation. The results of the experiment therefore suggest that men’s voices are more likely to be mixed to sound “transparent” and natural while women’s voices are more likely to be mixed to sound “opaque” and technologically mediated.

Overall, this experiment demonstrates that within verse and chorus sections in CoSoD, there is a significant difference between the treatment of men’s and women’s vocals in terms of Environment and Width. This suggests that some mixing parameters contribute to the sonic differentiation of men’s and women’s voices in popular music.

5. CONCLUSION

CoSoD is a 331-song corpus of all multi-artist collaborations for facilitating appearing on the 2010–2019 *Billboard* “Hot 100” charts. Each song in the dataset is annotated with metadata, formal sections, and aspects of vocal production (including reverberation, layering, panning, and gender of the artists). As outlined in Section 2, CoSoD has several implications for MIR research. It provides annotated data for structural segmentation tasks and a listener-centered perspective on vocal mixing that could be useful for automatic music mixing tasks. The dataset could also be used to determine how these parameters interact with song form. Further study could also examine the relationship between the vocal range of an artist in a given section, their type of vocal delivery (rapped, spoken, or sung), and mixing parameters. Finally, the dataset also allows for the examination of the ways in which Environment, Layering, and Width values tend to be grouped together to create specific vocal production effects.

The dataset also facilitates musicological study of multi-artist collaborations post-2010 and gender norms. The experiment in Section 4 demonstrates this, as its results suggest that, for the chorus and verse data sampled from 287 songs in the dataset, men’s voices are more likely to be narrow and less reverberated than women’s. Opportunities for future research include examining whether there is a significant difference in the way Environment, Width, Layering, or other parameters are applied to women’s and men’s voices *within* collaborations that feature mixed- and same-gender vocalists. In other future work, we plan on expanding the annotations in the dataset with time-aligned lyrics, harmonic analyses, and additional performance data for the voice extracted using AMPACT [49, 50]. These annotations will include both spectral features and semantic descriptors, and the data will be encoded in relation to vocal-line transcriptions, where possible [51]. We also plan on providing annotations on vocal production parameters in sections performed by multiple artists and examining how vocal production parameters correlate with mixing parameters such as panning.

Finally, while our dataset focuses on gender, we are also interested in encoding other aspects of identity, such as race, in order to provide an intersectional perspective on artists’ identities. However, categorizing artists according to race proves to be more problematic than gender. Matthew D. Morrison writes that “white (and other non-black) people freely express themselves through the consumption and performance of commodified black aesthetics without carrying the burden of being black under white supremacist structures” [52, p. 791]. In other words, white and non-Black artists—such as rappers Iggy Azalea and G-Eazy, or singer Bruno Mars—often assume particular sonic characteristics that implicitly associate them with commodified notion of Blackness. By categorizing all white artists together, for instance, we would ignore this phenomenon and the way it is sonically realized. Further work needs to be done to understand how to best expand on CoSoD, or datasets in general, to account for this dynamic.

ABSTRACT

Recently, there has been a surge in Artificial Intelligence (AI) tools that allow creators to develop melodies, harmonies, lyrics, and mixes with the touch of a button. The reception of and discussion on the use of these tools - and more broadly, any AI-based art creation tools - tend to be polarizing, with opinions ranging from enthusiasm about their potential to fear about how these tools will impact the livelihood and creativity of human creators. However, a more desirable future path is most likely somewhere in between these two polar opposites where productive and ethical human-AI collaboration could happen through the use of these tools. To explore this possibility, we first need to improve our understanding of how music creators perceive and utilize these types of tools in their creative process. We conducted case studies of a range of music creators to better understand their perception and usage of AI-based music creation tools. Through a thematic analysis of these cases, we identify the opportunities and challenges related to the use of AI for music creation from the perspective of the musicians and discuss the design implications for AI music tools.

1. INTRODUCTION

In the past few years, there has been an increase in the creation of AI tools that support various musical activities. These activities are varied, including music recommendation/organization [1], sound synthesis [2], composition [3–5], and mixing [6, 7]. Current discourse on the use of AI-based tools in music production often presents two polarized perspectives: one that sees AI as an opportunity for innovation and progress [8, 9], while the other views it as a threat to the artistic creativity and livelihood of human creators [10–12]. However, a more nuanced and desirable approach entails a productive and ethical collaboration between humans and AI in the creative process, allowing both human creators and AI tools to create something neither could easily do alone.

Discussion around the perception of AI and music creativity tends to be focused on evaluation of the product of the AI [13–15], legal issues [14, 16], or human-computer interaction [17], and not on the implications and connections these factors have on the creative thinking of musicians, though there is growing interest in this domain [18, 19]. Additionally, while there has been discussion within the MIR community around the ethical implications of AI in music creation [18, 20], the experience of using AI to perform songwriting tasks [17], and the perspectives of expert users in creative music information retrieval [21, 22], there is still a need to further understand how creative MIR tasks are impacted by AI tools based on creative context. Even within the ISMIR community, in the last decade, there were fewer than 20 publications that discussed AI music creation tools, and less than half of them considered the creator’s perspective before developing the tool.

Musicians engage in creativity in many different ways through generating products such as compositions, analyses, and performances [23]. Our paper aims to address the impact of AI tools on the perception and work of one such domain: composition. Within composition we explore the impact of AI on what Peter R. Webster [23, p. 22] describes as "Creative Thinking," or "the mental processes associated with creative production." We will refer to those who engage in this act of creative thinking in composition as *creators*, their environment/creation goals as *creative context*, and the act of creative thinking as the *creative process*. This paper addresses three research questions: (1) In what way do creators perceive and envision the use of AI tools during their compositional process?, (2) How does their creative context influence their use of AI? and (3) What design implications can we derive to inform the creation of AI tools for music creators?

Our paper extends knowledge about how AI impacts the creative process of musical creators and adds to the discussion of expert users of creative MIR and human-AI collaboration in music creation acts. [19,21,22,24,25] To address these questions we conducted six case studies across a selection of creative contexts and our results are collected in a model that emphasizes the fluidity of roles that AI can play across creative thinking in composition and represents the start of future work aimed at building a dynamic model of human-ai musical creativity.

2. RELATED WORK

The idea of using computational means in composition is not a recent development. Over the course of music history, creators have considered various ways to develop algorithmic procedures to help with their process [26]. Since the early days of the computer, programmers and music creatives alike have utilized their skills to create programs that allowed them to continue this tradition; creating computer-aided compositions (CAC) and computer-aided algorithmic compositions (CAAC). As a whole, CAC tools require user intervention - correction to misnoted parts, adjustment of autotuned voices, and creators choosing which electronic instruments to employ and when [27]. CAAC tools, unlike CAC tools, are intended to be used to help "make music with minimal human intervention" [28]. Popular examples of CAAC tools include programs such as Opusmodus [29] - a library for real-time computer-aided composition in Max [30] - and more. These tools are extremely distinct in their purpose and use, helping to algorithmically aid creators, with rhythmic trees, polymetric notation, and data visualizations of algorithmically-generated material. When defining algorithmic composition, Pearce et al. [31] state:

Many who write programs for music composition are motivated by artistic goals: these programs are used to generate novel musical structures, compositional techniques and even genres of music...The composer may use an existing computer program or she may write a program herself: since identical motivations are involved, we count both of these as algorithmic composition. [31, p. 5]

In both cases, the question arises: *What is creativity and what does it mean for computers to be part of the creative process?* This question has been discussed in many ways in multiple fields, as scholars from the humanities [32, 33], the sciences [34–36], HCI [37, 38] and MIR [21, 22] have speculated for years over how the use of computer systems changes the creation process.

Through their exploration of using AI to co-songwrite, Micchi et al. [17] list two potential ways in which AI tools could assist creators: through (1) automation and (2) AI as suggestion. They note that while AI as automation is more akin to the tasks given to AI outside of the artistic field, the idea of AI as suggesting solutions to compositional tasks, acting as a partner in the process, is unique to the use of AI within creative pursuits. As Tipei et al. [39] discuss in their paper where student composers utilized DISSCO (Digital Instrument for Sound Synthesis and Composition), compositions were still considered by users to be collaborative, as participants were able to add, modify, or reject contributions made by the software and other users. Researchers compared this interaction to the process of collective improvisation, with the software playing a key role as a collaborator and manager in this compositional process - "[the computer/software]...becomes part of the process not only by performing a vast number of operations very quickly,

but also as a consequential contributor to the creative effort" [39]. More specifically, this implies that AI simultaneously acts as a collaborator in the process and as a tool, allowing the creator to explore different possibilities of how AI can be applied within their workflow.

3. STUDY DESIGN AND METHODS

We employed an exploratory, multi-subject case study method [40] to examine how creators perceive the use of AI tools within their compositional process. Using multiple-subject case studies allows us to better explore the phenomenon of AI within the compositional process across a variety of contexts in order to build a stronger basis of understanding and is useful for formulating concepts for theory construction [40, 41].

Our case selection strategy was focused on representing diverse cases within the varied creative contexts of both western art music and western popular/commercial music traditions [42]. Our cases included a classical/jazz music composer, a film and video game music composer, an interactive media composer, an electroacoustic composer, a sound artist, and a DJ. Due to the scope of the study and resources, we did not include case studies of programmers, listeners, or creators outside the western context, though these communities will be explored in further studies.

There were a total of six creators, one for each case, all of which were over eighteen years of age and recruited via email. Of the recruited participants, all had heard of AI tools and five worked actively with AI tools within their process. While all creators were actively working within the music field professionally, the film music creator and the intermedia creator were the only ones not affiliated with an academic institution as a student, though both had been trained within western academic music schools. All participants had been composing over five years at the time of the interview.

For each case, we conducted in-depth, semi-structured interviews between 60 and 90 minutes. Interview questions for this study were generated via a review of the existing literature on the use of AI in music composition and production, where we identified relevant themes and topics (e.g., definitions of AI, AI creativity, typical tools in music creation). Topics ranged from participants' experiences with AI-based tools in music production, their perceptions of the advantages and disadvantages of using AI, and their views on the ethical implications of AI in music creation. Both descriptions of the case contexts and interview questions can be found at

the url: https://github.com/micheleneuman/ISMIR23_supplemental_material.

All interviews were conducted online over Zoom and fully transcribed and edited for clarity. We created the codebook using a mix of the inductive and deductive approach [43]. Initially, two of the authors created the first draft of the codebook using thematic analysis of the transcribed interviews. The codebook was iteratively refined by adjusting and aligning the themes that emerged from the interview data with those from existing literature. Using the final codebook, we first coded the interviews separately on the qualitative coding software ATLAS.ti, then came together to discuss any discrepancy with a goal of reaching an agreement and assigning final codes following the consensus model [44].

4. RESULTS

During analysis, 12 categories emerged which were grouped into two main sets: AI as Collaborator and Democratization of Music Creation. The themes were influenced by the current or lack of use of AI by the creators and the reasoning behind their choices. Themes that arose such as tool sharing are common practice among communities of creators, especially on the internet [45, 46], but within the this study, refers specifically the sharing of AI and ML tools.

Coding the interview transcripts led to the insight that creators had specific creative tasks with which they would or would not feel comfortable utilizing AI tools, as well as parts of the process in which they would consider the use of AI. The most common code within our analysis was "Types of AI Contribution" in which the creators reflected on how they would personally use AI within their own process. This included tasks such as creating repositories (P4) and mastering songs (P6). The least common code was "Sharing of Tools." As a whole, all participants had some knowledge of what AI was, and all but the jazz/classical creator had utilized it in some capacity within their workflow. Three of the creators used also used non-musical AI (such as text-based AI) in their process.

Based on our analysis, we present the *Human-AI Creative Collaboration Model* (Figure 1) to represent the use of AI tools throughout the compositional process of music creators situated within the western tradition of composition who may employ computer assisted tools. The model is comprised of three parts: Factors on Influences, AI Roles, and Creation as Process.

4.1 Factors on Influences

The far-most left section of our model represents the various contextual factors that impact creators' perception on where AI should fall within their creative process. These factors are broken into three parts within our model: personal context, social context, and creative goal. While all creation contexts are different, these are the three most common aspects that arose from our analysis.

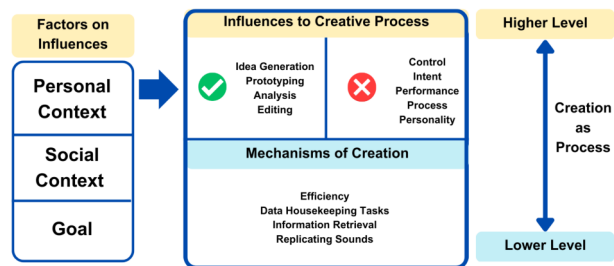

Figure 1. Human-AI Creative Collaboration Model

4.1.1 Personal Context

The *Personal Context* is defined by the individual creator's familiarity with their own creative process and their music literacy. When reflecting on whether or not participants thought that an AI tool would be helpful to them, they considered where it would fall into their process and how much control they would be able to maintain over the final product. Because our participants had been composing for over five years, they already had a strong idea of how their process worked and a familiarity with their personal context of musical creation. Creators commented on their desire to have AI tools that are flexible enough to work within their current creative process, are interoperable with existing compositional software, and have clear and concise interfaces to help with facilitating their adoption and use.

For example, the film music creator and DJ who work in more commercial settings, with tighter schedules, mentioned utilizing AI tools that were already integrated within software they used such as Ozone [7] and Logic's Drummer [47]. If integration is not possible, they suggested AI should be designed in a way that it does not interfere with the use of a primary creation tool. The electroacoustic creator, interactive music creator, and sound artist preferred to use older forms of AI due to developer transparency. The participants differentiated older models from the newer models, suggesting that newer models were hidden behind a corporate "black box" in order to work. These creators preferred supervised learning algorithms to unsupervised learning algorithms, so that they could change the open source code and exert more creative control (P5). As they had more experience with AI, they were more open to learning and working with AI tools. All participants also commented that current AI tools were not able to support their process in the ways that they wanted due to the lack of control and low-fidelity outputs.

4.1.2 Social Context

Creators also consider *Social Context*; this includes their current community of practice where they often converse and share their art with (other creators, their audience) and their educational and musical upbringing. Many aspects of the act of creativity are tied to the sociocultural aspects of making music [48]. Those whose communities were most open to using AI tools, often in more experimental creative contexts such as in academic experimental com-

munities, were much more willing to engage with the idea of AI in different parts of their process. The jazz/classical composer was adamant that they were very skeptical of AI in part because the community around them was also very skeptical, especially with a strong tradition of composition within the western art context.

Similarly, they decided on what was an appropriate use of AI by comparing the impact the tool had on others. Participants raised the issue of bias in AI and using the creative works of others. All creators noted that most large-scale models rely on Eurocentric training data that may not align with their individual artistic expressions or requirements, feeling that the AI would "flatten" their work with it has "biases and this kind of Eurocentric Westernization of aesthetics" (P5). P4 noted, "There's been a big problem in the past couple of weeks with people coming out talking about how that's not right, to be able to use someone's likeness and their voice however you want." This sentiment highlights the worry that there was oversight in the ways in which these models are being created and distributed, leading to potential harms in taking the intellectual property of others and using it to quickly make financial gains, a sentiment echoed by others in the music industry [15]. Furthermore, participants expressed worry about the impact of such rapidly generated artworks on not only their personal work, but also on the general public's perception of art as a whole.

Participants also talked about how AI tools opened up the potential for more types of creators to get involved in the music creation process. Our DJ participant discussed their use of the AI tool Ozone, which he uses to digitally master his songs. While the tool costs 50 USD to purchase, the participant could use it to process all of his songs and have them match the audio specifications needed to upload to streaming services such as Spotify within seconds, whereas if it was sent to a mastering engineer, each song would cost him hundreds of dollars to master. In the same vein, multiple participants mentioned that one of the potential abilities of AI music tools would be the ways it could potentially allow entry-level musicians to bypass some of the extensive music education they would need before being able to create music, including the cost and time investment of said education. "I think it can really accelerate the learning process, the process of studying music and experiencing all this music that we've documented...I think it can kind of build each person's personal vocabulary of what music is." (P1). These participants qualified their statements by clarifying that this would not mean users should bypass the whole process of learning the art of composition. Rather, the ability to create music without networking and funding as a necessity in the creative process is a kind of "freedom" one participant noted, one which began with the advent of the personal computer and has only continued to expand as the process is simplified (P2).

4.1.3 Creative Goal

Lastly, *Goal* refers to creators' specific reason for composing (i.e. for a film, for a commission, a performance). The

goal can put pressure on creation time, influence the social practices and expectations, and change the personal workflow of the creator.

4.2 Potential AI Roles: Influences and Mechanisms

At the center of the model, we present the different ways that AI could potentially be used in the creation process. Participants expressed an overall positive view towards the potential of AI tools as collaborators. Participants also personified the AI in their process stating it was similar to having a "second person" check over their work or a way to bounce off other ideas with the AI tools. While the list is not exhaustive, these represent the most common tasks that creators in our study talked about. These roles were primarily impacted by the concept of "control" of a creative output across the process. All participants agreed that computational creativity cannot supplant human creativity. While participants recognized that AI can "create something" and output a product that mirrors human creativity, such as P4 stating that they were "...sure AI could create something like a poem, for example, that would be really hard for me to tell if it was from a human or from an AI," they highlighted that AI lacks the deliberate decision-making of human creators, continuing they would have a hard time "emotionally connect[ing] with it."

In the former case, participants discussed engaging in a process of "play" with the AI, which allowed them to explore a variety of prompts and generate a collection of potential options that they could later modify or combine to achieve their artistic goals. P5 noted: "So sometimes when I'm stuck, I like to grab some of the models I pre-trained and just ask it something." The creators used the tools to explore, both as a way to spark new ideas and as a way to generate a large repository of content to remix in their own way. Within this process though, the creators emphasized the AI does not make the final choice. The final decision was always made by the creator to maintain their artistic agency.

For all of the participants, within the context of their own compositional process, intention and choice was as important as the creative product. One participant stated, "You can have [AI] generate some sort of electronic music code for you and that sort of just skips for me a whole important step in the process, because in my process of creating live electronic music, there's sort of an interplay between my coding and my writing. I think a lot will be lost if you just take out an entire part of that process" (P3). Another participant remarked, "For me, creativity also involves the decision-making in a big way. And then to determine where to end things. It doesn't seem that my experience with AI so far affords these possibilities" (P6).

Elaborating on this idea of creative control, P6 noted: "I feel that it doesn't sound like me, or especially with music compositions and working with some of these AI that will give you a MIDI file, you know?", implying some kind of loss in the creator's personality in automatically generated music pieces. P1 stated that "AI seems to be something that's designed to do some of that channeling of an idea for

you. It seems like AI is kind of trying to be designed to do the human part of the process." Personality Theory related to intellectual property, put forward by thinkers like Emmanuel Kant and George Hegel [49], suggests that a person's personality is incorporated into their creative work during the labor process, and is therefore an essential part of their work. When an AI takes that labor away from the creator, creators felt that the work now no longer has their personality, and thus is no longer their creation.

4.2.1 Influences to Creative Process

The top section *Influences to Creative Process* lists tasks that directly influence the final artistic product, allowing for integrity of expression by the creator. On the left side are *acceptable influences*. These tasks involve aspects that help prompt ideas or create inspiration. Tasks that fall within the *acceptable influences* do not need to be as integrated with the programs creators already use, though they should integrate with the overall creative process - especially in the ideation phase, where many creators felt AI influences fit best. These tools should allow for continuous reiteration, with understandable in-tool design signifiers that indicate the ways they can edit, change, and manipulate the AI's data before and after each iteration. Once this ideation phase is over, there should be a clear way to export their ideas into a new software or system, again allowing for the interoperability that is vital for music creator's process; this could be done in a number of ways such as using MIDI files, WAV files, or MusicXML.

Participants also discussed ways that AI tools could go beyond what humans are traditionally capable of, and in that way become a partner in the expansion of their compositional capabilities. One potential function as noted by a participant was the ability to use AI as a music analysis tool, helping users pinpoint things they were not aware of or even able to perceive with human hearing, such as "the sound field...expanding from the front to the back" (P6). Another participant described how their current use of AI as part of their process has changed how they see the world around them, gaining a new understanding around what could be used or turned into data which allows them to create patterns and connections within their music (P5). AI tools also helped many creators find relationships between sounds, found materials, words, and pictures. One participant explained it as a "feedback loop" (P6).

The right side displays aspects of the creative process where creators are not comfortable engaging in Human-AI collaboration. They felt using AI with these tasks negatively affect the creative process by taking away an essential component of their creations. This includes losing the ability to control their intent and choices, not being able to specify performance parameters/low-fidelity outputs, and interfering with their process and creative personality.

4.2.2 Mechanisms of Creation

The lower section is titled *Mechanisms of Creation*. It includes types of Human-AI collaborations where our participants had little issue if AI took over the process com-

pletely, often searching for and utilizing AI that could complete these tasks. In general, *mechanisms* are tasks that occur within the creative process that do not require direct decision-making by the music creators, including house-keeping tasks such as file naming, information retrieval tasks such as looking for electronic instruments, and replicating sounds. Many participants noted they would use AI to complete tasks to help speed up their process or complete tasks they did not want to do. These tasks often had to do with analyzing data in some way. For example, P3 noted "I have an idea that I want to do, and I just use the AI to make that idea happen faster."

4.3 Creation as Process

Lastly, on the far right side is a spectrum representing what we call "Creation as Process," emphasizing the role of iteration and thinking that happens during the process of writing music [23, 32]. For all of the participants, within the context of their own creative process, intention and choice was as important as the creative product. One participant stated, "You can have [AI] generate some sort of electronic music code for you and that sort of just skips for me a whole important step in the process, because in my process of creating live electronic music, there's sort of an interplay between my coding and my writing. I think a lot will be lost if you just take out an entire part of that process" (P3). Another participant remarked, "For me, creativity also involves the decision-making in a big way. And then to determine where to end things. It doesn't seem that my experience with AI so far affords these possibilities" (P6).

The spectrum represents the level of intellectual engagement needed in each task, ranging from highly intentional choices to mechanical and repetitive tasks. Within the process of creating, the given AI tasks may move to higher or lower levels along the spectrum, sometimes influencing the process more and other times receding to lower levels of impact. The creative process is fluid, meaning that both the factors *and* roles of the AI can change over the course of creation.

5. DISCUSSION

Although our focus on only six case-studies of music creators in specific creative contexts presents a limitation to our study, we believe that our focus allowed us to explore possible applications of AI tools to creators' needs, and allowed us to form initial insights into the perception of the use of AI tools in the creative process. Musical creativity is not a monolith and it is our belief that in order to understand how to design specific AI systems that support creative musical tasks, we need to know how creative thinking is conceived by those engaging in these types of musical activities. Our main contribution in this paper is to begin to situate certain AI tasks as potential helpful or potentially harmful to the creative process of those who create.

In this study, we argue that the discussion around the threat that AI poses to both the jobs of creators and artis-

tic integrity is of importance to creators; emphasizing that co-creation of music in the context of music composition is dependent not only on the larger creative context, but on the process of creative thinking as well. Our work suggest that Andersen and Knees [21, 127] notion of the importance of an "individual user[s'] models of music perception as well as a solid understanding of usage context" is not only needed for exploring dissimilarity in search, but also for understanding AI systems in the other forms creative endeavors. Knees et al.'s [50] consideration of the use of "strangeness" for artists recommendations is useful in AI systems as so far the AI is helping to generate new ideas for creators; though strangeness is one aspect of many needs that a creative engages with in AI music systems. Other tasks such as analysis and editing are also elements of creative MIR tasks that may be helpful to facilitating the creative process, though often can occur at different points or simultaneously with the task of idea generation. We argue that there is a need to understand how specific creative processes view and interact with AI at all stages. While there are some aspects of the use of AI that many of our cases agreed on, such as allow AI to take over tasks that have little to no control over the final product of creative thinking which is echoed in other literature [50, 51], our study also indicated that the role of AI is also dependent upon personal, social, and creative goal related factors that are constantly in flux. The Human-AI Collaboration Model demonstrates our belief that the role that AI plays on creative thinking is highly flexible within music creation and that without a clear understanding of how creators are thinking, AI systems can hurt musical creative practices of musicians.

Oliver Bown has warned against the possible negative affect that AI tools can have if it disrupts cultural applications and creation of music. [33]. If music AI systems are designed to limit creator control, intent, or process, they could potentially lead to Schröter's notion of the "(possible) automatization of artistic work" [52]. Full control over the final artistic product and an understanding of the creator's emphasis on their process are the most important aspects to developing tools that can support, instead of harm, human creativity - as noted by Knees, it is important that the user is given agency in the process of "co-creation" with high-level control of the generative process [19].

While it is true that the concept of "Explainable AI" [53–55] can help to educate those who worry about the role AI plays in future creative endeavors, it is not a full solution to the lack of user trust or changing user hesitancy in tool adoption. Recent fears over data misuse by generative AI, backed up by online discussions and even legal investigations into data scraping [56] and intellectual property [57] have made creators fear utilizing AI tools, with creators fearing that AI is trained on data that does not meet their personal artistic goals or actively hurts other artists. Increasing common knowledge about the functions of AI tools would create more trust in these systems and encourage users to integrate them more into their creative process [58], but there is also a need to design in systems

in such a way that creators feel they can ethically use these systems in their own work. This means ethically sourcing material and allowing for the control of elements within AI systems.

Designers of AI tools for creators should consider what role they expect for their tool to play within specific creation processes and make choices that support this. The specific inputs, outputs, and needs of an AI system will change over the creative process. Because AI tasks can move up and down in importance, that means that it is highly possible to have a mismatch of the execution and evaluation of AI systems that may lead to less cohesion between the creator and the AI as they will continually need to reevaluate how these systems fit in their workflow.

6. CONCLUSION AND FUTURE WORK

Our findings support that creators have concerns surrounding the transparency of and lack control within AI tools, but that there is still much to do in relation to understanding the exact needs of creative users. In order to develop useful AI tools, designers must consider the specific creation context, existing processes of creators, control of creator, and the fluidity of creating. Our *Human-AI Creative Collaboration Model* is designed to help developers and researchers who create AI systems to consider the variety of factors and influences that exist on creative process and how they might intersect with a creators experience. We hope that this work encourages developers and other MIR researchers to continue to consider advancing Human-AI collaborations that align with music creators' needs. There are a variety of tasks that AI can perform, and considering if tasks are impacting creative thinking in a different phases of creation will allow for a more ethical and productive experience for music creators.

While we interviewed different creation contexts within our case studies, there is still a need for future work to consider how differences in cultural background, musical training, and experience with AI factor into Human-AI creative thinking. Composing music can happen in a variety of other contexts not explored in this study, including as part of music education and cultural situations. Yet, composition is only one form of creative thinking within music and future work might will continue work to identify the differences that arise when using AI systems within different forms of creation such as music analysis and performance. Creators may be utilizing all these forms of thinking across the creative process in non-linear ways. There is still much to learn about the impact that AI will have on music as an art; if designed and deployed ethically, AI offers the opportunity to enhance human creation and provide new avenues for creating and learning about music. But, in order for AI to support musicians in any form of creative thinking, we need to ensure we are designing AI tools with creators in mind.

ABSTRACT

Symbolic music is widely used in various deep learning tasks, including generation, transcription, synthesis, and Music Information Retrieval (MIR). It is mostly employed with discrete models like Transformers, which require music to be tokenized, i.e., formatted into sequences of distinct elements called tokens. Tokenization can be performed in different ways, and recent research has focused on developing more efficient methods. However, the key differences between these methods are often unclear, and few studies have compared them. In this work, we analyze the current common tokenization methods and experiment with time and note duration representations. We compare the performance of these two impactful criteria on several tasks, including composer classification, emotion classification, music generation, and sequence representation. We demonstrate that explicit information leads to better results depending on the task.

1. INTRODUCTION

Most tasks involving using deep learning with symbolic music [1] are performed with discrete models, such as Transformers [2]. To use these models, the music must first be formatted into sequences of distinct elements, commonly called tokens. For instance, a token can represent a note attribute or a time event. The set of all known tokens is commonly called the vocabulary, and each token is associated to a unique integer id. These ids are used as input and output of models.

Compared to text, tokenizing music provides greater flexibility, as a musical piece can be played by different instruments and composed of multiple simultaneous notes, each having several properties such as pitch, duration and velocity. As a result, it is necessary to represent these elements in conjunction with the time dimension. To achieve

this, researchers have developed various methods of tokenizing music, which are introduced in the next section.

While these works offer model performance comparisons between tokenization strategies, their main differences or similarities are not always clearly stated. Few experiments have been conducted to compare model performances using different tokenization strategies. Additionally, these studies mostly focus on music generation, for which evaluations are performed on results obtained autoregressively, which accumulates biases [3] and is arguably difficult to evaluate [4].

This paper’s primary contribution is a thorough and well-designed comparison of common tokenization techniques. Our focus is on two critical aspects: the representation of time and note duration. We believe that they are significant and impactful design choices for any music tokenization approach. Through experiments on composer classification, emotion classification, music generation, and sequence representation, we demonstrate that these design choices produce varying results depending on the task, model type, and inference process. Autoregressive generation benefits from explicit note duration and time shift tokens, while explicit note offset is more discriminating better suited for contrastive learning approaches.

We present next the related works, followed by an analysis of music tokenization, experimental results, and finally a conclusion. The source code is available for reproducibility. ¹

2. DECOMPOSING MUSIC TOKENIZATION

2.1 Related works

Early works using discrete models for symbolic music, such as DeepBach [5] or FolkRNN [6], rely on specific tokenizations often tied to their training data. Since then, researchers introduced more general representations applicable to any kind of music. The most commonly used are *Midi-Like* [7] and *REMI* [8]. The former tokenizes music by representing tokens as the same types of events from the MIDI protocol, while the latter represents time with *Bar* and *Position* tokens and note durations with explicit

¹ <https://github.com/Natooz/time-duration-music-modeling>

Tokenization	Time		Note duration	
	TimeShift	Bar + Pos.	Duration	NoteOff

REMI [8]	-	✓	✓	-
Structured [17]	✓	-	✓	-
TSD [15]	✓	-	✓	-
Octuple [10]	-	✓	✓	-

Table 1: Time and note duration representations of common tokenizations. Pos. stands for Position.

Duration tokens. Additionally, REMI includes tokens with additional information such as chords and tempo.

More recently, researchers have focused on improving the efficiency of models with new tokenizations techniques: Compound Word [9], Octuple [10] and PopMAG [11] merge embedding vectors before passing them to the model; 2) LakhNES [12] and [13], SymphonyNet [14] and [15] use tokens combining several values, such as pitch and vocabulary.

2.2 Music tokenization design

When analyzing the possible designs of music tokenization, we can distinguish seven key dimensions:

- **Time:** Type of token representing time, either *TimeShift* indicating time movements, or *Bar* and *Position* indicating new bars and the positions of the notes within them. We can also consider the unit of *Time-Shift* tokens, either in beats or in seconds.²
- **Notes duration:** How notes durations are represented, with either *Duration* or *NoteOff* tokens.
- **Pitch:** Most works use tokens representing absolute pitch values, although recent work shed light on the expressiveness gain of representing as intervals instead [16];
- **Multitrack representation:** The representation of several music tracks in a sequence, i.e., how are the notes linked to their associated track.
- **Additional information:** Any additional information such as chords, tempo, rests, note density. Velocity can also falls in this category;
- **Downsampling:** How "continuous-like" features are downsampled into discrete sets, e.g. the 128 velocity values reduced to 16 values;
- **Sequence compression:** Methods to reduce the sequence lengths, such as merging tokens and embedding vectors.

As time and note duration can both be represented in two different ways, existing tokenizations can be easily classified based on these dimensions, as shown in table 1.

² In this paper we only treat of the beat unit. The MIDI protocol represents time in *tick* unit, which value is proportional to the time division (in ticks per beat) and tempo. Hence, working with seconds would require a conversion from ticks.

However, other dimensions offer a broader spectrum of potential designs.

For instance multitrack can be represented by Program tokens³ preceding notes as in FIGARO [18], distinct tracks sequences separated by Program tokens as in MMM [19], combined note and instrument tokens as LakhNES [12] and MuseNet [13], or merging Program embeddings with the associated note tokens (MMT [20], MusicBert [10]). One could even infer each sequence separately and lately model their relationships with operations aggregating their hidden states as in ColBERT [21].

The MIDI protocol supports a set of effects and metadata that can also be represented when tokenizing symbolic music, such as tempo, time signature, sustain pedal or control changes. Some works also include explicit Chord tokens, detected with rule-based methods. Nevertheless, only a few works experimented with such additional tokens so far ([8, 22]).

Previous works have mainly compared tokenization strategies by evaluating models with automatic and sometimes subjective (human) metrics, but often do not proceed to comparisons between the ways to represent one of the dimensions we introduced previously. [8] compared results for the generation task, for the use of Bar and Position tokens versus TimeShift in seconds and beats.

To the best of our knowledge, no comprehensive work and empirical analysis have fairly compared these possible tokenization choices. Conducting such an assessment would require an extensive survey. In this paper, we specifically focus on the time and note duration representations, as they are the two main characteristics present in every tokenization.

We want to highlight the importance of the explicit information carried by the token types, as they directly impact the performances of models. TimeShift tokens represent explicit time movements, and especially the time distances between successive notes. On the other hand, Bar and Position tokens bring explicit information on the absolute positions (within bars) of the notes, but not the onset distances between notes. One could assume that the former might help to model melodies, and the latter rhythm and structure. For note duration, Duration tokens intuitively express the absolute durations of the notes, while NoteOff tokens explicitly indicates the offset times. With NoteOff, a model would have to model note durations from the combinations of previous time tokens.

Our experiments aim to demonstrate the impact of different combinations of time and note duration tokens on model performance and which combinations are suitable for different tasks. Next, we introduce our methodology.

3. METHODOLOGY

3.1 Models and trainings

For all experiments, we use the Transformer architecture [2], with the same model dimensions: 12 layers, with di-

³ Following the conventional programs from the MIDI protocol.

mension of 768 units, 12 attention heads and inner feed-forward layers of 3072.

For classification and sequence representation, it is first pretrained on 100k steps and a learning rate of 10^{-4} , then finetuned on 50k steps and a learning rate of 3×10^{-5} , with a batch size of 48 examples. An exception is made for the EMOPIA dataset, for which we set 30k pretraining steps and 15k finetuning steps, as it is fairly small. These models are based on the BERT [23] implementation of the Transformers library [24]. We use the same pretraining than the original BERT: 1) from 15% of the input tokens, 80% is masked with a special MASK token, and 20% is randomized; 2) half of the inputs have 50% of their tokens (starting from the end) shuffled and separated with a special SEP token, and the model is trained to detect if the second part is the next of the first.

For generation, the model is based on the GPT2 implementation of the Transformers library [24]: it uses a causal attention mask, so that for each element in the sequence, the model can only attend to the current and previous elements. The training is performed with teacher forcing, the cross-entropy loss is defined as: $\ell = -\sum_{t=1}^n \log p_{\theta}(x_t | \mathbf{x}_{\leq n})$.

All trainings are performed on V100 GPUs, using automatic mixed precision [25], the Adam optimizer [26] with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-8}$, and dropout, weight decay and a gradient clip norm of respectively 10^{-1} , 10^{-2} and 3. Learning rates follow a warm-up schedule: they are initially set to 0, and increase to their default value during the first 30% of training, then slowly decrease back to 0.

10% of the data is used for validation during training, and 15% to test models. Inputs contains 384 to 512 tokens, and begin with a BOS (Beginning of Sequence) token and end with a EOS (End of Sequence) one.

3.2 Tokenizations

We investigate here the four combinations of possible time and note duration representation. In the results, we refer to them as *TS* (TimeShift), *Pos* (Position), *Dur* (Duration) and *NOff* (NoteOff). It is worth noting that *TS + Dur* is equivalent to *TSD* [15] and *Structured* [17], *TS + NOff* is equivalent to *MIDI-Like* [7], and *Pos + Dur* is equivalent to *REMI* (without additional tokens for chords and tempo).

We apply different resolutions for Duration and TimeShift token values: those up to one beat are downsampled to 8 samples per beat (spb), those from one to two beats to 4 spb, those from two to four beats to 2 spb, and those from four to eight beats to 1 spb. Thus, short notes are represented more precisely than longer ones. Position tokens are downsampled to 8 spb, resulting in 32 different tokens as we only consider the 4/* time signature. This allows to represent the 16th note. We only consider pitches within the recommended range for piano (program 0) specified in the General MIDI 2 specifications⁴: 21 to 108. We then deduplicate all duplicated

notes. Velocities are downsampled to 8 distinct values. No additional token (e.g., Chord, Tempo) is used.

We perform data augmentation by creating variations of the original data with pitches increased and decreased by two octaves, and velocity by one value. Finally, following [15], we use Byte Pair Encoding to build the vocabularies up to 2k tokens for generation and 5k for other tasks. All these preprocessing and tokenization steps were performed with MidiTok [27].

4. GENERATION

For the generative task, we use the POP909 dataset [28]. The models start with prompt made of between 384 to 512 tokens, then autoregressively generate 512 additional tokens. Evaluation of generated results remains an open issue [4]. Previous work often perform measures of similarity of certain features such as pitch range or class, between prompts and generated results, alongside human evaluations. Feature similarity is however arguably not very insightful: a generated result could have very similar features to its prompts while being of poor quality. Human evaluations, while being more reliable on the quality can also induce biases. Besides, [8] already shows results on an experiment similar to ours.

Hence we choose to evaluate results on the ratios of prediction errors: Token Syntax Error (TSE) [15]. This metric is bias-free and directly linked to the design choices of the tokenizations. It allows us to measure how a model achieves to make reliable predictions based on the input context and the knowledge it learned.

We use the categories from [15]:

- **TSE_{type}**: an error of type, e.g., when the model predicts a token of an incompatible type with the previous one.
- **TSE_{time}**: a wrong predicted Position value, that goes back or stay in time.
- **TSE_{dupn}** (duplicated note): a note predicted whereas it was already being played at the current time being.
- **TSE_{nnof}** (no NoteOff): a NoteOn token been predicted with no following NoteOff token to end it.
- **TSE_{nnon}** (no NoteOn): NoteOff token predicted whereas this note was not being played.

For each generated token, a rule-based function analyzes its type and value to determine if both are valid, or which type of error was made otherwise. The overall number of errors is normalized by the number of predicted tokens.

The results are reported in table 2. We first observe that the type error ratios are lower than in other categories. This is expected since it is less computationally demanding to model the possible next types depending solely on the last one, rather than on the value of the predicted token, for

⁴ Available on the MIDI Manufacturers Association website.

Figure 1: Histograms of the note onset positions within bars (top-row), note offset positions within bars (middle-row) and note durations (bottom-row) of the generated notes. There are 32 possible positions within a bar, numerated from 0 (beginning of bar) to 31 (last 32th note). The durations are expressed in beats, ranging from a 32th note to 8 beats.

Figure 2: Token type succession heatmaps of the generated results. The horizontal axis denotes the next token type per from the ones on the vertical axis. Each row is normalized to a sum of 1.

which the validity depends on a the whole previous context.

Position tokens bring almost no type errors, but a noticeable proportion of time errors. When decoding tokens to notes, this means that the time may go backward, and resulting in sections of overlapping notes.

Although Duration tokens seem to bring slightly more note duplication errors, the use of NoteOn and NoteOff tokens results in a considerable proportion of

Tokenization	TSE _{type} ↓	TSE _{time} ↓	TSE _{dupn} ↓	TSE _{nnon} ↓	TSE _{nnoF} ↓
<i>TS + Dur</i>	$< 10^{-3}$	-	0.014	-	-
<i>TS + NOff</i>	$< 10^{-3}$	-	0.001	0.109	0.040
<i>Pos + Dur</i>	0.002	0.113	0.032	-	-
<i>Pos + NOff</i>	0.002	0.127	0.005	0.095	0.066

Table 2: Prediction error ratios when performing autoregressive generation. - symbol stands for not concerned, and can be interpreted as 0.

note prediction errors. NoteOff tokens predicted while the associated note was not being played (TSE_{nnon}) does not have undesirable consequences when decoding tokens to notes, but it pointlessly extends the sequence, reducing the efficiency of the model, and may mislead the next token predictions. Additionally, NoteOn tokens predicted without associated NoteOff (TSE_{nnoF}) result in notes not properly ended. This error can only be handled by applying a maximum note duration after decoding. Explicit Duration tokens allows to specify in advance this information, for both short and long notes. Conversely, with NoteOff tokens, the note duration information is implicit and inferred by the combinations of NoteOn, NoteOff and time tokens. This can be interpreted as an extra effort for the model. Consequently, some uncertainty on the duration accumulates over autoregressive steps during generation. Based on these results, the best tradeoff ensuring good predictions seems to represent time with TimeShift tokens and note duration with Duration tokens.

In fig. 1 we observe the positions within bars and durations of the generated notes. In all cases, onset positions are more distributed at the beginning of the bars. This is especially the case with Bar and Position tokens, for which we may find unexpected rests at the end of bars,

when `Bar` tokens are predicted during the generation before that the current bar is completed. The `TS + Dur` combination places note onsets much more on even positions. The probability mass of `TimeShift` tokens (especially for short values) seems to be much higher. However, this is not the case for the `TS + NOff` combination, as `TimeShift` tokens have to be predicted to move the time on odd positions of note offsets. As shown in fig. 2, right after the model is likely to predict a next note, resulting in evenly distributed onset distribution.

Finally, the use of `NoteOff` tokens tends to produce longer note durations, especially when combined with `Position` tokens. In this last case, we can assume that the model might "forget" the notes currently being played, and that it struggles more to model their durations that have to be implicitly deduced from the past `Bar` and `Position` tokens.

Tokenization	Top-20 composers \uparrow	Top-100 composers \uparrow	Emotion \uparrow
<code>TS + Dur</code>	0.973	0.941	0.983
<code>TS + NOff</code>	0.962	0.930	0.962
<code>Pos + Dur</code>	0.969	0.927	0.963
<code>Pos + NOff</code>	0.963	0.925	0.956

Table 3: Accuracy on classification tasks.

5. CLASSIFICATION

For some classification tasks, symbolic music is arguably better suited than audio or piano roll. This is particularly true for classical music feature classification, such as composer [29]. Mono-instrument music with complex melodies and harmonies and no particular audio effect benefit from being represented as discrete for classification and modeling tasks. Given this, it felt important to us to conduct experiments on such task.

We choose to experiment with the GiantMIDI [30] dataset for composer classification and the EMOPIA [31] dataset for emotion classification. The results, as shown in table 3, indicate that there is very little difference between the various tokenization methods. However, the combination of `TimeShift` and `Duration` consistently outperforms the others by one point

The classification task involves modeling the patterns from data that are characteristic to composers or emotions. Here, it seems that the time distance between notes, and their explicit duration play a role in these task, more than note offsets or onset positions. This comes with no surprise for the composer classification task, considering that the data is largely composed of complex music with dense melodies and harmonies, featuring mostly short successive notes. Intuitively, patterns of note successions and chords are more easily distinguishable with explicit durations. With implicit note durations, the overall patterns must be deduced by the combinations of `NoteOn` and `NoteOff` tokens while keeping track of the time.

6. SEQUENCE REPRESENTATION

The last task that we wished to explore is sequence representation. It consists in obtaining a fixed size embedding representation of an input sequence of tokens $p_\theta : \mathbb{V}^L \mapsto \mathbb{R}^d$. Here $\mathbb{V} \subset \mathbb{N}$ denotes the token ids of the vocabulary \mathcal{V} , L is the variable input sequence length, and d the size of embeddings. In other words, the model learns to project an input token sequence into a embedding space, thus providing a universal representation. We find this task interesting and well-suited to assess model performances as it directly trains it to model the relationships between tokens within the input sequence and between different representations themselves. While the real-world applications of this task for symbolic music are currently limited, it serves as a useful benchmarking technique for measuring how tokenization impacts the learning of models.

This task has previously been addressed in natural language processing by SentenceBERT [32] or SimCSE [33]. We adopted the approach of the latter, which uses contrastive learning to train the model to learn sequence representations, for which similar inputs have higher cosine similarities. The sequence embedding is obtained by performing a pooling operation on the output hidden states of the model. We decided to use the last hidden state of the BOS token position, as it yielded good results with SimCSE [33]⁵. We trained the models with the dropout method: during training, a batch of n sequences $\mathcal{X} = \{\mathbf{x}_i\}_{i=0}^n$ is passed twice to the model, but with different dropout masks, resulting in different output sequence embeddings $\mathcal{Z} = \{\mathbf{z}_i\}_{i=0}^N$ and $\bar{\mathcal{Z}} = \{\bar{\mathbf{z}}_i\}_{i=0}^N$. Although the dropout altered the outputs, most of the input information is still accessible to the model. Hence, we expect pairs of sequence embeddings $(\mathbf{z}_i, \bar{\mathbf{z}}_i)$ to be similar, so having a high cosine similarity. To achieve this objective, we train the model with a loss function defined by the cross-entropy for in-batch pairwise cosine similarities (sim):

$$\ell_i = -\log \frac{e^{\text{sim}(\mathbf{z}_i, \bar{\mathbf{z}}_i)/\tau}}{\sum_{j=1}^N e^{\text{sim}(\mathbf{z}_i, \bar{\mathbf{z}}_j)/\tau}} \quad (1)$$

As a result, the model will effectively learn to create similar sequence embeddings for similar inputs, while pushing apart those with dissimilarities. We kept a 0.1 dropout value to train the models, and used the GiantMIDI dataset [30].

Evaluation of sequence representation is intuitively performed by measuring the distances and similarities of pairs of similar sequences. We resort to data augmentation by shifting the pitch and velocity of the sequences in order to get pairs of similar music sequences. The augmented data keeps most of the information of the original data. As such, the models are expected to produce similar embeddings for pairs of original-augmented sequence. Ideally, the cosine similarity should be high, yet not to be equal to 1, as this would indicate that the model fails to capture the differences between the two sequences. The results, presented in fig. 3, indicate that `Position`-based tokenizations per-

⁵ SimCSE uses a `CLS` token which is equivalent to `BOS` in our case.

Figure 3: Density plots of cosine similarities between pairs of original and augmented token sequences.

form slightly better. Therefore, it appears that explicit note onset and offset positions information facilitates models to obtain a universal musical representation.

Unlike classification, the contrastive learning objective models the similarities and dissimilarities between examples in the same batch. In this context, note onset and offset positions appear to be helpful for the models to distinguish music.

We also note the contrasting results when augmenting the velocity. Increasing it by one unit, which would be equivalent to playing just a little bit louder, have arguably a very small impact. As a result, the models mostly produces embeddings that are almost identical for the original and the augmented sequences, but also exhibits uncertainty for a notable proportion of samples.

To complement these results, we estimated the isotropy of sets of sequence embeddings. Isotropy measures the uniformity of the variance of a set points in a space. More intuitively, in an isotropic space, the embeddings are evenly distributed. It has been associated with improved performances in natural language tasks [34–36], because embeddings are more equally distant proportionally to the density of their area, and are in turn more distinct and distinguishable. We choose to estimate it with the intrinsic dimension of the sets of embeddings. Intrinsic dimension is the number of dimensions required to represent a set of points. It can be estimated by several manners [37]. We choose Principal Component Analysis (PCA) [38], method of moments (MOM) [39], Two Nearest Neighbors (TwoNN) [40] and FisherS [41]. The results, reported in table 4, show that the embeddings created from the *Pos + Dur* combination tend to occupy more space across the dimension of the model, and are potentially better distributed.

7. CONCLUSION

We have discussed the importance of different aspects of symbolic music tokenization, and focused on two major ones: the time and note duration representations. We showed that different tokenization strategies can lead to

Tokenization	IPCA \uparrow	MOM \uparrow	TwoNN \uparrow	FisherS \uparrow
<i>TS + Dur</i>	213	42.6	34.3	17.5
<i>TS + NOff</i>	161	43.7	32.7	17.5
<i>Pos + Dur</i>	146	39.1	33.1	17.1
<i>Pos + NOff</i>	177	45.2	35.6	17.8

Table 4: Intrinsic dimension of sequence embeddings, as an estimation of isotropy.

different model performances due to the explicit information carried by tokens, depending on the task at hand.

Explicitly representing note duration leads to better classification accuracy as it helps the models to capture the melodies and harmonies of a music. Modeling durations, when represented implicitly, adds an extra effort to the model. However, the note offset position information it brings have been found to be more discriminative and effective in our contrastive learning experiment.

For music generation, the time representation plays a significant role, for which the note onset and offsets distributions vary due to the successions of token types. Implicit note durations are less suited for the autoregressive nature of this task, from a prediction error perspective, and sometimes "forgetting" notes being played resulting in higher durations.

We did not explore music transcription, for which we can assume that implicit note durations (note onset and offset) might be better suited. When training with chunks of log-scaled mel-spectrograms as done by [42, 43], these may contain frequencies of unended or not begun notes. Specifying their original durations might approximate onsets might alter model performances.

Future research will further explore the other dimensions of music tokenization, such as multitrack or metadata, on transcription and other tasks analogous to natural language understanding.

MUSICAL MICRO-TIMING FOR LIVE CODING

Max Johnson¹, Mark Gotham^{1,2}

¹ Department of Computer Science and Technology, University of Cambridge

² Department of Computer Science, Durham University

ABSTRACT

Micro-timing is an essential part of human music-making, yet it is absent from most computer music systems. Partly to address this gap, we present a novel system for generating music with style-specific micro-timing within the Sonic Pi live coding language. We use a probabilistic approach to control the exact timing according to patterns discovered in new analyses of existing micro-timing data (jembe drumming and Viennese waltz). This implementation also required the introduction of musical metre into Sonic Pi. The new metre and micro-timing systems are inherently flexible, and thus open to a wide range of creative possibilities including (but not limited to): creating new micro-timing profiles for additional styles; expanded definitions of metre; and the free mixing of one micro-timing style with the musical content of another. The code is freely available as a Sonic Pi plug-in and released open source at <https://github.com/MaxTheComputerer/sonicpi-metre>.

1. INTRODUCTION

1.1 Metre *Versus* Rhythm

Metre is distinct from rhythm in that it primarily concerns a kind of mental representation for processing events in musical time; a common analogy casts metre as a “grid” or “template” for categorising rhythmic events [1–3].

Although metre often involves familiar notions such as “the beat”, and definitions often emphasise intuitive ideas like regular periodicity, a clear-cut definition of metre is surprisingly hard to pin down. This is especially so when trying to capture the extremely wide range of musical-cultural contexts for which some concept of metre might be relevant. Nevertheless, notwithstanding the complexities of these terms, and putting any more specific definition of these terms to one side, it is reasonable to argue that some form of both “rhythm” and “metre” feature in almost all known musics: “rhythm” in the sense of events occurring in time, and “metre” in some form of semi-regular cycle of event expectation.

1.2 On Micro-Timing in Theory and Practice

“Micro-timing”, in turn, refers to the specific timing of both those actual rhythmic “events” and of the metrical “grid” positions. While rhythm and metre are sometimes *modelled* in terms of a completely regular underlying pulse (e.g., 1-1-1-1-) and small integer combinations thereof (e.g., 2-1-1-), it is impossible in practice for a human performer to play with the mechanical precision of identical gaps between successive events.¹ Moreover, musicians make a virtue of this. A close look at the micro-timings in human performance reveals deeply sophisticated, style-specific micro-timing strategies, a.k.a. “groove”.²

Even when distinguishing between a mental “grid” for events (metre) and the actual placement of those events (rhythm), it is appropriate to discuss micro-timing for both the rhythm and the metre. This distinction is sometimes cast in terms of a difference between “categorical” and “expressive” timing where events may be expressively altered from their expected (categorical) position [5], but note that the “categorical” position itself is also subject to micro-timing strategies because the “expected” positions are not spaced with equal, 1:1 regularity. In short, although micro-timing is sometimes described in terms of “small deviations” from simple (natural number) pulse relations, it is necessary also to consider micro-timing as part of the metre itself. To continue the “metre as grid” analogy: the gaps between grid lines are not evenly spaced.

In practice, these micro-timing durations are too short to learn in a declarative fashion (verbal or mathematical). Partly for that reason, they are also typically neglected by notation systems (including Western staff notation). Nonetheless, these micro-timing strategies clearly *are* taught and learned in the way that most music has been passed on: through listening, playing, and embodiment.

Computers enable us to achieve a level of timing regularity beyond our human capability. As ever, the technology not only extends what we can do, but invites us to consider new techniques, questions, and aesthetics. And the human’s micro-timing can of course be combined with the computer’s extreme timing precision, as when an MC raps over a beat. Computers are also used to perform the micro-timing *analysis* discussed here. However, computers are currently less exploited as a tool to help us engage in *creative uses* of micro-timing strategies.

2. RELATED WORK

A substantial research field has grown to analyse the micro-timing strategies in different musical styles. This has included work on the Viennese waltz (from Bengtsson and Gabrielsson’s landmark 1977 work to Yang’s 2022 analysis of ‘The Blue Danube’ [6, 7]), jembe music from Mali (notably through Rainer Polak’s career-long focus on this repertoire, [8–10]), and a recent surge of work on Afro-Cuban and Latin musics (see, for instance, [11, 12]).

Creating music with synthetic micro-timing has also been explored as part of the broad field of MIR, but has concentrated on attempting to model human-like expressive timing [13]. For example, Flossman et al. use probabilistic models for expressive performance rendering [14, 15]. There has been very little academic work on integrating style-specific timing analyses into computational settings. The closest examples are in the commercial sphere: Ableton Live, for instance, features “grooves” which shift MIDI events from quantised positions according to micro-timing styles, including a probabilistic element and the option to create new “grooves” from any human performances (via MIDI).

Musical live coding is a way of creating and performing music by writing and modifying code in real time. While there may or may not be pre-made materials, live manipulation of the material is a given. Given the inherent “liveness” of live coding,³ it is arguably an ideal part of the computer music pantheon to integrate human micro-timing. Yet most live coding languages lack not only micro-timing functionality, but even a full representation of musical metre, typically encoding only events in time, or at most an anaemic representation for beats and/or time signatures. For example, the commercial Max/MSP language uses its `transport` object to allow access to bar and beat numbers for the current time signature. An exception is McLean’s open-source Tidal Cycles which uses a cyclic notion of time that can be subdivided to achieve more complex hierarchies [17].

In summary, although there has been much research into the analysis of micro-timing in different musical styles, and the application of expressive timing to computer-generated music, we still lack implementations of style-specific micro-timing in most computer-music software, and even foundational notions of musical metre in most live coding environments. This project seeks to address those issues through an implementation of both metre and style-specific micro-timing for Sonic Pi: a popular live coding language and IDE designed to support a range of creative possibilities while being simple enough to use as an educational tool for use in schools [18].⁴ We aim to improve not only how “life-like” the generated music sounds in general (and thus, arguably the “liveness” of that live coding), but also to do this in a style-specific way. In this paper we report on implementation of two case studies as well as a general framework for integrating further styles.

³ This is discussed in Chapter 5 of [16], for instance.

⁴ Sonic Pi’s domain-specific language is written in Ruby and uses the SuperCollider sound synthesis server to produce sounds [19].

Figure 1: An example of how `MetreTree` and `MetreLeaf` objects are nested to construct a metrical hierarchy for $\frac{2}{4}$. The total duration d of each node is also displayed, and the duration of a parent node is the sum of the durations of its children [22, 23].

3. IMPLEMENTING METRE

This section describes the model of metre we have implemented for Sonic Pi. We argue that this is useful for a range of applications including (but not limited to) use as a basis for micro-timing as described below (§4). As discussed, metre is a very widespread phenomenon in general but specific aspects differ. We can broadly distinguish here between the specifically *hierarchical aspects* (important for some styles but not all) and the more general notion of *categorical positions* in a metrical cycle (much more widespread, and axiomatic for the kind of micro-timing systems discussed and implemented here).

3.1 Modelling Metrical Hierarchy with Trees

A favoured method for encoding metrical hierarchy in a data structure is through trees. See Forth [20] for a detailed mathematical treatment of trees used in this context and the `music21` Python library [21] for a popular implementation. Our approach shares some high-level ideas with `music21` (and indeed Forth, and others), but differs in the specific implementation.

The tree structure is implemented by the `MetreLeaf` and `MetreTree` classes. Figure 1 shows the default tree structure formed by these objects and their durations for a Western $\frac{2}{4}$ time signature. Note how the duration of a parent node is the sum of the durations of its children.

To model tree data structures of any depth with a succinct, finite representation, we follow the Western notational assumption of dividing each `MetreLeaf` into two equal parts to get the next level where not specified otherwise.⁵ Users can specify the full depth of a tree as necessary against this assumption.

3.2 The `MetreLeaf` Class

A `MetreLeaf` object is the leaf node of the metrical tree structure. It has an instance variable `fraction` which represents the duration of the `MetreLeaf` as a fraction of a whole note. For example, a leaf node with the duration of one quarter note will have the value $\frac{1}{4}$.

⁵ See [24] for discussion of this point, of metrical “well-formedness”, and the notion of “binary”, “ternary” and wider metrical structures.

The class contains a `subdivide()` method, which divides the `MetreLeaf` by two a given number of times, s . It returns a new `MetreTree` with 2^s `MetreLeaf` children, each of value $f/2^s$ where f is the fraction of the original `MetreLeaf`.

3.3 The `MetreTree` Class

A `MetreTree` object represents the hierarchical tree or subtree of a metre. The instance variable `sequence` is an ordered list representing this node's children and contains any combination of `MetreLeaf` objects and other `MetreTree` objects. For example, the hierarchy in Figure 1 could also be written in list form as:

$$\left[\left[\frac{1}{8}, \frac{1}{8} \right], \left[\frac{1}{8}, \frac{1}{8} \right] \right]$$

Each list is a `MetreTree`, and each fraction is a `MetreLeaf`. The `MetreTree` class contains several methods for manipulating and extracting information from the metrical hierarchy it represents. The two most important of these are explained in more detail below.

3.3.1 Getting Metrical Levels

Metrical level refers to the depth level of a metrical hierarchy. Here, we base our representation on the *beat level*, which is divided to get *division levels*, and grouped to get *grouping levels*.⁶ The `get_level()` method allows a user to “flatten” the tree structure to a specified depth, accessing the sequence of events at a given metrical level.

For flattening to a division level ($l > 0$) or to the beat level ($l = 0$), we perform a recursive depth-first search on the tree. For each child in the sequence list, if it is a `MetreTree`, the method is recursively called until the base case of $l = 0$ is reached. At this point, all the children of that node are combined into one `MetreLeaf` equal to the sum of their durations. If the child is instead a `MetreLeaf`, it is subdivided l times to reach the desired metrical level.

For a grouping level ($l > 0$), we find an estimate of the structure of higher metrical levels by clustering nodes together. It is an estimate because this information is not in the `MetreTree`'s representation of the metre, so is just one possibility for the higher structure. The algorithm recursively clusters nodes until the desired metrical level l is reached. The number of nodes combined in each cluster is determined by the smallest prime factor of the number of nodes at the level below. For example, if level $l + 1$ has four nodes, they will be clustered in groups of two. If it has nine nodes, they will be clustered in groups of three.

Some examples of the output of the flattened tree for the following complex hierarchy are shown in Table 1:

$$\left[\left[\frac{1}{8}, \frac{1}{8} \right], \left[\frac{1}{16}, \frac{3}{16} \right], \frac{1}{8}, \left[\frac{1}{4}, \left[\frac{5}{16}, \frac{3}{16} \right] \right] \right]$$

⁶ Centring the beat level in this way reflects the psychology of metre better than alternative “top down” and “bottom up” approaches.

l	<code>get_level(l)</code>
-2	$\left[\frac{11}{8} \right]$
-1	$\left[\frac{1}{2}, \frac{7}{8} \right]$
0	$\left[\frac{1}{4}, \frac{1}{4}, \frac{1}{8}, \frac{3}{4} \right]$
1	$\left[\frac{1}{8}, \frac{1}{8}, \frac{1}{16}, \frac{3}{16}, \frac{1}{16}, \frac{1}{16}, \frac{1}{4}, \frac{1}{2} \right]$

Table 1: Examples of the output of `get_level(l)` at different metrical levels l for an example hierarchy. Note how level $l = -1$ is formed by the clustering of level $l = 0$.

Figure 2: An example metrical hierarchy for $\frac{2}{4}$ showing those metrical events at each level which coincide with offsets x and y .

3.3.2 Getting Exact Metrical Events

We define an *offset* as a position in the metric cycle represented by the quarter length duration to have elapsed since the beginning of the cycle.⁷ The `metrical_level_indices()` method of the `MetreTree` class finds any metrical events occurring at a given offset, and returns their index.

Consider the example shown in Figure 2. Offset x occurs on the first event of all three levels, so the function would return $L_0(x) = L_1(x) = L_2(x) = 0$, where $L_l(x)$ is the index of an event at level l that offset x occurs on. Offset y occurs only on the last event of Level 1 and the second-to-last event of Level 2, so the function would return $L_1(y) = 3, L_2(y) = 6$.

This method is important because it is used later to determine the “categorical” position to link an event to and, through that, which micro-timing probability distribution to apply.

3.4 Bar Class

The `Bar` class is a representation of a single metrical cycle,⁸ and each instance of it has an associated metre. A `Bar` object is responsible for:

⁷ “Quarter length” is a semi-standard measurement for a length of time in symbolic values where the unit length is one “quarter note” duration (UK: “crotchet”).

⁸ A more precise definition would account for *hypermetre* where bars occur at the beat level [25], but the simple definition is sufficient for our purposes. Note that “bar” is the UK English equivalent of “measure” (USA).

```

play :C4      use_metre '4/4'
sleep(1)
play :E4      bar do
sleep(1)      add_note :C4, 0, 1
play :G4      add_note :E4, 0, 1
sleep(0.5)    add_note :G4, 1, 1
play :E4      add_note :E4, 1, 1
sleep(0.5)    add_note :C4, 0, 1
play :C4      end
    
```

(a) Old (above left) (b) New (above right)

(c) Western musical notation:

Figure 3: A bar of music represented by (a) the original Sonic Pi syntax, (b) our new metre commands, and (c) traditional Western music notation. Note how the original Sonic Pi syntax loses information about the metre. The second and third arguments to `add_note` are the metrical level and duration (l and d in §3.4).

- Keeping track of playback position during the cycle.
- Converting a note length given as a metrical level and a duration into a quarter length.
- Checking if a note or rest fits in the remaining time in the cycle, and updating the bar’s playback position accordingly.

A note’s length is specified by a metrical level and a duration, where the duration is in the units of an event at the specified metrical level and acts as a multiplier. For example, if a note’s length is defined as $(l, d) = (0, 3)$, its unit length is the duration of an event at level $l = 0$, and it lasts for $d = 3$ of these units.

The `add_note()` method checks if a note fits into the bar’s remaining time; if it cannot, an exception is raised. This ensures the total (“actual”) duration of the bar matches its metre’s (“nominal”) duration.

3.5 Playing Music

This framework for musical metre enabled the creation of new Sonic Pi commands. Figure 3 shows a comparison between the original Sonic Pi commands, our alternative commands, and traditional Western music notation.

There are two main commands for metre. The first is `use_metre(m)`, which changes the current thread’s metre to m (using a thread-local variable). The second is `bar do ... end`, which creates a new Bar object, stores this to a thread-local variable, then executes a block of user code.

A user can use `add_note` to play a note on the current synthesiser. This works by first getting the current Bar object from the thread-local variables and calling the Bar’s `add_note()` method to check if the note will fit in the bar. It then passes the note pitch to Sonic Pi’s `play` function which creates the sound, and finally applies `sleep` for the remaining duration of the note.

4. MICRO-TIMING

4.1 Storing Micro-Timing Information

In order to add micro-timing functionality to our implementation, we first needed a way of representing and storing the micro-timing information for different musical styles. We implement this by storing each event in the metrical cycle, the theoretical (isochronous) position of that event in the cycle (e.g., 1), and the typical displacement of the from this position (the μ of the micro-timing, e.g., +0.004). Actual event occurrence is modelled by normal probability distribution around these μ values.

Samples can then be drawn from these distributions using the Box-Muller transform [26] on uniform random samples from Sonic Pi’s random number generator. Sonic Pi’s generator produces a deterministic, repeatable sequence of pseudorandom numbers, which means the output of a Sonic Pi program sounds the same each time it is run [27].

4.2 Applying Micro-Timing

When a user sets a metre with the `use_metre` command, they can optionally specify a style as well. This causes all music played with that metre to use the micro-timing of the chosen style.

At the start of each new bar, the `Metre` object samples new values from the `Style`’s probability distributions. When a note is played inside the bar, the `add_note` command requests the timing shift that should be applied to the note from the `Metre`. To calculate this, the `Metre` object calls its `metrical_level_indices()` method to determine which timing values from each level to use. The individual timing contributions of each metrical level are summed to produce an overall timing shift for the note. A positive value means the note should be played slightly late; a negative value means slightly early. This is returned to `add_note` which then uses Sonic Pi’s `time_warp` function to adjust the timing of the call to `play`.

For example, if the sampled timings, T_l , for each level, l , are:

$$\begin{aligned}
 T_0 &= [0, 0.1] \\
 T_1 &= [0.03, 0, 0, -0.02]
 \end{aligned}$$

and the metrical level indices, L_l , for each level, l , are:

$$\begin{aligned}
 L_0 &= 1 \\
 L_1 &= 3
 \end{aligned}$$

then the timing shift, t , would be calculated by:

$$\begin{aligned}
 t &= \sum_{i \in T.keys} T_i[L_i] \\
 &= T_0[L_0] + T_1[L_1] \\
 &= 0.1 + (-0.02) \\
 &= 0.08
 \end{aligned}$$

Therefore, the note will be played 0.08 quarter lengths after the reference value.

5. CASE STUDIES

Creating music with realistic micro-timing using the implementation we have described requires a set of probability distributions which accurately characterise a style of music. Clearly this is best implemented with data derived from real-life examples of the musical style in question. This project uses two different styles of music as contrasting case studies for evaluation: jembe (or “djembe”) drum music from Mali and Viennese waltz music. These two styles both have robust, well-known micro-timing characteristics. The distributions derived here form the “preset” styles included in our Sonic Pi plugin.

5.1 Jembe Data Analysis

Jembe is a style of West African music involving a small ensemble of drummers (typically 3–4). It provides an ideal case study for our purposes because it has a highly consistent micro-timing strategy [8]. Malian drummers have been shown to exhibit some of the most consistent timing (lowest levels of variability) between performers in the world [28].

Moreover, jembe music is relatively constrained in terms of its pitch, timbre, and number of instruments. This also helps by enabling a clear focus on timing. Extensive research into the micro-timing of jembe music has included the release of high-quality datasets of processed live recordings [8–10].

The first dataset is from Jacoby et al. [10] and consists of 11 processed recordings of a piece called ‘Suku’, which is a very commonly played piece in this style. The second dataset is from the “Interpersonal Entrainment in Music Performance” (IEMP) Data Collection [29, 30]. This consists of 15 recordings across three different pieces: ‘Manjanin’, ‘Maraka’, and ‘Woloso’. Both datasets here use recordings made by Rainer Polak in Mali. The datasets supply the following information:

- Onset of the drum stroke in seconds since the start;
- Phase: beats since the start of the *current cycle*;
- Cycle (bar) number: a natural number count;
- Categorical metrical position within the cycle associated with this event (integer, 0–11).

5.1.1 Micro-Timing Estimation

The pieces of jembe music in the dataset use a metre with four beats,⁹ each of which divides into three, for a total of 12 metrical events at the first division level (similar to $\frac{12}{8}$ in Western classical notation). It is at this level, referred to as the “pulse”, that the main micro-timing occurs.

Recall that the probability distributions described in §4.1 store the displacement of each event. We calculate this from the phase given by the datasets with the following equation:

$$\text{displacement} = \frac{(\text{phase} \times \text{beat division}) - \text{metric position}}{2}$$

⁹ See Polak [8] for an ethnographically sensitive discussion of the extent to which metre applies in this context.

The phase is multiplied by the beat division (in this case, 3) to convert it into pulse units. The metric position at the pulse level is subtracted to get the displacement. The final division by 2 converts the displacement into quarter lengths (because each pulse unit is an eighth length).

For example, if an onset has metric position = 6 and phase = 2.01, the displacement would be calculated by:

$$\text{displacement} = \frac{(2.01 \times 3) - 6}{2} = 0.015 \text{ quarter lengths.}$$

Once the displacement has been calculated for each drum stroke, we were then able to estimate the distribution of displacements for each of the twelve metric locations using maximum likelihood estimation (MLE).

5.1.2 Tempo Estimation

Generating a synthetic piece of jembe music requires analysis of other musical features as well as the micro-timing to sound realistic. One of these is the *tempo*, which in jembe pieces of music typically increases substantially over the duration of the performance [10], with the last 15 seconds or so showing the tempo increasing at a much faster rate.

The *inter-beat interval* (IBI) is defined as the time between two consecutive beats in a piece of music, from which the instantaneous tempo can be calculated [31]. A moving average can be applied to the instantaneous tempo to obtain an estimate of the global tempo.

For the jembe data, we first filtered all the onsets to include just those played by Jembe 2 (because it plays on every beat as discussed in [10]), then filtered these to only consider onsets on the beats. We then calculated the inter-beat interval in bpm and applied a moving average with window size 10 to smooth the tempo estimate.

Inspection of the smoothed tempo graphs (§6.2) showed a logarithmic trend for the first ~95% of the piece. A sharper increase follows this which was modelled by a quadratic curve. To fit curves to the data, we used the `optimize.curve_fit` function from the SciPy Python library, which uses a non-linear least squares method [32]. The parameters estimated by the curve fitting are then used in Sonic Pi to control the tempo of a synthetic jembe piece during playback.

5.2 Waltz Data Analysis

The Viennese waltz is a style of fast waltz notated in $\frac{3}{4}$ (but often counted in 1), originally intended for ballroom dancing, and now often performed in concerts by Western classical orchestras.

The Viennese waltz provides a useful comparison to Malian jembe in evaluating this project’s micro-timing implementation. The fast three beats ($\frac{3}{4}$) and typical hypermetrical grouping in 2s and 4s make that *metrical structure* somewhat similar to that of jembe music, but with a very different micro-timing profile. Distinctive micro-timing can be observed on (at least) the beat level, where it has a characteristic short-long-medium pattern [6, 33].

At the time this work was carried out, the micro-timing in Viennese waltz had not been studied in as much detail or

Figure 4: A histogram plot of the positions of each pulse within the cycle for Suku. Dashed lines show the isochronous division of the cycle for reference. Black curves show the PDF of the MLE-derived probability distributions and the colours distinguish to the four beat.

as recently as jembe and there were no existing datasets of Viennese waltz performances with micro-timing. Therefore, we constructed a new dataset comprising of 30-second samples from seven waltz recordings performed by the Vienna Philharmonic Orchestra, all of which have noticeable and statistically significant micro-timing.

We then performed automatic beat tracking on this dataset using the libfmp Python library [34] (a dynamic programming approach introduced by Müller [35]), with some small manual corrections. Since the beat level is where the primary micro-timing in the Viennese waltz occurs, no additional onset detection was necessary.

Calculating the micro-timing displacement of each beat from onset times alone involves first identifying the start and end of each cycle, estimating the onset of each beat as if they were isochronous, then finding the difference between this and the actual onset to get the displacement. Once the displacements were derived, maximum likelihood estimation was again used to fit the probability distributions as discussed above for the jembe case.

6. RESULTS

6.1 Micro-Timing Estimation

Figure 4 shows the results of the micro-timing estimation for one of the jembe pieces in the datasets: “Suku”. The histograms show the positions within the cycle where the 12 pulses occurred (phase). The dashed lines indicate where the event would occur if they were isochronous: from this the existence of the micro-timing can be seen clearly by the positions of the second and third pulses in each beat. By examining the positions of the histograms, we can see that the length of each pulse follows a short-medium-long pattern (SML), which is consistent across each beat. Also shown are the probability density functions (PDF) of the maximum-likelihood estimated normal distributions. The plots/data for each beats showed the same pattern which also corresponds to other jembe pieces and matches results previously reported by Polak [8].

Figure 5 shows the results for the waltz dataset. The calculations use the first beat as the definition for the start of the cycle, so every Beat 1 has a displacement of 0. The early onset of the second beat can be clearly seen in the plot ($\mu = -0.0743$, $\sigma = 0.0795$). A one-sample t -test confirms the micro-timing as significant ($t = -16.5$, $p = 0.000$). Beat 3 shows no significant deviation from a

Figure 5: A histogram plot of the displacement of the second and third beats for the waltz dataset. Dashed lines show the metrical grid. Black curves show the PDF of the MLE-derived probability distributions.

3-part isochronous division of the cycle, so the overall pattern identified is the short-long-medium (SLM) discussed elsewhere [7].

6.2 Jembe Tempo Estimation

The results of the jembe tempo estimation showed the increase in tempo throughout the piece that is characteristic of Malian jembe music. The more dramatic speedup at the end is also reflected in this data – this is why we fit two different curves to the data. For example, in “Suku”, the tempo starts at around 135 bpm at the beginning of the piece and ends at around 175 bpm. The tempo results match those found by Jacoby et al. [36], and each jembe piece showed the same trend.

7. CONCLUSION

In this project, we have investigated and implemented probabilistic style-specific micro-timing in a musical live coding language. To do this, we extended the Sonic Pi language with implementations of both musical metre and micro-timing, and we performed data analysis on recordings of music from two case study styles to generate music with realistic micro-timing.

In further work (not reported here but available on request), we conducted a user study to assess how “realistic” our synthesised micro-timing sounded for each of the case study styles. Significant results were obtained for the Viennese waltz, however participants struggled more with the jembe, likely due to their unfamiliarity with the style. Future work could conduct a new user study with expert participants, as in Neuhoff [37].

Naturally, other future work could focus on additional styles with well-documented micro-timing, such as jazz swing rhythms [38], candombe drum ensembles from Uruguay [11, 39], and Brazilian samba music [11, 40]. Likewise, larger datasets for the styles reported here would enable more accurate distributions – two notable datasets of Viennese waltz recordings have been released even since the work reported here: Weigl et al. [41] and Yang [7].

As for software functionality, we imagine extensions including new *variable gridline* positions in DAWs, and additional controls within Sonic Pi to dynamically adjust the “*strength*” of the *micro-timing*.

8. ACKNOWLEDGEMENTS

Thanks to Rainer Polak for his invaluable advice and feedback on this project, for his years of research on jembe music, and for releasing the data that made that case study possible. Thanks indeed to all who provided feedback on this project. This research was conducted in the context of author MG's time as an Affiliated Lecturer at the Department of Computer Science and Technology, University of Cambridge. We thank Alan Blackwell and others for their role in organising and supporting this.

ABSTRACT

Optical Music Recognition (OMR) is a well-established research field focused on the task of reading musical notation from images of music scores. In the standard OMR workflow, layout analysis is a critical component for identifying relevant parts of the image, such as staff lines, text, or notes. State-of-the-art approaches to this task are based on machine learning, which entails having to label a training corpus, an error-prone, laborious, and expensive task that must be performed by experts. In this paper, we propose a novel few-shot strategy for building robust models by utilizing only partial annotations, therefore requiring minimal human effort. Specifically, we introduce a masking layer and an oversampling technique to train models using a small set of annotated patches from the training images. Our proposal enables achieving high performance even with scarce training data, as demonstrated by experiments on four benchmark datasets. The results indicate that this approach achieves performance values comparable to models trained with a fully annotated corpus, but, in this case, requiring the annotation of only between 20% and 39% of this data.

1. INTRODUCTION

Optical Music Recognition (OMR) is a research field dedicated to developing computational methods for transcribing musical notation from document images into digital formats [1]. While this task could be accomplished manually, the vast number and heterogeneity of music documents make this approach tedious, costly, and error-prone. The development of OMR systems has the potential to enhance music heritage accessibility and preservation, as well as enable the application of analysis algorithms to increase knowledge about this cultural legacy.

OMR typically follows a sequential workflow, which divides the transcription process into simpler tasks. The initial task is called Document Image Analysis (DIA), which is itself a research field that studies how to obtain

a segmented version of the image by isolating the different layers of interest, such as staves, lyrics, instructions, ornaments, etc [2]. In the literature, multiple strategies can be found to perform this *layout analysis*, ranging from heuristic approaches that exploit specific features of the images to deep learning techniques. Although heuristic approaches achieve high performance in controlled scenarios, these solutions are poorly generalizable. To obtain better and generalizable results, the current trend is to rely on machine learning and, more specifically, on neural network architectures [3].

The application of deep learning in layout analysis has been extensively studied, as evidenced by several state-of-the-art works [4, 5]. However, a major drawback of these methods is the requirement for a large amount of annotated data for their training. This is particularly problematic for the layout analysis of music scores since their high variability in appearance and styles makes necessary the annotation of each new application domain in order to train robust models. Despite the importance of this issue, it has been overlooked in the OMR literature, with domain adaptation being the only explored solution [6]. Nevertheless, this technique also requires full annotations (even if it is from a different domain) and the performance obtained is not good or robust enough, which also makes it an impractical solution.

In this work, we propose a novel few-shot strategy for building robust models for layout analysis by utilizing only partial annotations, therefore requiring minimal human effort. Specifically, we introduce a masking layer and an oversampling technique to train models using a small set of annotated patches from the training images. Our approach aims to drastically reduce the manual workload without compromising performance, making it of particular interest to real-world applications. Experiments on four benchmark datasets indicate that this approach achieves performance comparable to models trained on a fully annotated corpus—but requiring the annotation of only between 20% and 39% of this data depending on the layer—thus making it a highly efficient and effective strategy.

2. RELATED WORK

Traditional OMR workflows relied on a combination of heuristic strategies to perform pixel-wise layout analysis and classify each pixel of the image according to a set

of categories [2]. A binarization process was commonly applied to simplify the complexity of the image to detect the ink pixels, either using generic approaches [7, 8] or other particular ones proposed for the musical context [9, 10]. The recognition and isolation of the staff and the lyrics were then carried out using also heuristic techniques [11, 12]. From these detected staves, the musical symbols were finally processed, sometimes carrying out another step to remove the staff lines, as can be seen in the review by Dalitz et al. [13] or in more recent works [14–16].

More recently, all these steps were combined by means of machine learning techniques. Calvo-Zaragoza et al. [17] proposed a Convolutional Neural Network (CNN) to directly classify each pixel of the image—performing a pixel-wise layout analysis—which was later improved using a U-net-like architecture—referred to as Selectional Auto-Encoder (SAE)—to more efficiently classify the image by patches [18]. This later work, on which our proposal is based, trained a set of SAE specialized in the detection of each layer of information—staff lines, notes, text, or background.

The main challenge with layout analysis approaches that rely on supervised learning is the large amount of annotated data needed to train the models [19, 20]. This requires the annotation at the pixel level of a reference set of images, which has to be done by hand, so it is not a scalable solution given the high level of detail of these annotations and heterogeneity in music documents. In addition, when this constraint cannot be fulfilled, these learning-based architectures fail to converge to obtain a suitable model for the task at hand.

In the literature, we can find different proposals that seek to alleviate this issue [21], two of the most common being the use of regularization strategies [22] and data augmentation processes [23]. We can also find more specific proposals for cases of remarkable data scarcity, i.e., with a considerably fewer number of annotated training samples. These scenarios are known as *few-shot learning* [24] and typically employ specific neural architectures to estimate the similarity of the data [25]. Some of the most typical examples of these techniques are Siamese Neural Networks [26], Matching Networks [27], Prototypical Networks [28], and Relation Networks [29]. For a comprehensive review of these strategies, the reader is referred to the work by Jadon [30].

Our proposal follows a few-shot learning approach, but instead of using a specific few-shot architecture, a state-of-the-art layout analysis model—the previously described SAE network—is modified to integrate a masking layer that enables training with very little data. This layer is complemented by an oversampling proposal used during the training process to draw samples at random positions around the chunks with annotated data. A mask is applied to these pieces and used by the added layer to avoid processing the non-annotated parts, which will randomly appear in different positions in each iteration, thus forcing the architecture to generalize the learned weights.

In the related literature, masks have been used for different purposes. For example, Medhat et al. [31] proposed the use of binary masks for sound classification to filter out certain frequency bands. It has also been explored for image classification, specifically, Suresh et al. [32] studied the use of masks as a pre-processing task to filter the background of images with hand gestures, making the model focus only on the gestures to be classified. However, as far as we know, masks have not been used either in binarization tasks or for few-shot learning cases, so that the model does not use the unlabeled areas.

3. METHODOLOGY

Our approach aims to build a robust few-shot learning model for layout analysis of music score images that classifies each pixel of an input image into one of the following categories: *staff*, *notes*, *text*, and *background*. In our context, the few-shot scenario can be represented as a manual annotation of a limited number n of portions or patches from a set of images \mathcal{I} , with $n \ll N$, where N is the total number of possible patches that could be sequentially extracted without overlapping from \mathcal{I} . Therefore, when n is small, less human effort and cost are required to annotate the training set.

Note that labeling only part of the image makes the rest of it uninformative, even if there are ink pixels. In a typical training process, only the annotated patches would be used. However, when the amount of data is limited, this would lead to overfitting of the model. Although data augmentation may help mitigate this problem, in a few-shot learning scenario, it is not very useful due to the little information to be altered.

Our proposal introduces a novel approach to extract a larger—and more varied—number of samples from the scarce labeled information. Specifically, it is proposed to extract random patches around the annotated areas—keeping a minimum $\lambda\%$ of labeled information—to obtain more varied samples, thus generating variations in the position of the elements and their labeling. Since some parts of the extracted patches will fall outside the annotated area, it is proposed to mark those parts with a special label (-1) so that they are not used during training. This approach allows us to control the number of samples to be drawn from the images and get enough variability in the data to train the model, as we will demonstrate in the experiments.

Formally, let $\mathcal{X} \in \mathbb{R}^{w \times h}$ be a collection of patches of size $w \times h$ drawn from the input set of images \mathcal{I} , and $\mathcal{Y} \in \{0, 1\}^{w \times h}$ be the corresponding pixel-level annotation matrices extracted from the annotation set \mathcal{L}^l for the layer to be processed $l \in \{\text{staff}, \text{notes}, \text{text}, \text{background}\}$, where 1 is used to label the ink of that layer and 0 the rest, either background or information from another layer. Additionally, let $\mathcal{S} = \{(x_i, y_i) : x_i \in \mathcal{X}, y_i \in \mathcal{Y}\}_{i=1}^{|\mathcal{S}|}$ represent an annotated collection of data where each datum x_i is related to label y_i by an underlying function $f^l : \mathcal{X} \rightarrow \mathcal{Y}$, that represents the objective function to be learned for each layer l , and for which the SAE state-of-the-art architecture will

be used. Note also that x^* will be used to refer to the input patches after applying the mask, which may contain values in the range $[0, 255]$, for the original pixels of the image, but also the value -1 as a mask to mark the parts without annotated information. This mask is therefore applied to the input data in \mathcal{X} and will be used by the masking layer (described below) added to the networks f^l to ignore those parts during the training process.

Algorithm 1 describes the oversampling method proposed to obtain the set \mathcal{S} previously described. This method receives as input the set of images \mathcal{I} , the set with the annotated data \mathcal{L} , the layer l to be processed, the $\lambda\%$ of minimum patch information, the total *size* of sampling to perform, and the set \mathcal{M} that contains the list of patches annotated with their coordinates in the input images. The algorithm first iterates through the number of patches annotated in \mathcal{M} (line 3) and for each one obtains the index j of the image it corresponds to (line 4). It then iterates for the number of samples that have to be extracted for that annotated patch (line 5) and, for each one, performs the following steps: 1) randomly selects the sample coordinates p using the mask of that patch and taking into account the minimum $\lambda\%$ of annotated pixels allowed (line 6); 2) extracts the patch x from \mathcal{I}_j using the coordinates p (line 7); 3) applies the mask to set a constant value (-1) in those pixels that are not part of the annotated area (line 8); 4) retrieves the layout annotations y for that sample (line 9); and 5) both x^* and y are added to the set \mathcal{S} . The algorithm repeats this process until reaching the requested *size*, finally returning the set \mathcal{S} obtained.

Algorithm 1 Random masking patches generator.

```

1: function SAMPLEGENERATION( $\mathcal{I}, \mathcal{L}, \mathcal{M}, l, \lambda, size$ )
2:    $\mathcal{S} \leftarrow \emptyset$ 
3:   for  $i \leftarrow 1$  to  $|\mathcal{M}^l|$  do
4:      $j \leftarrow \text{getPatchIndex}(\mathcal{M}_i^l)$ 
5:     for  $k \leftarrow 1$  to  $\frac{size}{|\mathcal{M}^l|}$  do
6:        $p \leftarrow \text{getRandomPosition}(\mathcal{M}_i^l, \lambda)$ 
7:        $x \leftarrow \text{getWindow}(\mathcal{I}_j, p)$ 
8:        $x^* \leftarrow \text{applyMask}(x, \mathcal{M}_i^l, p)$ 
9:        $y \leftarrow \text{getWindow}(\mathcal{L}_j^l, p)$ 
10:       $\mathcal{S} \leftarrow \mathcal{S} \cup (x^*, y)$ 
11:    end for
12:  end for
13:  return  $\mathcal{S}$ 
14: end function

```

Note that the `getWindow(\cdot)` function may apply additional data augmentation to the sample in order to further increase its variability.

This oversampling process is complemented by the proposal of a masking layer that is added to the network architecture f^l to ignore the pixels that are not annotated. This layer, as indicated in Section 2, has been previously used in other proposals to skip time steps in sequence processes and to mask the background in classification tasks. In this proposal, we adapt it to ignore the parts of the input with this mask and also propagate the mask to the following

layers so that the non-annotated parts are not taken into account during the training process. Intuitively, the masking layer acts as a regularizer and data augmentation process. Given that the annotated and non-annotated parts will vary in position and size across iterations, the network is forced to generalize the weights learned during training by having to use different connections of the network and non-annotated pixels will not be used.

4. EXPERIMENTAL SETUP

This section describes the corpora and metrics considered for evaluation and the implementation details of the neural architecture.¹

4.1 Corpora

For the experiments, we considered the following 4 datasets with manual pixel-wise annotations of 4 layers of information (*staff*, *notes*, *text*, and *background*). Figure 1 shows some examples for each manuscript and Table 1 includes a summary with their details.

- **EIN**: 9 high-resolution scanned pages of neumatic notation belonging to the Einsiedeln, Stiftsbibliothek, Codex 611(89), from 1314.²
- **SAL**: A set of 10 high-resolution images of pages from the Salzinnes Antiphonal manuscript (CDM-Hsmu M2149.14), in neumatic notation. It is available in the *Cantus Ultimus* platform.³
- **MS73**: Selection of 10 pages of square music notation from the miscellaneous choir book ‘*Dominican, CDN-Mlr MS Medieval 0073*’ from Northern Italy, written between 13th and 15th centuries. This corpus is stored in the McGill Library collection, and it is online available through *Cantus Ultimus*.⁴
- **CAP**: A compilation of mensural notation manuscripts from the 17-18th centuries belonging to the ‘Cathedral of Our Lady of the Pillar’ in Zaragoza (Spain), introduced for OMR purposes by Calvo-Zaragoza et al. [33]. We use a subset of the corpus, with 10 manually pixel-wise annotated pages.

In all the cases, we used 4 images for training, 2 images for validation, and the remaining for testing. After preliminary experiments and also based on previous proposals, we selected a patch size of 256×256 pixels to extract from these images. To be fair and more realistic, we use the same number of samples for the validation set as for the training partition. This is because, in a real case, it would be necessary to annotate the validation partition as well, so it is not fair to use the entire pages to validate the models in a few-shot scenario. This does not apply to the test set, for which we use all available data.

Figure 1: Examples of images extracted from the corpora described in Table 1. In the ground truth images: red pixels represent the staff lines annotation, black is used for music symbols, blue for text, and white for the background.

Corpus	# imgs	Resol.	Layers (%)			
			BG	St	No	Te
EIN	9	6496 × 4872	87.9	3.5	2.7	5.9
SAL	10	5847 × 3818	87.6	2.4	2.5	7.5
MS73	10	6990 × 4797	93.4	1.8	1.8	3.0
CAP	10	2126 × 3065	85.7	6.6	5.1	2.6

Table 1: Details of the corpora considered including the number of images (# imgs), the average resolution and the proportion of pixels for each layer of interest, with **BG** for background, **St** for staff lines, **No** for notes, and **Te** for text.

4.2 Metrics

To evaluate the performance of our few-shot approach, we resorted to the F-score (F_1) figure of merit to avoid possible biases toward any particular class given the inherent label imbalance in the datasets considered (see Table 1). Assuming a binary classification scenario, this metric is defined as

$$F_1 = \frac{2 \cdot TP}{2 \cdot TP + FP + FN}, \quad (1)$$

where TP, FP, and FN denote the True Positives, False Positives, and False Negatives, respectively.

Finally, given the non-binary nature of the task at hand, we considered the use of the macro-averaged F-score (F_1^m) as the average of the F_1 values computed for each layer. Mathematically, this metric is defined as

$$F_1^m = \frac{\sum_{l=1}^{|\mathcal{L}|} F_1^l}{|\mathcal{L}|}, \quad (2)$$

where F_1^l is the F_1 calculated for the layer l assuming a one-versus-all evaluation framework and $|\mathcal{L}|$ represents the total number of layers of information (in our case 4).

4.3 Implementation details

The architecture considered is based on a previous work [18], in which a framework consisting of a series of SAE models—one for each layer to be predicted—was proposed. SAE follows a U-net architecture, in which an image of size $w \times h$ (in our case a 256×256 pixels patch) is given as input, and the output is a matrix of the same size that contains the confidence value of pixels belonging to the layer of interest. In our case, we have four layers to be predicted, so we will have four SAE models, each one specialized in one particular layer.

For the experimentation, we resort to the same architecture proposed in the original work. An encoder with four blocks composed of a convolutional layer of 32 filters of 3×3 , a sub-sampling of 2×2 , a batch normalization, a Rectified Linear Unit (ReLU) activation, and a dropout of 0.4. On the decoder side, the blocks follow the same scheme except for the sub-sampling, which is replaced by an oversampling of the same rate. The last layer of the decoder is connected to a convolution with one 3×3 filter and a sigmoid activation to obtain the result of the prediction with values between 0 and 1. This architecture was only changed to add the masking layer after the input.

Note that each SAE was trained using the binary cross-entropy loss for up to 200 epochs with a batch size of 16, and an early stopping criterion of 20 epochs of no improvement on the validation set. Adam optimizer [34] was used with a learning rate of 0.001.

Furthermore, to favor the convergence of the model, the input images were normalized in the range $[0, 1]$. The mask was applied over this result, so the inputs can actually contain the values $\{-1\} \cup [0, 1]$. For the extraction of patches, a value of λ of 2.5% was used, since it allowed obtaining chunks with sufficient information. In addition, we also considered standard data augmentation to increase data variability by applying random rotations between -45° and 45° , zoom variations between 0.8x and 1.2x, and horizontal and vertical flips.

5. RESULTS

This section presents and discusses the results obtained with the proposed method.

First, a preliminary experiment was carried out to analyze the influence of the amount of oversampling. For this, starting from a single annotated patch, we studied the result obtained by increasing the number of randomly extracted samples around the annotated patch using the proposed technique. Fig. 2 shows the average results of this experiment in the validation set for all layers and considering both the application and non-application of data augmentation. For a small number of randomly extracted samples, the proposal achieves approximately 30% of F_1^m . The average result is improved as the number of samples extracted increases, reaching over 70% of F_1^m for 512 samples and barely improving for the case of 1 024 samples. Additional data augmentation does not help to improve the results, only for cases of sample size equal to or less than 128. This may be because the proposed oversampling method can be considered as a data augmentation process, so that, from a given amount of sampling, there is enough variability and other techniques of data augmentation may not be necessary.

Figure 2: Preliminary experiment to study the influence of the number of samples drawn randomly from one annotated patch of 256×256 pixels. The result obtained in terms of F_1^m (%) in the validation partition is shown, considering both the application and the non-application of additional data augmentation.

Based on these results, the sampling size is set to 512 for the following experiments. Also, since standard data augmentation seems detrimental in combination with our proposal, we decided not to use it.

The selected configuration was evaluated using the test set, carrying out an analysis of the influence of the number of patches annotated (from 1 to 32) and the influence of these being extracted from the same page or from several (up to 4, which would generate more variability). Fig. 3 shows these results compared to two baselines: an upper one representing the state-of-the-art model [18] trained with all available information (if the entire training set was annotated) and a lower bound training this model with only one annotated patch (in both cases without applying the proposed masking layer). One initial observation is that the three case studies (with 1, 2, or 4 pages) demonstrate comparable trends. The results, as expected, show an increasing trend with the number of annotated samples, from an

average F_1^m of 40% when training with one annotated sample to $\sim 62\%$ when using 32 annotated patches, and stabilizing (or improving less) from 16 to 32 annotated patches.

If these results are compared with the baselines, it can be seen how the proposal exceeds the lower bound by 16% when training with one annotated sample and that it equals or even improves the upper baseline in the cases with 1 and 2 pages from 16 annotated samples. Also, it is only 7% worse than the state of the art for the 4-page case but with a much lower annotated data requirement (32 samples, which represents 39% of the total information).

Layer	Annotated samples						Baseline

Table 2: Average results in terms of F_1 (%) for each layer considering 1 page in a few-shot evaluation. The percentage of annotated information is indicated between parentheses. **Bt** represents the bottom baseline, which is the state-of-the-art model trained with 1 annotated sample per page, and **Up** is the upper baseline, with full pages used for training. Both baselines do not apply any masking.

From these results, we now analyze in detail the case of a single page, since it represents the most extreme case as it has less variability available for the annotation. Table 2 shows a summary of the results obtained individually for each dataset and layer considered, including the baselines and the percentage of the image used in each case. As in the previous results, it is observed that the performance of our approach improves as more annotated samples are used. In this case, we can analyze how the results vary according to the layer and the corpus evaluated. In general, the proposal improves the bottom baseline, in some cases, such as *staff*, *notes*, and *text*, by a wide margin. However, note that this baseline fails to converge on most layers, except for the *background* one. In this case, on average, the proposal only improves the baseline by using 32 samples—39% of the image. This is due to the fact that for fewer annotated samples, poor overall results are obtained for the MS73 dataset. This may be because this dataset presents a greater variability of backgrounds. In

Figure 3: Average results in terms of F_1^m (%) with respect to the number of annotated samples (from 1 to 32) and the number of pages (from 1 to 4). Dashed lines represent baseline results for reference. The upper reference line indicates the results of the state-of-the-art model trained with fully annotated pages, while the lower reference line represents the results obtained when only one sample is annotated. Note that both baselines do not use the proposed masking method.

Figure 4: Example of the results obtained in SAL for the four layers considered in this work. The method was trained with 32 samples drawn from one page. White represents the detected information for the particular layer.

fact, the rest of the layers of that corpus also obtain low-performance values when the annotated data is scarce.

Regarding the upper baseline, it can be seen how the proposal, on average, improves it in all layers, although it requires a different number of labeled samples depending on the layer. As stated before, on average, from 16 patches or 20% labeling, a better result is achieved. It is interesting that for the simplest and more homogeneous layers (such as staff and background), the upper baseline obtains a better result and it is more difficult for the proposal to overcome it, while for the more difficult ones that present greater variability (notes and text), the baseline obtains a worse result while the proposal achieves a greater margin of improvement. This may be due to the fact that the proposal performs some overfitting in the simplest cases with less variability and, therefore, requires a greater number of labeled samples to learn it.

To complement the quantitative results, Fig. 4 shows an example of prediction for SAL. As can be seen, the background and the staff layers are correctly retrieved, and some false positives can be found in the notes layer. The text layer seems the most challenging as it is not able to differentiate the ink of the text from other elements. However, the text is recovered, and the false positives could be removed by combining the predictions obtained for the other layers.

6. CONCLUSIONS

In this work, we presented a few-shot neural approach for pixel-wise layout analysis of music score images. The proposal includes a masking layer, which acts as a regular-

izer, that is combined with an oversampling technique to leverage the limited annotated information available. The oversampling technique extracts annotated parts of the images at different random positions at each training iteration, leaving annotated and non-annotated information in different positions of the input. This strategy forces the neural architecture to generalize the learned weights, similar to a data augmentation process but adapted to the case of few-shot and partial annotation in documents.

The proposal is evaluated on four benchmark datasets to study the influence of the amount of annotated data in the layout analysis task. We found that the number of annotated samples is key to optimizing performance, and annotating a relatively small number of them—between 16 and 32 samples, which represents using only between 20% and 39% of the total information—can achieve average results of 65.5% of F_1^m , which is very close to the result obtained by the state of the art (72%) using the entire training set annotated. It is also interesting to note that the proposal obtains similar results when labeling more pages, so it is enough to have a single page for training and perform a partial annotation of between 16 and 32 patches.

In general, the approach shows very competitive results in few-shot scenarios. Therefore, we hope this research can open doors to new avenues in this line. Reducing the amount of annotated data required for pixel-wise layout analysis is essential, and techniques such as domain adaptation and transfer learning may help to reduce human effort. We plan to investigate new ways to address this problem, including to combine domain adaptation techniques with our masking proposal and studying the feasibility of incremental and active learning.

ABSTRACT

Drummers spend extensive time practicing rudiments to develop technique, speed, coordination, and phrasing. These rudiments are often practiced on "silent" practice pads using only the hands. Additionally, many percussive instruments across cultures are played exclusively with the hands. Building on these concepts and inspired by Einstein's probably apocryphal quote, "Make everything as simple as possible, but not simpler," we hypothesize that a dual-voice reduction could serve as a natural and meaningful compressed representation of multi-voiced drum patterns. This representation would retain more information than its corresponding monotonic representation while maintaining relative simplicity for tasks such as rhythm analysis and generation. To validate this potential representation, we investigate whether experienced drummers can consistently represent and reproduce the rhythmic essence of a given drum pattern using only their two hands. We present TapTamDrum: a novel dataset of repeated dualizations from four experienced drummers, along with preliminary analysis and tools for further exploration of the data.

1. INTRODUCTION

1.1 Motivation

Music is a fundamental aspect of human culture, and rhythm is a central element of musical expression. Many different cultures have developed complex and sophisticated rhythmic traditions that are deeply rooted in their history, language, and social structures [1]. Representing music, and more specifically rhythm, in a symbolic form is crucial for a wide range of purposes, including communication, and preservation of musical traditions. Moreover, symbolic representations of music are essential for enabling the efficient processing and manipulation of musical data by computers, enabling new possibilities for music analysis and creation. However, representing complex rhythmic patterns in a notation system that accurately captures their essence and feeling can be a challenging task,

particularly when the rhythms are highly complex or involve multiple layers of interlocking patterns.

Some attempts on representing percussion in a domain specific-way have been made, initially focusing on a single stream of onsets [2]. In [3], Toussaint offers a holistic analysis of rhythmic patterns, with an approach largely centred around monotonic representations. Representing a rhythmic pattern in a monotonic stream of offsets has indeed proven to be successful for some tasks like transforming a sequence of taps to a fully-orchestrated percussive pattern in GrooVAE [4]. However, while a rhythmic pattern reduced to a monotonic stream of its onsets retains part of its horizontal structure related to temporality, it also loses its vertical quality, which is related to the interplay between different voices [3]. As a result, a monotonic pattern transformation fails to capture the complete essence of a multi-voice rhythm, as noticed by Lartillot and Bruford [5]. Inspired by Einstein's probably apocryphal quote, "Make everything as simple as possible, but not simpler," in this work we hypothesize that a dual-voice reduction could serve as a more natural and meaningful compressed representation of multi-voiced drum patterns than its monotonic equivalent, and that this representation could preserve some quality related to the interaction or tension between instruments, while maintaining relative simplicity for tasks such as rhythm analysis and generation.

The rationale behind this approach can also be related to the role of the human motor system in rhythm perception. The importance of the motor system in rhythm creation and perception is rooted in the fact that many musical rhythms are based on movements that involve two limbs. It was previously documented that the synchronisation of movement to a musical pulse happens automatically, whether of the hand movements [6, 7], walking [8], or dancing [9]. A number of studies prove that motor areas of the brain play a significant role in beat perception and synchronisation. As Patel and Iversen argue in [10], the ability to coordinate two limbs in a synchronised and precise manner is essential for playing musical instruments and dancing to music. This is exemplified by the tradition of drumming, which typically involves striking a drum with two hands. The renowned drummer Jaki Liebezeit, even simplified his drum kit to only require two hands to play, and developed a rhythmic notation system called E-T that employs only two symbols to represent any rhythm, accommodating any musical situation [11]. Thus, the use of two limbs in music and rhythm is not only a fundamental aspect of motor

coordination, but also a practical consideration in the representation and communication of musical rhythms.

A bell pattern is a two-voiced pattern frequently used in West African music, which is usually used as a key pattern to suggest a temporal organisation for different instruments and musicians [12]. This pattern is used from the Sub-Sahara, to West Africa, to the central lands of Congo and the Nyusa lands in Southeast Africa [13]. Agawu [14] claims that the notoriously complex rhythms in West African music can be represented with a bell pattern, which could usually be played with two-voiced percussion instruments. This African tradition migrated to the new world during the colonial period. Rooted in the Caribbeans, the Clave cross-rhythm also splits the beat into two voices, one regular beat and another irregular [15].

Additionally, subjective rhythmization is a widely recognized phenomenon in auditory perception [16], which occurs when individuals are exposed to monotonous auditory stimuli such as the ticking of a clock. Rather than hearing a simple "tick-tick-tick" pattern, our brains transform the sound into a more complex rhythmic sequence, such as "tick-tock-tick-tock," comprising two distinct parts. This naturally occurring cognitive process enhances the subjective perception of rhythm and makes the stimulus more engaging and dynamic to the listener. The concept of rhythm streams, which is linked to the theory of auditory streaming, is examined by Witek et al. [17]. Their research reveals that the addition of a single instrumental component to a monotonic rhythmic pattern can greatly influence its perceived rhythm, whereas the addition of another component to a two-instrument pattern has a discernible impact only in certain instrumentation contexts. Finally, Lartillot and Bruford [5] argue that any rhythm can be reduced to an oscillation between two states: high and low. Their rule-based system transforms multi-voice patterns into a monotonic stream of timed events representing the toggles between the states and their accentuations.

All the aforementioned evidences provide support for the initial hypothesis that simplified, dual-voice representations of multi-voice rhythmic patterns may be adequate in communicating both the vertical and horizontal characteristics of rhythm.

1.2 Rhythm Pattern Dualization

To formalize this idea, we introduce the novel concept of dualization of rhythm patterns. The task of rhythm dualization could be defined as the transformation of any multi-voice rhythmic pattern to another pattern composed of a maximum of two voices, while preserving the coherence and the perceptual essence of the original rhythm as much as possible. Dualization involves simplifying and highlighting the most essential features of complex rhythmic patterns. This dualized representation can be viewed as a form of abstraction, in which the most essential features of a rhythm are distilled and represented in a way that is easier to process, grasp, and perform.

Dualization could also enhance the creative and expressive potential of contemporary musicians, by provid-

ing them with a tool for exploring and adapting traditional rhythmic patterns in new and innovative ways. Moreover, the study of dualization can shed light on the cognitive and neural mechanisms involved in rhythm perception and performance, as well as the cultural and historical factors that shape rhythmic traditions. By introducing this novel concept, we hope to stimulate further research and innovation in the field of rhythm notation, and to advance our understanding of the cognitive, cultural, and creative processes involved in rhythmic expression.

In the next section, we present the dualization experiments we have conducted with the participation of four highly skilled professional drummers to validate our hypothesis. We introduce the dataset that emerged from these experiments, which serves as a valuable resource for our analysis. In Section 3, we delve into a detailed analysis of this dataset, shedding light on key findings and insights. Subsequently, in Section 4, we highlight potential applications and promising avenues for future research.

2. METHODOLOGY

While monotonic representations of multi-voiced rhythms can be obtained by simply flattening any rhythmic pattern, the process of dualizing a multi-voiced rhythm appears to be less straightforward. To further support our hypothesis that dualized patterns can serve as a natural and more meaningful compressed representation of multi-voiced drum patterns compared to their monotonic counterparts, we aimed to investigate whether there is a level of consensus or consistency in how multi-voiced patterns can be dualized. To this end, we recruited 4 professional drummers and conducted various dualization exercises, exploring different approaches and gathering insights into the process of dualization.

2.1 Preparation of Rhythmic Material

To ensure a diverse range of rhythms for dualization, we utilized Magenta's Groove MIDI Dataset [4]. This dataset comprises of 13.6 hours of live recordings performed on a Roland TD-11 electronic drum kit, each labeled with beat type (i.e. "beat" or "fill"), time signature, and style. The recordings are not quantized (neither in time nor velocity) and vary in duration and styles. For our work, we focused on the "beat" subset of the dataset resulting in 503 original recordings. In this subset, only twelve performances were not in 4/4 meter, and subsequently, we dismissed them. Table 1 summarizes the distributions of styles within the final selected samples.

	Rock	Funk	Latin	Jazz	Hip-hop	Other
Count	124	42	41	34	25	79
Percentage	36%	12%	12%	10%	7%	23%

Table 1. Style distributions within the 345 2-bar samples selected from GMD

The original GMD recordings vary from several seconds to a few minutes. As a result, for each session we

selected a single 2-bar segment with the highest total cosine similarity with every other 2-bar segments within the session (similarity was calculated between fully quantized patterns). This approach ensured that we had a diverse and representative set of 2-bar rhythms from different sessions and styles for our dualization experiments. These representative segments were further processed to exclude patterns that contained only 2 or less voices (which would have made the dualization task trivial). This left us with a final set of 345 individual meaningful and non-trivial 2-bar loops, suitable for our dualization experiments.

2.2 Data Collection Sessions

We hired 4 drummers with expertise in Western drumming tradition, two of them with conservatory experience, as shown in Table 2. Each drummer participated in several individual sessions of approximately one hour each. The experiments consisted of playing 2-bar multi-voice drum loops to the participants and asking them to concurrently perform dualized versions using only drum sticks on a Roland HandSonic HPD-15 MIDI drum pad. Participants were instructed to only hit the left region of the drum pad with the left hand and vice-versa.

	P1	P2	P3	P4
Age	41	20	24	22
Experience (Years)	25	11	10	9
Dominant Hand	Left	Left	Right	Right

Table 2. Demographics of the participants

For each of the data collection sessions, an Ableton Live¹ project was prepared in advance, containing the drum patterns to be dualized at their original tempo, without any velocity or timing quantization. As shown in Figure 1, the sessions were set up such that the participant would listen to a looping 2-bar pattern and after 1 or 2 repetitions would start to concurrently play their dualized interpretations of the pattern. The participants were allowed to continue their dualizations for as many repetitions as desired until they were confident in the accuracy of the dualization. All the drum patterns in all of the sessions were synthesized using a single sound source.² No auditory feedback of dualizations were provided to the participants except for the acoustic sound of the drum pad.

Figure 1. Set up of the dataset collection sessions

2.3 Post Session Questionnaire and Interviews

After the first recording session, each participant was given a questionnaire and an open interview was also conducted.

¹ www.ableton.com

² Neutral preset of Addictive Drums 2’s Fairfax sound pack

The questionnaire comprised of three sections: (1) general information about the participant, (2) assessment of the intuitiveness of the task and confidence in their performance, and (3) exploration of how various rhythmic factors and metrics (e.g., number of instruments, tempo, genre, density, syncopation, mostly extracted from [18, 19]) could potentially influence the dualization process. Parts 2 and 3 of the questionnaire utilized a 7-point Likert scale ranging from 0 to 6. Results from these two parts are summarized in Table 3.

	P1	P2	P3	P4	Avg.
General Impressions					
Intuitiveness	4	5	6	5	5
Confidence	6	3	4	4	4.25
Influence of Rhythmic Features*

LMH Dynamics	6	4	3	4	4.25
LMH Density	3	4	4	6	4.25

Table 3. Summary of the questionnaires.

* refers to the perceived importance that different rhythmic features have on the dualizations. LMH refers to the Low, Mid and High frequency regions. Descriptors taken from [18, 19].

Additionally, after the questionnaire, open interviews were conducted with each participant. In the following sections, we provide a summary with some of the more relevant an recurrent topics discussed.

2.3.1 Meaningfulness, Replicability and Universality

All four participants unanimously agreed that the concept of dualization is valid and meaningful. Despite one of them admitting to not having thought much about it before, they all found the concept intuitive and useful after the session. Despite that the patterns in the introductory sessions were randomly repeated without notifying the participants, they were able to notice the duplication of the same 2-bar tracks in the session, and they strongly believed that even though their corresponding dualized patterns might not be identical, they would likely share a high similarity. While the results were not entirely conclusive (as discussed in the next section), all participants also expressed confidence in having similar mindsets as their peers while dualizing the same rhythm. Participant 1 justified this idea by referencing the development of the Western percussive tradition from the snare drum, stating that fundamentally, drummers listen to key elements represented by the snare.

2.3.2 The Effects of Style and Repetition

One participant stated that genre greatly influences which voices to focus on; for example, in the case of rock, the snare and the bass drum would more often be followed,

whereas in jazz-influenced styles, the hi-hat and the ride cymbal could probably be included in the reduction, as they emphasise lay back and swing. However, not all participants agreed on interpreting dualization solely as the replication of the two most prominent voices. Some believed that they needed to first digest and understand each rhythm, before extracting its essential form for dualization. Two participants also mentioned that listening to the same pattern repeatedly in the experiment promoted a "dualization refinement", listening more deeply to each iteration and thus refining the extraction of the pattern's rhythmic essence.

2.3.3 Problems with the Recording Sessions

Participants reported some issues during the recording sessions, such as using always the same VSTI for all patterns, independently of their musical style. Also, the use of Roland HPD-15, which has a single surface with multiple pads, seems to encourage some drummer habits such as paradiddles, and some participants would have preferred a separated two-pad device. Some tracks were inadequately selected for a 4/4 based recording as Participant 1 interpreted them as a 6/8 time signature, even though GrooveMIDI labelled them as in 4/4. For some swing and shuffled rhythms sometimes the last semiquaver was cut. Participants were also aware of the style bias and of the abundance of Western influenced styles specifically rooted from a snare drum tradition.

3. DATASET AND ANALYSIS

In this section, we will start with providing an overview of the dataset. Subsequently, we will provide a preliminary analysis of the collected dualizations. The objective of this analysis is to establish whether there is any validity to the hypothesis that professional drummers are able to dualize drum patterns with some level of consistency, so as to establish whether further research on this topic is warranted.

During the dataset collection sessions, we had a limited time span during which all four participants were available. For the initial session, we had access to all four participants. This session was set up in a manner that would allow us to investigate two main questions: (1) whether a single drummer dualizes a given pattern consistently at different times (Intra Participant consistency) and (2) how consistently different drummers dualize the same drum pattern (Inter Participant consistency). As such, we selected 24 drum patterns to be presented randomly three times to each of the four drummers without notifying them about the repetitions (Subset A1). During the first stage of the data collection sessions, Participant 1 was able to participate longer, as a result, 48 more drum patterns were dualized by him in the same manner (Subset A2).

During the A2 sessions, Participant 1 notified us that he was aware that we were testing a single drum pattern multiple times. Following this comment, he told us that, if needed, he can dualize the drum patterns in two different ways, in his own terms, in a "simple" and a "complex" manner. Inspired by this comment, we confirmed with the

other participants about this view of dualization. Subsequently, we modified the remaining sessions so as to explore whether there is any consistencies among the "simple" and "complex" dualizations. We were able to partially conduct these sessions with Participants 1 and 2 (Subset B1), while the remaining sessions were only conducted with Participant 1. Table 4 summarizes the collected data.

The final dataset consists of 1116 dualizations obtained from the participants. These dualizations were obtained from the set of 345 unique drum patterns. Moreover, each of the drum patterns were used in a single dualization test, that is, for example, a drum pattern used in Subset A1 was not reused in the A2, B1 and B2 subsets. The decision to not reuse the drum patterns in different subsets was made to maximize the number of drum patterns for which at least one set of dualizations were available in the final dataset.

In Section 3.1, we will use the collected dataset to provide a preliminary analysis on whether there are any intra/inter participant consistencies between the dualizations obtained at random from all four participants (Subset A1) - see Figure 2. Lastly, in Section 3.2, we will compare simple dualizations with their complex counterparts from both intra- and inter-participant perspectives. The analysis presented in this section has been done on a binary representation of the dualizations, fully quantized to a 16th note grid. Moreover, it should be noted that, as confirmed with the participants, a given dualization can be reproduced using an inverse hand combination. As such, to compare the rhythmic similarity between the dualizations, a hand-agnostic measure should be employed (e.g. *LOROLL* and *ROLORR* patterns should be treated as identical - *L* and *R* refer to *Left* and *Right* hand hits at a 16th note time step and 0 refers to silence).

Figure 2. Inter-/Intra- pairs. For each drum pattern, intra-pairs are selected from each of the participants. Inter-pairs are selected by pairing a participant's repetition with all other repetitions corresponding to the same test.

To this end, we focused our analysis on the flattened versions of the dualizations, that is, the left and right hand patterns were superimposed onto a single sequence (e.g. *101011*). While this approach does not explore the function of each of the dualized streams, we believe that it is valid as a preliminary investigation, because if the flattened patterns show no rhythmic consistency, further analysis on the function of each hand may not be warranted. In other words, the validity of our hypothesis is contingent upon the presence of rhythmic consistency in the dualized patterns, and further analysis may be needed to determine the functional aspects of each hand in the dualizations.

Subset		Tested Drum Patterns	Repetitions Per Test				Total Dualizations
			P1	P2	P3	P4	
Three Repetitions (A)	Multi-Participant (A1)	24	3	3	3	3	288 (24×3 × 4)
	Single Participant (A2)	48	3	-	-	-	144 (48×3 × 1)
Simple vs Complex (B)	Multi-Participant (B1)	69	2	2	-	-	276 (69×2 × 2)
	Single Participant (B2)	204	2	-	-	-	408 (204×2 × 1)
Total		345	762	210	72	72	1116

Table 4. Summary of the collected dataset

3.1 Three Repetitions (A1 Session, Participants 1-4)

In Subset A1, we presented 24 drum patterns³ to each of the four participants three times in a random order, resulting in a total of 288 obtained dualizations. We first examine the consistency of each participant’s dualizations over the three repetitions (intra-participant analysis), and then we investigate the consistency of each of dualizations with their counterparts⁴ from other participants (inter-participant analysis). To establish the similarity between two given patterns, we used the Jaccard similarity measure, defined as the ratio of the overlap of two sequences divided by the union. Moreover, to establish the perceptual similarity of the dualizations, we used Edit Distance [20, 21], defined as the minimum number of operations (insertions, deletions, or substitutions) required to transform one sequence into another. Figures 3 and 4 summarize the results of inter/intra-participant analysis using a pair-wise comparison. In both cases, in order to establish a baseline comparison, we also calculate the Edit and Jaccard values for the same number of pairs randomly selected (each random pair comes from dualizations obtained from two randomly selected participants and are ensured not to be associated with the same drum pattern).

Figure 3. Intra-Participant Analysis of Subset A1

The results of the intra-participant distributions (Figure 3) show that the Edit distances are smaller for any of the four participants’ repetitions compared to the distance between randomly paired dualizations. Similarly, the Jaccard similarities are also higher than the random pairs.

Unlike the intra-participant distributions, the edit distances for inter-participant dualizations have some overlap with the random pairs. This overlap is also observed in the Jaccard similarity values. However, despite this overlap, the inter-participant distributions still show a trend towards higher similarity values compared to the random pairs. The lower consistency between inter-participant dualizations, compared to the intra-participant dualizations may be an indicator that experienced drummers have a consistent du-

alized interpretation of rhythms, however, these interpretations vary to some extent compared to other drummers. While this is a possibility, we believe more comprehensive analysis is required prior to making this conclusion as there are a number of limitations to the approach taken in this paper.

The current state of our analysis imposes several restrictions and simplifications that limit the depth of our study of the dataset. Firstly, it is constrained to the flattened versions of the dualizations. Secondly, it dismisses (quantizes) the velocity and micro-timing information, which are important factors in drumming that can affect nuances and groove. Experienced drummers often utilize velocity and micro-timing to add expressiveness to their playing, potentially leading to differences in the perceived rhythm. Therefore, a comprehensive investigation of the dualizations should incorporate these dimensions for a more nuanced understanding.

3.2 Simple/Complex (B Sessions, Participant 1)

As mentioned previously, Participant 1 pointed in the open interview that a dualization can be done in different manners: simple and complex. For further exploring this idea, in a second phase of the dataset collection sessions, two participants were asked to first dualize a drum pattern in a simple manner, and also immediately after, re-dualize the same pattern in a more complex manner. These sessions were partially conducted with Participants 1 and 2 (session B1), and more tests were done using Participant 1 (session B2). For the sake of brevity, we focus the analysis of this subset on Participant 1 (a total of 273 paired simple and complex dualizations).

Figure 5 shows that a major distinction between the simple and complex dualizations of Participant 1 is that the simple versions are considerably less active than their complex counterparts. One interesting observation is that the activity level of the dualizations obtained from Participant 1 during the first session (A1) (in which this simple/complex distinction had not been introduced) are more on par with the complex dualizations. This observation

Figure 5. Step Densities. Left two distributions correspond to the 273 simple and complex dualizations obtained from P1 in sessions B1 and B2; remaining four correspond to 72 dualizations per each participant in A1

along with the step density distributions for Participants 2-4 raises a question that perhaps, unless restricted, the drummers default to more active dualizations. This tendency may be explainable from two perspectives: (1) in most styles, the hands are generally highly active as they are responsible for playing the majority of the drum kit, and (2) the dualizations may be by default more biased towards the rudiments that many drummers strenuously practice using their hands.

To further analyze the simple and complex dualizations, we calculated the edit distance and Jaccard distance between each pair of dualizations (see Figure 6). Similar to section 3.1, to establish a baseline comparison, we used an equal number of uncorrelated simple and complex pairs from Participant 1 dualizations. The results here show that, while lower in general, the distribution of the edit distances between the simple and complex pairs are partially overlapping. Moreover, this distribution is higher than the intra repetition distribution in Subset A1. These trends are also evident in the Jaccard similarity distributions. These differences relative to the intra distances in subset A1 are fully expected knowing that the dualizations are intentionally varied in this experiment.

Figure 6. Distributions of distances/similarities between all of the Participants simple dualizations and their corresponding complex dualizations

4. APPLICATIONS AND FUTURE WORK

The majority of our work has been focused on data collection and curation, as well as preparing tools to allow the community to easily explore and study the data. All the collected data have been carefully processed and organized for both A and B subsets. Moreover, we have prepared an accompanying website that enables researchers to listen to all paired repetitions while also visualizing the piano rolls. Lastly, we have also developed an open-source API that allows for easy access to the data, visualization, synthesis,

and analysis using both pre-implemented and third-party tools of interest. All these resources are publicly available at <https://taptamdrum.github.io>.⁵

We envision that the dataset can be used in a variety of studies. Rhythm reduction studies could use it to examine the simplification of multi-voiced patterns into dual-voiced ones. The dataset can also be used to develop computational models for drum pattern reduction. These models would be highly valuable as they allow for easier study of polyphonic drum patterns. Moreover, knowing that the dualizations of a single participant for a given drum pattern are highly correlated (i.e. they are perceptual interpretations of the same pattern), researchers can validate whether the features extracted from the dualizations are also highly correlated. This would provide a way to evaluate the effectiveness of rhythm feature extraction algorithms and potentially improve them. Similarly, to establish the perceptual relevance of rhythmic distance/similarity measures, researchers can use the simple/complex subset of the dataset to ensure that the proposed measures result in reasonable distances that correlate with the perceptual re-interpretations of a given pattern.

Lastly, the dataset can also be used for drum generation tasks. For instance, a generative model could be developed so as to convert a dual sequence into a full drum pattern (similar to single voice rhythm into multi-voice drum generators [4, 22]). Such generative models can be used in many creative ways as during the inference stage, each of the left/right streams fed into the drum generator can be extracted from separate instruments/sources. Moreover, the random repetitions and the simple/complex repetitions can be used in developing deep metric learning models that rely on paired training samples.

5. CONCLUSIONS

In this work, we presented TapTamDrum, a novel dataset consisting of 1116 dualizations of drum patterns performed by four experienced drummers, covering 345 unique drum patterns selected from Magenta’s GrooveMIDI dataset. The analysis conducted in section 3.1 provides valuable insights into the dataset. Firstly, it shows that there are intra-participant consistencies in the dualizations. That said, the inter-participant analysis are less definitive and require further detailed investigation. Moreover, the simple/complex comparisons (section 3.2) show that the complex dualizations are significantly more active than the simple ones while adhering to some level of rhythmic consistency with their simple counterparts. The analysis conducted in this work was preliminary and limited and has not explored the full potential of the dataset. The main focus of this work was to collect, curate, organize the dataset and also provide resources for prompt exploration of the data. To this end, we have prepared an accompanying website and an open-source API. Finally, this dataset can be used in a variety of rhythm related studies ranging from perception to generation.

ABSTRACT

Real-time music information retrieval (RT-MIR) has much potential to augment the capabilities of traditional acoustic instruments. We develop RT-MIR techniques aimed at augmenting percussive fingerstyle, which blends acoustic guitar playing with guitar body percussion. We formulate several design objectives for RT-MIR systems for augmented instrument performance: (i) causal constraint, (ii) perceptually negligible action-to-sound latency, (iii) control intimacy support, (iv) synthesis control support. We present and evaluate real-time guitar body percussion recognition and embedding learning techniques based on convolutional neural networks (CNNs) and CNNs jointly trained with variational autoencoders (VAEs). We introduce a taxonomy of guitar body percussion based on hand part and location. We follow a cross-dataset evaluation approach by collecting three datasets labelled according to the taxonomy. The embedding quality of the models is assessed using KL-Divergence across distributions corresponding to different taxonomic classes. Results indicate that the networks are strong classifiers especially in a simplified 2-class recognition task, and the VAEs yield improved class separation compared to CNNs as evidenced by increased KL-Divergence across distributions. We argue that the VAE embedding quality could support control intimacy and rich interaction when the latent space’s parameters are used to control an external synthesis engine. Further design challenges around generalisation to different datasets have been identified.

1. INTRODUCTION

There is increasing interest in deep neural networks for processing audio in real time with sufficiently low latency to be used in musical performance. There is also a drive to provide small self-contained platforms that could perform inference *at the edge*, that is, on a device that can be fitted in a musical interface or a musical instrument [1–3]. Many of the tasks in Music Information Retrieval, such as onset

detection [4], playing technique classification [5], timbre transfer [6], re-synthesis of musical information [7] and generative composition [8], find an application in the design of Digital Musical Instruments (DMI) and augmented instruments, as long as the solutions conform to real-time requirements. For Real-Time MIR (RT-MIR), two physical constraints that limit the application of Deep Neural Network (DNN) models are *causality*, implying the inability to look into the future, and *low action-to-sound latency* [9]. Acceptable action-to-sound latency in music performance was found to be 10 ms [10] for percussion instruments, and the latency’s *jitter* (the variation) was also found to be a factor in the quality of the interaction [11]. Although there are ways to work around higher latencies, for example by synthesising generic attacks before a specific sound is generated [12], the ideal approach would be to develop a system fulfilling the latency constraints in the first place.

In this work, we investigate RT-MIR for the processing and mapping of guitar body hit sounds to augment the timbral palette of the instrument in percussive fingerstyle. Percussive fingerstyle is an extended guitar technique that uses layered arrangements, alternate tunings and hits on the guitar’s body to create the impression of a “one-man band” [13]. Our method relies on deep learning to develop recognition and embedding learning of guitar body percussion. Our model addresses the task of generating representations of body hits according to performers’ percussive gestures, separating them by hand part and location. One possible application is to map such a description as parameters for a synthesis engine, such as real-time physics-based synthesis. We adapted an Automatic Drum Transcription (ADT) model based on a Convolutional Neural Network (CNN) to fit the practical constraints of an augmented instrument for percussion. Our longer-term aim is to design a network that not only works as a classifier, but also describes guitar body hits with a set of features unique for each sample, to support control intimacy [14] and try to achieve the same level of nuance afforded by acoustic instruments. To this end, we propose a variation of our model that jointly trains a classifier and a Variational Autoencoder (VAE) [15].

2. BACKGROUND

Percussion DMIs. In opposition to the direct control offered by acoustic percussion, digital percussion instru-

Barthet, “Real-Time Percussive Technique Recognition and Embedding Learning for the Acoustic Guitar”, in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

ments have historically afforded indirect control of discrete events [16], with hit dynamics often being the only expressive parameter over individual hits. Jathal [17] provides a detailed description of commercial digital percussion instruments, emphasising the fact that they force the player to adapt their technique to the tool, usually a set of buttons or a zone-based sample trigger. The author also advocates for the design of interfaces that interpret the technique that performers of a particular acoustic instrument have already mastered: traditional techniques will be the first sensorimotor reference that expert players will use for the exploration of DMIs [18], and they have been used in the past as the basis for controllers to navigate synthesiser spaces [19].

Hit classification. One approach is to take data from audio transducers or other sensors for on-the-fly event detection and classification, and the use of that data to trigger the generation of a sound associated to that category. Examples are Turchet *et al.*'s Smart Cajón [20], Jathal's HandSolo [17] and Zamborlin *et al.*'s Mogeos [21]. This approach is well supported by music tools and software for machine learning in music such as `bonk~` for Max/PD [22], `timbreID's barkSpec~` and the `Wekinator` [23]. This has also been applied to the acoustic guitar through the work of Lähdeoja [24] and Stefani *et al.* [3, 25], the latter applying fully-connected DNN layers for multi-class classification of guitar techniques, including percussive ones. No direct attempts have been made to use machine learning to achieve a description beyond classification, especially one that would support Moore's *control intimacy* [14].

Automatic Drum Transcription in MIR. A task related to guitar percussion classification in MIR is Automatic Drum Transcription, the audio-based detection and inference of score notations for percussive parts. Current literature does not only address the Western drum kit, but also other percussion instruments such as the tabla [26]. A recent review [27] reports that, in the current state of the art in ADT, solutions either use non-negative matrix factorisation (NMF) or look into the relationships between hits and tackle the problem with a language model or a recurrent neural network. The most relevant system for our application is based on a CNN that jointly performs event detection and classification for ADT using a sliding buffer of 150 ms [28] and was trained on the MIREX17 drums dataset [29]. Mattur Ananthanarayana (MA) *et al.* fine-tuned the model on a dataset of tabla strokes, noting a resemblance between Kick Drum, Snare Drum and Hi-Hat sounds and the tabla strokes themselves [30].

Real-time DNNs for music performance. Our purpose is not the direct re-synthesis of guitar body hits, but rather the control of the parameters of a synthesis engine. However, we are inspired by the introduction of neural networks as tools for music performance, through solutions such as Neural Audio Synthesis and Neural or Differentiable Digital Signal Processing (DDSP). Bottlenecks and latent spaces have been used with VAEs [31, 32] and autoencoder-like structures [33] for re-synthesis of sounds

Tool	Latency
<code>bonk~</code> (Puckette [22])	6 ms
Stefani <i>et al.</i> [3]	20 ms
RAVE (Caillon <i>et al.</i> [34])	DAW-defined
Mogeos (Zamborlin [21])	23 ms
HandSolo (Jathal [17])	17 ms
Tabla stroke classifier (MA <i>et al.</i> [30])	150 ms

Table 1: Reported buffer values for detection and inference for some of the works and studies cited in this section.

and timbre transfer, with successful real-time implementations such as RAVE [34] and DDX7 [7]. NN-based solutions have also been applied to model linear [35] and non-linear audio systems, such as guitar amplifiers [36] and stomp-box overdrives [37, 38]. Solutions exist to load an arbitrary neural DSP network into a plugin to be run in a DAW, such as the Neutone VST host by Qosmo¹ and IRCAM's `nn~`² Max/PD external.

Latency. The impact of latency and jitter in music performance systems was investigated, for example, by McPherson *et al.* [11]. Table 1 reports the measurements published by the authors cited so far on the latency of their tools, specifically the duration of analysis and inference rather than audio input-to-output latency, which is system-dependent more than algorithm-dependent. Most tools that are meant for real-time use achieve latencies in the region of 20 ms, which exceeds Wessel and Wright's 10 ms ceiling for musical instruments [10].

Challenges in rich representation. Gesture classification toolkits like `bonk~` have been deployed in many music-making interfaces, including guitars [24], but they were shown to make percussive guitar performers uneasy owing to the chance of misclassification for ambiguous or unexpected inputs [39]. Standard classifiers also do not represent subtle variability within gestural categories, leading to a small gestural *bottleneck* [18]. Related studies in Human-Computer Interaction (HCI) also promote the design of DMIs sensitive to the *micro-scale* of musical actions, the scale of differences across gestures of the same category [40]; authors have suggested that rich and controllable behaviour could be as important as high classification accuracy for creative applications [41]. Dimensionality reduction of input representations through VAEs, as performed for example by RAVE, could help investigate these rich dimensions.

3. METHODOLOGY

3.1 From taxonomy to datasets

This work builds upon our two prior studies on the investigation of the technique of percussive fingerstyle [13] and the design of a prototype augmented guitar to optimally capture those techniques [39]. Those observations firstly

4-class	Heel - H, Thumb - T, Fingers - F, Nails - N	None	<i>TablaCNN</i> , <i>PercCNN</i> , <i>PercVAE</i>
4-class + 5-class (Hierarchical)	Heel - H, Thumb - T, Fingers - F, Nails - N	Soundhole, Upper Bout, Lower Bout, Upper Side, Lower Side	<i>TablaCNN</i> , <i>PercCNN</i>

Table 3: Output layers mapped to guitar body percussion taxonomy.

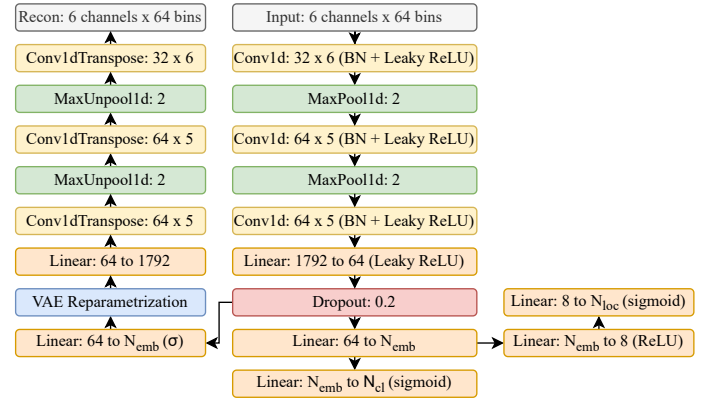

led to the creation of a *taxonomy of guitar body percussion*, inspired by the work by Goddard on the taxonomy of bass playing techniques [42]:

$$\left\{ \begin{array}{l} \text{hit} \\ \text{scrape} \end{array} \right\} \text{ the guitar with } \left\{ \begin{array}{l} \text{heel} \\ \text{thumb} \\ \text{fingers} \\ \text{nails} \end{array} \right\} \text{ at the } \left\{ \begin{array}{l} \text{soundhole} \\ \text{upper bout} \\ \text{lower bout} \\ \text{upper side} \\ \text{lower side} \end{array} \right\}$$

This was used to create the labelled dataset *GPercRep* by producing 50 examples (one hit per second) of each combination of taxonomy attributes, excluding those that are ergonomically impossible, e.g. reaching the lower sides of the body with the heel of the hand. This leads to an imbalanced but ecologically valid dataset [43]. Each combination was repeated at four dynamics levels (*p*, *mp*, *mf*, *f*). All recordings were made by the first author on the guitar built for [39], which has a six-channel output made out of one magnetic pickup and five piezo sensors on each of the locations (soundhole, etc..., see taxonomy above). The guitar had 12-53 gauge strings in standard tuning, muted with the left hand, and the hits were played with the bare right hand. After excluding scrapes from the analysis, as they require a time-based gesture follower, the dataset has 3,157 examples extracted from 52 minutes and 37 seconds of audio at 44.1 kHz. The dataset is currently not public.

3.2 Network architectures

The baseline model for our experiments is an adaptation of the tabla transcription model proposed in MA *et al.* [30]. This network processes three stacked spectrograms with different time/frequency resolutions on a window of 150

Figure 1: Architecture of *PercCNN*. The extra layers for location classification are on the right-hand side, the decoder of *PercVAE* on the left. $N_{emb} = 2$, $N_{loc} = 5$, $N_{cl} = 2$ or 4.

ms. Each frame of the spectrogram has an 80-bin Mel representation of a window.

To adapt this network to real-time requirements we constrained the input window to be 512 samples, or 11.6 ms. Our adaptation (*TablaCNN*) receives one window of six single Mel-frequency spectra, one for each pickup of the prototype. A further modification (*PercCNN*) processes down-sampled FFT features through three one-dimensional convolutional layers and a bottleneck layer of two dimensions before the output (Figure 1). To perform dimensionality reduction jointly with classification, we implemented reparametrization from the bottleneck layer and a decoder mirroring the encoding CNN (*PercVAE*).

3.3 Output classes

The labels according to the guitar body taxonomy were simplified to: (i) a 2-class scenario with “kicks” (heel hits, in reference to kick drum sounds that heel hits are supposed to imitate) and “non-kicks”; a 4-class output implementing all hand parts; (ii) 4-class hand part plus another 5-class output trained on hit location on the body (hierarchical output). The hierarchical output was not implemented on the VAE. This gave us a total of eight network configurations. Tables 2 and 3 illustrate differences between network architectures, and the mappings between the taxonomy in Section 3.1 and the output layers.

Loss functions used were Binary Cross-Entropy for 2-way classification, Cross-Entropy for 4-way classification, and a sum of two equally weighted Cross-Entropies for hierarchical classification (hand part and location). The VAE used the following loss function, where $\gamma = 0.001$ and $\beta = 3$ after hyperparameter search, and BCE replaced by Cross-Entropy in the four-class model:

$$L_{VAE} = BCE + \gamma(MSE_{Recon} + \beta KLD)$$

3.4 Training, data augmentation, cross-validation

All networks were trained on the *GPercRep* dataset with hold-out cross-validation: a stratified 20% of the shuffled dataset was reserved for testing, whereas the remainder of

	<i>GPercRep</i>					<i>GPercHeel</i>	<i>GPercPat</i>		
	K	NK	F	N	W/Avg	Recall	K	NK	W/Avg

PercCNN - Hierarchical	95.73	82.05	87.60	94.18	90.12	69.55	0.00	85.14	63.10

Table 4: F-Measure (as percent) for each network on the three test datasets (hold-out of *GPercRep*, *GPercHeel* and *GPercPat*). **H** = heel, **K** = kick, **T** = thumb, **NK** = non-kick, **F** = fingers, **N** = nails, **W/Avg** = weighted average.

the examples was used for training (80%) and validation (20%). All networks were trained with an Adam optimiser for 100 epochs with a batch size of 128, saving the model with the highest accuracy on the test set. We trained with the following data augmentation functions: high-pass at 80 Hz, high-pass at 160 Hz, *tanh()* waveshaping distortion with gain of 5, phase inversion and random changes in gain between the six channels of each example. Those functions are meant to represent the different input impedances and different gains of other audio preamplifiers.

Further to the *GPercRep* dataset, generalisation was checked by performing cross-dataset evaluation [44]. We recorded a snippet of real-world guitar percussion patterns (*GPercPat*); musically coherent patterns, still with no tonal sounds, were played, rather than hits repeated every second. Acquisition was done with a different audio interface, which led to a different combination of gains and frequency responses across channels in the input audio. The dataset was annotated only with a “kick” and “non-kick” label, leading to 85 hits in one minute of audio.

Testing on the *GPercPat* dataset highlighted a bias in our networks against heel hits or “kicks”. An explanation was thought to be the lack of balance across classes in the dataset, however the issue was not mitigated by balancing the dataset, ensuring the same number of examples for each category. To gather further information about this phenomenon, we created a third dataset consisting exclusively of 601 heel hits, acquired and labelled with the same taxonomy as *GPercRep*: this will be called *GPercHeel*.

3.5 Evaluation metrics

The classification performance of the networks was evaluated with Precision, Recall and F-measure for each category, as a 2-class or 4-class problem (see Table 3).

We also wanted to quantitatively investigate the quality of the network’s embeddings. Thus, we made subsets of the data in *GPercRep* according to each label the network was trained on (kick VS non-kick or hand part), and for each category, we drew distributions for each of the other parts in *GPercRep*’s taxonomy: for example, we divided non-kicks according to their location or their dynamics. Then we calculated the KL-divergences between

the probability distributions of each sub-category. The hypothesis behind this method is that, if the embeddings do not carry any meaningful information beyond the classes that the network was trained on, the distributions will overlap and their KL-divergences will be small and noisy. If, on the other hand, different hit properties lead to different positions in the embeddings, KL-divergences will be different across sub-categories and the sub-categories will be arranged following a certain order of similarity.

Reconstruction metrics for the VAE were not evaluated beyond their inclusion in the loss function. Future work could focus on the correlation between better reconstruction and better separation of each feature.

4. EVALUATION

4.1 Classification

Table 4 contains the F-Measure for the predictions of each network, with the three test datasets. In the case of *GPercHeel*, only the Recall is reported; the Precision is always 1, as all hits are heel hits and there cannot be false positives (non-heel hits classified as heel hits).

2-Class discrimination. All networks are able to precisely discriminate between kicks and non-kicks with an F-measure above 99%. The *GPercHeel* dataset shows much reduced but still effective classification, especially with *PercCNN*. However, the test on *GPercPat* exposes a generalisation problem: despite performing data augmentation during training, all networks show a bias toward non-kicks. *PercCNN* and *PercVAE* return only non-kicks in the dataset, despite the two classes being visually separable when data points are extracted and plotted from their embeddings (not pictured). This result may suggest that the networks still overfit to the extent that they are very sensitive to the way that the data is acquired.

4-class discrimination. Uniformly across the tests, the networks yield an F-measure around 90% for *GPercRep*. The introduction of the classification by location (in the two *Hierarchical* networks) does not affect the score of the hand-part classifier. *GPercHeel* yields a similar Recall score, although higher in the case of *TablaCNN* networks. Interestingly, the weakest model in *GPercRep*, the 4-class

Figure 2: Embeddings from *GPercRep*: example with finger hits labelled by dynamics, with matrix of KL divergence across the distributions of each dynamic level.

PercCNN, ends up being the best model in *GPercPat*, although an F-measure of 74% for kick hits may still not be satisfactory in musical performance. *PercVAE* shows better performance than *PercCNN*, although it still fails to generalise to *GPercPat* and defaults to flagging all events as non-kicks.

The F-Measures in our results are higher on average than the ones found in MA *et al.*'s work on tabla hit transcription [30]. At the same time, our results fall below the 95% accuracy achieved by Stefani [45] with an 8-class discriminator on guitar techniques, and the 97% by Jathal [17] on the three-way discriminator for tabletop drumming. These results, however, are not directly comparable as the figures refer to different datasets.

4.2 Computation times and latency

	Avg	Std Dev
PercCNN	0.496	0.332
TablaCNN	0.422	0.496
PercCNN in Max	12.675	1.132
System (PercCNN)	22.310	0.670
System (no NN)	9.922	0.020

Table 5: Computation times in μ s of both networks measured through TorchScript in a C++ wrapper, then end-to-end within Max and with an external analogue excitation.

Our models all require a fixed 11.6 ms input buffer to populate the input window after an event is detected, for example through a time-based attack detector [46].

TorchScript was used to wrap the two-class (*PercCNN* and *TablaCNN*) into a C++ test routine and a Max/MSP external for a synthetic soak test and real-world latency tests on a laptop with an Intel i7-8665U CPU running Windows (Table 5).

PercCNN and *TablaCNN* have comparable latencies in the synthetic test. They both execute in less than half a millisecond on average when called 10,000 times. The real-world latency measured manually within Max/MSP (over 30 examples) reports a value that is consistent with the 11.6 ms window plus the synthetic timing reported above, with the attack detection not introducing much further latency or jitter. The low-power laptop used requires an audio buffer size of 256 samples to comfortably run **PercCNN** in real time alongside a suitable synthesis engine: the total system latency jumps to 22 ms when probing with a Bela³ board attached to the laptop's sound card (averaged over 500 examples). Input and output buffers can be greatly reduced on ad-hoc hardware or software.

4.3 Embeddings

As introduced in Section 3.5, the distribution of subclasses of the taxonomy within each class was explored in the embeddings of each network. In addition to a visual and qualitative inspection of the distribution through scatter plots, KL-Divergence is used here as a similarity metric to measure the distance between distributions. In the following analysis, we will take finger hits divided according to dynamics as an example, but our observations are valid for all other hand parts, and versus hit location (e.g. heel hits

³<https://bela.io>

divided by body location).

Classifier embedding. When *PercCNN* is only trained as a classifier, the four dynamic points overlap in the embeddings (Figure 2a). KL-Divergences range between $2 \cdot 10^{-5}$ and 0.2, so this range of numbers will be used as a baseline for the interpretation of further results. *PercCNNHierarch*, trained to discriminate according to hand part and location, shows very precise segmentation of hit locations but no meaningful segmentation by dynamics (not pictured⁴).

Embedding with PCA. *TablaCNN*'s embeddings are not a bottleneck within the network itself, but they are calculated through PCA on the 128-dimensional dense layer. Principal Component Analysis is shown to disentangle some of the other features in the dataset, as the dynamics subclasses are distributed along a right-to-left gradient (Figure 2b). The KL-Divergence across those distributions reaches a maximum of 20.1.

Embedding/VAE latent space. *PercVAE* shows a similar but more pronounced subdivision in the 2-dimensional latent space. The right-to-left gradient is visible but the KL-Divergence is much greater at a maximum of 43.2. The KL-Divergence values steadily increase from *p* to *f*, more evidently than in the embeddings extracted via PCA. This was noticeable also when hits were segmented by location (not pictured): for example, Lower Side had a KL-Divergence of 30.8 versus Upper Side, 31.7 vs Lower Bout, 38.7 vs Upper Bout, and 40.7 vs Soundhole.

5. DISCUSSION

The evaluation shows that all our models act as very accurate 2-class classifiers. Even though classification accuracy is not as high as in other situations (with different datasets), the simplicity of our models and the 11.6 ms input buffer makes them faster than those systems, and well suited for implementation on an edge device.

Challenges. The main issue arising from our evaluation is the poor generalisation to our *GPercPat* dataset. Still, we have anecdotal evidence that these networks do not behave like poor classifiers in the real-world context of musical performance with our augmented guitar prototype, the HITar⁵. The 2-class *PercCNN* was coupled with a time-domain hit detector and made to run in real time; its continuous output probability was mapped to a linear interpolation of parameters on the modal synthesis engine MetaSynth by CNRS-AMU PRISM [47]; the signal chain was connected to a different guitar (same make and model) to the one the network was trained with; the network is able to reliably adapt synthesis parameters even when used by players other than the main author. There is scope to expand the training and the evaluation by involving more guitars, more players and different data augmentation techniques. However, the augmented guitar that we built allows

us to pursue a further type of *behavioural* evaluation with guitar players. In particular, musicians performing in real time may adapt their gestures until they reliably produce a desired set of outcomes, something not possible with pre-recorded data. A study on the performance of guitar players with different network configurations running on the augmented guitar prototype will help investigate the degree to which the musicians can adapt to the expectation of the network; such a study would continue our work in [39].

Support for rich interaction. We observed that *PercVAE* is able to encode differences in hit dynamics and location within the embeddings without being trained to discriminate between them; rather than separating them with decision boundaries like *PercCNNHierarch*, each subcategory overlaps neighbouring subcategories, providing a smooth transition that could map well to continuous quantities such as dynamics or location on a surface. The use of a bottleneck layer is also a more efficient solution than PCA, as performing PCA would require extra matrix computation that was not captured in the timings measured at Section 4.2. The parameters of a synthesis engine such as MetaSynth could be controlled not just by the categorical output of the discriminator, but also by the latent representation of the VAE, either directly or through a transform. A mapping function could be designed between the embeddings and synthesis parameters, or the embedding vectors could be exposed directly to synthesisers as MIDI Polyphonic Expression (MPE) [48] controls.

6. CONCLUSIONS

We presented three adaptations of Automatic Drum Transcription for guitar body percussion classification and embedding learning, to support real-time music performance and the augmentation of an acoustic guitar through Deep Neural Networks. We chose and simplified a model for ADT that was shown to be effective in the detection of tabla strokes; a variant was also proposed which supports high-level continuous feature representation through the use of embeddings jointly trained as a Variational Autoencoder's latent space. All network configurations were trained on a dataset of percussive fingerstyle hits acquired *ad hoc*, and they were tested on a hold-out portion of that dataset plus two other datasets of similar material. The networks performed very well on a simplified 2-class discrimination, and comparably to the state of the art on the full 4-class stroke classification with smaller latency. However, they generalise poorly on a dataset that was recorded with different computer equipment. The embeddings were analysed both qualitatively and quantitatively through KL-Divergence between subclasses in the taxonomy; they show that the network encodes some information beyond the categories with which it was trained. We argue that this information can be used to support richness in musical interaction with digital and augmented instruments based on DNN analysis.

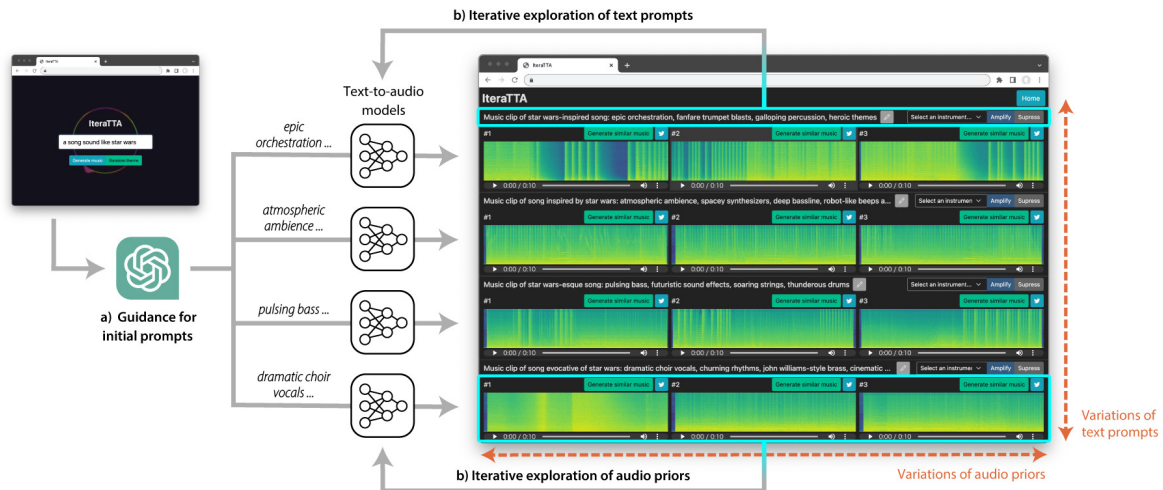

Figure 1. IteraTTA is an interface dedicated for allowing novice users to show their creativity in text-to-audio music generation processes. It provides a) computational guidance for constructing initial prompts and b) dual-sided iterative exploration of text prompts and audio priors.

ABSTRACT

Recent text-to-audio generation techniques have the potential to allow novice users to freely generate music audio. Even if they do not have musical knowledge, such as about chord progressions and instruments, users can try various text prompts to generate audio. However, compared to the image domain, gaining a clear understanding of the space of possible music audios is difficult because users cannot listen to the variations of the generated audios simultaneously. We therefore facilitate users in exploring not only text prompts but also audio priors that constrain the text-to-audio music generation process. This dual-sided exploration enables users to discern the impact of different text prompts and audio priors on the generation results through iterative comparison of them. Our developed interface, IteraTTA, is specifically designed to aid users in refining text prompts and selecting favorable audio priors from the generated audios. With this, users can progressively reach

their loosely-specified goals while understanding and exploring the space of possible results. Our implementation and discussions highlight design considerations that are specifically required for text-to-audio models and how interaction techniques can contribute to their effectiveness.

1. INTRODUCTION

Recent advances in generative machine learning techniques open up novel ways for a diverse group of individuals to engage in creative processes [1, 2]. Specifically, music generation models can foster creative expression among novice users, who may not necessarily possess formal musical knowledge [3, 4]. Consequently, several approaches have been proposed to enable users to control various musical attributes of generated audios, such as specifying the note or rhythm density [5, 6] and chord progression [7–9]. Text-to-audio models [10, 11] are promising in terms of allowing users who are not familiar with the concepts of such musical attributes to generate their own sounds.

Nevertheless, there are still several gaps toward deploying such models to support the creativity of novice users. For example, the models rely on annotated labels of music clips presented in their training datasets [12–14], which primarily consist of musical descriptions such as genres, instruments, and moods. Therefore, providing such infor-

Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

mation as a text prompt is crucial for enabling fine-grained control over generated music audios. However, this may prove challenging for novice users due to disparities in artistic vocabulary among individuals with varying levels of musical knowledge [15]. Experimentally, it has been suggested that non-musicians tend to rely more on abstract concepts, such as the pleasantness or complexity of music, when appreciating musical pieces [16], which may pose difficulties in fully exploring various text prompts.

Moreover, understanding the space of possible results is also challenging, particularly when compared to the use of text-to-image models. In text-to-image generation, users can look over various generation results at a glance, which fosters their understanding of the space and helps them decide on directions to explore [17]. From the perspective of explainable AI (XAI), we can say that such results serve as *explanations by example* [18] because the results implicitly invite the users to infer the behavior of the models. However, in text-to-audio generation, users cannot simultaneously listen to multiple generation results, thus impeding their comprehension and ability to efficiently explore the space. These points imply that specific design considerations are necessary to fully leverage the potential of text-to-audio models and exploring them would also provide a new perspective in terms of XAI.

In this paper, we introduce IteraTTA, an interface dedicated to the text-to-audio (TTA) music generation processes of novice users. This interface enables iterative exploration of both text prompts and audio priors, allowing users to gain a comprehensive understanding of the space of possible results by sufficiently constraining the generation processes. We constructed this interface based on our observations and related literature on creativity support, which emphasize the importance of 1) computational guidance for constructing initial prompts and 2) dual-sided iterative exploration of text prompts and audio priors. Moreover, we deployed the interface as a publicly-available Web service and analyzed the diverse ways in which users utilized it in their creative processes. Our results and discussions shed light on ways to utilize models developed in the MIR community to unleash the creativity not only of expert users [19] but also of individuals with varying degrees of musical knowledge.

2. RELATED WORK

2.1 Music Generation Techniques

Music generation has been one of the central topics with the MIR community [20–24], and recently, generative machine learning techniques have been widely employed for this purpose [24, 25]. While methods for symbolic music generation that output MIDI files have been popular [26–32], some methods use generative models to directly output audio, leveraging their expressiveness [33–36]. For example, Jukebox [33] and RAVE [34] use variational autoencoders and autoregressive models trained on large-scale music datasets to generate diverse music audios.

Controllability in music generation has been also em-

phasized [5–9, 37–39] because it is vital to open up its applications for supporting users’ creative processes [40, 41]. For instance, Music FaderNets [5] allows users to modify the rhythm and note densities of generation results, while Music SketchNet [6] enables them to specify pitch contours and rhythm patterns. Wang *et al.* [7] and Dai *et al.* [8] have proposed methods to further constrain the chord progression of generation results. However, as mentioned in Section 1, users are not always familiar with such concepts, and then, they would have difficulties in using these methods to output music audios they want to generate. We acknowledge that some methods [38, 39] provide perceptual control that does not require extensive musical knowledge: emotion-based musical generation. Nevertheless, they are based on Russell’s valence-arousal model [42] consisting of four classes, which limits the range of controls and may hamper users’ agency [43] when the methods are used to support their creative processes.

In this context, recent text-to-audio models [10, 11] can be an effective tool for such novice users. These models learn the relationship between music audios and their text descriptions (more specifically, latent representations encoded from the descriptions by RoBERTa [44]) and use it to guide results in generating new audios from an inputted text (*i.e.*, text prompt). As RoBERTa can encode text prompts with variable length and content, the models can provide flexible control without requiring specific musical knowledge of rhythm patterns or chord progressions. Moreover, they allow users to constrain generation results not only by text prompts but also by audio priors, ensuring that the results have similar characteristics to the priors. For example, the diffusion model [45] employed by AudioLDM [11] usually uses Gaussian noise for the seed of its generation process, but by using a noise-infused audio prior, we can obtain generation results preserving the characteristics of the provided audio.

Here, text-to-image models that use similar schemes have been shown to unleash the creativity of novice users, allowing them to iteratively explore open-ended variations of text prompts [17] and customize their intermediate results by specifying image prior constraints [46]. Similarly, text-to-audio models can be leveraged to provide users with such iterative exploration or customization. However, we also expect that text-to-audio music generation processes may pose several specific difficulties, as explained in Section 1. Therefore, we explored how interaction techniques can address these challenges by developing an interface dedicated to text-to-audio models.

2.2 Interfaces for Music Generation

There is a series of research on building interfaces to let users interact with music generation techniques effectively [47–53]. MySong [47], for instance, involves a music accompaniment generation model, with which users can control the happiness or jazziness of generation results. Louie *et al.* [49] proposed an interactive interface for novice users so that they can use a symbolic music generation technique with control of happiness or randomness.

The interface also allows users to constrain generation results by providing music priors, which was experimentally confirmed to be effective in iteratively refining the results. Zhou *et al.* [52,53] utilized a user-in-the-loop Bayesian optimization technique to enable novice users to iteratively explore melodies composed by a generative model.

These interfaces underscore the significance of providing controls and supporting iterative exploration in facilitating the creativity of novice users using music generation techniques. Consequently, the provision of recent text-to-audio models to novice users would be highly suitable for this purpose, as they offer more flexible control, compared to using several parameters such as happiness, while also allowing the use of audio priors. Our paper contributes to this series of research by examining design considerations of interfaces for text-to-audio music generation processes, aiming to expand the scope of applications of recent techniques developed in the MIR community.

3. DESIGN REQUIREMENTS

As stated in Section 1, our goal is to leverage text-to-audio models to facilitate the creative expression of novice users regardless of their musical knowledge. To this aim, we embarked upon an examination of potential challenges that these users may encounter during text-to-audio music generation processes and subsequently derived a set of design requirements to address these issues. Guided by the principles of human-computer interaction, we utilized the think-aloud protocol [54, 55] by involving three volunteers who self-reported that they possessed no formal musical training beyond compulsory education. Specifically, we provided the volunteers with access to one of the latest text-to-audio models [11] on Google Colab using its official implementation¹, which enabled them to provide any text prompts and subsequently listen to three music audios generated from the text prompts. Here, since the remotely-participated volunteers were Japanese speakers recruited via word-of-mouth communication, we told them that they can use DeepL Translator to translate text prompts into English to obtain better results with the model that is mainly trained on the dataset with English text labels [12–14]. They freely used the model for approximately 30 minutes while sharing their screens on a video call and verbalizing their thoughts and feelings. This allowed us to identify the challenges that they encountered and the factors that contributed to these challenges. We then conducted semi-structured interviews to validate the challenges identified and to gain further insight into the reasons behind them. Their responses were analyzed based on open coding [56], which yielded the following design requirements in line with the existing literature on creativity support.

3.1 Computational guidance for constructing initial prompts

We observed that the volunteers frequently encountered difficulty in formulating appropriate text prompts to initi-

ate their use of the model. For example, one volunteer entered the phrase “a song sounds like star wars,” resulting in audio containing a battle cry with a space-like sound effect. This can be attributed to the characteristics of the text labels in the dataset used to train the model [12–14]. Specifically, the labels of music clips consist primarily of musical descriptions such as genres, instruments, and moods, like: “An orchestra plays a happy melody while the strings and wind instruments are being played [14].” Therefore, providing such a description would be essential to ensure that the model trained on the dataset generates music audio as intended. The volunteer was unable to generate music-like audio until he attempted several prompts and finally entered “solemn music starting with a trumpet fanfare.”

In the context of creativity support, two underlying factors could explain the aforementioned observation. First, an inherent gap in artistic vocabulary exists between expert and novice users [15]. Without deep musical knowledge, it can be challenging to conceive a precise description of music audios. Additionally, novice users often have loosely-specified goals when starting a creative endeavor [57–59]. They refine their objectives gradually by exploring the space of possible results through iterative exploration [60, 61]. However, the dependency of text-to-audio models on precise descriptions of clearly-defined goals makes it difficult for novice users to initiate such exploration. This suggests that supporting them computationally in constructing initial prompts could potentially facilitate the creativity of novice users.

3.2 Dual-sided iterative exploration of text prompts and audio priors

We also observed that the volunteers encountered challenges in efficiently exploring the generated results. One volunteer who had prior experience with text-to-image models mentioned the point, as:

“Unlike text-to-image models, comparing various results at a glance was difficult with the text-to-audio model. So, finding a text prompt reflecting my intention most faithfully became much tougher.”

In other words, iteratively trying different text prompts would not necessarily assist users in comprehending the space of potential results, although it is necessary for novice users to refine their loosely-specified goals [60,61]. Therefore, users cannot determine which direction would be closest to their goals and what text prompt to try next. Another volunteer mentioned an issue he faced, as:

“I once found a generation result with a good melody, but I wanted to change its tone. So, I added ‘with a flute’ to its text prompt and regenerated. However, the melody was then completely changed, which was frustrating.”

This implies that we need to let users utilize not only text prompts but also audio priors to constrain the tune of generation results. In sum, supporting the creativity of novice users in text-to-audio music generation processes requires enabling them to efficiently explore variations of both text

¹<https://github.com/haoheliu/AudioLDM>

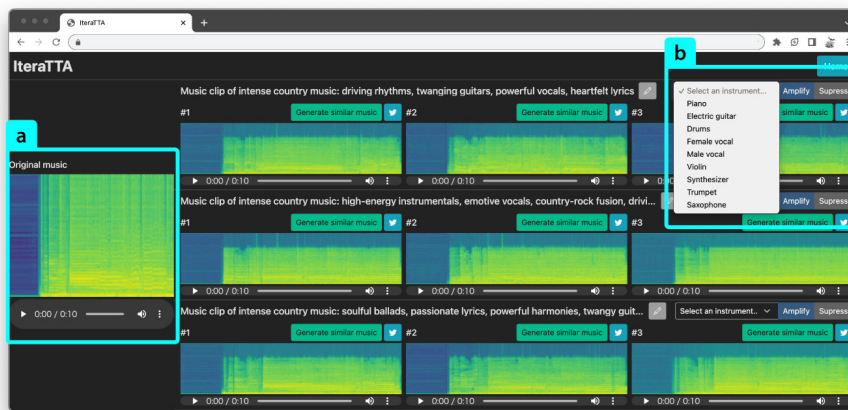

Figure 2. To facilitate the exploration of text prompts and audio priors, IteraTTA allows a) comparison of generation results with an audio prior and b) instant edit of a text prompt.

prompts and audio priors, allowing them to iteratively refine their goals by understanding the space of possible results. This demands us to develop an interface specifically tailored for text-to-audio models to provide such dual-sided exploration of text prompts and audio priors.

4. IteraTTA

Based on the above design requirements, we present IteraTTA, a dedicated interface for text-to-audio music generation processes. It was implemented as a Web-based system, allowing novice users to instantly benefit from the latest text-to-audio models in their creative processes.

4.1 Design

As illustrated in Figure 1, our interface requires users to first input a theme phrase for music audios to generate. The inputted phrase need not include precise musical descriptions since IteraTTA leverages a large language model to derive such descriptions suitable for text-to-audio models using knowledge embedded in the models [62]. Specifically, the interface queries a large language model that “Please give me four variational lists of comma-separated phrases describing what does a music clip of “[*theme phrase*]” sound.” It then uses the four responded phrase lists as a variety of the first text prompts to start the music generation processes in parallel. This feature allows novice users to translate loosely-specified goals in their minds into musical descriptions, which can also help them to envisage variations of text prompts to explore.

IteraTTA then generates three music audios for each of the four prompts. The generated audios are arranged in two dimensions (see Figure 1), which enables novice users to understand how different music audios are generated by different text prompts, and also, how different music audios are generated by the same text prompts. This is intended to assist users in identifying which text prompts and audio priors are closely aligned with their goals and which direction is worth exploring. If a user identifies

a suitable candidate text prompt, they can customize the prompt and generate new music audios with it. Alternatively, if the user discovers a suitable music audio, they can use it as an audio prior to generate new music audios. In essence, the user can explore the subspace of possible results that are proximate to their goals by constraining either text prompts or audio priors, while gradually refining their goals by themselves.

We have incorporated several features to facilitate the exploration of text prompts and audio priors, as shown in Figure 2. For instance, when a user specifies an audio prior, IteraTTA enables the user to compare generated results with it. It also offers an instant editing feature of text prompts, allowing users to amplify or suppress the sound of a selected instrument. This is achieved by simply adding a phrase of “with strong [*instrument*]” or “with no [*instrument*]” into a text prompt, but it provides an example of how they can modify generation results through prompts.

4.2 Implementation

As mentioned, we developed IteraTTA as a Web-based system to invite novice users for trying music generation with it. For the implementation of its back-end server, we utilized Python with FastAPI and incorporated an API of GPT-3.5² to construct initial prompts, while AudioLDM [11] was employed to generate the music audios. The length of music audios to generate was predetermined at 10 seconds so that our GPU server harnessing an NVIDIA RTX 2080 Ti can afford the generation of 12 audios (3 audios × 4 prompts) simultaneously. On average, the generation process takes approximately 15 seconds. In addition, we used DeepL API to translate text prompts into English when they were provided in non-English languages because we observed that it led to better results in Section 3. For the front-end interface of IteraTTA, we utilized Vue.js, which enables users to download the generated music audios or share them on Twitter.

²We used gpt-3.5-turbo of <https://platform.openai.com/docs/models/gpt-3-5>.

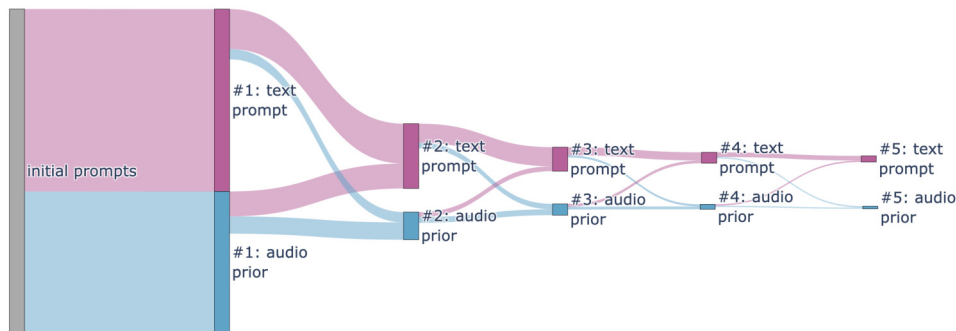

Figure 5. Visualization of how the users utilized the dual-sided exploration of IteraTTA.

teraction log of the service and obtained Figure 5. While some users just tried the exploration feature once, we found that others made iterative use of the feature, alternating between providing text prompts and audio priors. Interestingly, one user repeated this refinement process 32 times, specifying text prompts 14 times and audio priors 18 times before sharing their final result on Twitter. These points imply that our design, which enables dual-sided iterative exploration, helped the users effectively utilize the text-to-audio model.

5.3 Unleashing the creativity of novice users

We lastly analyzed the users’ responses to the feedback form, which received 33 responses in total. Overall, most of them expressed their affirmative experiences with the text-to-audio music creation processes, like:

“It was a very interesting trial. I can interact with it throughout the day.”

“In my personal opinion, it can be used as a source of sampling materials and an idea generator. As a person who usually composes music, I never had any negative feelings about composing from text using this. It is wonderful.”

The latter comment suggests that the features of IteraTTA prepared for novice users can also benefit experienced users in different ways.

It is also notable that the users left comments implying the importance of the design requirements discussed in Section 3, such as how they enjoyed the open-ended exploration starting from loosely-specified theme phrases.

“It was fun to encounter songs that fit the theme I provided but I had never heard before.”

“I really enjoyed the points that I could take advantage of ChatGPT’s ability to associate and verbalize even seemingly unconnected ideas, which allowed me to provide crazy theme phrases that would not be understood by a human. I also learned a lot about how to describe songs by looking at the derived text prompts.”

Interestingly, in the form, some users left a successful prompt that they reached after exploration:

“I would like to report that including a phrase of ‘simple progression’ or limiting the number of tracks yielded stabilized music audios, like: ‘Ideal harmonious song: balanced instrumentation, band sound, simple chord progressions, rhythmic drum patterns, catchy pop melody, up to 12 tracks.’”

“Adding ‘clear sound quality’ produces less noisy audios.”

It is surprising that, even though we provided no explicit description of the behavior of text-to-audio models, the users were able to gain such knowledge by themselves through the iterative exploration with IteraTTA. While such *prompt modifiers* (also known as *quality boosters*) [64] that influence results in a specific way have been discovered for text-to-image models in a community-driven manner [17, 64], the above comments would be the first examples for text-to-audio models, to the best of our knowledge. We assume that this is a manifestation of users’ creativity in text-to-audio music generation processes and would be hard to derive without IteraTTA.

6. CONCLUSION

This paper introduces IteraTTA, an interface specifically designed for supporting novice users in their text-to-audio music generation processes. Its design is guided by two main principles, providing a) computational guidance for constructing initial prompts and b) dual-sided iterative exploration of text prompts and audio priors. The former can help novice users translate their loosely-specified goals into text prompts, which serve as starting points for exploration, even if they do not have rich artistic vocabularies. The latter is important for enabling them to comprehend the space of possible results and gradually refine their goals. To examine how diverse users utilize IteraTTA in their creative processes, we deployed it as a publicly-available Web service and analyzed users’ behaviors, which highlight the importance of these design considerations in supporting the users’ creativity. Importantly, these principles are applicable not only to the specific text-to-audio model but to other models, including those to be proposed in the near future. We believe that this paper can serve as a foundation for enabling novice users to benefit from state-of-the-art models in the MIR community.

ABSTRACT

The directivity of a musical instrument is a function that describes the spatial characteristics of its sound radiation. The majority of the available literature focuses on measuring directivity patterns, with analysis mainly limited to visual inspections. Recently, some similarity metrics for directivity patterns have been introduced, yet their application has not been fully addressed. In this work, we introduce the problem of musical instrument retrieval based on the directivity pattern features. We aim to exploit the available similarity metrics for directivity patterns in order to determine distances between instruments. We apply the methodology to a data set of violin directivities, including historical and modern high-quality instruments. Results show that the methodology facilitates the comparison of musical instruments and the navigation of databases of directivity patterns.

1. INTRODUCTION

The analysis of the directional sound radiation characteristics of musical instruments is a rather old topic in the literature with first works by Olson [1] and Meyer [2–4] dating back to the seventies. In the past few decades, numerous studies were proposed mainly focusing on accurate measurements of the directivity patterns [5–8] or on qualitative comparisons of the instrument characteristics [9–11].

Recently, the interest in spatial audio technologies [12] for virtual and augmented reality increased the attention towards the modeling and analysis of directivity patterns. In particular, the modeling of directional sound sources showed to provide improved sound field reconstruction for the navigation of sound scenes [13, 14]. Therefore, different solutions have been proposed to include the directivity of acoustic sources in simulation frameworks such as boundary and finite element methods [15], numerical simulation [16] and geometrical acoustics [17]. As a matter of fact, the directivity of sound sources impacts on the accuracy of room acoustics simulation [17] and it was shown to be relevant for auralization [18].

In [19], the authors demonstrated that users are able to perceive differences between omnidirectional and directional sound sources, however the evaluation is limited to a single-tone dependent directivity pattern. In the work [20], it was shown that fluctuations occurring in the directivity patterns due to the movements of the musician influence the perception of listeners both in anechoic and reverberant conditions. More recently, in [21], the difference between frequency-dependent directivities and an *average* directivity pattern has been investigated proving the importance of modelling specific frequency-dependent directivities by means of listening tests.

Several studies [22–26] focus on the analysis of voice directivity patterns. In particular, [23, 25] analyze the patterns associated to held or isolated vowels and consonants from speech and singing voice [24]. Interestingly, the results on mouth and vocal tract configurations [26] showed their impact on the directivity pattern shape.

As far as the musical instruments are concerned, most of the works put the emphasis on accurate measurement procedures. Typically, the directional sound pressure is acquired in anechoic environments and under controlled conditions [6, 7]. Alternatively, near-field acoustic holography [27, 28] has been employed for the evaluation of the directional sound radiation using scanning microphone arrays [29]. More recently, a flexible procedure for measuring the directivity pattern of sound sources that works in low-reverberant environments was introduced in [8].

In [9], the directivity patterns of forty one orchestral instruments have been acquired and analyzed. The instruments were played by musicians, rather than mechanically excited, showing that the presence of the player body has the effect of smoothing the patterns. Nevertheless, although [9] draws an interesting analysis of the patterns, the evaluation is mainly limited to graphical inspection without a systematic comparison of the directivity patterns.

As a matter of fact, the quantitative and objective comparison of directivity patterns is still an open challenge. In the literature, some simple metrics have been proposed [30–33]. Although effective, the interpretation of the results and the quantification of the differences might not be easily interpreted. In general, most of the proposed metrics rely on the correlation between the directivity patterns, either in the spherical harmonics domain [30] or in the spatial domain [32]. In [30], the authors employed the normalized cross correlation (NCC) over the spherical harmonics coefficients of the directivity patterns. The anal-

ysis assessed similarities of partials at a given frequency generated by different played pitches. In [34], a rotation-invariant version of the NCC has been proposed to compare the directivity patterns of the data sets in [9,35], which have been made available through [36]. The devised metric has been used to find similarities across the partials of one instrument or between different instruments and a visualization of the corpus through MultiDimensional Scaling (MDS) [37] has been provided.

More recently, in [38], a novel set of metrics has been introduced, which includes the Jaccard similarity index (JSI) and the centers of mass distance (CMD) in addition to NCC. Both JSI and CMD are derived from the analysis of the so-called *principal radiation regions*, namely angular regions of the directivity pattern which exhibit the highest sound energy radiation. In [38], the metrics are used for the characterization of directivity patterns of prestigious historical violins enabling the quantitative comparison of the instruments. Nonetheless, the analysis is limited to a small set of 10 instruments and the conclusions drawn by the analysis of each metric, although relevant, are not readily combined.

In this work, we aim to exploit available similarity metrics for directivity patterns in a comprehensive and systematic fashion. Considering the problem of musical instrument retrieval based on the directivity pattern features [34, 39], we introduce novel distances, namely the Jaccard similarity distance (JSD) based on JSI, and the directivity index distance (DID) derived from the so-called *directivity index* (DI), which are combined with the CMD in a cumulative *Directivity Pattern Distance* (DPD). The proposed distances are blind with respect to the source type, because they work directly on the directivity values. Therefore, ideally they can be applied on any kind of sound sources, including musical instruments of different families. The joint adoption of multiple distances allows us to take into account different aspects of the directivity patterns without limiting the comparison to a single metric. Moreover, the introduced DPD provides a single-valued solution that represents the distance between the directivity patterns combining the information provided by each considered metric.

Although the proposed distances can be applied on different musical instruments, we tested them on a data set of violin directivities. As a matter of fact, violins represent an interesting case study due to the highly variability of directivity patterns among the instruments [40, 41]. The corpus contains a total of 18 instruments equally divided between 10 historical and 8 modern high-quality violins. To the best of our knowledge, this is the largest data set of violin directivity patterns evaluated in the current literature. The analysis allowed us to observe interesting similarities among the instruments, identifying relevant information in the data set. In particular, modern instruments are relatively distant from the historical ones. Moreover, thanks to the adoption of DPD, we could identify clusters of historical instruments made by one violin maker and two modern “twin” violin. Similarly to [34], we exploit the MDS tech-

Figure 1. Example of directivity pattern $D(\phi, \theta, \omega)$ of a Genelec 8030A at 1.4 kHz, taken from [43]. The principal radiation region \mathcal{P} is delimited by a solid black line, while the center of mass \mathbf{r} is marked by a black cross. The reference system is reported from top and frontal views.

nique for the visualization of the data set, which allows us to graphically assess the distances between the instruments observing the clusters of similar violins within. The obtained results pave the way to the retrieval of musical instruments according to their directional sound radiation and open novel perspectives for the exploitation of directivity pattern databases.

2. SIMILARITY METRICS FOR DIRECTIVITY PATTERNS

Let us define the directivity pattern of an acoustic source as the square-integrable function $D(\cdot) \in \mathbb{L}^2(\mathbb{S}^2)$ describing the energy of the directional sound radiation. The directivity pattern is thus defined over a unit sphere comprising all the possible directions of emission. It follows that the directivity pattern can be conveniently expressed through the widely adopted spherical harmonics expansion [5, 8, 13] as

$$D(\phi, \theta, \omega) = \sum_{n=0}^N \sum_{m=-n}^n C_n^m(\omega) Y_n^m(\phi, \theta), \quad (1)$$

where $\phi \in [0, 2\pi]$ and $\theta \in [0, \pi]$ are the azimuth and inclination angles, respectively, $C_n^m(\omega)$ are the spherical harmonics coefficients associated with the source directivity pattern and $Y_n^m(\phi, \theta)$ is the spherical harmonic of degree n and order m [42]. It is worth noting that the directivity pattern (1) depends on the temporal frequency ω . Moreover, in (1), we assumed the directivity pattern to be band-limited being N the maximum expansion order. In Fig. 1, an example of a loudspeaker directivity pattern is reported.

2.1 Data model

2.1.1 Binary directivity pattern

In [38], the principal radiation region of a directivity pattern is defined as the set of adjacent directions \mathcal{P} that correspond to the maximum acoustic energy emission. In particular, given a threshold value τ , the principal radiation region is defined as

$$\mathcal{P}(\omega) = \{(\bar{\phi}_p, \bar{\theta}_p) : D_{\text{dB}}(\bar{\phi}_p, \bar{\theta}_p, \omega) \geq \tau\}, \quad (2)$$

where $\tau = -3$ dB and

$$D_{\text{dB}}(\phi, \theta, \omega) = 10 \log_{10} \left(\frac{D(\phi, \theta, \omega)}{\max(D(\phi, \theta, \omega))} \right) \quad (3)$$

represents the normalized directivity pattern in decibel scale with \max the function extracting its maximum value.

In Fig. 1, the principal radiation region \mathcal{P} is delimited by a solid black line.

The thresholding procedure in (2) allows one to define the binary directivity pattern indicating the principal radiation region as

$$\bar{D}(\phi, \theta, \omega) = \begin{cases} 1 & (\phi, \theta) \in \mathcal{P}(\omega) \\ 0 & \text{otherwise} \end{cases}. \quad (4)$$

The adoption of the binary patterns is preferable rather than considering only the direction of the maximum, i.e. a single point, in the directivity pattern. As a matter of fact, the binary pattern indicates the regions of high energy emission, i.e. principal radiation, which can have arbitrary shape and extension accordingly to the overall directional characteristics of the directivity pattern.

2.1.2 Centers of mass

Although the binary pattern (4) provides a comprehensive representation of the principal radiation regions, it is convenient to further identify a ‘‘preferred’’ direction of emission for each region. Therefore, we define the center of mass for a principal radiation region \mathcal{P} as [38]

$$\mathbf{r}(\omega) = \frac{1}{M} \sum_{p \in \mathcal{P}(\omega)} m_p \mathbf{r}_p, \quad (5)$$

where $\mathbf{r}_p = [\sin \bar{\theta}_p \cos \bar{\phi}_p, \sin \bar{\theta}_p \sin \bar{\phi}_p, \cos \bar{\theta}_p]^T$ are the points belonging to the set defined in (2). In practice, the directions of \mathcal{P} are weighted using the corresponding energy value in the normalized pattern, namely

$$m_p = \frac{D(\bar{\phi}_p, \bar{\theta}_p, \omega)}{\max(D(\cdot, \omega))}, \quad \text{with } M = \sum_{p \in \mathcal{P}(\omega)} m_p. \quad (6)$$

The center of mass of the directivity pattern is marked in Fig. 1 by a black cross.

2.2 Distance Metrics

In order to compare the directivity patterns of acoustic sources within a data set, we rely on a set of metrics recently proposed in [38]. Differently from customarily directivity pattern comparisons, where a single metric is considered, the employment of multiple metrics allows us to take into account different characteristics that are captured by each metric.

2.2.1 Jaccard Similarity Distance (JSD)

According to [38], we define the Jaccard similarity index (JSI) between two binary directivity patterns as

$$\text{JSI}_{k,j}(\omega) = \frac{|\bar{D}_k(\omega) \cap \bar{D}_j(\omega)|}{|\bar{D}_k(\omega) \cup \bar{D}_j(\omega)|}, \quad (7)$$

where \cap is the intersection operator and \cup is the union between the binary patterns of the k th and j th sources. From the definition in (7), it follows that $\text{JSI}_{k,j}(\omega) = 1$ when two binary patterns match exactly, while $\text{JSI}_{k,j}(\omega) = 0$ when the corresponding principal radiation regions do not

overlap. In order to interpret the JSI in terms of a distance, we introduce the JSD metric as

$$\text{JSD}_{k,j}(\omega) = 1 - \text{JSI}_{k,j}(\omega), \quad (8)$$

so that the JSD decreases up to 0 when two principal radiation regions are matched and the maximum value of JSD is 1, indicating two completely disjoint regions.

2.2.2 Center of Mass Distance (CMD)

The CMD is defined in order to compute the distance between two centers of mass as [38]

$$\text{CMD}_{k,j}(\omega) = \arctan \left(\frac{|\mathbf{r}_k(\omega) \times \mathbf{r}_j(\omega)|}{\mathbf{r}_k(\omega) \cdot \mathbf{r}_j(\omega)} \right), \quad (9)$$

where \times and \cdot denote the vectorial cross and dot products, respectively. As in [33], when multiple centers of mass are present inside the directivity patterns, the vectors \mathbf{r} (5) are selected in order to retain the lowest $\text{CMD}_{k,j}(\omega)$ values.

2.2.3 Directivity Index Distance (DID)

The directivity index (DI) is a well-known feature that describes the directionality of a sound source [33]. In particular, the DI measures how much energy is concentrated around the principal directions of a directivity pattern. In this work, we consider the DI of the normalized directivity patterns defined as

$$\text{DI}_k(\omega) = \frac{1}{\int_0^{2\pi} \int_0^\pi \hat{D}_k(\phi, \theta, \omega) d\phi d\theta}, \quad (10)$$

where \hat{D}_k is the normalized directivity pattern of the k th source in linear scale. The DI in (10) is computed with respect to the maximum value of the directivity pattern, which in case of normalized patterns is equal to 1. It follows that high DI values occur for directivity patterns with large principal radiation regions, and vice versa.

In order to compare two directivity patterns in terms of their DI values, we define the DID as

$$\text{DID}_{k,j}(\omega) = \sqrt{(\text{DI}_j(\omega) - \text{DI}_k(\omega))^2}, \quad (11)$$

where DI_k and DI_j are the DI (10) of the k th and j th sources, respectively.

2.2.4 Directivity Pattern Distance (DPD)

In order to conveniently compare two sound sources in terms of their directivity features, we introduce an overall metric that combines the previously defined JSD, CMD and DID into a scalar value. Hence, we define the so-called directivity pattern distance DPD metric as

$$\text{DPD}_{k,j} = \overline{\text{JSD}}_{k,j} + \frac{\overline{\text{CMD}}_{k,j}}{\max(\overline{\text{CMD}}_{k,j})} + \frac{\overline{\text{DID}}_{k,j}}{\max(\overline{\text{DID}}_{k,j})}, \quad (12)$$

where $\overline{\text{JSD}}_{k,j}$, $\overline{\text{CMD}}_{k,j}$, $\overline{\text{DID}}_{k,j}$ denote the mean of the three distance metrics over the frequency axis. It must be noted that the values of $\overline{\text{CMD}}_{k,j}$ and $\overline{\text{DID}}_{k,j}$ in (12) are normalized with respect to the maximum value encountered in the data set under analysis, such that all the components of the sum vary within the same dynamic range, i.e. between 0 and 1, and thus have the same relative importance in the definition of DPD.

3. EVALUATION

3.1 Data set of violin directivity patterns

The proposed methodology is applied to a data set of violin directivities. The data set includes the frequency-dependent directivity patterns of eighteen violins, including ten historical violins made between the 16th and 17th centuries and eight modern violins made during the last two centuries. For all the instruments, the owners provided consent for the usage of the results in an anonymous fashion. For this reason, and for the ease of reading, we will denote all the historical violins with labels H1–H10, while we will refer to the modern ones as M1–M8.

Concerning the collection of modern violins, it is noteworthy that the instruments labeled with M1–M6 are fine violins selected among the candidates of the “Antonio Stradivari International Triennial Competitions of Stringed instrument making”. The competition, held in the city of Cremona since 1976, embraces both Cremonese and international competitors. Moreover, violins M7 and M8 were made by a Cremonese luthier and are known as “twin violins”. The twin violins were built by employing the very same block of tonewood and following the same geometrical model. As a matter of fact, previous research already showed the high similarity in all the spatial characteristics of their sound.

The patterns were collected experimentally through the measurement procedure described in [8] and were evaluated at varying frequency within the range [200, 5000] Hz using a 4th-order spherical harmonics expansion in (1). The instruments are played by one professional violinist who is free to move and play comfortably, while the source position and orientation are estimated by the system enabling the measurement of the directivity as described in [8]. The data processing pipeline and the computation of the metrics is developed using the MATLAB software.

3.2 Analysis of the metrics

To assess the significance of the proposed distance metrics, we first compare the frequency-averaged values of \overline{JSD} , \overline{CMD} and \overline{DID} computed over the set of violin directivity patterns to those obtained for the same data with a commonly used similarity metric, namely NCC. The NCC metric provides a measure of the element-wise similarity between two patterns. In order to properly compare the previously defined distances with the baseline, the NCC between the patterns of the k -th and l -th violins is formalized in terms of a distance as

$$\overline{NCC}_{k,l} = 1 - \frac{1}{S} \sum_{s=1}^S \frac{\widehat{D}_k(\phi, \theta, \omega_s) \widehat{D}_l(\phi, \theta, \omega_s)}{\|\widehat{D}_k(\phi, \theta, \omega_s)\| \|\widehat{D}_l(\phi, \theta, \omega_s)\|}, \quad (13)$$

where ω_s is the s -th frequency at which the directivity patterns are evaluated, with $s = 1, \dots, S$ and S the total number of frequency bins in the data set. In this way, $\overline{NCC}_{k,l}$ is close to zero when two patterns are similar and reaches a value equal to 2 when they are inversely correlated. Fig. 2 shows a comparison between all the metrics under study. For any possible pair of metrics, a 2D scatter plot is

Figure 2. Comparison between proposed distance metrics (\overline{JSD} , \overline{CMD} , \overline{DID}) and Normalized Cross Correlation (\overline{NCC}). For each combination of metrics, a 2D scatter plot of the corresponding frequency-averaged values is shown. Z-score normalization is applied to ensure the same dynamic range along the axes [44]. Linear regression is performed to analyze the correlation between the metrics. The regressed line and the R^2 value, measuring the degree of correlation, are highlighted in red.

reported. The coordinates of the markers in the plot correspond to the two distances for all the possible pairs of violins in the data set. Z-score normalization is applied to the resulting values to ensure the same dynamic range along the axes [44]. The scatter plots in the first row show the comparison between \overline{NCC} (13) and each of the proposed metrics, while the scatter plots in the second row present the comparison between \overline{JSD} , \overline{CMD} and \overline{DID} only. By inspecting the resulting distributions of points, it is possible to highlight correlations between the metrics.

On the one hand, it can be noticed that some pairs of metrics exhibit a point distribution that concentrates along a line. A linear trend, in fact, can be observed in Fig. 2a and 2b, showing the $(\overline{NCC}, \overline{JSD})$ and $(\overline{NCC}, \overline{CMD})$ point distributions, respectively. Although less emphasized, a similar trend can be noticed in Fig. 2d and 2e, reporting the distribution of $(\overline{JSD}, \overline{CMD})$ and $(\overline{JSD}, \overline{DID})$, respectively.

The presence of linearity in these point distributions can be interpreted as due to correlation, i.e. shared information, between the metrics under analysis. This can be particularly true for \overline{NCC} and \overline{JSD} , which both measure the degree of pattern matching by definition. More interestingly, however, correlation can be observed between \overline{CMD} and \overline{NCC} . We can thus conclude that two violins with similar principal directions of radiation tend to exhibit highly matching directivity patterns. Furthermore, \overline{JSD} and \overline{CMD} can be used instead of \overline{NCC} to provide two similarity measures by looking at the pattern shape and at the principal direction of radiation separately without losing information. Indeed, Fig. 2d shows that \overline{JSD} and \overline{CMD} are less correlated than when considering \overline{NCC} .

On the other hand, Fig. 2c and Fig. 2e do not exhibit a linear distribution. We can interpret this evidence as the absence of correlation between \overline{DID} , \overline{NCC} and \overline{CMD} . As a matter of fact, \overline{DID} measures the difference in the directivity index of two patterns, which is related to the energy distribution, and thus extracts an energy-related informa-

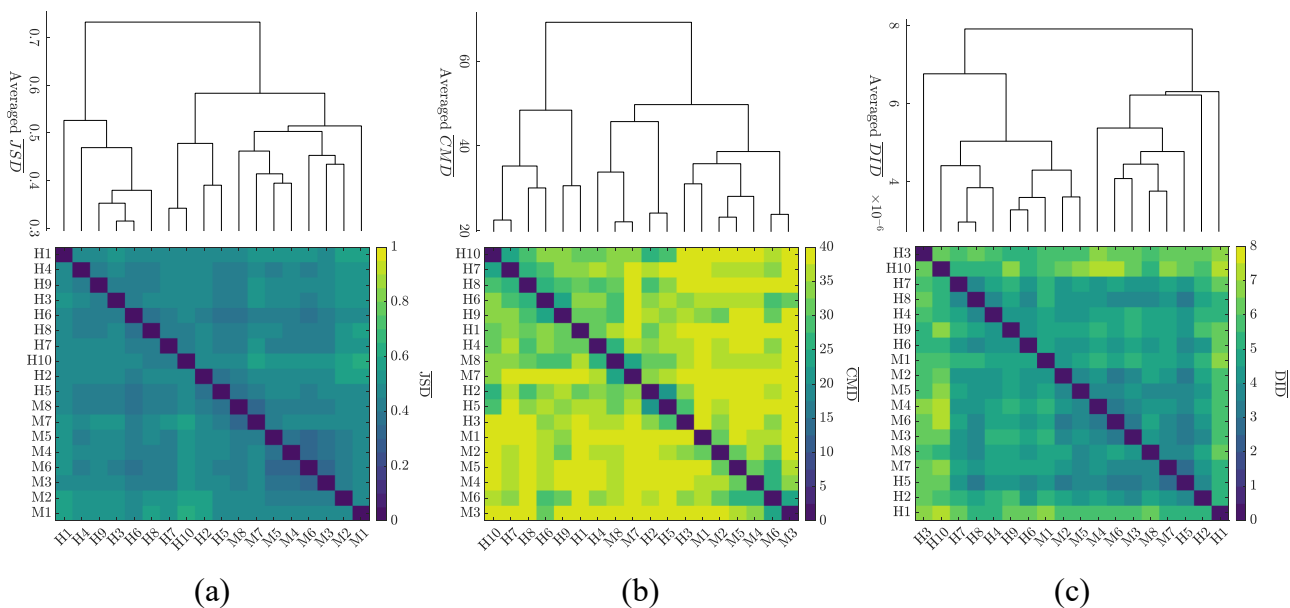

Figure 3. Evaluation of violin similarity based on \overline{JSD} (a), \overline{CMD} (b) and \overline{DID} (c). The elements inside the matrices are obtained by averaging the frequency-dependent distance values. Pairs of similar violins are denoted with dark blue colors, while dissimilar violins are highlighted in yellow. Hierarchical clustering algorithms are employed to sort the elements inside the resulting matrices. The resulting dendrograms are reported above each distance matrix.

tion that is not captured by the other metrics.

A quantitative measure of the correlation between the metrics under analysis can be evaluated by performing linear regression on each point distribution. The regressed lines are denoted in red inside each 2D scatter plot. The regression accuracy is assessed in terms of the coefficient of determination R^2 , which is related to the Pearson correlation coefficient in the case of simple linear regression. The resulting R^2 values are reported as an inset inside each plot. According to [45], the values range between 0 and 1, and moderate and strong correlation occurs for values greater than 0.3 and 0.6, respectively.

It can be noticed that the pair $(\overline{NCC}, \overline{JSD})$ shows moderate to strong correlation, with $R^2 = 0.57$. Moderate correlations can be observed for $(\overline{NCC}, \overline{CMD})$, $(\overline{JSD}, \overline{CMD})$ and $(\overline{JSD}, \overline{DID})$, with $R^2 = 0.42$, $R^2 = 0.33$ and $R^2 = 0.38$, respectively. Finally, no correlation occurs for $(\overline{NCC}, \overline{DID})$ and $(\overline{CMD}, \overline{DID})$, with $R^2 = 0.09$ and $R^2 = 0.03$, respectively.

3.3 Violins clustering based on similarity metrics

In order to group musical instruments that exhibit a sound emission with similar spatial characteristics, the proposed distance metrics can be used together with classical clustering methods. In this case, hierarchical clustering methods are employed, based on the generation of dendrograms [46]. In particular, the proposed similarity metrics are used for the iterative definition of the dendrogram. It is worth to underline, that the adopted clustering algorithm does not require any training data and it is applied directly on the computed similarities. Fig. 3 shows the distance matrices assessing the pairwise similarity between all the violins in the data set under study. The matrix elements in Fig. 3a, 3b and 3c are obtained using the frequency-averaged \overline{JSD} ,

\overline{CMD} and \overline{DID} values, respectively. Pairs of similar violins are highlighted with dark blue colors, while dissimilar violins are colored in yellow. The elements of each distance matrix are sorted according to the leaf order of a dendrogram tree. The Ward’s method [47] is used to generate the tree branches, such that similar violins concentrate inside the matrix.

By inspecting the resulting distance matrices, it is noteworthy that the order of the elements in the matrix varies depending on the specific distance considered. However, expected groups of violins can be highlighted. In Fig. 3a, the subsets of historical and modern violins are clearly distinguished, being placed at the top-left and bottom-right corners of the \overline{JSD} matrix, respectively. In particular, the twin violins (M7-M8) exhibit the minimum \overline{JSD} value in the matrix and the remaining modern violins (M1-M6) cluster together. The same behavior occurs also in Fig. 3b and 3c, although at different locations inside the matrices.

Regarding the historical violins, H1 appears to be very different with respect to the rest of the data set. In particular, high values are encountered for \overline{JSD} and \overline{DID} , which are related to the pattern shape and energy, respectively. Conversely, the same violin is more similar to other historical violins concerning the principal directions of radiation.

Fig. 4 shows the results of violin clustering based on the proposed overall metric DPD. On the left, the dendrogram computed with the Ward’s method is shown, while on the right the resulting distance matrix is reported, with the elements sorted following the dendrogram hierarchy. Pairs of violins characterized by DPD values close to either zero or the maximum are colored in green or white, respectively.

Typically, clusters can be extracted from the hierarchy of the dendrogram tree by applying a thresholding with re-

Figure 4. Violin clustering based on the proposed DPD metric. Small distance values correspond to pairs of similar violins and are highlighted in green, while pairs of dissimilar violins exhibit high distance values and are highlighted in white. The elements inside the matrix are sorted according to the dendrogram tree, shown on the left. Clustering is performed by thresholding the dendrogram tree. The threshold is denoted with a cyan line, while the resulting clusters are colored in red.

spect to the tree height. We decide to subdivide the dendrogram at a height equal to 1.9, i.e. the mean value between the height of the lowest branch in the tree and the height of its root, denoted with a vertical dashed cyan line. As a result, seven clusters are identified inside the data set: (i) three consisting of a single violin (i.e. H1, H10 and H3), (ii) one cluster made of five historical violins (i.e. H4-H6-H7-H8-H9), (iii) one cluster made of two historical violins and the twin violins (i.e. H2-H5-M7-M8), (iv) one cluster with four modern violins (i.e. M3-M4-M5-M6) and (v) one cluster with two modern violins (i.e. M1-M2).

The obtained clusters are coherent with the similarities extracted from the single proposed metrics. In particular, the distinction between historical and modern violins and the high similarity between the twin violins (M7-M8) are emphasized by the DPD. Moreover, hierarchical clustering based on DPD is able to recognize a cluster with five historical violins i.e. H4-H9-H6-H8-H7. Remarkably, the instruments belonging to this cluster have been made by the same luthier.

3.3.1 Visualization of the data collection through MDS

Given the similarity analysis of the violin directivity patterns based on the proposed DPD metric, the employment of MultiDimensional Scaling methods (MDS) allows one to easily visualize and navigate the collection of data [37]. In practice, MDS methods enable the mapping of the violins into a multidimensional space so that the similarities between the musical instruments in the data set are preserved.

Fig. 5 shows a 3D representation of the data set based on MDS. In this case, the coordinate system results from the use of Nonclassical MDS with the distance matrix shown in Fig. 4 as input. Each marker in the scatter plot corresponds to a violin, and the same marker color is used to denote violins belonging to the same cluster.

4. CONCLUSION

In this paper, we tackle the problem of directivity patterns comparison by introducing a novel distance metric denoted

Figure 5. 3D representation of the violin data set based on Multidimensional Scaling. Nonclassical MDS is applied on the resulting DPD matrix to map the violins into a three-dimensional space. Each marker in the scatter plot corresponds to a violin. The same marker color is used for violins belonging to the same cluster.

as DPD, which is based on a combination of different similarity metrics and features of the patterns. This approach allows one to compactly compare the similarity of directivity patterns exploiting the different information provided by JSD, CMD and DID. The considered metrics are compared within each other and with respect to the well-known NCC, highlighting that they provide mutually uncorrelated information.

We analyzed a data set of directivity patterns of 18 violins divided between 10 historical and 8 modern instruments. Through the use of DPD, we were able to identify clusters of similar instruments among which a set of historical instruments made by the same maker and two “twin” violins. Finally, the MDS technique enabled the visualization of the violin data collection starting from the computed distances.

We foresee the application of the proposed approach for the retrieval of musical instruments based on directivity pattern characteristics. This opens new perspectives for the navigation of data sets of directivity patterns which can be used to provide a more realistic acoustic presence of musical instruments within spatial audio applications.

POLYRHYTHMIC MODELLING OF NON-ISOCHRONOUS AND MICROTIMING PATTERNS

George Sioros
University of Plymouth
georgios.sioros@plymouth.ac.uk

ABSTRACT

Computational models and analyses of musical rhythms are predominantly based on the subdivision of durations down to a common isochronous pulse, which plays a fundamental structural role in the organization of their durational patterns. Meter, the most widespread example of such a temporal scheme, consists of several hierarchically organized pulses. Deviations from isochrony found in musical patterns are considered to form an expressive, micro level of organization that is distinct from the structural macro-organization of the basic pulse. However, polyrhythmic structures, such as those found in music from West Africa or the African diaspora, challenge both the hierarchical subdivision of durations and the structural isochrony of the above models. Here we present a model that integrates the macro- and micro-organization of rhythms by generating non-isochronous grids from isochronous pulses within a polyrhythmic structure. Observed micro-timing patterns may then be generated from structural non-isochronous grids, rather than being understood as expressive deviations from isochrony. We examine the basic mathematical properties of the model and show that meter can be generated as a special case. Finally, we demonstrate the model in the analysis of micro-timing patterns observed in Brazilian samba performances.

1. INTRODUCTION

Isochrony has been a fundamental element of computational and cognitive models of musical rhythm, which are often inspired by the organization of rhythms found in Western classical music theory [1]. The advantages of isochrony as a structural foundation for the organization of music are numerous, from the potential to explain our ability to synchronize to music [2–5], to defining higher level qualities such as tempo [1, 6]. However, while periodicity is common in music, strict isochrony is almost never observed [7] and many studies document with empirical data the systematic durational patterns from music around the world, which do not fit into an isochronous structure, including the Viennese waltz [8], Brazilian Samba [9–11], Mali Jembe music [12] and the Norwegian Telespringar [13].

Generally, such patterns are understood on the basis of an underlying structural basic isochronous pulse and expressive deviations from it [14]. Although an isochronous pulse may not be directly observed and measured in the music signal, a steady beat may be inferred by the listener, most evidently when we bob our head or tap our feet to the music. Numerous beat tracking algorithms exist in the music information retrieval literature [15] and even cognitive models have been formalized that attempt to imitate this behavior [16, 17]. In most music-theoretical and cognitive models of rhythm, the beats of the basic isochronous pulse are grouped together, say every two or three, resulting in slower pulses that coincide with all faster ones, forming a hierarchical structure often referred to as meter [1, 18].

Typically, deviations from isochrony are modeled by processing repeating rhythmic patterns to derive statistical properties, such as the mean deviation from an isochronous pulse at each location of the repetition cycle (see for example [10]). Such statistical models only describe the processed recordings and cannot be generalized. They do, however, provide evidence that deviations from isochrony may be more than a mere expressive element of the performance, and are rather structural components of music [12].

Polyrhythmic music challenges the principle of hierarchical organization of rhythms. Polyrhythms are organized on the basis of multiple isochronous pulses of different periods that do not coincide [19–21]. Polyrhythmic elements are found in music around the world, with most representative examples coming from West Africa and the African diaspora [22, 23]. Even in groove-oriented music, where a strong sense of pulse is felt, short patterns that suggest an alternative pulse are common [24] and evidence indicate that they are central to experiencing groove [25]. Perhaps unsurprisingly, certain polyrhythmic music traditions also exhibit large and systematic deviations from isochrony [26]. It has been proposed that the deviations from isochrony and the polyrhythmic character of music from the African diaspora are related, one enhancing the other [9, p. 234, 23].

This paper presents a music-theoretical model that constructs non-isochronous grids from different isochronous pulses within a polyrhythmic context. Essentially, it attributes systematic non-isochronous patterns to underlying polyrhythmic structures that may be considered fundamental to the organization of the rhythmic patterns. In section 2, we present relevant music-theoretical concepts. Section 3, introduces a mathematical formalization of our model along with its key properties. In section 4, we employ the model to analyze Brazilian samba performance data taken from existing literature.

2. BACKGROUND

2.1 Structural isochrony

In music theory, meter is formalized as a hierarchical structure that groups pulses periodically [18]. In typical mainstream Western music, the events are aligned across the voices in such a way that the salient moments coincide to form a metrical hierarchy (Figure 1). The different levels of the hierarchy correspond to various regularities found in the rhythm. While each level takes the form of a steady pulse, the various levels are stacked so that slower pulses coincide with all faster ones. Consequently, the periodicities in the articulated patterns in the music should also align in a similar fashion, although each voice may not necessarily articulate a specific metrical level. The periodic grouping of the beats has been formalized as a prime factorization problem [27–29]. Generative models of meter that can be implemented in computer algorithms have been developed as a set of transformations [30] and an abstract context-free grammar [31]

As a cognitive mechanism, meter is understood as oscillations that represent the attentional energy of the listener [3, 4, 32] or a predictive schema [33] that expresses our expectations about the timing of musical events [34]. The limitations of our cognition impose temporal limits to the pulses of the metrical hierarchy [1, p. 29, 35]. At the lower limit, the shortest pulse has a period of ~100ms, and at the upper limit, the longest pulse has a period of ~1.5s. The highest metrical salience is observed for pulses with a moderate period of ~700ms [6]. Tempo is then defined as the frequency of the most salient isochronous pulse of the metrical hierarchy.

The durations of the sound events are classified by the listener into discrete categories [2, p. 382, 36–39] that are influenced by the sensation of a pulse or meter evoked in them, so that a certain duration may be interpreted as a dif-

Figure 1: The metrical structure (bottom) emerging from The first two bars of “Conquest of Paradise” of composer Vangelis (top). Events are marked with (o). The three pulse levels of the metrical hierarchy (|) have periodicities of simple integer ratios 1:3:4 and are aligned with no phase differences.

Figure 2: Example of a Non-Isochronous meter. The middle metrical level is non-isochronous and can be constructed as the Euclidean rhythm $E(4,9)$.

ferent category when listened in a different metrical framework [40]. A rhythmic pattern is essentially coded as a series of nominal durations that are a multiple of the basic isochronous pulse of the metrical hierarchy.

Despite the fundamental role that isochrony plays in the construction of meter, non-isochronous grouping of beats create non-isochronous metrical levels and meters (NI meters) [1, Ch. 7] (see Figure 2 for an example). Such groupings are based on the principle of maximal evenness [1, 41, 42] which is also the basis for the Euclidean rhythms that are encountered in many traditional rhythms [43, 44]. Such non-isochronous patterns are constructed by distributing a number of onsets k as evenly as possible over a number of beats n of an isochronous pulse. A Euclidean rhythm can then be denoted as $E(k,n)$ [43].

2.2 Micro-timing

While the metrical hierarchy determines durational categories for musical events, continuously variable timing determines an expressive level of organization of rhythms [14]. Systematic deviations from the nominal durations are typically measured in ms or as a percentage of the nominal beat duration to allow for an easier comparison between music segments with different tempi (Figure 3). The phenomenology of micro-timing has been discussed within the context of various music genres (see [9, 12, 45, 46] for some examples). Micro-timing modeling typically relies on statistical analysis of the timing of musical events over the duration of a performance to identify systematic, non-isochronous patterns [10, 47].

Figure 3: Onsets (o) may not exactly align with the isochronous pulse and have expressive (micro) timing deviations denoted with arrows (→).

2.3 Polyrythms

Polyrythms have been described in music theory as a form of metric dissonance [19, 20]. While consonant pulses align to give rise to the hierarchical structure of meter, dissonant pulses intertwine. Typically, polyrythms consist of pulses with distinct beat durations that are not simple integer multiples of one another. The ratio between the beat durations of the two pulses determines the length of the repetition cycle of the entire polyrhythm. The number of beats of each pulse within a cycle of the polyrhythm n_1 and n_2 are related to the beat durations of the two pulses ΔT_1 and ΔT_2 :

$$\frac{\Delta T_1}{\Delta T_2} = \frac{n_2}{n_1} \quad (1)$$

Figure 4: The 2/3 polyrhythm. A basic isochronous pulse subdivides both the 2-beat and the 3-beat pulses.

Polyrhythms can then be represented as $n_1|n_2$. Figure 4 depicts a polyrhythm in which 2 beats of one pulse have the same duration as 3 beats of a second pulse. The pulses that constitute a polyrhythmic structure may have a common faster subdivision with a beat duration longer than the perceptual threshold of 100ms, resulting in a type of grouping dissonance or polymeter [21].

2.4 Polyrhythms as flexible spaces

In principle, onsets are assumed to belong to one of the pulses of a polyrhythm, even if they are not perfectly aligned. However, it has been proposed that in music from the African diaspora, the intervals between the pulses of a 16|12 polyrhythm define a flexible space [23]. Events occurring between a beat from the 12-beat pulse and a beat from the 16-beat pulse may have a ‘mixed’ character, belonging at the same time to both pulses. Here, we extend this concept of ‘mixed’ character events to create non-isochronous grids that combine the character of both pulses of a polyrhythm. In this way, we formalize (micro) timing deviations from isochrony as a structural element of musical rhythms rooted in polyrhythms.

3. NON-ISOCHRONOUS GRIDS

3.1 Definition and construction

Non-isochronous pulses are constructed from two isochronous pulses of different periods. We will refer to the constructed non-isochronous pulses as grids (NI grids) to better distinguish them from isochronous pulses. The NI grid is formed by gradually changing the positions of the beats of one isochronous pulse towards a proximate beat of the other pulse. We call the first pulse the ‘formative’ pulse and the later pulse the ‘target’ pulse of the NI grid (Figure 5). The new beat positions for the NI grid are determined by:

$$N_i = F_i + S_i \cdot (T_j - F_i) \quad (2)$$

where i is the beat index of the formative pulse, F_i is the formative’s beat time, T_j is the target’s proximate beat time and S_i is the ‘shift’ as a fraction of the distance between the two beats taking values in the range $[0, 1]$.

In principle, each beat may be shifted independently to form an NI pattern with multiple durations. Here, we examine the case of a uniform shift, where all formative beats are shifted by the same parameter S towards the nearest beat of the target pulse. Then, as S goes from 0 to 1, the formative pulse is being ‘morphed’ into the target pulse. While the relative shift S is uniform, the individual beat

Figure 5: Construction of a non-isochronous grid by uniformly shifting the beats of a formative pulse towards the nearest beat positions of a target pulse.

displacements in time units (e.g. ms) will still have different values as the distance between the beats of the two pulses is not the same for all beats. Furthermore, S can also exhibit dynamic variations. In this sense, it should be understood as analogous to tempo, which can serve as a uniform parameter within a given time span and can also exhibit variations over the duration of a piece.

NI grids constructed by a uniform shift consist of only two beat classes, which we refer to as Short and Long for simplicity. If ΔF is the period of the formative pulse and ΔT the period of the target pulse, then the two beat classes’ durations are:

$$\Delta N = (1 - S) \cdot \Delta F + S \cdot \Delta T \cdot k \quad (3)$$

where, k can take one of two values:

$$k_{Short} = \left\lfloor \frac{\Delta F}{\Delta T} \right\rfloor = q, k_{Long} = \left\lceil \frac{\Delta F}{\Delta T} \right\rceil = q + 1 \quad (4)$$

where $\lfloor \cdot \rfloor$ and $\lceil \cdot \rceil$ denote the floor and ceiling functions.

The durations of the Short and Long beats are limited within a NI grid. For $S = 0$, both the Short and Long beats have a duration equal to the period of the formative pulse ΔF , which is the upper limit for the Short beats and the lower limit for the Long beats. Conversely, for $S = 1$, the Short beats reach their shortest duration and the Long beats their longest duration which are integer multiples of the duration of the period of the target pulse ΔT . When $\Delta F < \Delta T$, i.e. $n_F > n_T$, then $k_{Short} = 0$ and $k_{Long} = 1$ and therefore the Short beats can reach a duration of 0.

By construction, the total number of beats of an NI grid is the same as the number of beats of the formative pulse. The number of Long beats of an NI grid can be calculated as the remainder of the division between the number of beats of the formative and target pulses:

$$n_{Long} = n_T \% n_F \quad (5)$$

3.2 Maximal evenness in NI grids

One of the key properties of the NI grids is that the Short and Long beats are evenly distributed; a direct consequence of the underlying polyrhythmic pulses being isochronous and the shift S being uniform. Different alignments of the pulses result in different rotations of the Short-Long beat pattern.

So far, we have examined shifts of the formative beats towards the nearest target beats. The above equations and the even distribution of the Short-Long beat classes also apply to shifts towards the next or previous target beat. Arbitrary combinations of the shifts, e.g. some towards the nearest beat and others towards the next beat, may also result in an even distribution of the two beat classes. However, this is guaranteed only when all formative beats follow the same rule. In Figure 6, the example of a 6 beat formative pulse and an 8 beat target pulse is shown. It follows from Eqn (5) that the number of Long beats in the resulting NI grid is 2, and the remaining 4 are Short. The different alignments of the formative and target pulses in Figure 6 produce the same Short-Long beat pattern but in different rotations.

Given a polyrhythm $n_F|n_T$ and its total duration, Eqns (3 - 5) can be used to calculate the durations and number of Long and Short beats in the corresponding NI grid as a

Figure 6: Three different alignments of a formative pulse with 6 beats and a target pulse of 8 beats produce the same pattern of evenly distributed Short-Long (L/S) beats, but in a different rotation. In A and B, all formative beats are shifted towards the nearest target beats. In C, the formative beats are all shifted forward, i.e. always towards the next target beat.

function of the shift S . The NI grid can then be produced directly by the Euclidean algorithm as a maximally even distribution of the two beat classes [1, 41, 43].

NI grids can be represented as polyrhythms with the additional parameter S : $NI(n_F | n_T, S)$. However, in contrast to polyrhythms, the order that the two pulses appear in the NI grid definition is important. The formative and target pulses are not equivalent as can easily be seen from Eqn (5), where the modulo operation is not commutative, and the fact that the number of beats of an NI grid is equal to the number of beats of the formative pulse, but not of the target pulse.

As a consequence of the even distribution of the Long and Short beats, every Euclidean pattern can be constructed as a NI grid (see Figure 7 for an example taken from [43]). In fact, it follows directly from the construction of Euclidean patterns that Euclidean patterns are equivalent to NI grids with a shift $S = 1$:

$$E(l, m) = NI(l | m, 1) \quad (6)$$

Figure 7: The Cuban cinquillo pattern is the Euclidean rhythm $E(5,8)$ and the NI grid $NI(5 | 8, 1)$.

Since the levels of a metrical hierarchy are evenly distributed, they can be constructed from NI grids. For NI meters, the process is similar to the construction of Euclidean patterns. However, typically, meters include isochronous pulses at all levels of their hierarchy and, therefore, these meters can be constructed from degenerate NI grids for which the Short and Long beats have the same duration.

4. APPLICATION TO SAMBA PERFORMANCES

Music events may be assigned to the beats of an NI grid. Similar to beat tracking, analyzing an observed durational

pattern requires aligning event onsets with beats. As not all beats in an NI grid are necessarily articulated, there may be more than one NI grid that fits the rhythmic pattern. Information about the polyrhythmic structures that may be expected for the music at hand can help reduce the search space and find meaningful solutions. Here, we demonstrate the potential of the model in musical rhythm analysis by constructing NI grids that fit the durational patterns found in Brazilian samba.

Various rhythmic patterns of samba recordings have been reported in the literature [9–11, 13]. They are considered a characteristic feature of the performances and an integral part of the style, although the degree of deviation from isochrony as well as the specific non-isochronous patterns measured vary between studies. In [10], the same Samba rhythm was recorded at three different tempi. From the recordings, mean durations of the four events that make up the basic repetitive pattern were calculated. The results, which are summarized in Table 1, show that all three tempi follow the same general Medium-Short-Medium-Long durational pattern. The relative durations however are different at each tempo, with the fast and preferred tempi showing the most similarity and the slow tempo being more distinct and closer to isochrony with a characteristic lengthened last event. Additionally, the two Medium events (1 and 3) were reported to be significantly different between them, indicative of Medium-Short and Medium-Long duration [10].

Here we hypothesize that the observed non-isochronous patterns of Table 1 are the result of an underlying polyrhythmic structure and we attempt to reproduce them as: 1) NI grids with a 4-beat formative pulse and 3-beat target pulse (section 4.1), and 2) NI grids with a 5-beat formative pulse and a binary target pulse (section 4.2). In section 4.3, we use the NI grids to propose potential explanations for the differences in the observed durations between the three tempi.

4.1 The 4-beat formative pulse hypothesis

Our first hypothesis is that the basic Samba pattern (Table 1) emerges from an underlying 4|3 polyrhythm. From Eqn (5), it follows that the corresponding NI grid consists of 3

Tempo - BPM	Event number			
	1	2	3	4
Measured in ms				
Fast - 133	121 ±7.1	69 ±6.0	112 ±5.1	153 ±8.6
Preferred - 100	157 ±8.7	110 ±8.4	142 ±5.8	196 ±9.0
Slow - 69	212 ±9.7	198 ±12.4	206 ±6.6	256 ±9.5
Measured in percent of the total duration				
Fast - 133	27	15	25	34
Preferred - 100	26	18	24	33
Slow - 69	24	23	24	29

Table 1: Mean durations and standard deviations of the four events of the basic Samba pattern from [8, Tbl. 3].

Figure 8: Potential NI grids with a 4-beat formative pulse for the Samba patterns of Table 1. A hypothetical alignment between the target (T) and formative (F) pulses is shown. The NI grids are specified on the left. The four events from Table 1 and the corresponding mean durations are indicated by grey circles and the integer numbers at the top.

Tempo NI grid	Event number			
	1	2	3	4
Fast $NI(4 3, 0.39)$	128.7 (7.7)	69 (0.0)	128.7 (16.7)	128.7 (24.33)
Preferred $NI(4 3, 0.27)$	165.0 (8.0)	110.0 (0.0)	165.0 (23.0)	165.0 (31.0)
Slow $NI(4 3, 0.09)$	224.7 (12.7)	198.0 (0.0)	224.7 (18.7)	224.7 (31.3)

Table 2: Theoretical durations in ms for the four samba events based on the NI grids of Figure 8. In parenthesis, the differences between the predicted durations and the observed mean durations for the respective events are shown for comparison with the standard deviations reported in Table 1. Difference greater than the respective standard deviations are shown in bold.

Long beats and a single Short beat. Since the NI grid has the same number of beats as the number of events in the Samba pattern, all four beats coincide with an event (Figure 8) and the shortest event duration (event 2) is aligned to the Short beat of the NI grid. Then, S is chosen so that it minimizes the difference between the theoretical beat durations and the mean event durations for the three different tempi. The results are summarized in Table 2.

The three different Samba patterns correspond to three different shifts S , so that events 1 and 2 of the Samba pattern are well aligned to the NI grid at all three tempi. However, since the NI grids consist of only two beat classes, events 1, 3 and 4 are matched to beats with the same duration and therefore this model cannot capture the characteristic longer 4th event and the difference in the durations of the two Medium events (1 and 3).

4.2 The 5-beat formative pulse hypothesis

Our second hypothesis is that the observed Medium-Short-Medium-Long pattern stems from the superposition of 5-

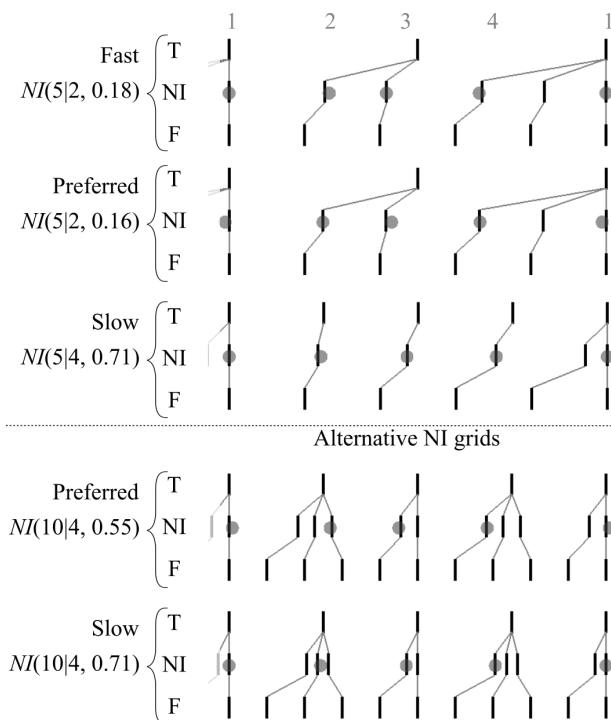

Figure 9: Potential NI grids with a 5-beat formative pulse (specified on the left) for the patterns in Table 1 (indicated here with grey circles) for the three different tempi. Two alternative NI grids are shown for the preferred and slow tempo duration patterns.

beat and a binary pulse. Since only 4 of the 5 beats of the NI grid coincide with events, the two beat classes may produce three distinct event durations and in this way reproduce more accurately the event durations in the pattern (Figure 9, top). As in the previous hypothesis, the Short beat is aligned with event 2. The longer fourth event in this hypothesis spans two beats.

In the fast and preferred tempi, the length of event 4 is roughly double of the 2nd event and therefore we hypothesize that it spans two Short beats. Consequently, NI grid consists of 3 Short beats and 2 Long beats and therefore it is derived from a 5|2 polyrhythm. In the slow tempo, the difference between the duration of event 4 and the rest of the events is smaller. Our hypothesis is that this longer event spans two beats but not of equal durations. Since the first 3 events have similar durations, we hypothesize that a NI grid based on a 5|4 polyrhythm can reproduce this pattern, with the 3 Long beats aligned to the first 3 events. Finally, as previously, S is chosen to minimize the difference between the theoretical and observed mean durations. The results are summarized in Table 3.

The 5-beat formative pulse hypothesis reproduces more accurately the observed Samba pattern. The differences between the theoretical and observed durations are below the respective standard deviations, except for event 2 and 3 at the preferred tempo. This is indicative of the inability of the 5|2 model to capture the subtle difference between the two Medium events.

Introducing a subdivision to the Formative and Target pulses can address the above shortcoming of the model. A

Tempo NI grid	Event number			
	1	2	3	4
Fast $NI(5 2, 0.18)$	115.7 (5.3)	74.5 (5.5)	115.7 (3.7)	149.0 (3.9)
Preferred $NI(5 2, 0.16)$	150.8 (6.2)	101.2 (8.8)	150.8 (8.8)	202.3 (6.3)
Slow $NI(5 4, 0.71)$	205.3 (6.7)	205.3 (7.3)	205.3 (0.7)	256.0 (0.0)
Alternative NI grids				
Preferred $NI(10 4, 0.55)$	164.9 (7.9)	110.3 (0.3)	137.6 (4.4)	192.2 (3.8)
Slow $NI(10 4, 0.71)$	205.3 (6.7)	205.3 (7.3)	205.3 (0.7)	256.0 (0.0)

Table 3: Theoretical durations in ms for the four samba events based on the NI grids of Figure 9. In parenthesis, the differences between the theoretical durations and the observed mean durations for the respective events are shown. Differences greater than the respective standard deviations are shown in bold.

10|4 NI grid can reproduce the differences between the durations of event 1 and 3 (Figure 9 and Table 3, alternative NI grids). The period of the 10-beat Formative pulse at this tempo is 61ms, which is below the perceptual threshold mentioned in section 2.1 for metrical subdivisions. Nevertheless, it may still be a plausible hypothesis considering the shortest event duration in the pattern at hand is 69ms. A similar hypothesis for the fast tempo would result in a period of 46ms for the Formative pulse, which was considered too fast within this context and was omitted. At the slow tempo, the alignment of the 10-beat Formative pulse is identical to the 5-beat one and thus offers no advantage.

4.3 Tempo dependence

The above hypotheses provide alternative explanations to those given in [10] for the tempo dependence of the basic samba pattern.

In the 4-beat formative hypothesis, we reproduce the patterns by gradually changing the shift S , from an almost purely binary pattern at slow tempo to a mixed character pattern at faster tempi. As the tempo becomes faster, the 4-beat pulse approaches the lower threshold for a metrical subdivision and events are pulled from their formative positions (period of 114ms) towards the ternary subdivision (period of 151ms), which is still significantly above the threshold.

In the 5-beat formative hypothesis, the tempo dependence is explained by the introduction of a subdivision in the target pulse at the slow tempo and change to the polyrhythmic structure from 5|2 to 5|4. At the preferred tempo, the small value of S indicates that events are mainly attracted to the faster 5-beat pulse (period of 121ms) and to a lesser extent to the slower binary subdivision (period of 303ms). As the tempo increases, S moves towards the binary pulse, possibly due to the 5-beat pulse crossing the 100ms threshold (91ms period). At the slow tempo, the binary pulse is subdivided, resulting in pulses with moderate

periods (174ms for the 5-beat pulse and 218ms for the 4-beat pulse) and a more mixed character pattern.

5. CONCLUSION

In this paper, we formalize a novel model for non-isochronous and micro-timing rhythmic patterns that departs from theoretical and cognitive models that emphasize the hierarchical grouping of isochronous pulses prevalent in Western classical music theories. Instead, our model is rooted in non-hierarchical polyrhythmic relationships, such as those found in African polyphony. By incorporating polyrhythmic structures consisting of two pulses, our approach integrates both the structural/macro level and the expressive/micro level of musical rhythms, which are traditionally treated as separate. The resulting construct of non-isochronous (NI) grids unifies these levels within a novel framework. Non-isochronous groupings such as the Euclidean rhythms are then a special case of the model. While, NI grids can model systematic timing deviations from isochrony, not all deviations from isochrony can be accounted for by NI grids, and expressive timing may introduce micro-timing deviations to NI grids.

Our model is a music-theoretical one and is not intended to represent cognitive processes directly. However, some of its predictions may be relevant to music cognition. For example, it has previously been argued that only two beat classes, Long and Short, are perceptually relevant and that Medium duration events must be understood as expressive variants of these two beat classes [48]. A subsequent study showed that this is indeed the case in Mali Drum Ensemble music [49]. Our model makes similar predictions about the existence of only two beat classes, albeit for different reasons and with different implications for the observed patterns. To assess the perceptual relevance of these predictions, further analysis of musical performances and behavioral experiments are needed.

The potential of non-isochronous grids in music analysis was demonstrated in the example of Brazilian Samba. We developed two concrete hypotheses for the basic Samba pattern reported in the literature [10], which model the most salient features of the measured event durations and offer alternative explanations and interpretations for their tempo dependence. Polyrhythmic interpretations of the non-isochronous patterns observed in Samba performances have been hypothesized before, for example in [9]. However, such hypotheses are typically explored in a phenomenological and abstract, conceptual form. Our model provides the basis for a formalized method of determining the details of the polyrhythmic and micro-timing character of the observed durational patterns.

A future study will further test our preliminary hypotheses and compare them with other accounts of samba patterns. For example, we will investigate the possibility that some of the variation in measured durations may be due to a dynamic shift S that changes from one repetition of the pattern to the next. In addition, we will explore the development and evaluation of automated methods for discovering NI grids that can account for the durational patterns observed in music from various genres and music traditions.

ABSTRACT

We introduce **CLaMP**: Contrastive Language-Music Pre-training, which learns cross-modal representations between natural language and symbolic music using a music encoder and a text encoder trained jointly with a contrastive loss. To pre-train CLaMP, we collected a large dataset of 1.4 million music-text pairs. It employed text dropout as a data augmentation technique and bar patching to efficiently represent music data which reduces sequence length to less than 10%. In addition, we developed a masked music model pre-training objective to enhance the music encoder’s comprehension of musical context and structure. CLaMP integrates textual information to enable semantic search and zero-shot classification for symbolic music, surpassing the capabilities of previous models. To support the evaluation of semantic search and music classification, we publicly release WikiMusicText (WikiMT), a dataset of 1010 lead sheets in ABC notation, each accompanied by a title, artist, genre, and description. In comparison to state-of-the-art models that require fine-tuning, zero-shot CLaMP demonstrated comparable or superior performance on score-oriented datasets. Our models and code are available at <https://github.com/microsoft/music/tree/main/clamp>.

1. INTRODUCTION

Symbolic Music Information Retrieval (MIR) is a field that deals with the automatic analysis and retrieval of music based on symbolic representations such as sheet music or MIDI files. Symbolic MIR has numerous practical applications, including music genre classification [1, 2], automatic music transcription [3, 4], and music recommendation systems [5]. However, traditional symbolic MIR approaches based on handcrafted features are often limited in their ability to capture the complex nature of music.

Deep learning has become increasingly popular in symbolic MIR [6–9] due to its ability to extract complex and

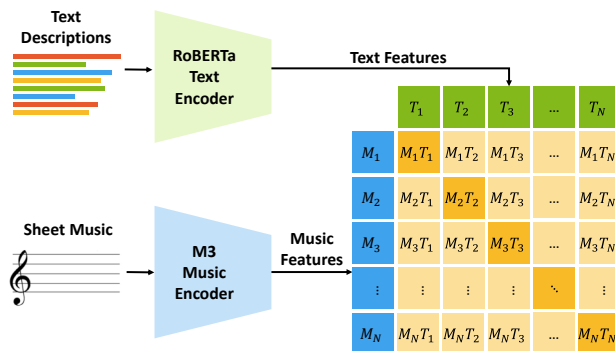

Figure 1. The architecture of CLaMP, including two encoders - one for music and one for text - trained jointly with a contrastive loss to learn cross-modal representations.

abstract music features from large datasets. However, obtaining sufficient labelled data can be costly and time-consuming, as most labelled symbolic music datasets are small in size [10–12]. To address this issue, semantic search and zero-shot classification techniques can be used to retrieve and label extensive unlabelled data. These techniques enable the search for music by a given open-domain query (e.g., "upbeat music with a fast tempo"), or the automatic identification of music characteristics based on customized labels without the need for training data.

To enable semantic search and zero-shot classification for symbolic music, it is necessary to establish a connection between music and language. This can be achieved through the use of contrastive learning [13–17] and pre-training [18–20]. Contrastive learning trains models to learn a feature space where similar sample pairs are grouped and dissimilar pairs are separated, while pre-training involves training a model on a large dataset that can be fine-tuned or directly applied to a specific task.

In this paper, we introduce a solution for cross-modal symbolic MIR that utilizes contrastive learning and pre-training. The proposed approach, **CLaMP**: Contrastive Language-Music Pre-training, is inspired by the success of vision-language models [13]. Unlike prior models that rely solely on symbolic music [9, 12, 21], CLaMP learns semantically rich representations of musical concepts from both sheet music and natural language. The contributions of this paper are as follows:

Sun, "CLaMP: Contrastive Language-Music Pre-training for Cross-Modal Symbolic Music Information Retrieval", in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

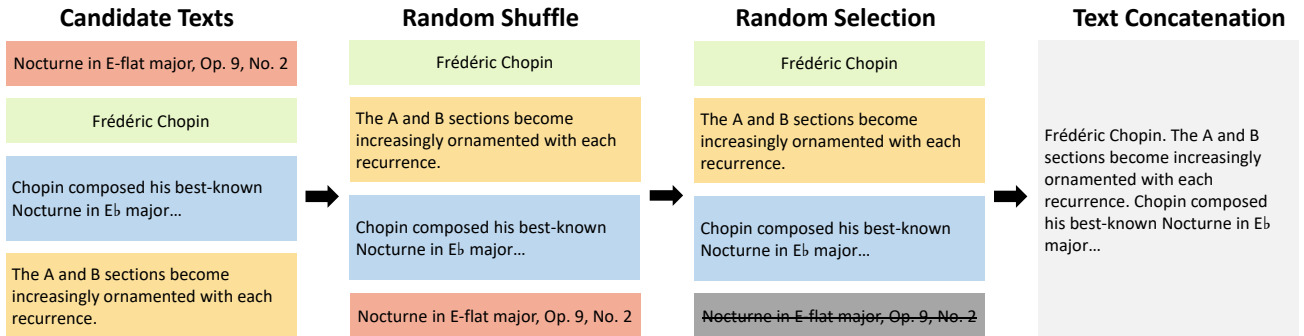

Figure 2. Text dropout is a data augmentation technique that involves a process in which candidate texts are shuffled randomly and then selected to form a concatenated text. In this example, three candidate texts were randomly selected and concatenated to produce the input text.

- CLaMP is a cross-modal model for symbolic MIR, which is pre-trained on WebMusicText (WebMT), a dataset of 1.4 million music-text pairs. To the best of our knowledge, this is the first model of its kind and it achieves comparable or better performance than existing state-of-the-art models without training.
- We propose multiple techniques to improve contrastive language-music pre-training. Our proposed techniques include applying text dropout as a data augmentation method, utilizing bar patching for efficient music representation, and implementing the masked music model pre-training objective.
- The cross-modal pre-training empowers CLaMP to perform tasks beyond the capabilities of unimodal models. It possesses unique features such as semantic search for desired music using open-domain text queries and zero-shot classification for new music.
- To facilitate the evaluation of semantic search and music classification, we release the WikiMusicText (WikiMT) dataset, which consists of 1010 music-text pairs sourced from Wikifonia and Wikipedia.

2. METHODOLOGY

This section presents CLaMP and its cross-modal symbolic MIR abilities. Additionally, we describe the WebMT dataset, which we created to pre-train our model.

2.1 Model Design

2.1.1 Contrastive Learning Objective

CLaMP jointly trains music and text encoders to represent the structural and semantic aspects of both modalities in a shared feature space. This is achieved using a batch construction method and objective [22, 23], as illustrated in Fig. 1, whereby the correct pairings of a batch of N music-text pairs are predicted. The music and text encoders employ global average pooling to obtain corresponding features from the last hidden states.

The objective of CLaMP is to minimize the distance between N paired music-text examples while maximizing the distance between $N^2 - N$ unpaired examples. We denote a

batch of N music-text pairs as $(m_i, t_i)_{i=1}^N$, where m_i and t_i represent the i -th music and text inputs, respectively. The music and text encoders are represented as f_m and f_t . The contrastive loss for $(m_i, t_i)_{i=1}^N$ is defined as follows:

$$\mathcal{L}_{CL} = -\frac{1}{2N} \sum_{i=1}^N \left(\log \frac{\exp(f_m(m_i) \cdot f_t(t_i)/\tau)}{\sum_{j=1}^N \mathbb{1}_{i \neq j} \exp(f_m(m_i) \cdot f_t(t_j)/\tau)} + \log \frac{\exp(f_m(m_i) \cdot f_t(t_i)/\tau)}{\sum_{j=1}^N \mathbb{1}_{i \neq j} \exp(f_m(m_j) \cdot f_t(t_i)/\tau)} \right), \quad (1)$$

where τ is a temperature hyper-parameter that controls the sharpness of the softmax distribution, and $\mathbb{1}_{i \neq j}$ is an indicator function that equals 1 if $i \neq j$, and 0 otherwise. The two terms in Eq. 1 consider either music-to-text or text-to-music logits.

2.1.2 Text Encoder

CLaMP includes a text encoder to extract musically relevant features from the input text. To achieve optimal performance, a pre-trained language model is used to initialize the text encoder. Furthermore, text dropout is employed as a data augmentation technique to prevent overfitting and improve the generalization ability of the text encoder.

Pre-trained Language Model RoBERTa [24] is a transformer-based language model pre-trained on a large corpus of English text using the Masked Language Modeling (MLM) objective [18]. This model is designed to be fine-tuned on downstream tasks and has demonstrated excellent performance as a text encoder for the contrastive language-audio pre-training [25]. To improve training efficiency, we used DistilRoBERTa [26] instead, which has fewer parameters (82M) compared to RoBERTa-base (125M) while achieving comparable performance.

Text Dropout Text dropout is a data augmentation technique that encourages models to learn robust features from input texts. This technique involves using a dataset consisting of multiple paired candidate texts from various sources for each musical composition. Similar to [27], for a given composition with L candidates, text dropout shuffles the set of candidate texts and randomly selects K texts, where K is uniformly and randomly sampled from integers ranging from 1 to L . These selected texts are concatenated to form a single input text for the text encoder, as shown in

Table 1. The average number of tokens per lead sheet in the WikiMT dataset with different encoding methods.

Encoding	Bar Patching	ABC Notation	OctupleMIDI [9]
Tokens	47.07±21.60	749.16±379.56	469.09±256.43

Fig. 2. Text dropout offers a wider range of possible text combinations and allows the model to learn more complex and diverse textual features.

2.1.3 Music Encoder

The CLaMP music encoder is designed to understand the complex musical structure and context within ABC notation. As a text-based format for symbolic music, ABC notation incorporates a wide range of musical symbols commonly used in sheet music. To keep all musical information while shortening sequence length, the encoding process utilizes the bar patching technique. To optimize performance, the music encoder is specifically designed for symbolic music understanding based on bar patching.

Bar Patching The bar in musical notation groups phrases by defining a fixed number of beats and each bar can be read and played as a single unit. It is separated by vertical lines, providing reference points for locating positions within a score.

Previous models [28–31] for ABC notation utilized character-based tokenization, resulting in sequences that are too lengthy to process efficiently. On the other hand, MeasureVAE [32] demonstrated the feasibility of encoding scores at the bar-level for music generation. To improve the efficiency of processing, we proposed bar patching, inspired by patch-based techniques in computer vision [33].

Bar patching divides a score into several small segments corresponding to bars or headers (i.e. meta-information) in ABC notation. In our implementation, each patch is assigned a maximum of 64 characters, covering 98.8% of the headers or bars in the pre-training dataset. We add an [END] token at the end of each patch to indicate the end of the sequence. Patches with fewer than 64 are padded with [PAD] tokens, while those with over 64 characters are truncated. For the vocabulary, 95 ASCII printable characters and three special tokens (i.e., [PAD], [MASK], and [END]) are considered, resulting in a total of 98 tokens. Thus, each patch can be represented as a 64×98 matrix. These patches are then flattened and projected into 768 dimensions embeddings and used as input tokens, as illustrated in Fig. 3.

Bar patching effectively reduces the average sequence length of the encoded music to less than 10% of the original ABC notation, as shown in Table 1. This technique improves the efficiency of representing music and facilitates faster computation while preserving all musical information in the notation.

Masked Music Model The Masked Music Model (M3) is a self-supervised model for symbolic MIR based on bar patching representation. The primary concept of M3 is to introduce random noise to certain patches of the input music, and then reconstruct the characters in the noise-

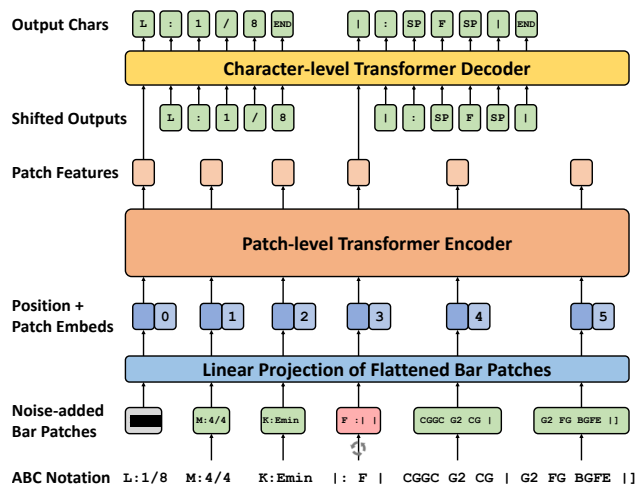

Figure 3. The masked music model architecture, where the encoder takes in a sequence of patches, and the decoder reconstructs character information of noise-added patches.

added bar patches based on the context. This pre-training enables M3 to learn from unlabelled musical data, making it useful for initializing the CLaMP music encoder.

M3 is based on an asymmetric encoder-decoder architecture, similar to MAE [34], as shown in Fig. 3. It uses an encoder to extract contextualized features of individual patches, along with a decoder, which is lightweight and autoregressively reconstructs the characters for each patch. After pre-training, the decoder is discarded and the encoder is used to initialize the music encoder of CLaMP.

The pre-training objective is inspired by MLM [18]. We first randomly select $M\%$ of the bar patches in the input music, and then the noise is added in three different ways:

- *Masking*: 80% of the selected bar patches are replaced with a special patch filled with [MASK] tokens. This encourages the model to learn to fill in missing information and understand the relationship between different musical elements.
- *Shuffling*: 10% of the selected bar patches are randomly shuffled internally. For example, a bar patch "| : F |" may be randomly shuffled to "F : | |" as shown in Fig. 3. This forces the model to learn the patterns and structures within bar patches.
- *Unchanged*: 10% of the selected bar patches are left unchanged. This can narrow down the gap between pre-training and fine-tuning.

M3 is trained to predict the original characters in the noise-added bar patches based on contextualized patch features. The model is optimized using the cross-entropy loss, which compares the predicted characters with the ground truth characters. The final objective is to minimize the average loss over all the noise-added bar patches in the training set. By denoising these bar patches, M3 learns to capture the dependencies and relationships between different musical elements and structures, allowing it to extract meaningful features from ABC notation.

Figure 4. The processes of CLaMP performing cross-modal symbolic MIR tasks, including semantic search and zero-shot classification for symbolic music, without requiring task-specific training data.

2.2 Cross-Modal Symbolic MIR

CLaMP is capable of aligning symbolic music and natural language, which can be used for various cross-modal retrieval tasks, including semantic search and zero-shot classification for symbolic music.

Semantic search is a technique for retrieving music by open-domain queries, which differs from traditional keyword-based searches that depend on exact matches or meta-information. This involves two steps: 1) extracting music features from all scores in the library, and 2) transforming the query into a text feature. By calculating the similarities between the text feature and the music features, it can efficiently locate the score that best matches the user’s query in the library.

Zero-shot classification refers to the classification of new items into any desired label without the need for training data. It involves using a prompt template to provide context for the text encoder. For example, a prompt such as "This piece of music is composed by {composer}." is utilized to form input texts based on the names of candidate composers. The text encoder then outputs text features based on these input texts. Meanwhile, the music encoder extracts the music feature from the unlabelled target symbolic music. By calculating the similarity between each candidate text feature and the target music feature, the label with the highest similarity is chosen as the predicted one.

2.3 WebMusicText Dataset

To facilitate the learning of relationships between natural language and symbolic music, we developed a dataset named WebMusicText (WebMT) by crawling an extensive collection of music-text pairs from the web. Our dataset comprises 1,448,750 pairs of music-text data, where all music files are in score-oriented formats (e.g., MusicXML, LilyPond, and ABC notation). To reduce the disparity between scores in different notations, we first converted all music files to MusicXML and then to ABC notation¹. In addition, to avoid information leakage, we removed any natural language (e.g., titles, composers, and lyrics) in ABC notation. The text parts of each pair were obtained

¹ <https://wim.vree.org/svgParse/xml2abc.html>

from corresponding meta-information (e.g., title and composer) or user comments, and are all in English. WebMT features diverse musical compositions, from monophonic folk music to polyphonic orchestral music, which enables the model to learn a wide range of musical information.

3. EXPERIMENTS

3.1 Settings

3.1.1 Models

- **MusicBERT** [9]: This model combines unsupervised pre-training with supervised fine-tuning, which achieved state-of-the-art results. MusicBERT is available in two settings: *MusicBERT-S/1024* (MusicBERT_{small}), and *MusicBERT-B/1024* (MusicBERT_{base}). MusicBERT-S/1024 consists of 4 layers and was pre-trained on the small-scale Lakh MIDI Dataset (LMD, 148,403 pieces) [35], while MusicBERT-B/1024 has 12 layers and was pre-trained on the large-scale Million MIDI Dataset (MMD, 1,524,557 pieces). Both models have a maximum length of 1024.
- **M3**: Our proposed music encoder is used to compare the performances of unimodal and multimodal models trained on the same dataset (i.e., WebMT). M3 comes with two settings: *M3-S/512* and *M3-S/1024*, with maximum lengths of 512 and 1024, respectively. In the following experiments, both settings use the 6 encoder layers only.
- **CLaMP**: Several variants were tested to verify the effectiveness of the proposed techniques for improving contrastive language-music pre-training. These include *CLaMP-S/512* which is the full model, *CLaMP-S/512 (w/o TD)* which removes text dropout, *CLaMP-S/512 (w/o M3)* which has a randomly initialized music encoder, and *CLaMP-S/512 (w/o M3, BP)* which removes both M3 and bar patching, and uses char-level tokenization to encode raw ABC notation instead. *CLaMP-S/1024* was included to verify the effectiveness of an extended maximum length.

3.1.2 Pre-training

The text encoder was initialized using DistilRoBERTa [26], with a maximum length of 128, and the music encoder was initialized using two settings: M3-S/512 and M3-S/1024. A length of 512 resulted in truncating 17.29% of compositions in WebMT, while a length of 1024 reduced truncation to 7.7%. Both models were trained for 40 epochs with 6 encoder layers and 3 decoder layers, an embedding size of 768, and a noise ratio of 45%. Based on these two M3 encoders, we developed CLaMP-S/512 and CLaMP-S/1024. Both of them were trained for 20 epochs, using the AdamW optimizer [36] with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$, and a weight decay coefficient of 0.01. The batch size is set to 640, and the temperature $\tau = 0.2$. The training process was accelerated and memory was saved by using mixed precision [37].

3.1.3 Evaluation Datasets

We introduce WikiMusicText (WikiMT)², a new dataset for the evaluation of semantic search and music classification. It includes 1010 lead sheets (melodies with harmonies) in ABC notation sourced from Wikifonia, each accompanied by a title, artist, genre, and description. The title and artist information is extracted from the score, whereas the genre labels are obtained by matching keywords from the Wikipedia entries and assigned to one of the 8 classes that loosely mimic the GTZAN genres [38]. The description is obtained by utilizing BART-large [39] to summarize and clean the corresponding Wikipedia entry. Additionally, following WebMT, the natural language information within the ABC notation is removed.

In addition to WikiMT, we use two other datasets to evaluate music classification: VGMIDI and Pianist8. VGMIDI [11] includes 204 score-oriented MIDI arrangements that were classified according to the valence-arousal model. Pianist8 [12] contains symbolic piano performances of 411 pieces from 8 composers with distinct styles, which were automatically transcribed from audio using a model presented in [8].

3.1.4 Metrics

We use the following three metrics to evaluate the effectiveness of models in various downstream tasks:

- Mean Reciprocal Rank (MRR) is used to evaluate ranking systems. This metric calculates the average of the reciprocal ranks of the correct answers, which measures the effectiveness of the ranking.
- Hit Ratio at K (HR@K) measures the accuracy of the model by checking if the correct item is among the top K recommendations, which is often used in recommendation systems.
- F1-macro score is a metric that assesses the overall effectiveness of a classification model. It is computed using the arithmetic mean (i.e., unweighted mean) of all the per-class F1 scores.

Table 2. Semantic search performance of CLaMP on WikiMT (1010 music-text pairs) under different settings.

Setting	MRR	HR@1	HR@10	HR@100
S/512	0.2561	0.1931	0.3693	0.7020
S/1024	0.2016	0.1436	0.3109	0.6554
S/512 (w/o TD)	0.1841	0.1248	0.2911	0.6188
S/512 (w/o M3)	0.1262	0.0802	0.1960	0.5119
S/512 (w/o M3, BP)	0.0931	0.0525	0.1584	0.4426

3.2 Results

3.2.1 Semantic Search

In the semantic search evaluation, we assessed different versions of CLaMP for semantic search, aiming to test the efficacy of contrastive language-music pre-training techniques. The pre-training dataset WebMT and the evaluation dataset WikiMT have no overlap, thus guaranteeing the validity of our evaluation results. In addition, as semantic search requires no additional training for this dataset, it demonstrates the generalizability of CLaMP.

Table 2 shows that our full model (CLaMP-S/512) outperforms all other models across all metrics. Interestingly, we discovered that increasing the maximum sequence length to 1024 (CLaMP-S/1024) did not lead to an improvement in performance. We attribute this to the fact that all lead sheets in the WikiMT dataset, once encoded with bar patching, have a length smaller than 512, which limits the potential advantages of the longer sequence length of CLaMP-S/1024. We also observed that the removal of the proposed techniques from CLaMP had a considerable negative impact on semantic search performance. Notably, the removal of M3 pre-training had the greatest effect on model performance, followed by text dropout and bar patching.

In conclusion, our evaluation of CLaMP on WikiMT shows that CLaMP-S/512 with all proposed contrastive language-music pre-training techniques is the most effective for the semantic search task. This highlights the importance of these techniques for effective pre-training and semantic search tasks. Additionally, increasing the sequence length (CLaMP-S/1024) did not improve the model’s performance. These results emphasize the significance of using appropriate pre-training techniques in language-music models and suggest that a longer sequence length may not necessarily result in better outcomes.

3.2.2 Music Classification

The goal of the classification evaluation is to assess how well the zero-shot CLaMP models perform compared to other fine-tuned models. In addition, to evaluate pre-trained models, linear probes are used to train a linear classifier for the classification based on the features from pre-trained models. Despite being less powerful and relying on pre-trained model features, linear classifiers offer a valuable means of quantitatively assessing feature quality [40].

Table 3. Classification performance of different models on three datasets: WikiMT (1010 pieces, 8 genres), VGMIDI (204 pieces, 4 emotions), and Pianist8 (411 pieces, 8 composers).

Model	WikiMT		VGMIDI [11]		Pianist8 [12]	
	<i>F1-macro</i>	<i>Accuracy</i>	<i>F1-macro</i>	<i>Accuracy</i>	<i>F1-macro</i>	<i>Accuracy</i>
<i>Linear Probe MusicBERT-S/1024</i>	0.2401	0.3507	0.4662	0.5350	0.8047	0.8102
<i>Linear Probe MusicBERT-B/1024</i>	0.1746	0.3219	0.5127	0.5850	0.8379	0.8413
<i>Zero-shot CLaMP-S/512</i>	0.2660	0.3248	0.5217	0.6176	0.2180	0.2512
<i>Zero-shot CLaMP-S/1024</i>	0.2248	0.3406	0.4678	0.5049	0.1509	0.2390
<i>Linear Probe M3-S/512</i>	0.2832	0.3990	0.5991	0.6667	0.6773	0.6909
<i>Linear Probe M3-S/1024</i>	0.3079	0.4020	0.5966	0.6522	0.6844	0.6958
<i>Linear Probe CLaMP-S/512</i>	0.3452	0.4267	0.6453	0.6866	0.7067	0.7152
<i>Linear Probe CLaMP-S/1024</i>	0.3449	0.4416	0.6345	0.6720	0.7271	0.7298

WikiMT was converted into the MIDI format using music21 [41] to be compatible with MusicBERT. In contrast, for VGMIDI and Pianist8, we employed MuseScore3’s batch conversion tool³ to convert the scores into the MusicXML format, which were then converted into ABC notation for use with M3 and CLaMP.

We conducted 5-fold cross-validation with the same folds to assess all linear probe models, using identical fine-tuning settings and a batch size of 10 to ensure consistency, given the limited size of the evaluation datasets. The linear probe CLaMP models used the music encoder only, while the text encoder was discarded. In the zero-shot classification setting, CLaMP had no previous exposure to these evaluation datasets during pre-training. We utilized manually designed prompts for the zero-shot CLaMP models.

The top half of Table 3 presents the comparison of the performance between linear probe MusicBERT and zero-shot CLaMP. The results found that the zero-shot CLaMP models demonstrated comparable or even superior performance compared to the linear probe MusicBERT models on WikiMT and VGMIDI datasets. Interestingly, the smaller zero-shot CLaMP-S/512 outperformed the larger linear probe MusicBERT-B/1024, indicating that the pre-training of CLaMP has enabled it to learn more generalizable features that are useful for zero-shot music classification. However, this trend was not observed on Pianist8, where MusicBERT models performed much better than zero-shot CLaMP models. This difference in performance can be attributed to the source of the datasets, as WikiMT and VGMIDI primarily focus on score information, whereas Pianist8 contains performance MIDI data derived from audio. Since both CLaMP and M3 were trained exclusively on score information, they lack knowledge of performance MIDI. However, we noticed that the performances of linear probe CLaMP models on Pianist8 significantly improved after fine-tuning compared to the zero-shot ones. This suggests that incorporating ABC notation from performance MIDI into the pre-training of CLaMP may enhance its ability to comprehend such data.

The linear probe CLaMP models show better performance compared to the linear probe M3 models, as indicated in the bottom half of Table 3, despite being pre-trained on the same dataset with the same architecture. This is attributed to the use of contrastive learning, which aligns the music encoder of CLaMP with the text modality, thus implicitly introducing textual information to the music encoder. Furthermore, we found that CLaMP-S/1024 performed better on Pianist8 than CLaMP-S/512, suggesting that a larger maximum length is beneficial for models to learn performance MIDI.

In summary, our evaluation demonstrates that zero-shot CLaMP performs comparably to state-of-the-art models in music classification. Furthermore, the incorporation of contrastive learning and textual information enhances the music encoder’s performance, resulting in better classification accuracy when compared to M3 which employed the same architecture. These results highlight the potential of CLaMP as a pre-training framework for symbolic MIR.

4. CONCLUSIONS

This paper introduces CLaMP, a pre-trained model that utilizes contrastive language-music pre-training techniques to build cross-modal representations between natural language and symbolic music. The model was trained on a dataset containing 1.4 million music-text pairs and has demonstrated unique abilities of semantic search and zero-shot classification for symbolic music. Compared to state-of-the-art models that require fine-tuning, zero-shot CLaMP exhibits comparable or superior performance in score-oriented music classification tasks without any training. However, the current version of CLaMP has limited comprehension of performance MIDI, and still has room for improvement. Future research will aim to expand its capabilities by scaling it up and pre-training it on larger datasets that incorporate a wider range of symbolic music formats beyond score-oriented ones. We expect that its cross-modal representations will facilitate research on new topics in music analysis, retrieval, and generation, and provide a foundation for the development of innovative systems and applications that integrate music and language.

GENDER-CODED SOUND: ANALYSING THE GENDERING OF MUSIC IN TOY COMMERCIALS VIA MULTI-TASK LEARNING

Luca Marinelli György Fazekas Charalampos Saitis

C4DM, Queen Mary University of London, UK

{l.marinelli, c.saitis, george.fazekas}@qmul.ac.uk

ABSTRACT

Music can convey ideological stances, and gender is just one of them. Evidence from musicology and psychology research shows that gender-loaded messages can be reliably encoded and decoded via musical sounds. However, much of this evidence comes from examining music in isolation, while studies of the gendering of music within multimodal communicative events are sparse. In this paper, we outline a method to automatically analyse how music in TV advertising aimed at children may be deliberately used to reinforce traditional gender roles. Our dataset of 606 commercials included music-focused mid-level perceptual features, multimodal aesthetic emotions, and content analytical items. Despite its limited size, and because of the extreme gender polarisation inherent in toy advertisements, we obtained noteworthy results by leveraging multi-task transfer learning on our densely annotated dataset. The models were trained to categorise commercials based on their intended target audience, specifically distinguishing between masculine, feminine, and mixed audiences. Additionally, to provide explainability for the classification in gender targets, the models were jointly trained to perform regressions on emotion ratings across six scales, and on mid-level musical perceptual attributes across twelve scales. Standing in the context of MIR, computational social studies and critical analysis, this study may benefit not only music scholars but also advertisers, policymakers, and broadcasters.

1. INTRODUCTION

The purpose of this study is to analyse gender-coding in a context where music is secondary to other modalities and serves a clear purpose, such as in advertisement. Our aim is to investigate how music may be employed to reinforce traditional gender roles in toy commercials, and we propose an automatic method for analyzing this phenomenon.¹ Our overarching research objective is to pro-

¹ https://github.com/marinelliluca/gender_coded_sound_ismir2023

vide a basis for a theory of message production. Specifically, a theory of the effects that message producers, their decision-making, or their unconscious gender biases have on the selection and composition of sound and music in toy adverts. For this goal, we propose an integrative approach combining content analytical (CA) variables, music perceptual ratings, and multimodal affective ratings to annotate toy commercials, and using multi-task learning (Fig. 1) to analyse the gendering of their soundtracks.

1.1 Gendered music styles as cognitive schemas

Empirical studies have demonstrated that gender and sex impact the perception and processing of music [1–3]. However, the idea that sex determines fixed differences in brain structure has been questioned due to potential misinterpretations, overestimations, and publication bias [4]. Gender schemas, instead, are *learned* cognitive networks of associations that guide an individual’s behavior by assimilating or rejecting gender-appropriate ideas and activities [5,6]. Schemas guide an individual’s perception, information processing, and memory retention, as they prevent information overload by organising one’s perceptual experience into a coherent and intelligible whole [6,7].

Popular music genres have been themselves theorised as cognitive schemas containing extramusical concepts that can be primed when a subject is exposed to the genre’s music [8,9]. Such schemas are formed through repeated exposure to the multimodal discourse encompassing music, which is to some extent globalised, but that also varies from culture to culture as a result of glocalisation.² processes [9] Schema theory has also been used in literary reading and analysis to explain organised "bundles of information and features" [10, p. 106-7] such as literary genres (e.g., science fiction, fantasy, horror).

While gendered language patterns in text and lyrics [11] may be relatively more straightforward to interpret, gender-coding in sound and music ensues from the historical sedimentation, in musical practice, of multimodal associations between gendered meanings in language, visual images, and musical structures [12]. For example, instruments have been consistently associated with masculinity or femininity, even when their sound is presented in isolation and not visually linked to the actual object [13,14]. Sergeant and Himonides [15,16] investigated whether in Western art music individual sounds or their organization

² A lexical blend of globalization and localism.

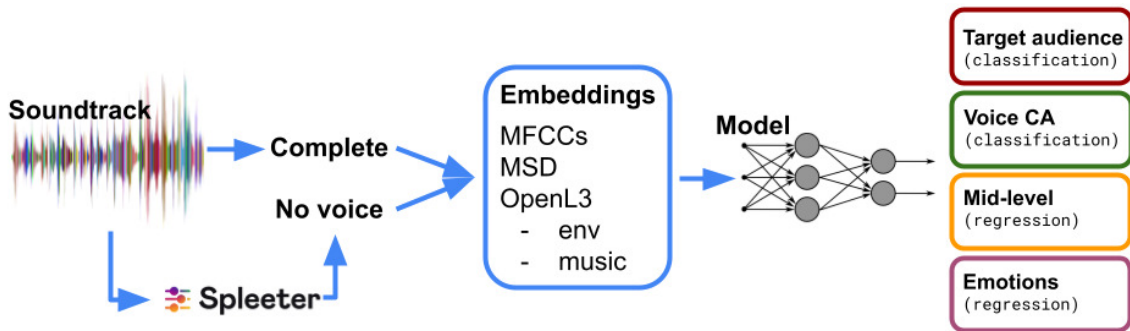

Figure 1. Brief overview of the experimental pipeline.

within a composition could infer the sex or gender of the performer or composer. Even though they found no correlation between the gender of the composers or performers and the gendering of music, raters agreed on the gendering of music, which was associated with features such as tempo, minor/major key, and tonal weight or density. Tagg [17] studied the reception of gendered meanings in TV theme tunes and also found high agreement among participants. Several musical dimensions, such as average tempo, rhythmic and dynamic regularity, and presence of active bass lines, may contribute to conveying gendered meanings. In a subsequent investigation, Tagg and Clarida [18] found that musical pieces linked to female characters were more prone to be classified as quiet and calm. Wang and Horvát [19] computationally extracted twelve descriptors of musical parameters and perceptual features for over 200k songs by more than 8k globally distributed artists across a multitude of popular music genres. They found statistically significant differences for eleven out of twelve musical parameters with regard to the gender of the composers, suggesting the existence of measurable, supra-genre, gendered music styles in the global music industry.

Some of these studies appear to contradict each other,³ while at the same time sharing the same fallacy, in that feminine and masculine patterns in the performance and composition of music should be considered on a par with distinct gendered styles in spoken language, such as Lakoff’s ‘women’s talk’ [20]. As such, these differences should not be understood in terms of a causal relationship between the gender of the artists and gendered musical patterns. Individuals may have a tendency to use forms of expression that they deem appropriate with regard to their identity, but given the performative nature of gender we cannot possibly generalise this behaviour (i.e., even strong correlation is not causation), as this would end up reinforcing gender stereotypes and their power relations.

Gender schemas therefore mediate our perception of music, and this relationship appears to be bidirectional. At the same time, music-primed schemas can alter our perception of other people’s ethnicity, rural/urban background, age, expertise [8], and even gender [21, 22]. We thus posit that not only gender roles and stereotypes can

be understood in terms of schemas, but also that masculine and feminine music styles can be viewed as *music-primed gender schemas*, which to some extent overlap with the former. We also presume that different music-primed schemas might exist for other intersectional factors, such as class.

1.2 Gendered toy marketing

Gender polarisation in TV advertising aimed at children has been consistently found in a large body of studies spanning over 40 years [23–25]. Differences in commercials targeted at girls, boys, and mixed audience have been found in terms of: sound (voices, background music and sound effects), language, transitions and camera work, setting, interactions and activities, and colours.

Specifically in terms of sound and music, Welch et al. [23] noted that in general the sex of the voice-over matched the target audience of the commercials, but that male narrating voices also occurred more often in mixed audience commercials, and subsequent research confirmed the same trend [25]. They also found that commercials targeted at boys had more noise, louder music, and more sound effects. Another study [24] conversely found that music used in girls’ advertisements is generally softer and more likely to have a sung narration style. Whereas, Johnson and Young [26] identified what they called “gender exaggeration:” male voice-overs tend to be exceedingly deep, growl-like or aggressive, whereas female voice-overs are often very high-pitched and singsong.

By interpreting music as an inherently multimodal discourse, a critical analysis of gender markers in children’s TV adverts can help to investigate the relation between music and hegemonic discourses on gender; and to promote further research towards a commercial and contemporary musical semiotics of gender. Analysing music in gendered advertising aimed at children allows a privileged glance into the birthplace of music-primed gender schemas.

1.3 Automatic discourse processing

Discourse analysis is an umbrella term that refers to approaches developed across diverse academic disciplines. This includes disciplines that first developed models for understanding discourse, such as linguistics, social semiotics and conversation analysis. But it also refers to other

³ [19] found significant correlations between the gender of the composers and characteristics of their music, while [16] did not.

All <i>N</i> = 606		Feminine <i>N</i> = 163	Masculine <i>N</i> = 149	Mixed <i>N</i> = 200

approaches that apply and extend these models of understanding to their particular academic field, such as cognitive psychology, literary criticism and *artificial intelligence* [27]. Research on discourse processing, an endeavour of natural language processing (NLP), is already at a stage where machine learning approaches are able, for example, to automatically detect social attitudes and political stances in online news or social media [28, 29].

Beyond textual discourse and NLP, denotative meanings in images and videos can be easily captured by machine learning techniques [30, 31]. However, works that try to address connotative meanings or the rhetoric of multimedia content are still in their infancy and such approaches are often not even framed as pertaining to discourse or semiotic analysis. Dinkov et al. [32] predicted the political ideological bias (left, centre, right) of media outlets using text, metadata, and audio (via speech processing techniques) from YouTube channels, but not visual content. Ye et al. [33] predicted the messages that image and video advertisements convey by explicitly modeling symbolic associations (e.g., gun for “danger”) and combining cues from multiple modalities, including the loudness in video soundtracks. Notably, none of these studies leveraged approaches and tools from music information retrieval.

1.4 Multi-task learning in MIR

In multi-task learning we train a single model to perform multiple related tasks simultaneously, leveraging shared information among tasks, which results in several benefits. Böck et al. [34] simultaneously modelled tempo estima-

tion and beat tracking of musical audio, showing state-of-the-art performance for both tasks. Wu et al. [35] combined multi-task and self-supervised learning, resulting in improved performance. Chowdhury et al. [36] proposed a VGG-style deep neural network to predict emotional characteristics of music based on mid-level perceptual features (e.g., melodiousness and tonal stability) and found that the loss in performance was negligible when compared to predicting emotions directly. Further improvements were obtained by training jointly on the mid-level and emotion annotations, with the small loss in performance justified by the gain in explainability of the predictions. Our study expands upon this foundation by incorporating emotions and perceptual features, while also adding more granular structure to facilitate a comprehensive understanding of the gendering of music in multimodal contexts.

2. DATASET

Our hierarchical data collection framework comprised CA variables at the lower level, music-focused ratings from experts at the middle level, and multimodal affective ratings at the highest level of subjectivity. Mid-level perceptual features, which describe relevant and instantly identifiable musical characteristics, exhibit high consistency across listeners and can be predicted from the acoustic signal. These features also correlate with music’s affective dimensions [37]. The emotion ratings were collected from adults rather than children because adults are better equipped to capture the commercials’ intended emotional impact. Fur-

thermore, research indicates that children exhibit adult-like emotion recognition capabilities by age 11 [38].

2.1 Sampling method

In March 2022, we collected a sample of 5614 videos from the official YouTube channel of Smyths Toys Superstores, a major UK toy retailer. To ensure comparability with previous studies [39,40], we selected only high-quality videos intended for television and excluded those without audio, formatted for mobile phones, or with substantial on-screen text. Additionally, we excluded advertisements featuring toddlers and pre-schoolers as these are actually targeted at parents. To minimise duplicates, we removed videos with the same title from our sample.

Given that we are interested in understanding the gendering of sound and music in the toy industry at large, we needed to enforce some balance across gender targets. We thus performed a *preliminary* classification of 1778 commercials based on their intended target audience (feminine, masculine or mixed audience) using simple heuristics regarding the gender of the majority of presenters featuring in the commercial, the colour coding of the video and ultimately the category of the product. This resulted in 780 'feminine', 509 'masculine', and 489 'mixed audience' commercials. A final sample of 606 commercials, spanning over 10 years from 2012 to 2022, was obtained by randomly sampling from each category 202 videos.

2.2 Content analysis (manual annotation)

The *gender orientation* (also *target audience*) of the commercials was determined by the gender of the actors/presenters. Following [26], in order to account for tokenism, whenever a presenter of the other gender was included in the background or for just a few seconds, these were considered token gender representations and not explicit market orientations. All fictional characters, even when realistic (e.g. from a video game), were not considered as actors/presenters and the corresponding commercials were coded as having no actors. Whenever commercials featured exclusively character 'dismemberment' (e.g., showing only hands without a face or head) [41] these were also coded as having no actors.

Four distinct items describing the sound of the voices in the commercial were collected using a coding schema based on Verna's research [42]. But unlike the original work, we coded for all voices in the commercial, both diegetic and non-diegetic. The reason for this choice is that there is no way to reliably distinguish between diegetic and non-diegetic sounds purely based on the audio signal. Commercials were coded in terms of *type of voices* ("Spoken", "Sung", "Both spoken and sung", "No voices"), then in terms of *voices age* ("Adults" which included young adults, "Children", "Children and adults", "No voices"), *gender exaggeration* of the voices ("All normal sounding", "Exaggeratedly masc.", "Exaggeratedly fem.", "No voices"), and finally in terms of *voice gender* ("Feminine", "Masculine", "Feminine and masculine", "No voices"). In order to determine the reliability of each variable, 15% of

the commercials was double-coded by two coders independently. For all variables we obtained Krippendorff's alpha levels above .80 (with 'gender orientation' and 'gender of the voices' exceeding .90), and therefore met the standards of reliability required for this type of analysis [43]. Out of 606 commercials analyzed, 163 were targeted at a feminine audience, 149 at a masculine audience, 200 at a mixed audience and 94 featured no actors or presenters. Contingency tables of the voice variables are shown in Table 1.

2.3 Music-focused and emotion ratings

Participants in our study were paid between £7 and £8 per hour (depending on their completion time) on Prolific.co. In order to minimise the effects of careless responding, a low-effort metric was computed by summing the length of all long strings for each participant, and those that scored above two standard deviations from the average value were screened out during data collection, as it was performed in batches of 50 participants. For 600 of the videos, we collected between five and six ratings on each music and emotion scale. At an initial stage, the remaining 6 videos were used as controls (i.e., were rated by all participants), but we do not leverage them as such in the current study.

Musically trained participants (at least three years of experience with an instrument) rated the soundtracks of the commercials on 15 music-focused bipolar scales [44, 45]: Electric/Acoustic, Distorted/Clear, Loud/Soft, Many/Few instruments, Heavy/Light, High/Low pitch, Punchy/Smooth, Wide/Narrow pitch variation, Harmonious/Disharmonious, Clear melody/No melody, Complex/Simple rhythm, Repetitive/Non-repetitive, Dense/Sparse, Fast/Slow tempo, and Strong/Weak beat. We collected a total of 4560 ratings from 152 participants from the UK (75 M, 77 F, aged 40 ± 14). Given that our focus is on music, but soundtracks consist of speech, music and sound effects, our question was formulated as follows: "The following are a series of perceptual attributes of music. You are asked to evaluate the *music in the background* in terms of the adjectives on each side of the scale."

To annotate the perceived affect of videos, we drew from the aesthetic emotions scale [46, AESTHEMOS], which was devised from an extensive review of emotion measures from different domains such as music, literature, film, painting, advertisements, design, and architecture, and is thus ideal, in its flexibility, for our use with multimodal stimuli. Given that our focus is on music and sound, in a preliminary study we limited our choice to a subset of 10 AESTHEMOS items that intersect with the 13 music emotions listed by Cowen et al. [47]. Of these, we kept only seven scales which showed significant discriminant capabilities: Happy or Delightful, Amusing or Funny, Beauty or Liking, Calm or Relaxing, Energising or Invigorating, Angry or Aggressive, and Triumphant or Awe-inspiring. We used a single unipolar item for each subscale, instead of two. We collected a total of 4530 ratings from 151 participants from the UK (76 M, 75 F, aged 39 ± 13). Given that our aim is to analyse the intended emotional profile, our question was formulated as follows:

Embeddings	Voice	Target F1	Secon. F1	Avg. R^2 emo	Avg. r emo	Avg. R^2 mid	Avg. r mid
mfcc	no	.79 ± .08	.66 ± .07	.02 ± .17	.36 ± .11	.14 ± .16	.48 ± .09
mfcc	yes	.78 ± .10	.65 ± .07	.06 ± .16	.38 ± .11	.13 ± .15	.43 ± .10
msd	no	.87 ± .05	.66 ± .06	.25 ± .11	.54 ± .08	.35 ± .14	.62 ± .09
msd	yes	.95 ± .04	.79 ± .05	.26 ± .15	.56 ± .09	.30 ± .12	.58 ± .09
openl3_env	no	.91 ± .05	.72 ± .06	.34 ± .10	.61 ± .08	.41 ± .10	.66 ± .07
openl3_env	yes	.95 ± .04	.77 ± .05	.34 ± .13	.62 ± .08	.35 ± .12	.62 ± .08
openl3_music	no	.87 ± .09	.71 ± .06	.31 ± .16	.56 ± .19	.39 ± .16	.64 ± .15
openl3_music	yes	.91 ± .11	.76 ± .10	.29 ± .17	.56 ± .19	.31 ± .14	.59 ± .13

Table 2. Mean and standard deviation from 5x repeated 5-fold cross-validation. 'Target' refers to the gender orientation of ads (binary); secondary tasks involve voice-related content analytical variables. 'No' represents models trained on voice-separated accompaniments, while 'Yes' indicates models trained on entire soundtracks.

"Toys commercials are targeted at an audience mainly consisting of children and aim at evoking the following emotions. Pay attention to both sound and images and rate each *intended* emotion accordingly."

2.4 Between-targets ANOVA

We first performed between-targets (i.e., gender targets of the commercials) one-way analyses of variance for each of the music-focused and emotion scales. When ANOVA assumptions were violated, we performed a Kruskal-Wallis H-test instead. Highly significant polarisation ($p < .001$) emerged for twelve of the mid-level music perceptual scales, with stark contrasts observed between feminine and masculine-targeted commercials, and commercials targeted at mixed audiences generally registering in-between values. Masculine adverts were more Electric than Acoustic, more distorted, disharmonious and with a less clear melodic contour than feminine ones. They also were more dense in terms of instrumentation, more Punchy, with stronger beats, and therefore were generally louder and heavier. Also in terms of rhythmic complexity, they were more complex than feminine-targeted commercials. Thus a clear picture emerges, as the soundtracks in boys' adverts are significantly more *abrasive* than those in girls' ads.

Similarly, stark contrasts ($p < .001$) were observed between feminine and masculine-targeted commercials for all affective scales, with commercials targeted at mixed audiences often registering in-between values. Commercials targeted at boys were the least "Happy or delightful", the least "Amusing or funny", "Calm or relaxing", and registered the lowest values on the scale "Beauty or liking". They instead were the most "Energising or invigorating", "Angry or aggressive", and "Triumphant or awe-inspiring". Apart from the scale "Amusing or funny", which scored the highest values within mixed audiences commercials, adverts targeted at girls displayed an opposite behaviour to those for boys. For example, they were the most "Calm or relaxing" and the least "Angry or aggressive". As previously highlighted with the music-focused scales, masculine-targeted commercials appear again to be significantly more *abrasive* than the feminine ones.

We report a more in-depth analysis in an upcoming

publication. In this paper, we exclude "Amusing or funny" from further analyses due to poor correlation with the mid-level features. We also exclude the three non-significant mid-level scales: Wide/Narrow pitch variation, Repetitive/Non-repetitive, and Fast tempo/Slow tempo.

3. MACHINE LEARNING PIPELINE

Our machine learning framework is a multi-task learning model implemented in PyTorch (Fig. 1). It was trained to simultaneously learn mid-level features regression, emotion regression, and all the CA variables (classes). These tasks share an initial hidden layer with 128 units and then branch out into separate sub-tasks. Each sub-task has its own hidden layer with 128 units and an output layer with dimensions corresponding to the specific task.

To avoid the jingle of the retailer in the last 5 seconds of most soundtracks, we trimmed them accordingly. Then with Spleeter [48] we separated voices and accompaniments. Features were extracted in non-overlapping chunks across the trimmed soundtrack and then averaged across the chunks. We computed 20-band MFCCs using *librosa* [49], along with their delta and delta-deltas, yielding 60-dimensional embeddings. A reimplementation of a state-of-the-art model trained on the million song dataset (MSD) [50] provided 256-dimensional embeddings. OpenL3 features were computed using the provided *conda* package [51], generating 512-dimensional embeddings for both environmental and music models.

The proposed model employs an equally weighted, combined loss function, incorporating the mean squared error for the mid-level features and emotion regression tasks, and cross-entropy loss for the classification tasks. The model was trained jointly on all tasks. We also used a model checkpoint and early stopping with a patience of 30 epochs (maximum of 200). Repeated 5-fold cross-validation was performed (10% test, 10% validation, for 5 repetitions, i.e. 25 "folds", as the random seed was not set) and utilised the AdamW optimizer instead of Adam for regularization. Further optimising the network to surpass the already remarkable results, as well as conducting ablation studies to evaluate the various components and design choices, is beyond the scope of our investigation.

Embeddings	Voice	Target F1	Secon. F1	Avg. R^2 emo	Avg. r emo	Avg. R^2 mid	Avg. r mid
mfcc	no	.52 ± .05	.67 ± .06	.04 ± .16	.37 ± .11	.14 ± .14	.48 ± .09
mfcc	yes	.48 ± .04	.67 ± .05	.05 ± .15	.38 ± .11	.15 ± .14	.46 ± .09
msd	no	.62 ± .05	.67 ± .06	.23 ± .15	.54 ± .10	.36 ± .12	.64 ± .07

Table 3. Same as Table 2, but results refer to ternary ‘Target’ classification.

4. RESULTS

Tables 2 and 3 reveal once again stark differences between the soundtracks of commercials designed for feminine and masculine audiences (the value "no" corresponds to models trained on the voice-separated accompaniments). In fact, the binary classification task on the soundtracks including voice achieves an impressively high Target F1 score of $.95 \pm .04$ using the MSD and OpenL3 env embeddings. It is also worth noting that even without voice, the soundtracks still contain enough information to classify the commercials with a high degree of accuracy, with the OpenL3 env embedding achieving a Target F1 score of $.91 \pm .11$. In a way, the dataset is so gendered that it can be considered a toy dataset in all senses.

Upon closer examination of the R^2 and r emotions metrics, we observe that they are relatively low across all experiments compared to mid-level metrics. This contrasts with previous research [36] where mid-level correlations were lower than those of emotions, as in our case the R^2 mid-level and r mid-level metrics are generally higher, with the OpenL3 embeddings performing the best.

When comparing Tables 2 and 3, the high performance of the MSD and both OpenL3 embeddings on the binary task, suggests that there are no significant differences in the soundtracks of mixed-audience commercials compared to those targeted at feminine or masculine audiences. This confirms the results from the analysis of variance and highlights the ability of these embeddings to perform similarly across different target audiences. Overall, we found that the OpenL3 embeddings performed better than others across all tasks, indicating superior generalizability, as already shown in previous research especially in the context of limited training examples [52]. However, the relatively low R^2 and r for emotions suggest that there is still room for improvement, possibly through multimodal fusion.

It is noteworthy that human voice plays a critical role in conveying higher-level connotations, as performance on the classification tasks *and* especially the emotion regressions generally improves when voices are present. Additionally, improvement in mid-level regressions on the accompaniments of the soundtracks (no voice) indicates that participants in the data collection were able to focus on the background of the soundtracks, as they were asked to.

Although the MFCCs are the worst performing, their

discriminative power on the target task and the decent performance on the mid-level features regression highlight the underlying "simplicity" of the task, in terms of the strong collinearity due to the degree of gender-polarization inherent in the dataset.

5. CONCLUSION

By examining the performance of different musical embeddings in classifying commercials targeted at different audiences, and by providing explainable inference of the target of the commercials, in terms of affective and of music perceptual features, this study sheds light on the role of music in gendered marketing strategies. Such approach has significant implications for advertisers, policymakers, and broadcasters, who recently faced a public backlash against the gendered marketing of toys and other products.⁴ Furthermore, the study highlights the importance of considering the role of music when regulating marketing strategies and developing more inclusive and diverse advertising campaigns. Our results suggest that gendered music styles in toy commercials emerge as a result of deliberate marketing strategies, as such styles reflect gender stereotypes that are "ludicrously old-fashioned and offensively out of touch" [53] and still prevalent in the industry.

By bringing together music analysis, machine learning, and critical analysis, this study illustrates the potential of interdisciplinary approaches, contributing to the emerging field of computational social studies. It highlights the importance of considering the role of music, among other modalities, in shaping societal norms and values and the need for greater awareness and accountability in the use of such affordances in marketing and other industries.

Future research can build on these findings by further investigating the relationship between gendered music and advertising strategies in different industries and contexts, exploring the impact of gendered music on consumer behavior and societal perceptions of gender, and developing new methodologies for creating more inclusive and diverse marketing campaigns. The results also emphasise the potential for the development of multimodal approaches to enhance the models’ performance on these tasks.

ABSTRACT

Nowadays, humans are constantly exposed to music, whether through voluntary streaming services or incidental encounters during commercial breaks. Despite the abundance of music, certain pieces remain more memorable and often gain greater popularity. Inspired by this phenomenon, we focus on measuring and predicting music memorability. To achieve this, we collect a new music piece dataset with reliable memorability labels using a novel interactive experimental procedure. We then train baselines to predict and analyze music memorability, leveraging both interpretable features and audio mel-spectrograms as inputs. To the best of our knowledge, we are the first to explore music memorability using data-driven deep learning-based methods. Through a series of experiments and ablation studies, we demonstrate that while there is room for improvement, predicting music memorability with limited data is possible. Certain intrinsic elements, such as higher valence, arousal, and faster tempo, contribute to memorable music. As prediction techniques continue to evolve, real-life applications like music recommendation systems and music style transfer will undoubtedly benefit from this new area of research.

1. INTRODUCTION

Music memorability is essential and has a wide range of commercial applications. For instance, content creators and marketing teams can use unique visual aids or audio components to captivate target audiences and distinguish themselves from other information sources [1, 2]. Sound logos, such as Netflix’s iconic “ta-dum,” are designed to engage listeners and promote brand recognition. In the realm of cognition literature, numerous studies have sought to understand the factors that contribute to music memorability [3–6]. For instance, [5, 6] bridged the gap between cognitive science and MIR by examining whether implicit or explicit memory for a single tune is impacted by

the type of encoding task and variations in timbre, tempo and structure.

However, music memorability remains a relatively unexplored area, particularly from a data-driven standpoint. Research related to music memorability includes the study of involuntary musical imagery (INMI) [7, 8], also known as “earworms,” which refers to the phenomenon where fragments of music become mentally lodged on repeat. For instance, Jakubowski et al. proposed a model that can determine whether a piece of music may induce the INMI effect by using statistical analysis and a random forest model [8]. However, the mechanism of INMI differs from music memorability since the former is a passive process while the latter can be active, e.g., everyone remembers how to sing “Happy Birthday,” but the song may not qualify as an earworm. Another line of prior studies [9–12] investigating the intrinsic memorability of multimedia content have predominantly focused on computer vision, with their findings suggesting that data-driven approaches can effectively determine memorability levels. Motivated by these studies, we break new ground in exploring music memorability from a data-driven perspective by compiling a novel dataset and employing machine learning techniques.

Specifically, to expand the scope of memorability detection and recognition in music information retrieval (MIR), we establish a new research domain called music memorability regression (MMR), which aims to predict a memorability score for a given music piece. We create an experimental procedure as shown in Figure 1 to collect a new dataset, the YouTube Music Memorability (YTMM) dataset, where memorability scores are determined by the percentage of participants who can recall the music piece after a certain period. This dataset provides reliable and consistent music memorability scores across all participants, paving the way for further research in the field. We also propose several baseline approaches for predicting music memorability, including feature engineering using hand-crafted music-related features and transfer learning techniques. These baselines not only demonstrate the potential of machine learning in addressing music memorability but also serve as a foundation for future work.

Despite the promise of machine learning in tackling music memorability by predicting memorability scores, its “black box” characteristics hinder the interpretation of machine decisions in MIR tasks. A straightforward approach would be to compute correlations without relying on black-

Figure 1. The music memory game, which allows data annotators to label music memorability scores reliably. The experiment is divided into three stages, each with a 3-minute long break in between. Each 18-minute stage is composed of multiple 5-second music pieces and short breaks.

box prediction models to glean insights about the relationship between memorability and musical features. However, given the complexity of analyzing music memorability, using a single feature results in an extremely low correlation with memorability, leading to inconclusive findings. One alternative would be to explore all possible feature combinations when calculating correlations, but the sheer number of combinations, e.g., $2^{20} - 1$ for just 20 features, renders this approach impractical. A/B testing could be used to determine which type of music is more memorable, but it suffers from similar drawbacks, such as being time-consuming and unable to account for all variables that may impact the experiment’s outcome. To make machine learning models reveal their “black box” characteristics, researchers are increasingly adopting explainable artificial intelligence (XAI) [13] for deeper insights. Building on previous interpretability analyses in audio processing [14, 15], we utilize Shapley Additive Explanations (SHAP) [16], a game-theoretic approach that clarifies the output of machine learning models, to identify the key components of memorable music.

Our main contributions are as follows: first, we present the new YTMM dataset with objective annotations of memorability scores, which will be publicly available for future research; second, we propose several deep learning baseline models for MMR; and finally, we explore the potential characteristics of memorable music pieces while providing interpretability for these deep learning-based methods.

2. RELATED WORK

In addition to the cognition literature on music memorability [5, 6], there are several related yet distinct terms, such as Involuntary Musical Imagery (INMI) or “earworms”—fragments of music that involuntarily come to mind [7]. Studies have examined earworms through interviews, environmental and psychological conditions leading to INMI, and the impact of melodic features and song popularity on spontaneous musical imagination [8]. Crucial differences between INMI and music memorability include: 1) INMI involves uncontrollable mental repetition, while memorability requires conscious recall; and 2) the stimuli in [8] are highly familiar to participants, whereas our study selects audios unfamiliar to most annotators to

mitigate the influence of individual listening histories on memorability. Another related concept is hook catchiness [17–20], which refers to the most easily recalled fragment of a musical piece. However, our focus lies in predicting the memorability of different music pieces rather than assessing the impact of various segments within the same tune on catchiness prediction and recognition. Furthermore, we ensure our stimuli consist solely of pure instrumental music clips to prevent any textual information from lyrics influencing music memorability.

Moreover, while deep learning has achieved significant success in supervised MIR tasks, it often demands large-scale annotated data. However, collecting useful annotations for MIR tasks can be costly, as it typically requires expertise and domain knowledge [21]. To tackle this challenge, various data augmentation and training strategies have been proposed [21–24]. For instance, McFee et al. [21] apply transformations such as pitch shifting, time-stretching, and adding background noise to the original waveform. Cubuk et al. [22] mask both time and frequency content to expand the input space in automatic speech recognition (ASR) and MIR tasks. To enhance learning robustness with limited data, Wu et al. [23] extract general music representations using a multi-task pre-trained encoder, inspired by speech processing research [25, 26]. Similarly, Castellon et al. [24] employ transfer learning from existing music generation architectures. However, not all the aforementioned methods are simultaneously open-source, computationally inexpensive, and interpretable. Therefore, in this paper, we focus on applying signal processing approaches like masking, with further details provided in Section 4.

3. DATASET CONSTRUCTION FOR MUSIC MEMORABILITY

In this section, we discuss the details of our dataset collection process and how music memorability is measured.

3.1 Audio Collection

To construct a dataset with objective music memorability scores, we first ensure that the audio samples are unbiased. We randomly select music by querying music-related videos using the YouTube API with random query keys, avoiding any specific music genre preference. Addi-

Task Type	# of Audios	# of Repetition (min)	# of Repetition (max)	# of Repetition (avg)	# of Repetition (std)
Filler	65	-	-	-	-
Vigilance	21	5	10	6.5	1.08
Short-Term Target	88	10	49	25.23	10.81
Medium-Term Target	41	61	131	110.33	16.32
Long-Term Target	20	155	276	222.05	36.64

Table 1. Details of different audio tasks in the music memory game.

Figure 2. Distributions of the audio published location and the distributions of the audio views in the final dataset.

tionally, we manually filter the music to confirm that the queried videos contain pure music content, excluding instrument tutorials or gadget unboxings. Next, we conduct a pilot study to verify that the selected audios are unfamiliar to most of the annotators in our target user group. Considering the annotators’ nationalities might not be as varied as the music collection’s, and language can be a memorable yet non-music-related element, we only use the intro part of each song. This approach helps eliminate other potential variables affecting music memorability. Also, the volume across all audio clips is normalized to minimize any memorable attributes unrelated to the music itself. Loudness normalization ensures the music is remembered based on its inherent qualities rather than its loudness.

We use only a segment of each audio for two reasons: i) to better eliminate confounding factors, such as vocal timbre, and ii) to shorten the period of annotations and prevent fatigue. We achieve this by truncating audios into structurally meaningful segments and applying proper time-stretching to alter the duration of an audio signal to a fixed length without distorting the audio. The segmentation process is supervised by an expert with a professional music education background. Note that time-stretching not only reduces modeling complexity but also prevents annotators from memorizing the audio based on its duration.

Ultimately, we collect 235 structurally meaningful 5-second audios with labeled music memorability scores. Our goal is to determine which types of music pieces are more likely to be memorized, rather than focusing on entire music clips, which are more complex and involve additional factors. This research can facilitate various applications, such as Netflix’s iconic “ta-dum” sound. The collected data can be found in the supplementary materials. Figure 2 illustrates the distribution of the collected audios concerning their published geographical locations and total views on YouTube, with view counts ranging from 10K to 100M.

3.2 The Music Memory Game

To annotate the memorability of the collected musical data, we follow the setting of image memory game [9] to design a novel music listening experiment. During the experiment, the recruited data annotators are asked to listen to 235 music pieces in total and answer whether the audio is repeated in the experiment or not. From a cognitive view, we define music memorability as long-term musical salience and the extent to which a musical piece continues to be remembered over time. In the music memory game, music memorability is measured as the tendency to correctly recognize a music piece when encountering it again in the experiment among all users. Specifically, let $x_j^{(i)}$ denote whether the i -th music piece can be recalled by the j -th data annotator, *i.e.*, 1 if the annotator recognized the i -th music piece. The memorability score of music i , denoted by $m^{(i)}$, is then calculated by:

$$m^{(i)} = \frac{1}{n_i} \sum_{j=1}^{n_i} x_j^{(i)}, \quad x_j^{(i)} \in \{0, 1\} \quad (1)$$

where n_i is the total number of data annotators for the i -th music.

To make the ground truth unbeknownst to all participants, music excerpts are split into three task categories: “vigilance”, “target”, and “filler”. Targets and vigilance targets are both repeated in the experiment, while the former are collected to be the true labels and the latter is used to make sure participants are attentive when labeling data. Moreover, fillers are used to stuff the spacing between the first and second repetition of a target and therefore is only presented once. The overview of the music memory game experimenting procedure is shown in Figure 1. The target-vigilance-filler split details can be found in Table 1. Rigorous criteria are enforced to monitor the performances of data annotators and preserve the quality of memorability labels. Specifically, annotations from users who detect vigilance repetition with an accuracy lower than 60% are automatically discarded. Furthermore, to prevent gathering biased memorability, all annotators only engage in labeling once. We recruited a total of 218 users from campus, with 163 clearing the vigilance accuracy level, 17% of passed annotators having professional music education backgrounds, and over 98% being between the ages of 20 and 29.

Differing from previous works on image memorability, our experiment is composed of three similar stages with breaks inserted in between. The reasons for using stages and breaks are two-fold. First, audios are sequential, there-

Figure 3. Memorability scores at various stages. The color symbolizes the rank of short-term memorability, while the lines represent stage relationships. The plot also shows Spearman’s rank correlations ρ between memorabilities measured at each stage.

fore it is more exhausting to label the memorability score to audios as compared to static images. Second, it usually takes some time for the earworm phenomenon to happen when listening to music. Hence, we assume memorability should be invariant even after encountering breaks that probably would reset the memory. The results of relations between repeat interval and memorability score are shown in Figure 3, where the lines exhibiting memorability scores across short-term, medium-term, and long-term repeats. The results manifest that the memorability score is indeed independent of the sequential context. Therefore, it is easier to memorize truly memorable pieces of music even after long breaks. The fact that Spearman’s rank correlation [27] between short-term, medium-term, and long-term are all greater than 0.64 also proves that the rank of memorability score is preserved across variant repeat intervals.

3.3 Labels and Consistency Analysis

To assure that collected labels are universal across all data annotators, we evaluate the human consistency according to previous work [9] by randomly splitting all participants into 2 groups and examining how well the memorability scores measured in the first groups matched the ones measured in the second group by averaging Spearman’s rank correlation [27] between randomly separated two halves of the participants 25 times. The average Spearman’s rank correlation coefficient ρ is 0.83, indicating the consistency of the collected data.

Figure 4 shows the scattering plot of music memorability and repeat interval. The graph demonstrates that mu-

Figure 4. Relations between memorability score and target repeat interval in log scale. The hue represents the level of fatigue.

sic possesses a linear relation between memorability score and log-scaled repeat interval. Please note that the fatigue level is another factor in the plot that also contributes to the memorability score of audio. The fatigue level, defined as the amount of audios listened without a 3-minute break, is a direct result caused by staging experiment and participating in taking a break in the middle since listening to more music at one time without resting reduces participants’ ability to identify repeated music pieces. The setting of inserting audio to random positions in the experiment procedure adds more context diversity to the process of memorizing music, thus making the labeled memorability scores more robust.

4. MUSIC MEMORABILITY PREDICTION

4.1 Learning with Handcrafted Features

Although feature extractions for deep learning models can be data-driven without being handcrafted, leading to a better result given sufficient training data, handcrafted features provide interpretable information for more insights. Therefore, we propose handcrafted features that can more accurately depict the low-level acoustic features or high-level semantic features of musical clips as shown in Table 2. For the low-level acoustic features that can be directly derived from the audio signal of music segments, we leverage the harmony, rhythm and timbre since they are most easily recognizable fragments of a piece of music [17] and describe the fundamental elements of a tune. Moreover, zero crossings and zero crossing rate are also extracted since they give the impressions into the frequency content of a signal. On the other hand, high-level semantic features are more abstract descriptions. Since the previous works in Psychology [28,29] mention the link between music emotion and memory, we introduce valence and arousal, which represent the mood of music pieces as features.

Another high-level feature is genre, which describes

Level	Category	Feature Implementation
Low-level	Harmony	mean, std of 12 pitch class
	Rhythm	beat per minute (bpm)
	Timbre	mean, std of 4-tracks (Vocals, Bass, Drums, Others)
	Zero Crossing	# of zero crossings & avg, median of zero crossings rate
High-level	Mood	valence, arousal
	Genre	Music, Musical Instrument

Table 2. Explainable handcraft features.

how likely a clip is belong to a certain type of music. Specifically, due to the unstable performance of existing algorithms for detecting sequences of chord labels, we employ chromagram (chroma) [30] as a representation of harmony patterns. To extract timbre information, the Mel-Frequency Cepstral Coefficient (MFCCs) is widely utilized. Although MFCCs is representative for timbre, its components are difficult to grasp intuitively. As a result, we treat MFCCs as a raw feature and find an alternative solution by first separating source audios into four components using source separation software Spleeter [31], and calculating their respective amplitudes to represent the characteristics of different instruments and frequency ranges. For the rhythmic pattern, although Tempogram [32] captures the underlying rhythmic pattern of raw audios, it is unable to provide precise insights to concretely measure the audio’s groove. Therefore, we instead utilize beat per minute (bpm) to represent general rhythm characteristics. We also use static valence and arousal values to describe perceived music moods, which are predicted by using Support Vector Regression (SVR) with a linear kernel trained on the PMemo dataset [33]. For genre features, we use the predicted music tagging and instruments from the downstream task of PANN [34]. Finally, SVR and Multilayer Perceptron (MLP) are employed as predictors to link audio features to memorability scores.

4.2 End-to-End Deep Learning

Deep learning [35] is featured by its ability to directly learn meaningful information from raw data, as opposed to using hand-crafted features. As a result, we also test end-to-end models to find if their feature-learning process improves performance. Our model uses spectrograms in Mel-scale as inputs, similar to previous end-to-end MIR tasks. Moreover, transfer learning [36], which applies previously learned knowledge to new data, has been found to significantly increase learning performance by skipping costly data-labeling procedures. Here, we use the self-supervised pre-trained Audio Spectrogram Transformer (SSAST) [37] since SSAST has been proved to achieve state-of-the-art results on numerous audio tasks, including audio event classification, keyword spotting, mood recognition, and speaker identification, after being trained on a vast amount of unlabeled data.

Method	Corr.	MSE	MSE STD
chroma + MLP	0.1740	0.0326	-
MFCCs + MLP	0.1179	0.0353	-
convnet features [38] + MLP	0.1889	0.0314	-
EHC features + SVR	0.2988	0.0339	0.0128
EHC features + SVR + PS	0.2084	0.0391	0.0129
EHC features + MLP	0.2656	0.0263	0.0058
EHC features + MLP + PS	0.2388	0.0275	0.0059
mel-spectrograms + SSAST	0.0124	0.0298	0.0061
mel-spectrograms + SSAST + PS	0.2658	0.0265	0.0074

Table 3. Spearman’s rank correlation and MSE loss between predicted and ground truth music memorability score using different models. Note that EHC features stand for explainable handcrafted features, PS stands for pitch shift data augmentation, and Corr. represents Spearman’s rank correlation.

5. EXPERIMENT RESULTS

Evaluation Metrics. Spearman’s rank correlation and mean squared error (MSE) loss are used as the metrics to evaluate the performance of music memorability prediction. The former indicates the ability to rank the relative memorability of different audios, while the latter indicates the absolute error of the predicted results.

Different Baselines. Here, we leverage Chroma and MFCCs along with their respective derivatives as two hand-crafted feature representations and fit the ground truth by Multilayer Perceptron (MLP) as two simple baselines. Moreover, we also use the convnet model as a baseline since it is the most referenced and available work in general music representation. The convnet model [38] utilizes CNNs for music tagging in the pre-training stage, and the extracted features serve as the representation for downstream tasks. Finally, Self-Supervised Audio Spectrogram Transformer (SSAST) [37] is also used as the baseline, which is a Transformer-based model with more parameters as compared to CNNs. SSAST pretrains the model with joint discriminative and generative masked spectrogram patch modeling.

Implementation Details. All the feature classifiers are pretrained without finetuning on the self-collected dataset. To handle the instability stemming from the limited labeled data, we normalize labels by subtracting the mean value, *i.e.*, predicting a relative value instead of an absolute value. For MLP and SSAST models, the learning rates are respectively set to $5e-5$ and $5e-6$ with the Adam optimizer [39]. We also conduct additional feature selection on the handcrafted features to improve the convergence of the MLP/SVR model (only select 25 features) due the small number of data samples. In addition, techniques including frequency masking, band stop filtering, and reverberation [26] are used to augment data, together with the pitch shifting augmentation. The results are reported by the average of the 10-fold outputs.

5.1 Prediction Results.

Table 3 compares the results of different prediction models, where SVR and MLP take explainable handcrafted

Model	Top-k feature selection	Corr.	MSE
MLP	k = 40 (no feature selection)	0.2160	0.0272
MLP	k = 35	0.2324	0.0270
MLP	k = 25	0.2656	0.0263
MLP	k = 20	0.2018	0.0271
SVR	k = 40 (no feature selection)	0.2168	0.0324
SVR	k = 35	0.2291	0.0340
SVR	k = 25	0.2988	0.0339
SVR	k = 20	0.2630	0.0354

Table 4. Spearman’s rank correlation and MSE loss for MLP/SVR models with different top-k feature selection.

features as inputs, and SSAST takes mel-spectrograms as inputs. The results indicate that chroma and MFCCs produce the worst results due to the ineffective feature extraction. For convnet features, the performance is better than chroma and MFCCs due to the pretraining. However, the amount of training data is too small to finetune the model on the music memorability regression task. SSAST outperforms other baselines since it incorporates the prior knowledge of spectrograms pre-trained by using advanced methods. Finally, Explainable Handcrafted Features (EHC) method produces the best correlation results by combining both low- and high-level features that help improve music memorability. These quantitative findings manifest that data-driven MIR tasks are notably reliant on huge data quantities to be resilient and general.

5.2 Ablation Study

Table 4 shows an ablation study on feature selection for handcrafted features, indicating that selecting top-25 features leads to the best overall correlation results. Moreover, Table 3 also shows an ablation study on extra pitch shifting for data augmentations. Small pitch shifts (less than 5 semitones) make the altered audio seem natural to the human ear according to [40]. Therefore, we add semitone shifts of -5 to 5 to our data. The results manifest that pitch shifting is effective for the models that take sequence information into account because applying mean pooling across time on harmony features in non-sequential models like SVR and MLP just forces the model to forecast the same value using multiple static chroma information. This may confuse the model on harmony characteristics. On the other hand, models with sequential information, such as SSAST, learn pitch-invariance after pitch shifting. The performance of SSAST notably decreases without pitch shift data augmentation, possibly due to its data-hungry nature as a Transformer-based model, *i.e.* requiring more data for optimal parameter tuning.

5.3 Interpretability

We attempt to gain insight into the intrinsic memory utilizing XAI methodologies. One post-hoc strategy for expressing black box models in a human-interpretable manner is SHAP [16]. Specifically, SHAP explanations are obtained by perturbing a specific instance in the data and observing the impact of these perturbations on the black-box

Figure 5. SHAP summary of the SVR model with RBF kernel [41]. The most important features are listed in decreasing order and the fact that feature value rises after the SHAP value shows a positive relationship between the two.

model’s output. As such, SHAP allows us to explore the factors that the model considers when determining memorability. Figure 5 visualizes the directionality impact of the top-5 features in SHAP, where the x-axis stands for SHAP value and each point is a SHAP value of a sample for a feature. Red color and blue colors respectively indicate higher and lower values of a feature. As such, we can observe the feature directionality impact based on the distribution. For example, the first row shows that a higher arousal value leads to high memorability scores, while a lower arousal value can lead to both high and low memorability scores. The important factors for the predictor among the EHC features include arousal, bpm, harmony (the feature "D mean") and the timbre features extracted from the source other than vocals, drums, and bass (the feature "other db mean"). According to Psychology research [28], normal individuals without brain damage find it easier to recognize musical excerpts with high arousal. The melodies are the main constituent elements of the source "others" after applying 4-stem Spleeter separation. This finding supports our understanding that we often focus on the main melody in music, and thus the chorus or hook of the song with outstanding melody usually represents the entire song.

6. CONCLUSION AND FUTURE WORK

In this work, we explore the novel task of music memorability regression (MMR) using a data-driven approach. The consistency of our newly proposed YouTube Music Memorability (YTMM) dataset supports our hypothesis that music memorability indeed exists and can be predicted. Furthermore, we investigate the use of feature engineering and self-supervised learning for predicting music memorability, highlighting the importance of prior knowledge and other training approaches, such as label normalization, for improving results with limited data. We make the dataset available online to encourage further research and development in the field of MMR. In the future, we plan to: 1) scale the dataset to better represent the memorability of full music structures, 2) investigate the potential of transfer learning trained on music-oriented datasets to enhance our current baselines, and 3) study the personalization issue since music memorability can be strongly related to the past musical experience of individuals.

ABSTRACT

Optical Music Recognition (OMR) is the field of research that studies how to computationally read music notation from written documents. Thanks to recent advances in computer vision and deep learning, there are successful approaches that can locate the music-notation elements from a given music score image. Once detected, these elements must be related to each other to reconstruct the musical notation itself, in the so-called *notation assembly* stage. However, despite its relevance in the eventual success of the OMR, this stage has been barely addressed in the literature. This work presents a set of neural approaches to perform this assembly stage. Taking into account the number of possible syntactic relationships in a music score, we give special importance to the efficiency of the process in order to obtain useful models in practice. Our experiments, using the MUSCIMA++ handwritten sheet music dataset, show that the considered approaches are capable of outperforming the existing state of the art in terms of efficiency with limited (or no) performance degradation. We believe that the conclusions of this work provide novel insights into the notation assembly step, while indicating clues on how to approach the previous stages of the OMR and improve the overall performance.

1. INTRODUCTION

Optical Music Recognition (OMR) is the field of research that enables the automatic reading of music notation from scanned documents [1]. OMR has become increasingly important due to its potential for a better preservation of music archives, while also facilitating new data to the wealth of Music Information Retrieval algorithms that rely on symbolic formats [2, 3].

As in many other fields, deep learning brought about a drastic change in the performance of the proposed approaches for OMR [4]. As we will mention in the next section, tasks that used to be a difficult barrier are now feasible

and successful models are known, e.g., staff detection [5] or the identification of musical symbols in the image [6]. However, although these tasks are the first obstacles of an OMR system, they are not enough to complete the process. Once the graphic elements have been identified, it is necessary to reconstruct the musical notation itself by inferring the syntactic relationships that exist between such elements, namely *notation assembly*.

To account for all existing relations, the retrieval is usually performed in a pairwise fashion among all the identified graphic units. On this note, given the (typically large) density of elements within music score images, the task exhibits a high computational complexity that complicates its integration in an end-user application. Therefore, in addition to accuracy, one must carefully take into account the efficiency of this type of schemes.

This work addresses the efficient estimation of all the syntactic relations among the elements of a music score using neural network. More precisely, we propose and assess two approaches to address this task in an efficient manner: one that is based on classifying each pair of elements employing a series of numerical features, while the other uses asymmetric kernels [7], which can be computed with high parallelization and provide results very fast. In our experiments, using the well-known MUSCIMA++ corpus, we will compare the trade-off between effectiveness and efficiency that these methods provide and discuss the experimental outcomes. In addition, assuming that the previous stages of the process may contain errors, we also assess the robustness of the assembly proposals by intentionally degrading the estimations of these precedent phases. This analysis is expected to provide useful insights for the adequate design of notation assembly methods in OMR.

The remainder of the paper is as follows: in Section 2, we provide some background on the field of OMR; in Section 3, we present the problem and the proposed approaches; in Section 4, the complete experimental setup is described; in Section 5, results are reported and discussed; and, finally, the main conclusions of the work are summarized in Section 6.

2. RELATED WORK

Traditionally, OMR has been considered a multi-stage process [8]. The legacy pipeline distinguishes four stages:

(i) *image preprocessing*, including tasks such as binarization [9], distortion correction, or stave separation [10]; (ii) *music symbol detection*, including steps such as staff-line removal [11], connected-component search, and classification [12]; (iii) *notation assembly*, where the independent components are related to each other to reconstruct the musical notation [13]; and (iv) *encoding*, in which the recognized notation is exported to a specific language that can be stored and further processed by computational means [14].

With the rise of deep learning, many of these steps have been reformulated as machine learning problems to be solved by neural networks [15, 16]. Also, many stages have been merged, giving rise to models that are capable of locating and categorizing the musical elements of the given image in a single step. This task has been the subject of extensive recent research [6, 17–19]. Alternatively, the so-called *holistic* or *end-to-end* approaches that seek to perform the entire pipeline in a single step have also been proposed, often with some prior pre-processing such as staff segmentation [14, 20, 21].

Although end-to-end approaches seem promising, so far they have only been successfully implemented for monodic music collections, where there is a clear left-to-right reading order. This is useful in many of the historical music heritage, such as plainchant or mensural music, where the different voices (if any) typically appear on different pages or sections, and staves are therefore monodic in the graphical sense. However, to deal with the common western modern notation, multi-stage OMR approaches seem to be the only ones capable of dealing with such complexity [4].

However, despite the aforementioned recent advances in the detection of music symbols with deep learning, there are hardly any proposals that complete the notation assembly stage employing machine learning techniques. To our knowledge, the only existing work that focuses on the retrieval of relationships using learning techniques is that of Pacha et al. [22]. In such work, for each pair of nodes, a single image is built with different channels: one that depicts the area of the image that contains both nodes, another that depicts the same region but only shows the first node, and a last one that depicts also the region of interest but only with the second node. A Convolutional Neural Network (CNN) is then trained to recognize whether or not there is a relationship between the nodes involved in this three-channel image. Despite the reported good results, the approach is tremendously inefficient, since it requires the independent construction and classification of an image for each pair of nodes. As we will see below, this scheme entails a huge computational complexity that makes it infeasible to use in practice.

In this paper, we especially focus on providing a solution to the notation assembly stage with a level of efficiency that enables its use in a real system, while keeping good accuracy figures.

3. METHODOLOGY

This paper follows the formulation proposed in previous works [19, 22, 23], where it is assumed that the computational reading of a music score, in the context of OMR, can be described by retrieving a graph structure from the image. In this graph, the atomic notation elements (referred to as “primitives”) represent nodes, while edges denote the relationships between them. Here, we are particularly interested in the retrieval of the edges, once the nodes have been detected somehow (for instance, with the existing approaches mentioned in the previous section). Note that, instead of relying on case-specific heuristics, we frame the task within a learning-based formulation due to its inherent capability of modeling any relationship among the primitives as far as there exists a set of annotated reference data. Therefore, the formulation is general and can be used as long as there is a training set consistent with the envisioned model for the music-notation graph.

3.1 Formulation

A graph is a mathematical structure that models pairwise relationships between elements—referred to as nodes or vertices—through its edges. Here, we aim to retrieve the edges (relationships) between each pair of nodes in music scores, where each node represents a music primitive—e.g., a notehead, a stem, or an accidental.¹ The formal definition of the problem is as follows.

We assume that for a given music score s there exists a graph g_s that represents its symbolic music notation. The graph is defined as a pair (V, E) , where V denotes the set of nodes and E denotes the set of edges. Two nodes $v_i, v_j \in V$ are connected if there exists an edge $e_{i,j} = (v_i, v_j) \in E$.

In the context of OMR, information about the set of symbols V corresponds to the *music symbol detection* stage of the OMR pipeline. Although they are still far from perfect, there are approaches in the literature that address this stage (cf. Sect. 2). Therefore, we here assume that there exists a function that maps s onto set V . Typically, each symbol $v_i \in V$ is further represented as a set of features with, at least, the following information: primitive class and coordinates within the image score. The problem we address from now on is how to get the set E given V , which corresponds to the *notation assembly* stage of the OMR pipeline.

The problem can be considered as a binary classification task in which a model predicts the class between each pair of nodes v_i, v_j present in the score. In this regard, $e_{i,j}$ is labeled as a 1 if there is a relationship between v_i and v_j , and 0 otherwise. The prediction of the relationship—henceforth, $\hat{e}_{i,j}$ —can be represented as a function $\varphi(v_i, v_j)$ that takes the two nodes’ features as input and computes the probability of connection, i.e., $P(e_{i,j} = 1)$. Figure 1 depicts a general outline of the methodology adopted in this work.

¹ Hereafter, we use the terms “node”, “symbol”, and “primitive” interchangeably: a graphical element placed in the music score with certain attributes.

Figure 1: General schema of the methodology for retrieving the edges of the music notation graph.

3.2 Approaches

From the formulation given above, it is important to emphasize that the complexity of predicting each possible edge belongs to $O(|V|^2)$. Therefore, the approaches to φ must take into account the computational cost to make the task feasible in practice. This is a driving criterion for our approaches below since, with a sufficient number of primitives in a score, no system depicting the aforementioned complexity would be practical in a real-world scenario.

We here propose two shallow neural architectures that take a pair of nodes and predict the class of the relationship. These two neural architectures are: (i) a Multilayer Perceptron (MLP) architecture that takes the input of each node’s features concatenated; and (ii) an asymmetric kernel model.

3.2.1 MLP architecture.

In this method, the features—attributes—of the nodes are first concatenated, forming a single feature vector that contains the entire information from the pair of nodes. Then, this vector is passed through a series of layers of an MLP. The final layer implements a function σ that models the probability of the two input nodes being connected:

$$\hat{e}_{i,j} = \sigma(\varphi_{\text{MLP}}([v_i, v_j]))$$

3.2.2 Asymmetric kernels.

In this second scheme, our proposed neural architecture learns an asymmetric kernel (AsymK) function [7]. This function is defined by $k(v_1, v_2) = (\langle \phi_{k_1}(v_1), \phi_{k_2}(v_2) \rangle)$, where $\langle \cdot, \cdot \rangle$ is the dot product of two N -dimensional points in two Hilbert spaces—features spaces. In this work, we use this asymmetric kernel as a similarity function between the two mapped features to distinct Hilbert spaces as:

$$\hat{e}_{i,j} = \sigma(\langle \phi_{k_1}(v_i), \phi_{k_2}(v_j) \rangle)$$

In this approach, $\phi_{k_1}(v_1), \phi_{k_2}(v_2)$ are kernels implemented as dense neural layers that map the initial node features onto two different (asymmetric) spaces that suit the task at hand. After computing the similarity score, a σ function is applied to obtain probabilities between 0 and 1.

Note that, since the embeddings are calculated only once per node, the scheme is remarkably efficiency. For

each possible relationship, it is only necessary to compute the dot product between node embeddings and apply the σ function. That is why the complexity is much lower than the previous approach.

3.2.3 Loss function.

In both neural architectures proposed, the objective is to minimize the binary cross-entropy (BCE) loss function

$$\mathcal{L}_{\text{BCE}} = \sum_{e_{i,j} \in E} e_{i,j} \log(\hat{e}_{i,j}) + (1 - e_{i,j}) \log(1 - \hat{e}_{i,j}) \quad (1)$$

where $\hat{e}_{i,j}$ corresponds to the probability predicted by the model and $e_{i,j}$ is the ground-truth data for the edge (1 for a positive relationship, 0 otherwise).

4. EXPERIMENTS

In this section, we describe the experimental setup for evaluating the neural architectures proposed. More precisely, the rest of the section presents the corpus considered for the experiments, the contemplated figures of evaluation, the implementation details of the two neural proposals, and the feature descriptions used.

4.1 Data

The experiments were carried out using the MUSCIMA++ dataset [23]. This corpus provides 140 handwritten music scores with manual annotations of the different musical symbols—primitives defined by the symbol bounding box and the corresponding class label—and existing relationships among them. The dataset provides the direction of the edges; in our work, however, an undirected edge is assumed between two nodes that are connected regardless of the specific direction (undirected graph). Figure 2 depicts an example from this corpus.

Figure 2: Example of a music score extracted from the MUSCIMA++ dataset.

Concerning the data partitioning, we follow a 5-fold cross-validation scheme. At each iteration, 60% of the dataset is used for training, 20% is used for validation, and 20% is used as test.

Finally, it must be highlighted that each music sheet depicts an average value of 734 primitives, which constitutes a large number of relations to be modeled. Due to this,

and as aforementioned, efficiency must be considered in the design of practical notation assembly strategies.

4.2 Figures of merit

We consider a two-fold assessment of the proposed approaches, *i.e.*, we evaluate their recognition capabilities as well as efficiency rates. These criteria are now detailed.

In terms of recognition performance, as in previous works considering the same evaluation corpus [22, 23], we resort to the F-measure (F_1) metric. Note that, instead of providing the average scores for the two classes, the figures reported exclusively refer to the positive relationships with the aim of measuring the quality of the retrieval.

Concerning the efficiency assessment, we measure the computation time in the prediction phase of the methods. Since this metric depends on the computational capabilities of the device used, all methods are run over the same machine to avoid any possible bias.² Moreover, each experiment is repeated 10 times, being the average processing time the one reported as the efficiency score.

4.3 Neural architectures

Regarding the MLP architectures, we consider two implementations with a varying number of layers and weights to balance the trade-off between efficiency and representational power:

- $MLP_{64,512}$: A three-layered fully-connected network comprising two hidden layers with 64 and 512, respectively, with *Rectifier Linear Unit* (ReLU) activations and a single output unit to compute the score of the binary classification.
- MLP_{32} : A two-layered fully-connected network comprising a 32-unit hidden layer and ReLU activation and a single unit as output.

Concerning the AsymK, ϕ_{k_1}, ϕ_{k_2} are implemented as two different 4-layered MLP comprising 512, 1024, 512, and 256 units, respectively, with ReLU activation. The idea is to generate two 256-dimensional embeddings—two points in different Hilbert spaces—to then compute the similarity through the dot product.

In all cases, the last operation is implemented as a *sigmoid* activation function to understand the output as a probability of a positive relationship. This probability is eventually thresholded considering a value of 0.5 to convert it in an actual decision.

Regarding optimization, all models were trained for 200 epochs using the Adam optimizer [24] with a learning rate of 10^{-3} .

4.4 Feature description

As aforementioned, the music-object detection stage of an OMR process retrieves, at least, the position (coordinates) of the detected object in the image sheet together with its

² The experiment was run over 8 cores of i7-7700K CPU at 4.20GHz with 16 GB of RAM memory, with no explicit parallelization or GPU speed-up.

estimated class label. For our relationship prediction approaches, we consider that each vertex ($v_i \in V$) is represented only by these features, being the inclusion of additional information left as future work.

Delving on the features considered, the spatial (position) information is directly encoded using four normalized values that denote the top-left and right-bottom corners of the bounding box. Conversely, the class information is processed by a 16-dimension learnable embedding layer to obtain an adequate representation for the task. Therefore, every single node is finally represented as a 20-dimensional feature vector.

5. RESULTS

Having introduced the different neural proposals as well as the experimental procedures, this section presents and discusses the results obtained. To establish a reference in the effectiveness that can be obtained for this task, we include the results of Pacha et al. [22], measured under the same experimental conditions as the rest of the methods in the work.³

The rest of the section separately studies and analyzes the two individual aspects considered, *i.e.*, performance efficiency and the ability to retrieve syntactic relationships between primitives.

5.1 Performance efficiency

Focusing first on the temporal aspect of the strategies, Table 1 shows the per-page average execution time of the contemplated notation assembly strategies. Note that, since this evaluation disregards the correctness of the estimation but simply assesses its temporal cost, all experiments are performed considering the ground-truth annotations.

Table 1: Efficiency results in terms of the per-page absolute execution time (in milliseconds) on the MUSCIMA++ corpus for the different notation assembly methods assessed. Each value corresponds to the average execution time obtained with 10 different iterations over all test samples.

	AsymK	MLP_{32}	$MLP_{64,512}$	CNN [22]
Execution time (ms)	< 0.5	55	176	$> 1.5 \cdot 10^6$

As can be observed, the existing CNN method [22] proves to be the least efficient among the considered strategies due to the large execution time it exhibits (roughly, 25 minutes per page). Such a point directly disables its possible integration in any practical system that comprises user interaction.

³ All experiments have been run considering the Python language (version 3.8), being the PyTorch (version 1.12.1) and PyTorch-lightning frameworks (1.9.1) particularly contemplated for reproducing the architecture proposed in Pacha et al. [22].

Oppositely, the different neural proposals presented in the work remarkably outperform these low-efficiency figures, achieving execution times in the order of a few milliseconds per page. More in detail, the AsymK stands as the most efficient strategy of the proposed ones as it reports figures several orders of magnitude faster than the MLP_{32} and $MLP_{64,512}$. Note that this is because AsymK exploits the parallelization of the dot product operation and the independent node processing while the two other proposals require more computation because of the classification framework they are based on.

It must be pointed out that the presented neural architectures depict execution times several orders of magnitude faster than the reference state-of-the-art method. In this regard, while the CNN strategy may be further optimized, the difference with the AsymK case—the most efficient strategy—must be considered as insurmountable.

5.2 Recognition capability

Let us now move to compare the estimation goodness of the different notation assembly strategies. As aforementioned, these methods take as input the result from a given framework that detects the primitives in the music score, *i.e.*, an object detection strategy.

Taking this into consideration, we will not consider any existing object detection approach as starting point, since other additional issues should be taken into account which are outside the scope of this work—*e.g.*, which object detection strategy to use, what confidence level to actually retrieve an object, or how to evaluate cases where a node is missing or has been predicted with the wrong label. Note that, since these questions are not related to the retrieval of the relationships themselves, any decision in this regard might bias the analysis of the models for the targeted notation assembly stage.

Nevertheless, to cover a greater number of possibilities in an agnostic way to the considered music-object detection step, we will simulate inaccuracies in the location process of the nodes. Specifically, we will consider a set of ranges for the Intersection over Union (IoU) metric between the original objects—the ground-truth annotations—and those generated for this experiment.⁴ For that, assuming that the MUSCIMA++ corpus depict an $IoU = 1$ (ground-truth annotation), we will progressively perturb the location of the objects—*i.e.*, altering the coordinates of the bounding boxes—so that the overall IoU metric degrades to the range $IoU \in [0.85, 0.95]$. This range will decrease in steps of 0.1 (*i.e.*, $[0.75-0.85]$, $[0.65-0.75]$, ..., $[0.05-0.15]$) to simulate scenarios depicting more limited symbol detection methods. In this way, our study focuses on general advantages and limitations of the notation assembly models, which can be then considered for developing more adequate pipelines for the previous stages. Figure 3 shows examples of how node locations are perturbed at some of the IoU levels considering

⁴ The IoU estimates the degree of overlap between two sets (in this case, areas of two music-notation objects) as the ratio of their intersection and their union.

the proposed strategy.

Considering this experimental set-up, Figure 4 shows the recognition rates in terms of F_1 achieved by the different neural schemes contemplated with respect to increasing IoU conditions (x-axis).

For the ideal scenario of perfect object-detection retrieval ($IoU = 1$), the reference CNN method [22] reports the highest recognition rate among all the schemes, with a value of $F_1 = 93.0\%$. However, the $MLP_{64,512}$ proposal shows slightly lower figures to the reference strategy— $F_1 = 91.9\%$ —thereby proving itself as a competitive alternative to the CNN-based method in terms of accuracy. In relation to the AsymK and MLP_{32} proposals, these two strategies depict the least competitive results among the ones studied. However, since the MLP_{32} case shows a more competitive performance than the AsymK method, the former may be deemed as an intermediate case among the best-performing strategies—CNN and $MLP_{64,512}$ —and the AsymK approach.

As the music-object detection becomes more realistic ($IoU < 1$), the neural models (except for CNN, which will be discussed below) do not degrade ostensibly but exhibit certain robustness up to reasonable IoU cases (above 0.5).⁵ Digging deeper into the curves, the most relevant phenomenon is that, although at the higher ranges the CNN approach maintains the best accuracy, it decays much faster than the MLPs. Specifically, from $IoU \in [0.75-0.85]$, the $MLP_{64,512}$ outperforms it in terms of F_1 , while maintaining the clear advantage in efficiency reported in the previous section. Furthermore, the rather shallow MLP_{32} approach also outperforms the CNN from $IoU \in [0.55-0.65]$, which are still likely values for music-object detection. These results reflect the adequacy of the efficient approaches proposed in this work, which are not only efficient enough to be used in practice but also keep greater robustness against very common distortions in previous stages to that of notation assembly in the OMR pipeline. In contrast, the AsymK shows a similar trend to the other efficient approaches, so from the perspective of this experiment it maintains the same advantages and disadvantages already discussed above (even higher efficiency but very poor retrieval).

As a last point, it must be noted that the results reported in this work may be considered as a turning point for the development of novel approaches to music-object detection in a complete OMR workflow. For example, using the efficient approaches of this work, one can prioritize retrieving most of the objects at the cost of slightly losing some location accuracy. An object that is not detected is impossible to relate correctly, but if it is detected, even if inaccurately it might connect successfully with other nodes (see Fig. 4).

As a final note, the whole experiments clearly prove that there is no single strategy capable of optimizing both contemplated criteria at the same time: high recognition rates imply large execution times (*e.g.*, the CNN method [22]),

⁵ While it is true that the models obtain very poor results for the lowest ranges, this is not relevant in practice because 0.5 is the minimum IoU threshold for most object detectors to consider a correct retrieval.

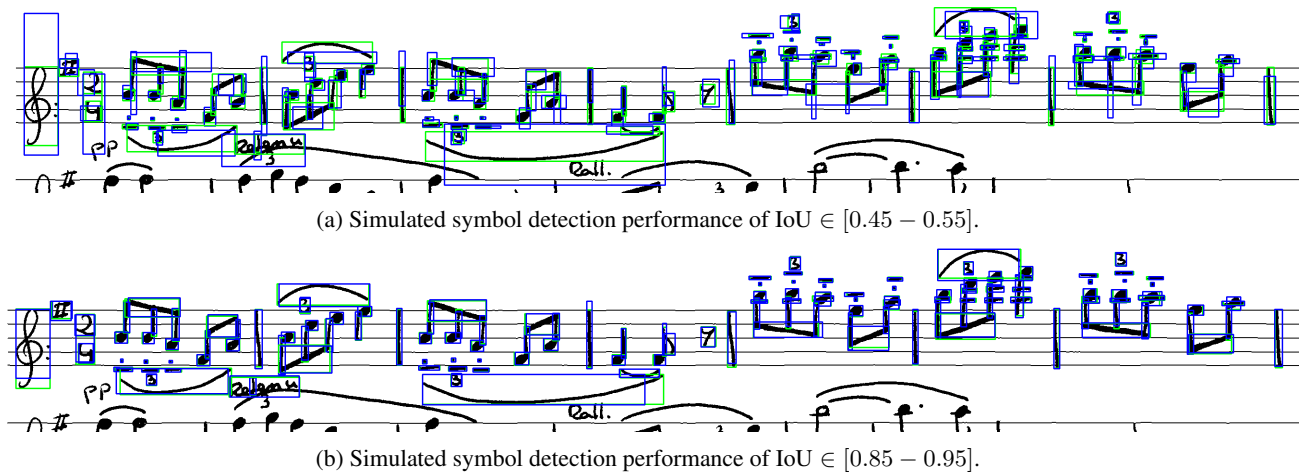

Figure 3: Examples obtained with our proposal under different simulated symbol-detection scenarios based on the overall IoU. The green and blue bounding boxes respectively denote the ground truth and the modified ones.

Figure 4: Results in terms of the F_1 metric for the compared note assembly strategies for different object detection performance rates based on the IoU score.

which results impractical in real-world applications) while faster strategies show more limited recognition rates (for instance, the AsymK case). In this regard, the proposed MLP-based architectures seem to provide an adequate balance between the two evaluation criteria, being particularly relevant to the MLP_{64,512} one as it shows a remarkable temporal efficiency with a slightly worse performance than the highest attainable recognition results by the CNN case.

6. CONCLUSION

Optical Music Recognition (OMR) represents the research field that studies how to computationally read music notation from written documents. Generally, these strategies comprise an initial phase in which the music-notation elements from a given image are located—symbol detection—followed by a notation assembly stage that estimates the relations among these elements to reconstruct the musical notation itself. However, while there exist a large number of approaches that address the former process, the latter one has been scarcely addressed in the related litera-

ture.

This work frames in this particular assembly stage. Considering the high number of possible relationships in a music score, this work proposes two neural architectures to address this task in an efficient manner: (i) a strategy based on a Multilayer Perceptron (MLP) scheme; and (ii) a model based on asymmetric kernels. The results obtained with the MUSCIMA++ benchmark corpus [23] show that the MLP-based approach achieves recognition rates comparable to those of the reference strategy by Pacha et al. [22] with considerably less computational cost. Moreover, the asymmetric kernel approach, while proven to be extremely fast, exhibits a noticeable loss of accuracy with respect to the highest attainable one. In addition, these results also prove MLP-based schemes as remarkably robust when facing adverse symbol detection scenarios compared to the state-of-the-art method.

Several avenues of future research are opened: on the one hand, it would be important to estimate the relevance of each error produced since it has not been yet studied what errors—missing positive relationships or predicting non-existing relationships—and what type of elements involved cause the most impact on the eventual OMR system. On the other hand, this work has considered the given labeling of the MUSCIMA++; however, it has not been explored in depth whether this annotation scheme is actually adequate for these learning algorithms. More consistent or easy-to-learn annotations may be possible, as long as the goal of correctly encoding music notation is still met. Besides, just as the music-object detection step has been integrated into a single process, it would be beneficial to train end-to-end models that take into account both object detection and notation assembly. In this way, the model could leverage contextual and semantic information, provided by the notation assembly stage, when detecting objects that would be otherwise difficult or impossible. Finally, it would be also relevant to carry out user studies to assess the usefulness of these efficient approaches in real-world OMR scenarios.

ABSTRACT

Synthesizer parameter inference searches for a set of patch connections and parameters to generate audio that best matches a given target sound. Such optimization tasks benefit from access to accurate gradients. However, typical audio synths incorporate components with discontinuities – such as sawtooth or square waveforms, or a categorical search over discrete parameters like a choice among such waveforms – that thwart conventional automatic differentiation (AD). AD libraries in frameworks like TensorFlow and PyTorch typically ignore discontinuities, providing incorrect gradients at such locations. Thus, SOTA parameter inference methods avoid differentiating the synth directly, and resort to workarounds such as genetic search or neural proxies. Instead, we adapt and extend recent computer graphics methods for differentiable rendering to directly differentiate the synth as a white box program, and thereby optimize its parameters using gradient descent. We evaluate our framework using a generic FM synth with ADSR, noise, and IIR filters, adapting its parameters to match a variety of target audio clips. Our method outperforms baselines in both quantitative and qualitative evaluations.

1. INTRODUCTION

Synthesizers provide musicians and sound designers with flexibility for exploring sound with various audio characteristics. However, the versatility of synths also poses challenges in terms of control, because manually searching over numerous parameters to seek a particular type of sound requires expertise, time, and effort. Synth parameter inference addresses these challenges by automating this search process to find parameters that best match a given target sound. Given a synth f with parameters θ and a target T , the search seeks the optimal parameters θ^* to minimize some loss L between the synth output and the target.

$$\theta^* = \operatorname{argmin}_{\theta} L(f(\theta), T) \quad (1)$$

If the synth f can be expressed as a white box program, a straightforward solution to Equation 1 would differentiate L wrt the parameters θ , and then minimize L by gradient descent. However, in practice, typical synthesizers f

contain discontinuous oscillators, like square or sawtooth waveforms, and discrete categorical parameters, such as choosing different waveforms and modules, that thwart traditional automatic differentiation (AD).

Researchers have developed several workarounds to avoid directly differentiating f . For example, genetic algorithms [1, 2] approximately solve Equation 1 at the expense of greater computation and potential artifacts from failures near local minima. Alternatively, Equation 1 may be approximated as black box models using deep learning: either the synthesizer can be approximated via a differentiable neural proxy [3, 4], or the entire argmin mapping can be approximated by a parameter prediction network [5, 6]. Similarly, the parameter space can be mapped to a VAE latent space for direct control [7]. However, the flexibility of deep learning approaches is constrained, as data collection and training are typically limited to specific synthesizers with fixed parameter choices, making it impractical to directly apply trained models to arbitrary synthesizers.

Graphics researchers developed recent methods to approximate the gradient for discontinuous white box image generation processes [8–10]. These generally integrate over the discontinuous function f , and approximate the gradient for the integral \hat{f} . This paper builds on $A\delta$ [10], which replaces the traditional calculus rules for AD to directly enable backpropagation on arbitrary discontinuous programs. Our method relies on the key observation that the discontinuous function will eventually be band-limited and sampled at some rate (e.g. 48kHz). Each sample represents an integration over a time interval that *may contain* a discontinuity. However, the band-limited function \hat{f} is continuous so differentiation rules can be developed for it.

Our optimization framework differentiates a pre-filtered white box synth, and solves Equation 1 via gradient descent. We adapt and extend the math in $A\delta$ [10] to differentiate discontinuous and discrete synth components, and also introduce heuristic methods for better convergence. We evaluate on a FM synthesizer and our approach finds parameters that better match the target than baselines qualitatively and quantitatively. Moreover, our framework allows musicians to incorporate domain expertise to flexibly modify and fine-tune synth modules. Because our white box approach does not incur training overhead, our framework can be flexibly applied to arbitrary synth programs.

2. RELATED WORK

Researchers have explored a variety of techniques to automatically search for optimal synthesizer parameters with-

out having to explicitly differentiate the synthesizer. Genetic algorithm (GA) approaches [1, 2] mutate and cross variants to search over the entire program space for arbitrary synthesizers, but suffer from excessive computation and difficulty in accurately converging to local minima without the guidance of the gradient. On the other hand, deep learning models can be used to directly predict the synthesizer parameters [5, 6, 11]. However, they heavily rely on the annotated datasets of synthesizer presets, therefore cannot be flexibly generalized to *any* synthesizer. Similarly, each trained model can only be used for one particular synthesizer patching, greatly limiting the flexibility of the method. Unlike learning methods, our approach does not rely on a dataset, and can flexibly differentiate *any* white-box program, supporting finetuning and parameter transfer between synthesizer patches. Our gradient-based process also converges more robustly than GA.

Alternatively, synthesizers can be defined by differentiable functions, therefore allowing optimal parameters to be learned through gradient descent. For example, neural audio synthesis methods use black-box neural networks to generate audio samples [12, 13]. The neural proxies can be combined with continuous synthesizer components as well, such as DDSP methods that incorporate digital signal processing modules [4, 14], and DWTS methods with learnable wavetables [15]. However, because these methods use continuous proxies, they usually do not match the exact parameterization of complicated discontinuous synthesizers, therefore cannot be flexibly used to control conventional synthesizers. Moreover, the neural modules introduce nontrivial inference overhead and are less efficient than synthesizers. Unlike the differentiable neural proxies, our method directly differentiates a white box program that can be any desired synthesizer. Therefore, it optimizes semantically meaningful parameters.

We leverage recent ideas from differentiable rendering in computer graphics. Researchers developed compiler frameworks to systematically differentiate arbitrary discontinuous programs [8, 10], and application-specific solutions to efficiently differentiate specific types of discontinuities in the rendering pipeline [9, 16]. Our method differentiates synthesizer discontinuities by combining these two approaches: we adapt the gradient rules from $A\delta$ [10] for use with discontinuous audio waveforms, and introduce a specialized gradient rule for discrete categorical choices.

3. METHOD

This section describes our optimization pipeline for synth parameter inference. Section 3.1 introduces our approach to differentiating a synth. Section 3.2 considers loss function options. Finally Section 3.3 discusses how to explore the multi-modality and avoid local minima.

3.1 Approximating the Gradient

We introduce a customized gradient, which includes differentiating at discontinuities, avoiding plateaus with zero gradient, and efficiently differentiating IIR filters. We first

Figure 1. Summary for our FM synthesizer and how they are differentiated. Dashed boxes and arrows are optional components whose connection is decided per target.

introduce $A\delta$'s [10] gradient rule for differentiating discontinuities and discuss its usage in audio synthesizers in Section 3.1.1, followed by our novel synthesizer-specific gradient rules in Sections 3.1.2 - 3.1.4.

3.1.1 Differentiating Discontinuous Waveforms

We view discontinuities as compositions of the Heaviside step function H , which evaluates to 0 on the one side of a discontinuity, and 1 on the other side. The discontinuity can be differentiated using the gradient rules from $A\delta$ [10]. The key idea is to approximate the gradient as if the discontinuous function is first convolved with a 1D box filter $\phi(t)$ along the time dimension t . As an example, if H is controlled by a continuous function c , we can differentiate the convolution of $H(c(t, \theta))$ with $\phi(t)$ by applying the Dirac delta's scaling property at the discontinuity t_d .

$$\begin{aligned} \frac{\partial}{\partial \theta} \int H(c(t', \theta)) \phi(t - t') dt' &= \int \delta(c) \frac{dc}{d\theta} \phi(t - t') dt' \\ &= \int \frac{\delta(t' - t_d) \frac{dc}{d\theta}}{\left| \frac{dc}{dt} \right|} \phi(t - t') dt' = \phi(t - t_d) \left. \frac{dc}{dt} \right|_{t_d} \end{aligned}$$

This can be approximated with two samples corresponding to two ends of the box kernel ϕ , denoted as t^+ and t^- . The box kernel $\phi(t - t_d)$ either evaluates to 0 or $\frac{1}{t^+ - t^-}$, depending on whether $H(c(t, \theta))$ evaluates to the same or different values at t^+ and t^- . Because c is continuous, $dc/d\theta$ can be computed with AD, and its evaluation on either t^+ or t^- approximates that of t_d because Lipschitz continuous functions are locally bounded. Finally, dc/dt is approximated by finite difference: $\frac{c(t^+, \theta) - c(t^-, \theta)}{t^+ - t^-}$. Because the audio signal already samples at a regular interval along the time dimension (e.g. 48kHz), we conveniently set the support of the box kernel to straddle the current sample and its neighbor. While the mathematical correctness in [10] is derived assuming a single discontinuity in the neighborhood, empirically the approximated gradient also works well for signals with sparse multi-discontinuities, such as when both the carrier and FM modulation waves are square. However, if the sampling rate is too low and causes aliasing, the $A\delta$ rule is unable to correctly approximate the gradient as if the signal was antialiased.

Discontinuous waves such as square and sawtooth can be constructed as periodic compositions of H . These discontinuities are differentiated using the gradient rules introduced in $A\delta$ [10] that are analogous to the equation above, where θ might e.g., be the frequency of a square wave. The gradient for the synthesizer parameters are obtained by differentiating the loss term (Section 3.2) using $A\delta$ gradient rules, which reduce to traditional AD for continuous parameters, combined with our

customized gradients (Sections 3.1.2 - 3.1.4). This approach is more accurate than differentiating a discontinuity naively smoothed with arbitrary linear or sigmoid transitions, especially when discontinuities are composited – for example, the composition of discontinuous modulation and carrier signals in an FM synthesizer.

3.1.2 Differentiating Discrete Categorical Choices

Section 3.1 discusses a simple scenario where the discontinuity can be sampled along the time dimension. However, the challenge remains for the discrete categorical choices, because for fixed parameterization, the corresponding discontinuity H evaluates to a constant for any time t , therefore the discontinuity cannot be easily sampled.

This section proposes a stochastic approach to differentiate the discrete parameters. We define a categorical node g as taking input from a discrete parameter x with potential choices A, B, \dots , and outputs to a floating point value:

$$g(x; \theta) = \begin{cases} g_A(\theta) & \text{if } x == A \\ g_B(\theta) & \text{if } x == B, \\ \dots & \end{cases} \quad (2)$$

g_A, g_B are floating point functions associated with choices A, B respectively, such as sine or square wave equations.

Our stochastic approach views the discrete parameter x as a discrete random variable \mathcal{X} with different samples X at different time steps. Therefore $g(\mathcal{X}; \theta)$ is a random variable as well. Throughout this section, we will use lowercase (e.g. x) for the synth parameters that need to be optimized, calligraphic (e.g. \mathcal{X}) for its corresponding random variables, and regular uppercase (e.g. X) for sampled values from the random variable. Note when \mathcal{X} has close to zero variance, it consistently samples the same choice for every time step, therefore X can be viewed as a constant identical to x . We further model $g(\mathcal{X}; \theta)$ similarly to an argmax operator, where each potential choice A, B, \dots is associated with a “score” random variable, and the output of g corresponds to the choice with the highest “score”. Specifically, the “score” for choice A is modeled as $\mathcal{Y}_A = \mu_A + \sigma_A \cdot \mathcal{U}$, where μ_A, σ_A are the mean and standard deviation, and \mathcal{U} is a uniform random variable with zero mean and unit variance. For any two neighboring samples with disagreeing categorical choices A and B , we view the inconsistency as a discontinuous branching conditioned on whether the sampled “score” Y for choice A is greater than B or not: $g = \text{select}(Y_A > Y_B, g_A, g_B)$. By forming the discontinuity this way, the gradient wrt $\mu_{A/B}, \sigma_{A/B}$ can be easily computed with the $\text{Ad}\delta$ gradient rules on the time domain. At convergence, the variance to every “score” variable should be reduced to a small value such that the categorical choice is sampled consistently.

The stochastic gradient rule works best when there is a high correlation between the functions associated with each choice g_A, g_B , etc. Intuitively, this allows g_A, g_B, \dots to form a smaller convex hull for the sampled output $g(X; \theta)$, therefore reducing the variance of the gradient estimation. Therefore when differentiating categorical wave-

form choices, we align the phase of the wave functions such that their correlation is maximized.

3.1.3 Avoiding Zero Gradient in Plateaus

Many synthesizer parameters have constraints on their values, such as the period for ADSR stages should be nonnegative, and the filters’ cutoff frequencies should be within a range to avoid singularities. A typical strategy for optimizing these constrained parameters in an unconstrained problem is to clamp the parameters: taking the min and max against their upper and lower bounds. However, clamping introduces another challenge for optimization: once the parameter clamped, the gradient wrt the parameter becomes zero across an entire “out of bounds” plateau in the loss function. For example, $\frac{\partial \max(\theta, 0)}{\partial \theta} = 0$ whenever $\theta < 0$.

We propose a heuristic workaround that avoids constrained parameters getting stuck at out-of-bound values, via a customized gradient for the min (or max) operator f :

$$f = \min(\theta, C) \\ \frac{\partial L}{\partial \theta} = \text{select}(\theta < C, \frac{dL}{df}, \max(\frac{dL}{df}, 0)) \quad (3)$$

Here the min operator compares with constant C , and we assume the gradient wrt f is already computed as dL/df . Note only the blue term in Equation 3 is different from traditional AD. The gradient for the max operator is similar to Equation 3, but $<$ and \max are replaced by $>$ and \min respectively. Note this is only a heuristic workaround for reverse-mode AD, and can not be used for forward-mode because it computes dL/df before differentiating f . Intuitively, our customized gradient will push the out-of-bound θ back to its valid range whenever the gradient wrt f wishes to bring the clamped value back to valid. We only apply this workaround when constraining parameter values against a constant, and generic min/max comparisons between two non-constants are still differentiated by AD.

3.1.4 Efficient IIR Filter Back-propagation

Infinite impulse response (IIR) filters are widely used in synths to flexibly control the timbre. However, differentiating the IIR filter introduces performance challenges because each output value at a certain time step recurrently depends on every input/output value in previous steps, and naively unrolling the gradient in the time domain is computationally expensive. We, therefore, avoid the complex dependency in the time domain by applying the filter in the frequency domain similar to [3]. During optimization, we only differentiate the multiplication between the unfiltered spectrogram and the frequency response of the filters. Because most popular filters (e.g. Biquad, Butterworth) used in synthesizers already have closed-form solutions for their frequency responses, requiring a frequency domain proxy does not restrict the expressiveness of this approach.

3.2 Loss Function

Unlike supervised deep-learning methods that could rely on losses in the parameter space at the cost of collecting the preset dataset, our optimization pipeline can only rely

on spectral and time domain losses. However, finding the ideal loss that is consistent with human perception is challenging for several reasons. Firstly, standard losses such as L2 on the (log mel) spectrogram only work well when distances between two signals are smaller than just noticeable difference (JND); but this is rarely the case during our optimization, as we start with random initial guesses, and the synthesizer may never even approach JND to an out-of-domain target. Furthermore, although deep perceptual metrics have been developed for speech signals (e.g., [17]), they do not generalize well to music synths.

We propose a heuristic combination of several different losses to approximate the perceptual similarity. The intuition is that the gradient to the majority of the losses should agree with human perception even if a few of them are noisy. In addition to standard losses, we also include the 1D Wasserstein distance [18] along the frequency dimension because of its wide applicability in matching distributions. Our final optimization loss is a weighted combination of the Wasserstein distance, L2, log mel L2, and a deep feature distance from the wav2clip model [19]. The weights are chosen such that each component has a relatively equal contribution. For the losses that work on a spectrogram (L2, log mel L2, and Wasserstein), we use three different window sizes (512, 1024, 2048) with 75% overlap between windows. The deep feature loss also uses the same window and hop sizes, but for efficiency, we stochastically evaluate the model using one of the window sizes per iteration. Additionally, because the deep feature model takes time domain signal as input, we need to apply inverse STFT to the spectrogram because of the frequency domain IIR approximation described in Section 3.1.4.

3.3 Identifying Perceptually Similar Results

Gradient-based optimizations may converge to a variety of local minima with different perceptual similarities to the target. Our framework runs multiple random restarts to avoid getting stuck at local minima. However, we are not aware of a quantitative metric that reliably characterizes the perceptual similarity for synthesizers [20, 21]. While we use our weighted loss in Section 3.2 to provide a gradient for the optimization, its absolute value does not precisely correspond to perceptual similarity: perceptually dissimilar results sometimes have lower loss than similar results. Thus, manual selection is needed to choose the best results. We also implement early termination to avoid wasting compute at local minima, and also a mechanism to identify good quality results after convergence.

Our early termination strategy is a generalization to the intuition that good initializations have a higher probability of good convergence. We generalize the heuristic to arbitrary iterations within the optimization, and terminate the ones with bad results at the end of a sequence of predetermined iterations. Additionally, because the weighted loss in Section 3.2 cannot reliably characterize perceptual similarity, we rely on the Pareto ranking [22] on multiple losses to identify bad results. We terminate optimizations whose Pareto rank on every non-deep-learning loss in Section 3.2

Figure 2. MOS listening test preference distribution.

is higher than $\text{ceil}(0.5 \max_rank)$, where \max_rank is the maximum Pareto rank for the current population. Our implementation checks for early termination every 100 iterations, starting at iter 200, and we run every optimization until full convergence and simulate the early termination.

We also note that when the optimization result is already close to the target at convergence, its loss metrics calculated from a larger window size better resemble perceptual similarity. Specifically, large L2 errors are usually bad. We therefore further omit any converged result whose L2 loss on the spectrogram with window size 2048 is 2x higher than the lowest among all results, and finally rank the remaining results based on the weighted sum of Wasserstein, L2, and log mel L2 on the same spectrogram.

4. VALIDATION

This section validates our proposed framework by optimizing the parameters of an FM synthesizer to match various audio signals for musical instruments and special sound effects. All the targets are downloaded from the web and are therefore out of domain. We first describe our FM synthesizer in Section 4.1 and evaluation setup in Section 4.2, then compare our method with two baselines through a user study (Section 4.3). Section 4.4 also shows the optimization convergence. Finally, Section 4.5 demonstrates the flexibility of our framework with a case study that modifies the synthesizer modules for better quality result.

4.1 Synthesizer Model

We choose an FM synthesizer as in Figure 1 following the recommendation from a synthesizer expert, because it is simple yet expressive enough to approximate most of our target signals. It has one carrier signal modulated by the weighted sum of four different signals. Each signal is parameterized with a categorical choice from the four base waveforms: sin, square, triangle, and sawtooth. Each modulation signal is also parameterized by ratio and index, which controls the frequency and the magnitude of the modulation. The FM signal will further be filtered by three Biquad equalizers (low/high shelf, peak) parameterized by their cutoff frequency, resonance and gain, and a pair of Butterworth low/high pass filters parameterized by their cutoff, bandwidth, and attenuation. After that, the filtered signal is multiplied by an ADSR parameterized with the duration of each stage, overall volume and that of sustain, the starting time of the attack, and optionally the exponential decay of the release as well as the scale, frequency, and phase to an optional AM envelope applied to attack, decay, and sustain. Finally, filtered white noise can be optionally added either by sharing the original ADSR or with a differ-

Figure 3. MOS listening test ratings (higher is better) for each of 16 target clips, grouped in 6 categories. Error bars correspond to 2SEM (standard error of mean). To save space we shorten names: Marim(ba), Xylo(phone), and Count(down).

ent ADSR. Optional configurations are included based on audio characteristics. For example, sustained sounds such as woodwind and brass uses the AM envelope for ADSR, and shorter sound such as percussion includes a filtered white noise with separate ADSR. The overall model includes 40 (e.g. oboe) - 70 (e.g. crotale) parameters.

We implement the FM synthesizer in PyTorch to leverage its AD framework. The gradient discussed in Section 3.3 is implemented as the customized backward pass, and AD is used for the rest of the computation (e.g. ADSR, STFT). Note this could also be generated by a compiler for arbitrary synthesizers similar to $A\delta$ [10].

4.2 Evaluation Setup

We compare with two baselines: traditional AD and zeroth order optimization with genetic algorithm NSGA-II. AD baseline uses the same optimization framework described in Section 3, except that the gradient described in Sections 3.1.1 - 3.1.3 is replaced by traditional AD. The zeroth order baseline does not require any gradient, and instead uses the genetic algorithm NSGA-II [23] to search over the parameter space. Because NSGA-II is multi-objective, it directly finds Pareto optimal solutions to the various loss functions in Section 3.2 without having to compute their weighted sum as in gradient-based optimization.

We use 16 different target sounds, including 12 musical instruments and 4 special sound effects listed in Figure 3. For ours and AD, we run the experiment with 100 random restarts for a maximum of 2000 iterations per restart. Note that because of the early termination described in Section 3.3, the actual number of iterations per restart varies. We additionally supply the NSGA-II with a reasonable sample range to the parameters, and run the algorithm with 100 population size and 2000 generations.

4.3 MOS Listening Test

As mentioned in Section 3.2, we have no perceptually-accurate loss for comparing synth output to target audio. Therefore, we rely on a Mean Opinion Score (MOS) test to qualitatively compare results for our method and baselines. For each method and target sound, we use the top 4 results based on the Pareto ranking from Section 3.3 for testing, resulting in 12 samples across 3 methods: ours, AD, and NSGA-II. These clips may be heard in our supplemental material.

Workers on Amazon Mechanical Turk (AMT) rate how similar each result is to the target on a scale of 1 (bad) - 5 (identical). They are “master” workers, English-speakers in the US, and are paid \$20 per hour. Each worker is asked

to rate all 12 samples for two different targets. We further embed four validation tests to filter out careless ratings: two that are intentionally corrupted from the two targets to be worse than any of the 12 samples to be rated, and two that are identical to targets randomly chosen from all 16 targets. Therefore each worker rates $2 \times 12 + 4 = 28$ samples for each assigned task called HIT (Human Intelligence Task). In the end we collected 240 valid HITs where each audio sample gets 30 ratings from 30 different workers.

We compute a preference score for each worker and each instrument: we calculate a mean rating for each method over the 4 rated samples. If Method 1 has a higher score than Method 2, we say that Method 1 is preferred by this worker. Figure 2 shows the preferences among pairs of methods aggregated across all workers. Our method outperforms both baselines by a larger margin, but AD is preferred more than NSGA-II. We compute the p-value for the hypothesis: *our average rating per user per instrument is higher than that of the baseline*. The p-value for the AD baseline is $2e-8$, and for the NSGA-II baseline is $3e-61$.

We additionally report in Figure 3 the rating for each target. Ours performs best when the FM synth is a good emulation of the underlying instrument, such as for woodwind or brass. AD has similar ratings to ours more frequently than NSGA-II, which is consistent with Figure 2. Note in all cases when baselines have similar or higher ratings than ours, the rating difference is always within the error bar, indicating the preference is not statistically significant. We characterize the cases where ours and baselines have similar ratings into two scenarios. The first one is when the target is less challenging, and can be easily reconstructed by various local minimums, such as Pop1 and Pop2. The second scenario is when the FM synth cannot nicely emulate the instrument, such as for Piano. Therefore none of the methods can converge close enough to the target, resulting in similarly low ratings.

4.4 Optimization Convergence

This section discusses the optimization convergence to demonstrate how frequently each method converges in the optimization. Figure 4 demonstrates two representative results: Horn for ours outperforms baselines and Xylophone for ours performs similarly to baseline AD. In both plots, all 100 populations for NSGA-II converge similarly because bad results are removed at the end of each generation. Unlike genetic algorithms, the 100 optimizations for both ours and AD have diverging performances because gradient-descent only explores the local parameter space and may be stuck at a local minimum. The early termina-

Figure 4. Comparing the convergence of ours and baselines for the 100 random restarts of two tasks. The x-axis reports simulated time: the number of function evaluations scaled with the actual runtime for each method. The y-axis reports the weighted loss for the optimization. For ours and AD, each transparent line corresponds to a restart. For NSGA-II, each transparent line plots the loss for the k th population at each generation ($k \in [1, 100]$). The median within all runs at a given time is shown as the solid line.

tion described in Section 3.3 conservatively removes some of the local minimums, but more importantly reduces the number of evaluations toward the end of the optimization because fewer restarts are still active. Typically, the convergence plot is consistent with the listening test result in Figure 3, but with the exception of Oboe, where NSGA-II converges to the lowest error, but its listening test performs worse than ours. But this is simply due to the choice of weights that combine multiple losses into one scalar: NSGA-II converges to lower Wasserstein and higher L2 and log mel L2, thus it is *not* Pareto superior to ours.

4.5 Case Study: Modify Synthesizer Modules

This section uses the Xylophone target as a case study to demonstrate that our white box method can be flexibly combined with user expertise to modify the synthesizer components to improve the quality of generated audio.

Similar to other targets, Xylophone is initially approximated by the synth model described in Section 4.1. It uses filtered white noise with independent ADSR to model the strike at the start of the sound. However, the optimization result is not ideal, specifically, the beginning of the audio sounds very different from the target. This can be verified by Figure 5, which compares the spectrogram for the first 0.07s of the sound between the target (a) and the optimization (b): the optimization has a longer attack stage.

We ask a synthesizer expert to identify the potential cause of the inconsistency: instead of using filtered white noise, the beginning of the audio may be better approximated by an impulse with IIR filters. We, therefore, use the following impulse component to replace the original filtered white noise. We first manually calibrate the starting time of the Xylophone within the target audio, and set the impulse at that location. Similar to the white noise, the impulse is also filtered by three Biquad equalizers (low/high shelf and peak) and a pair of low/high-pass Biquad filters. Because the impulse is not static, we have to optimize the IIR parameters in the time domain rather than the frequency domain as in Section 3.1.4. Therefore we avoid using any Butterworth filters mentioned in Section 4.1 for a faster backward pass. Because the original optimization

Figure 5. Visualizing the spectrogram for the Xylophone target (a), original optimization (b) using filtered white noise described in Section 4.1, and finetune result (c) using an impulse module described in Section 4.5. The spectrogram is computed with window size 512 and hop size 128.

nically approximates the target except at the beginning, we only compute the loss for the first 2048 samples, and keep all the FM-related parameters fixed to only optimize the newly added IIR parameters, the scale of the impulse, and the original ADSR parameters that are initialized with their previously optimized values. To better characterize the filtered impulse signal, we use smaller spectrogram window sizes: 128, 256, and 512 with 75% overlap. Figure 5(c) shows the spectrogram of the finetune result that indeed better matches the attack stage of the target. Perceptually it also sounds better: please refer to supplemental material.

Note the finetuning process described in this section cannot be supported by deep learning methods without re-collecting a new dataset and re-training the model for any change in the synthesizer design. Because our method directly optimizes the white-box programs, we can flexibly add the synthesizer components and reuse any parameters from previous optimizations.

5. CONCLUSION AND FUTURE WORK

This paper proposes to find synthesizer parameter settings that best match a given target sound by directly differentiating the white-box synthesizer program. We adapt and extend recent methods from differentiable rendering to differentiate the discontinuous and discrete components of the synthesizer, and design an optimization pipeline to solve the problem through gradient descent. We validate our method through user studies on Mechanical Turk, where our result is preferred over baselines by a large margin. We further demonstrate the benefit of differentiating white-box programs through a case study, where we can flexibly modify and finetune synthesizer components.

This work suggests several directions for future research. Our framework only searches for synthesizer parameters, and leaves patch connections fixed. Nevertheless, the gradient rules described in Section 3.1 provide a potential solution. It could be easily extended to optimize binary connection decisions, therefore the general patch connection could be optimized if viewed as compositions of binary choices. Additionally, because no perceptually accurate loss exists for music, our framework relies on a combination of various loss terms (Section 3.2) together with a Pareto rank based early termination strategy to improve convergence. Future work on perceptual similarity could simplify and improve our process.

ABSTRACT

Brain decoding allows the read-out of stimulus and mental content from neural activity, and has been utilised in various neural-driven classification tasks related to the music information retrieval community. However, even the relatively simple task of instrument classification has only been demonstrated for single- or few-note stimuli when decoding from neural data recorded using functional magnetic resonance imaging (fMRI). Here, we show that drums, instrumentals, vocals, and mixed sources of naturalistic musical stimuli can be decoded from single-trial spatial patterns of auditory cortex activation as recorded using fMRI. Comparing classification based on convolutional neural networks (CNN), random forests (RF), and support vector machines (SVM) further revealed similar neural encoding of vocals and mixed sources, despite vocals being most easily identifiable. These results highlight the prominence of vocal information during music perception, and illustrate the potential of using neural representations towards evaluating music source separation performance and informing future algorithm design.

1. INTRODUCTION

The goal of brain decoding is to infer mental states and perceptual information from neural activity [1, 2]. Common neuroimaging techniques such as functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) allow data acquisition in a non-invasive manner, which has resulted in rapid developments in brain-computer interfaces (BCI) [3, 4].

Although fMRI- and EEG-based models both make use of neural activity for decoding, the form of information retrieved is substantially different. That is because fMRI offers (sub-)millimetre spatial resolution at the cost of low

Figure 1. We compared the decoding performance of convolutional neural networks (CNN), random forests (RF), and support vector machines (SVM) in classifying drums, instrumentals, vocals, and mixed naturalistic musical sources based on human auditory cortex activation (highlighted in green) as recorded using fMRI.

temporal resolution, whilst EEG provides a millisecond-level temporal resolution at the expense of poor spatial resolution [2, 5]. Consequently, fMRI-based decoders typically rely on spatial representations of neural activation as features, whilst EEG-based decoders exploit the temporal dynamics of neural activity.

In the context of music information retrieval (MIR), both fMRI- and EEG-based decoders have been employed for a variety of classification/estimation tasks, such as genre [6–9], pitch [6, 10–12], rhythm [13, 14], musical emotion classification [15–21], song identification [22–25], music composition [26], beat and note onset detection [27, 28], and acoustic feature extraction [29], as well as reconstruction from heard and imagined melodies [30–35].

However, a problem that has remained under-studied is the decoding of different instruments within a song based on brain activity. This is despite its intimate relation to the standard MIR task of music source separation, which seeks to decompose a musical sound mixture into a linear sum of instrumental sources [36, 37]. Although music and speech source separation share the same goals, the key difference is that sound sources from multiple musical instruments are more correlated in music than in speech [36].

The most relevant literature on neural-driven music source separation is the work by Cantisani et al. [38, 39]. Their initial work showed that EEG can be used to decode listeners’ attention deployment to a particular instrument

from naturalistic polyphonic music mixtures [38]. The approach was to first record listeners' EEG as they were presented with solo instrumental sources. A temporal response function was then trained to reconstruct the solo instrumental sources from EEG. This response function was later applied to the EEG signal when subjects listened to the polyphonic mixtures. The attended instrument was identified as the one that showed the highest correlation with the reconstructed source. In their subsequent work [39], they showed that the reconstructed sources from their EEG attention decoding model can be used as contrastive priors to inform a non-negative matrix factorisation-based source separation model.

On the other hand, relevant work based on fMRI data seems to be lacking. While existing studies have identified the role of the auditory cortex in processing timbre [40, 41] via correlational approaches, even the relatively simple task of decoding musical instrument category has only been restricted to single- or few-note stimuli [19, 42].

In this paper we address this gap by showing that distinct musical sources, namely drums, instrumentals, and vocals from naturalistic musical stimuli, as well as their mixtures, can be decoded from spatial representations of neural activation recorded using fMRI on the single-trial level. We report that decoding performance was the highest when detecting the presence of vocal information in the auditory stimulus, and we explain our model decisions in terms of patterns of neural activations. Importantly, unlike most existing decoding studies which have relied on a single classification algorithm, we additionally compared performance across three decoders, convolutional neural networks (CNN), random forests (RF), and support vector machines (SVM), to enhance the generalisability of our findings. In the last section of this paper, we also discuss how brain activity could be used in the future to evaluate music source separation and inform algorithm design.

2. METHODS

2.1 Experimental stimuli

Experimental stimuli consisted of 15-second musical audio excerpts derived from the beginning of the chorus section of 24 unreleased pop and rock songs within an in-house music dataset created by professional musicians.

Four versions of each song—*drums*, *instrumentals*, *vocals*, and *mixed*—were compiled, resulting in a total of 96 stimuli. The versions were produced by first separating the original song into *bass*, *drums*, *other*, and *vocals* using a state-of-the-art music source separation model, Demucs-v4 [43]. Due to the frequency response of MRI-compatible noise-isolating earphones (Sensimetrics S15), *bass* and *other* were linearly combined to form an *instrumentals* version. A 100-ms fade-out was then applied to the *drums*, *instrumentals*, and *vocals* versions, followed by loudness normalisation to the EBR U 128 standard. Finally, the normalised *drums*, *instrumentals*, and *vocals* versions of each song were linearly combined to form the *mixed* version, which was also normalised for

loudness. We chose to use the *mixed* version rather than the original song to ensure that decoding was not biased by differences in loudness from the underlying versions. We made sure that each song actually included drums, vocals, and other instruments before source separation, and we checked our resulting stimuli after source separation to ensure that they were free from audible artefacts and separation errors, and that they did not contain silences at the start and end that would shorten the stimuli.

2.2 Data acquisition

Data were collected from 24 healthy, normal-hearing adults aged between 19-34 with their written informed consent. The 96 music stimuli were presented over eight runs whilst functional gradient echo planar images ($TR/TA/TE = 2/2/0.025$ s, voxel size = $3 \times 3 \times 3$ mm³, 33 slices, flip angle = 77° , 188 volumes per run) were acquired using a Siemens Prisma 3T MRI scanner. Each run lasted approximately 6 minutes, and was separated by a short break of around one minute. Stimulus presentation was counter-balanced across runs, with the constraint that each run contained three samples of the four versions, all stimuli came from different songs, and that each song (regardless of version) appeared only once every other run. Stimulus presentation within a run was randomised. To maintain attention, subjects were also asked to rate their preference on a 1-9 scale within a 4-second time window using a button box after each stimulus presentation. Our study was approved by the Ethics Committee at RIKEN.

2.3 fMRI data preprocessing

Functional MRI data for each subject were preprocessed using fMRIPrep [44]. Functional images were first corrected for slice-timing differences, motion artefacts, and susceptibility distortions, then co-registered to subjects' anatomical image, and then normalised to standard MNI-space using the ICBM 152 Nonlinear Asymmetrical template. Next, for each subject, we fitted a general linear model in each voxel to estimate the blood oxygen level-dependent (BOLD) response on the single-trial level using SPM [45] following a 'least-squared all' approach [46]: each stimulus was modelled as a separate regressor in the design matrix, and a parametric modulator that varied by subjects' stimulus rating was also added to control for differences in preference. Another regressor was included to account for variance during the rating period. These regressors were modelled as boxcar functions and convolved with the canonical haemodynamic response function (HRF). Six motion, one cardiac, and one respiratory regressors were further added to the design matrix to control for motion- and physiology-induced artefacts. Model parameters were estimated using restricted maximum likelihood, and the resulting parameter estimates at each voxel provided a spatial representation (i.e., *beta maps*) of neural activations for each stimulus separately, which we used for subsequent decoding.

As we were interested in stimulus differences in the neural-perceptual level, we considered voxels in the hu-

Figure 2. Architecture of our CNN-based decoder.

man auditory cortex (see Figure 1) as decoding features. These were obtained by applying a mask to the bilateral early-auditory and auditory-associative regions in the HCP-MM1 brain atlas [47,48], and then flattened into a 1D-vector using `nilearn` [49].

2.4 Decoding analyses

We performed two decoding analyses. The first was a four-way classification task, whose goal was to classify which of the four versions a stimulus belonged to based on subjects’ brain activation as summarised by its beta map. The second was a binary recognition task, whose goal was to detect the presence of drums, instrumentals, or vocals in the stimulus from brain activation. As an example, for drum-recognition, *drums* and *mixed* versions would be assigned a positive label, whilst *instrumentals* and *vocals* versions would be assigned a negative label.

We also examined whether decoding performance depended on neural information encoded in the left, right, or both auditory cortices. This was motivated by neuroscientific findings suggesting a right-lateralised hemispheric dominance to musical stimuli [50], and that the left auditory cortex may be more sensitive to rapid temporal features in an auditory stimulus whilst the right may be more sensitive towards spectral features [51].

To enhance the generalisability of our findings, we performed leave-one-subject-out cross-validation, where each decoder was trained on data from 23 subjects and tested on 1 remaining subject. Note that brain decoding between subjects is generally harder than decoding within subjects, because the decoder must additionally overcome individual differences in structural and functional organisation of the brain when predicting on an unseen subject [52].

2.5 Implementation

We trained three types of classifiers—convolutional neural networks (CNN), random forests (RF), and support vector machines (SVM)—for our two decoding tasks. While classical approaches such as SVMs and RFs remain popular [53], CNNs have also been recently used to decode visual objects [54], vocal emotions [55], and musical pitch [10] from fMRI data. We implemented CNN decoders on TensorFlow2, whilst RF and SVM were implemented on `scikit-learn`¹.

Training data were first put through a variance threshold to remove features that gave identical outputs (e.g., at

the boundary of the brain), and then scaled using a robust scaler, before decoders were fitted.

Our CNN decoders (see Figure 2) were inspired by ConvNeXt [56], which is a family of purely convolutional neural networks that recently achieved state-of-the-art performance in image classification. Input features first passed through a 1D-convolution layer (96 units, kernel size = 4), and a ConvNeXt-like residual block. This block comprised a 1D-convolution layer (96 units, kernel size = 7), followed by layer normalisation, 1D-convolution (384 units, kernel size = 1), GELU activation, another 1D-convolution (96 units, kernel size = 1), and a residual connection layer followed by ReLU activation. Outputs of the residual block then passed through three dense layers (1024, 512, and 256 units, respectively), a flattening layer, and finally a dense layer with softmax output. All convolution layers had a stride length of 1 (except for the first, which had a length of 4) and `same`-padding. Each model was trained to minimise categorical entropy loss for 200 epochs, and early-stopped if validation performance did not improve after 25 epochs (with best weights restored). Data from two random subjects ($\sim 10\%$) in the training set were held-out for validation, and we selected a batch size of 512, and an AdamW optimiser [57] with learning rate = 0.001 and weight decay = 0.0001 for training.

RF decoders were trained with bootstrapping using 100 trees in the forest, at least 1 sample per leaf, and 2 samples per split. Quality of split was assessed with Gini impurity.

SVM decoders were trained using regularisation parameter of 1 with squared-L2 penalty and a linear kernel for a maximum of 10,000 iterations.

3. RESULTS AND DISCUSSION

3.1 Four-way classification

Table 1 and Figure 3 show the leave-one-subject-out cross-validation performance of CNN, RF, and SVM decoders in classifying whether a stimulus belonged to *drums*, *instrumentals*, *vocals*, or *mixed* versions of a song, given auditory cortex activation. To test the statistical significance of our results (see Table 2), we fitted linear mixed models with the interaction between classifier and hemisphere (and lower order terms) as fixed effects and a maximal random effects structure with subject as a grouping factor.

All classifiers showed significantly above-chance performance (all $p < 2.2 \times 10^{-16}$, see Supplementary Information¹) in decoding accuracy and Area Under the Receiver Operating Characteristic Curve (ROC AUC), suggesting that despite the slow temporal resolution of fMRI, correlated sources of the same song can be decoded and classified from spatial representations of brain activation.

For all classifiers, accuracy and ROC AUC were highest when decoding from the bilateral auditory cortex, followed by the right and left hemispheres. Resolving significant interaction effects between classifier and hemisphere for accuracy and ROC AUC furthermore revealed that accuracy was significantly worse when decoding from the left compared to the right and bilateral auditory cortices for CNN,

and compared to the right for SVM. Likewise, ROC AUC was significantly lower when decoding from the left compared to the bilateral auditory cortex for all classifiers, and compared to the right for CNN and SVM. Although these results corroborate previous findings (e.g., [50]) that support a dominant role of the right auditory cortex in processing musical stimuli, they nevertheless show that both auditory cortices were engaged and provided useful information for decoding.

Confusion matrices in Figure 4(A) provide further insight on decoding performance. We notice that across the three decoders trained on both hemispheres, recall was the highest for *drums* and the lowest for *mixed*. The high recall for *drums* could be because they were the most temporally regular and had limited pitch possibilities. Furthermore, *mixed* and *vocals*, as well as *drums* and *instrumentals*, were often misclassified as the other. These suggest a similar neural representation between *mixed* and *vocals*, as well as *drums* and *instrumentals*. Whether this pairing is contingent on the stimulus set, the part of a song used (here, our stimulus excerpts were taken from the beginning of the chorus section), and the experimental design remains to be verified in future studies.

3.2 Neural representations

To explain the impact of each voxel towards classification, we turned to SHapley Additive exPlanations (SHAP) [58]. SHAP decomposes a model prediction into the additive contribution of each feature from the mean using game theory. Figure 4(B) shows the mean-averaged contribution of voxels in the bilateral auditory cortex towards classifying a stimulus as belonging to the four versions in Subject 4 using a CNN. We notice that the pattern of contributions were quite similar for *mixed* and *vocals*, which could explain the misclassification of the two labels observed above. Furthermore, there were substantial contributions from both

Figure 4. (A) Confusion matrix (normalised along rows) for each decoder when trained on the bilateral auditory cortices, pooled across all subjects. Notice that *drums* recall was highest, and a consistent misclassification between *mixed* and *vocals*, as well as *drums* and *instrumentals*. (B) Mean additive contribution of each voxel in the bilateral auditory cortex towards classifying a given label for one subject using a CNN decoder derived using SHAP [58].

auditory cortices, again indicating a bilateral engagement during music processing.

3.3 Recognition task

We next tested whether decoding performance in recognising the presence of drums, vocals, or instrumentals varied from the left and/or right auditory cortex. Results from leave-one-subject-out cross-validation are summarised in Figure 5 and Tables 1 and 2.

Resolving significant main effect of tasks for accuracy and ROC AUC revealed substantially higher decoding performance across CNN, RF, and SVM in recognising vocals compared to drums and instrumentals (see Supplementary Information¹). That the presence of vocal information was most robustly encoded from neural activation patterns is very interesting, as it suggests that listeners show an enhanced sensitivity towards perceiving human voice in music. This finding is in line with the view that singing vocals play a prominent and powerful role in communicating and expressing meaning and emotion during music listening [59, 60]. We speculate that the presence of vocal information might have additionally engaged neural populations involved in language processing, which consequently increased its dissimilarity amongst other labels.

Significant main effects of classifier for accuracy and ROC AUC also indicated superior performance of CNN and RF over SVM when averaged across recognition tasks. However, significant task-by-classifier interactions for both measures suggest that performance varied according to recognition task. Resolving the interaction revealed

significantly lower accuracy and ROC AUC for SVM compared to CNN and RF in drums recognition. Significantly higher ROC AUC was also observed for CNN compared to SVM in recognising instrumentals. Nevertheless, we were not able to detect any meaningful differences in laterality across tasks or classifiers.

3.4 Feature-encoding specificity

Thus far, we relied on neural activations in the auditory cortex as input features for our decoding models. To assess the specificity of information encoding, we repeated the above analyses in two other sensory processing brain regions, namely the bilateral `primary-visual`, and the `somatosensory-and-motor` regions as derived from the HCP-MM1 brain atlas [47, 48]. As before, we assessed the statistical significance of decoding performance using linear mixed models. However, rather than comparing the effects of hemisphere within the auditory cortex, we now compare performance across the bilateral auditory, primary visual, as well as somatosensory-motor cortices.

In the four-way classification task, we observe in Table 1 and the Supplementary Information¹ that decoding from the bilateral auditory cortex resulted in significantly higher accuracy and ROC AUC compared to the two other sensory cortices across all classifiers (all $p < 2.2 \times 10^{-16}$).

Interestingly, decoding accuracy and ROC AUC were also significantly above chance when CNNs and RFs were trained using features from the visual and somatosensory-motor regions (with no significant differences between these two regions). Furthermore, resolving signifi-

Figure 5. Box plots comparing performance in recognising the presence of *drums*, *instrumentals*, or *vocals* in a musical stimulus using left and/or right auditory cortex activation as decoding features. Significantly higher decoding performance was detected in the *vocals* recognition. Dashed lines indicate chance performance.

cant cortex-by-classifier interactions showed significantly lower accuracy and ROC AUC when decoding from the primary visual cortex using SVM compared to CNN and RF, and from the auditory cortex using RF compared to CNN, as well as lower accuracy when decoding from the somatosensory-motor cortex using SVM compared to RF.

A similar picture could be seen in recognition performance. Significant main effects of cortex for recognition accuracy and ROC AUC indicate superior performance when decoding from the auditory compared to visual or somatosensory-motor regions. Resolving significant cortex-by-task interactions further revealed that the significantly higher performance in recognising vocals compared to drums or instrumentals was specific to the auditory cortex. By contrast, accuracy and ROC AUC for instrumentals were significantly higher than drums in the auditory and somatosensory-motor areas, as well as in the primary visual cortex (ROC AUC only).

Engagement of the primary visual cortex during music has been suggested to be related to mental imagery [61,62], which is thought to be an important way through which music evokes emotions [63]. Likewise, the somatosensory cortex has been said to encode the emotional percept or feeling states associated with music [15], whilst auditory-motor interactions during music perception is thought to be related to the integration and updating of hierarchical predictions of the musical beat [64, 65]. Combined with the substantially higher performance observed when decoding from the auditory cortex, these suggest that while musical sources could be decoded from visual and somatosensory-motor regions, the information encoded is unlikely to be related to the auditory content itself. Rather, such representations might encode affective or metrical information from associated cognitive processes that arise when perceiving the four different musical sources.

4. CONCLUSION AND FUTURE PERSPECTIVES

In this paper, we demonstrated that drums, instrumentals, vocals, and mixed sources of naturalistic music can be decoded from human auditory cortex fMRI data on the

single-trial, between-subject level. While decoding performance was the highest for CNN, performance across all classifiers—CNN, RF, and SVM—were above chance and suggested similar neural representations for vocals and mixed sources. An especially high performance in vocals recognition across all classifiers further pointed towards an enhanced perceptual sensitivity towards vocal information during music listening. Taken together, our results show that despite the low temporal resolution of fMRI, the high spatial resolution it offers could still provide relevant information for decoding in neural-driven MIR tasks.

Although our specificity analyses highlighted the auditory cortex in encoding stimulus-relevant information compared to other sensory areas, the perception of different musical sources is a hierarchical process that engages higher-order brain regions in the prefrontal cortex via dorsal and ventral pathways [66, 67]. Future work could examine differences in representations along these two pathways to shed light on neural mechanisms involved in auditory-object processing.

In the context of music source separation, one future possibility is to use neural data for evaluation. While current subjective evaluation of music source separation algorithms typically rely on explicit ratings such as MUSHRA or mean opinion scores, ratings are known to be prone to response biases [68–70] and might consequently fail to adequately reflect subjects’ perception. This could be overcome by directly evaluating performance on the neural-perceptual level. Future work could, for example, compare the neural representations of source-separated stimuli from different algorithms or hyperparameters. Separation quality could be determined by identifying the algorithm that maximises dissimilarity in neural activation across the different sources. Another possibility is to assess sensitivity to each instrument by examining neural activation in response to different mixing proportions. This would provide perceptual priors that could be used to constrain the parameter space in future music source separation algorithms. While these prospects may seem too challenging at this time, we envision that our work will help pave the way in that direction.

ABSTRACT

Music Emotion Recognition (MER) refers to automatically extracting emotional information from music and predicting its perceived emotions, and it has social and psychological applications. This paper proposes a Dual Attention-based Multi-scale Feature Fusion (DAMFF) method and a newly developed dataset named MER1101 for Dynamic Music Emotion Recognition (DMER). Specifically, multi-scale features are first extracted from the log Mel-spectrogram by multiple parallel convolutional blocks. Then, a Dual Attention Feature Fusion (DAFF) module is utilized to achieve multi-scale context fusion and capture emotion-critical features in both spatial and channel dimensions. Finally, a BiLSTM-based sequence learning model is employed for dynamic music emotion prediction. To enrich existing music emotion datasets, we developed a high-quality dataset, MER1101, which has a balanced emotional distribution, covering over 10 genres, at least four languages, and more than a thousand song snippets. We demonstrate the effectiveness of our proposed DAMFF approach on both the developed MER1101 dataset, as well as on the established DEAM2015 dataset. Compared with other models, our model achieves a higher Consistency Correlation Coefficient (CCC), and has strong predictive power in arousal with comparable results in valence.

1. INTRODUCTION

With the rising demand for music consumption and the explosive growth of music content, Music Emotion Recognition (MER) demonstrates its critical position in music understanding and applications. It has been widely used in personalized music recommendation [1], music therapy [2], music education [3], music generation [4], etc.

To portray human emotions, two main types of models were differentiated in the past [5]: discrete emotion model [6, 7] and dimensional emotion model [8–11]. The discrete emotion model describes human emotion as categor-

ical adjectives, such as happiness, anger, sadness, joy, etc. However, limited words cannot adequately describe human emotions, different emotions are better described on a continuous scale than as a set of discrete values. In Russell's two-dimensional valence-arousal (V-A) emotional model [12], emotions are described as points on the plane that is spanned by the arousal and valence axes. This turns the problem of emotion prediction into a two-dimensional regression issue based on Russell's emotion model. This paper is focused on the study of Dynamic Music Emotion Recognition (DMER), which predicts the emotion of music using continuous V-A values at a short interval.

Among the existing studies, Long Short-Term Memory (LSTM) has received extensive attention in the DMER due to its superiority in sequence modeling [8, 13–15]. Convolutional Neural Network (CNN) is used to extract features in many fields. Researchers have recently focused on improving emotion recognition accuracy using a combination of CNN and Recurrent Neural Network (RNN) [9, 16–18]. However, LSTM-based models still use handcrafted features as input, and some widely used handcrafted feature operations will lose high-level features. The CNN-RNN-based model mainly uses a fixed-scale CNN. Due to its fixed receptive field, the learned CNN features are limited, and the emotional crucial features of different fields of view are not extracted. Moreover, various problems exist in existing music emotion datasets, which also hinder the progress of DMER.

This paper proposes a novel Dual Attention-based Multi-scale Feature Fusion (DAMFF) model and develops the music emotion dataset MER1101 for DMER. On the one hand, our model first utilizes multi-scale convolution to extract features at different temporal-frequency spans from the log Mel-spectrogram. Then, we propose a Dual Attention Feature Fusion (DAFF) module for fusing multi-scale context features from spatial and channel dimensions to enhance the expressive ability of CNN. Finally, the BiLSTM model processes these features and predicts V-A emotional labels. On the other hand, we develop a high-quality dataset named MER1101. Compared with the existing publicly available datasets in the MER domain, MER1101 contains 1101 music snippets from 16 genres with richer languages, more extensive size, and more balanced emotion label distribution. We evaluate our method using the MER1101 dataset and DEAM2015 [19] dataset.

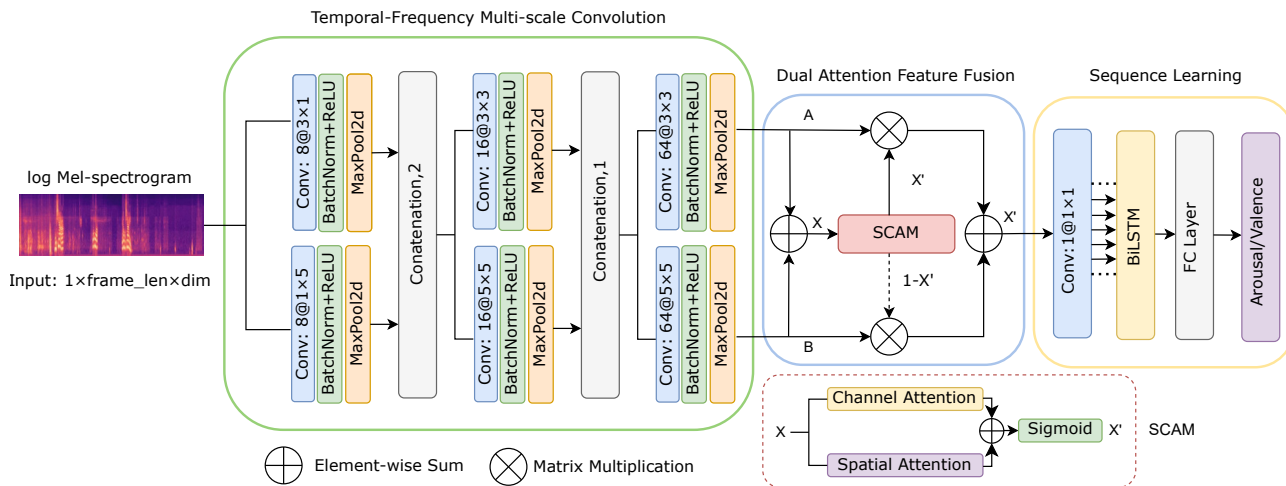

Figure 1. DAMFF model architecture. The input is 2D spectrogram. The architecture combines temporal-frequency multi-scale feature extraction, dual attention feature fusion, and sequence learning to achieve dynamic emotion prediction for music.

On the MER1101 dataset, we achieve a Consistency Correlation Coefficient (CCC) of 0.4223 for arousal and 0.1115 for valence. On the DEAM2015 dataset, we achieve a CCC of 0.4203 for arousal and 0.0151 for valence. Experimental results show our method outperforming a number of baseline and SOTA models in DMER, by means of an improved CCC metric.

2. RELATED WORK

Researchers have made many efforts in the DMER in the past few years. In the early days, RNN made a breakthrough in this field due to their advantages in sequence processing. In the “Emotion in Music” task at MediaEval from 2013 to 2015, LSTM-based methods achieved state-of-the-art performance [20]. Li *et al.* [8] pointed out that in music composition, performance, and annotation, the emotion in music is related to the previous and future contexts. Therefore, they chose Bidirectional LSTM (BiLSTM) as the regression model and proposed a multi-scale fusion method based on an Extreme Learning Machine (ELM) to improve the performance of the BiLSTM model. But the LSTM-based models mentioned above use suboptimal hand-crafted features as input, making it difficult to improve emotion recognition.

Later, researchers began to employ CNN for high-level invariant features extracted from raw music data [21–23]. Pons *et al.* [24] discussed how convolution filters with different shapes are suitable for specific musical concepts and experimentally proved that the size of CNN filters can be interpreted in both the temporal and frequency dimensions of the spectrogram. Researchers have combined CNN and RNN to improve the accuracy of emotion recognition, Malik *et al.* [16] proposed a two-dimensional V-A space continuous emotion prediction method composed of stacked convolution and recurrent neural network. Compared to using BiLSTM [15] only, this method achieved better results with fewer parameters; Dong *et al.* [9] replaced the

connection between the input layer and the hidden layer of the RNN with a CNN to adaptively learn the sequential-information-included affect-salient features from the spectrogram; Zhang *et al.* [25] extracted MFCCs and Cochleagrams from raw music data as input features, and adopted an audio feature fusion method based on the combination of CNN and BiLSTM to predict the emotional V-A values in music. However, CNN-RNN-based models still have problems with limited convolutional receptive fields. For MER, due to the limited size of the convolution kernel, the convolution is mainly biased towards learning local information, which is insufficient for learning the correlation between the spatial and channel axes.

Various attention mechanisms are devised to solve the above problem in speech emotion recognition [21, 26, 27]. Guo *et al.* [26] proposed a representation learning method with spectral-temporal channel (STC) attention, which was integrated with CNN to improve representation learning ability; Zhang *et al.* [21] applied multi-scale region attention in deep convolutional neural networks to focus on emotional features at different granularities; Zhang *et al.* [27] implemented an attention layer on the arousal, valence, and dominance tasks and completed multi-task predictions to capture the contribution of different parts of each task. Nonetheless, the attention mechanism is currently not widely applied in the field of DMER.

In this paper, we propose a novel attention module, the Spatial Channel Attention Module (SCAM), which considers spatial and channel dimensions to capture the relative importance of features and integrates multi-scale convolutions for enhanced representation learning. We aim to build an attention mechanism that extracts salient information from multiple dimensions and can fuse contextual information.

J. S. Gómez-Cañón *et al.* [28] summarized existing MER datasets. But they have some problems, for example, some datasets have insufficient number of music, and some datasets have no dimension labels. After our com-

prehensive comparison, the three datasets CH818 [29], P-MEmo [30] and DEAM [19] are relatively suitable for the DMER task. However, all three datasets have some disadvantages. The songs in the CH818 dataset only contain Chinese pop songs and are not public, while P-MEmo only Western pop songs; The annotators and annotating times of the training set and evaluation set in the DEAM2015 dataset are different, resulting in a discrepancy in performance [19]. To enrich existing musical emotion datasets, we develop a high-quality dataset, MER1101. MER1101 contains 1101 music snippets, which is better than most datasets in the MER domain in terms of genre, language, number of music, and has more balanced distributed emotion annotations.

3. METHODOLOGY

The proposed DMER processing method consists of three phases. Firstly, we build a Temporal-Frequency Multi-scale Convolution network using three different shapes of convolutional filters. Secondly, we propose a Dual Attention Feature Fusion network to focus more on the channel and spatial with important information and fuse multi-scale convolutional features in different dimensions. And finally, we employ BiLTSM, building a map from emotion-crucial features to emotional space. The specifics are as follows.

3.1 Temporal-Frequency Multi-scale Convolution

CNN has been proven effective at tackling various visual tasks [31, 32]. In vision tasks, the filter dimension has spatial meaning, and the audio spectrogram filter dimension corresponds to temporal and frequency [24]. We design a temporal-frequency multi-scale convolution module with three types of filters to capture various musical features. From the musical point of view, the temporal filter (l -by- n) can learn temporal dependence in music; the frequency filter (m -by- l) can learn pitch and timbre, and the square filter (m -by- n) can learn different musical features according to the size of m and n . As shown in Figure 1, we extract features through three layers of parallel convolutional blocks in the Temporal-Frequency Multi-scale Convolution module.

Firstly, we take the 30-second log Mel-spectrogram as input and perform distinct convolution operations on each 0.5-second segment to keep the individual properties at each moment. Secondly, the first layer introduces 3×1 and 1×5 filters to capture features along the temporal and frequency axes, and their outputs are concatenated along the time dimension. Finally, the concatenated results of the first layer are put into consecutive parallel convolutional layers with kernel sizes 3×3 and 5×5 . The output of the second layer is concatenated along the channel dimension, while the output of the third layer is fed into a dual attention feature fusion module for feature fusion. After each convolutional layer, batch normalization [33], the ReLU function [34] and max pooling are applied.

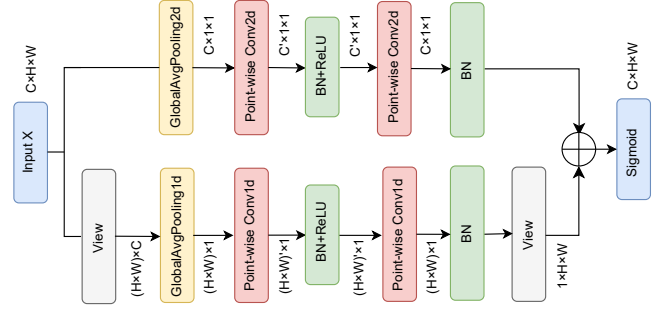

Figure 2. SCAM model architecture.

3.2 Dual Attention Feature Fusion

To further enhance the representation ability of CNN and capture the important information, we design a Dual Attention Feature Fusion (DAFF) module to focus more on the channel and spatial with important information for fusing multi-scale convolutional features. As shown in Figure 1, the DAFF module includes the Spatial Channel Attention Module (SCAM). By element-wise summing the outputs of 3×3 and 5×5 convolutions, we get a feature map $X \in R^{C \times H \times W}$ as input to SCAM, which is then fed into the spatial and channel attention modules, respectively. In Sections 3.2.1 and 3.2.2, we describe the proposed SCAM in detail.

3.2.1 Channel Attention Module

We convert a single channel into 64 channels through the Temporal-Frequency Multi-scale Convolution, strengthening the temporal correlation between distinct channels. In this case, we use the channel attention mechanism, which focuses on *what* the essential features are. While traditional attention mechanisms only focus on temporal structures, channel attention can learn the importance of different channels to deactivate features that do not contribute much to emotion. Figure 2 shows the channel attention module, similar to the Squeeze-and-Excitation block [35]. The module is mainly divided into two parts: squeeze and excitation operations. Specifically, given an input feature $X \in R^{C \times H \times W}$, we first use Global Average Pooling independently for each channel to aggregate spatial information and generate a channel attention map $C \in R^{C \times 1 \times 1}$. Next, we perform an excitation operation using two point-wise convolutions to enable cross-channel interaction. Finally, the channel attention map $C \in R^{C \times 1 \times 1}$ is obtained. In short, the channel attention map is calculated as follows:

$$C = \beta(\text{Conv}2d_2(\delta(\beta(\text{Conv}2d_1(\text{Pool}2d(X)))))) \quad (1)$$

where δ and β denote the ReLU function and batch normalization, respectively, and $\text{Pool}2d$ and $\text{Conv}2d$ represent the global average pooling2d and point-wise convolution2d, respectively.

3.2.2 Spatial Attention Module

We propose the spatial attention model, which exploits the spatial relationship between features to generate a spatial

attention map. Spatial attention focuses on *where* the important features are and supplements channel attention.

The spatial attention module obtains the spatial attention map in four phases. First, the input feature through view operation is converted into a spatial feature map $S' \in R^{(H \times W) \times C}$. Second, a global pooling operation is applied along the channel axis to compress the channels to obtain spatial-level features. Third, we use two point-wise convolutions to execute excitation operations and get feature weights at distinct positions. Finally, the resulting spatial attention map is translated into $S \in R^{1 \times H \times W}$. In short, the spatial attention map is calculated as follows:

$$S = \beta(\text{Conv1d}_2(\delta(\beta(\text{Conv1d}_1(\text{Pool1d}(X)))))) \quad (2)$$

where δ and β denote the ReLU function and batch normalization, respectively, and *Pool1d* and *Conv1d* represent the global average pooling1d and point-wise convolution1d, respectively.

After that, we perform an element-wise sum operation on the output of the dual attention and through the sigmoid function to obtain a new attention weight map $X' \in R^{H \times W \times C}$.

$$X' = \text{Sigmoid}(S \oplus C) \quad (3)$$

3.2.3 Feature Fusion Strategy

In order to effectively aggregate multi-scale context information, we introduce the fusion strategy in [36], as shown by Dual Attention Feature Fusion in Figure 1. The output of SCAM is represented as X' , $1 - X'$ by the solid line and dotted line, respectively. Based on the SCAM, the multi-scale feature fusion can be expressed as:

$$Z = X' \otimes A + (1 - X') \otimes B \quad (4)$$

where A and B represent the outputs of 3×3 and 5×5 convolutions respectively, $Z \in R^{C \times H \times W}$ is the fused feature.

3.3 Sequence Learning

Through the DAFF module, we get emotion-crucial features from multi-scale convolutional features. After reducing dimension, the features of the entire 30s of music snippet are input into the Bidirectional LSTM (BiLSTM) for long-term sequence learning. Finally, the emotional features are mapped to the emotional space with the help of a fully connected layer.

4. EXPERIMENTS

4.1 Dataset

We conduct our experiments on the DEAM2015 [19] dataset and our newly developed dataset MER1101. The details of each dataset are given below.

DEAM: This dataset was developed in the ‘‘Emotion in Music’’ (EiM) task [37] of the MediaEval benchmark. We utilized the DEAM2015 dataset, with the training set consisting of 431 30-second samples and the evaluation set consisting of 58 full-length songs. This dataset is the

most commonly used benchmark in dynamic music emotion recognition, but Cronbach’s α of the evaluation set is 0.29 ± 0.94 for valence, which is relatively low [19]. Furthermore, due to the different spatio-temporal environments and annotators of the emotion annotation process of the training set and the evaluation set [19], the performance derived from the training and evaluation set shows a non-negligible discrepancy, especially in the valence dimension.

MER1101¹: Similar with DEAM, MER1101 is also based on Russell’s valence-arousal emotion model. It contains 1101 music snippets gathered from the internet, with each ranging in duration from 16.5 seconds to 125.5 seconds. The dataset has both discrete and dimensional labels. Every song in the dataset has been annotated by three music experts and ten college students. The annotators listened to the song once and annotated the emotional adjectives of the song. After they were familiar with the song, they listened to it twice and annotated the V-A values. Annotators were only paid the full fee after their work had been reviewed. Student-labeled Cronbach’s α arousal is 0.6295 ± 0.3574 , 0.5624 ± 0.3766 for the valence. Expert-labeled Cronbach’s α arousal is 0.3556 ± 0.3442 , 0.2420 ± 0.3148 for the valence.

Compared with other music datasets, the MER1101 dataset has the following four advantages: 1) The dataset contains more genres (16 genres), including pop, DJ dance, chinoiserie, electronic, hip-hop, etc.; 2) It contains richer language, meeting the ratio of nearly 5:3:1:1 for Chinese, English, Japanese and Korean, and other languages; 3) The samples in our dataset distribute more balanced in the emotional quadrants and there are no more than three songs by the same artist in each V-A quadrant; 4) The size of our dataset is relatively larger than the current music datasets.

Our dataset can be used for a variety of music tasks, such as music genre classification, music generation with emotion, music emotion recognition, *etc.*

4.2 Evaluation Metrics

We use the Concordance Correlation Coefficient (CCC), Pearson Correlation Coefficient (PCC), and Root Mean Square Error (RMSE) as evaluation metrics. Each metric is computed by the ground-truth and predicted V-A values for each song and averaged across songs. The CCC combines the characteristics of PCC and RMSE to evaluate not only the trend of emotional changes but also the disparity between predictions and ground-truth. As a result, we consider CCC to be the most important evaluation metric.

4.3 Experimental Setup

Since DEAM2015 predefines the training and evaluation set configuration, we only describe the dataset division for MER1101 here. Firstly, we choose 925 songs lasting more than 30 seconds from the MER1101 dataset and randomly split them into a training set (80% of the data) and an evaluation set (20% of the data). Then, we split each song in

¹ See <https://ismir-2023.github.io/MER1101/> for details.

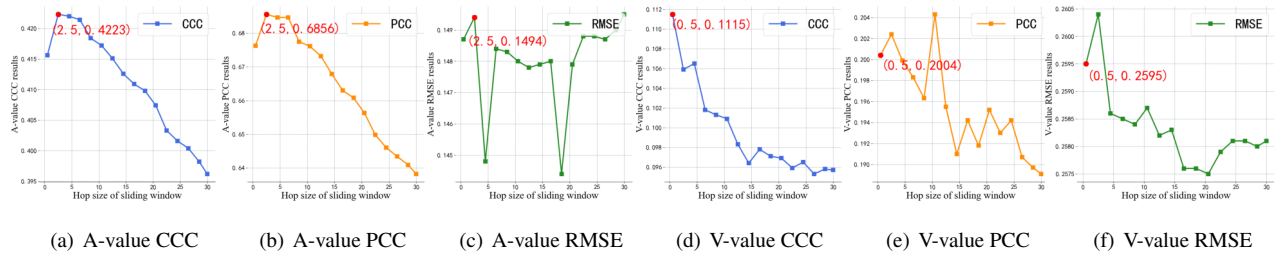

Figure 3. The CCC, PCC, and RMSE of arousal and valence with different hop sizes on the MER1101 dataset.

the training set into 30-second segments and kept complete songs for the evaluation set. The final training set contains 1526 30-second music snippets, and the evaluation set contains 185 complete songs. The DEAM dataset uses the official training and evaluation sets. To obtain a more accurate comparison and minimize accidental errors, we use 5-fold cross-validation on both datasets.

The log Mel-spectrogram is extracted using librosa [38], where the Mel band is 128, the sampling rate is 44100Hz, and the window size and hop size are 60 ms and 10 ms, respectively. The size of the convolution kernel is shown in Figure 1. We utilize the Adam optimizer for training, with learning rate of 0.0003, training epoch of 100, and batch size of 32. To prevent overfitting, we adopt the early stopping strategy. In addition, we use CCC and RMSE as loss functions for arousal and valence, respectively.

4.4 Experimental Results

4.4.1 Hop Size Selection of Sliding Window

For the MER1101 dataset, we train the model with music snippets of fixed duration, while the durations of the music snippets are variable during the test. Thus, we could not directly predict the emotion of the whole music. We propose a sliding window-based testing scheme to address this issue and ensure the continuity of the predicted V-A curves. During testing, we utilize the window size of T seconds and the hop size of t seconds. Each T second of audio in the window is input to the model, and the corresponding T seconds V-A curves are predicted. The first window takes the prediction result of T seconds, and each subsequent window only takes the result of the last t seconds.

We investigate the impact of hop size on the results of music emotion recognition on the MER1101 dataset. We set the window size to 30s, the same as the training set sample duration. Figure 3 shows the experimental results, CCC and PCC change significantly and show a downward trend with increasing hop size, and the change in RMSE is not obvious. We observe that with the increase of the hop size, the emotion prediction effect decreased significantly, demonstrating that the shorter hop size performs better. During listening to music, the user’s emotion at a certain moment is an accumulation of previous music content. Therefore, providing the model with as much con-

text as possible benefits emotion recognition. A shorter hop size can provide more context for the model to predict the current musical mood. In the experiments on the MER1101 dataset below, we adopt hop sizes of 2.5s and 0.5s for arousal and valence, respectively.

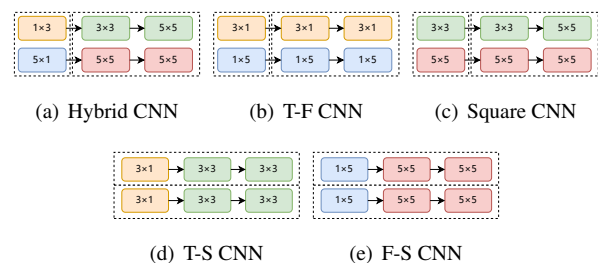

Figure 4. Five CNN architectures.

Model	Arousal			Valence		
	CCC \uparrow	PCC* \uparrow	RMSE* \downarrow	CCC \uparrow	PCC \uparrow	RMSE \downarrow
Hybrid CNN	0.4223	0.6856	0.1494	0.1115	0.2004	0.2595
T-F CNN	0.4120	0.6787	0.1478	0.0846	0.1363	0.2684
Square CNN	0.4130	0.6894	0.1439	0.0732	0.1343	0.2703
T-S CNN	0.4090	0.6881	0.1458	0.1085	0.1959	0.2542
F-S CNN	0.4150	0.6804	0.1562	0.1046	0.1640	0.2800

* The result of the significance test (Student’s t test) show that there is no significant difference between the results of this metric.

Table 1. Experimental results of different CNN architectures on the MER1101 dataset.

4.4.2 Impact of CNN filters

In this section, we compare the influence of different CNN architectures on the experimental results of the MER1101 dataset. In this paper, we adapt three types of convolution: temporal filters (l -by- n), frequency filters (m -by- l), and squared filters (m -by- n). Convolution filters of different shapes have different musical concepts. We combined them into five architectures. In Figure 4(a), the CNN architecture used here is a “Hybrid CNN” architecture. Figure 4(b) uses the temporal filters and frequency filters, and we call it the “T-F CNN” architecture. Figure 4(c) only uses a square filter, so we call it “Square CNN” architecture. Figure 4(d) and Figure 4(e) are referred to as “T-S CNN” and “F-S CNN”, respectively. The experimental results are shown in Table 1, which show that the “Hybrid CNN” architecture has better expressiveness on the DMER

Model	MER1101 dataset						DEAM2015 dataset					
	Arousal			Valence			Arousal			Valence		
	CCC ↑	PCC ↑	RMSE ↓	CCC ↑	PCC ↑	RMSE ↓	CCC ↑	PCC ↑	RMSE ↓	CCC ↑	PCC ↑	RMSE ↓
CRNN [16]	0.2798	0.5177	0.1625	0.0573	0.1033	0.2721	0.3488	0.5885	0.2197	0.0053	-0.0292	0.3542
BCRSN [9]	0.1741	0.3770	0.3063	0.0660	-0.0647	0.4143	0.3168	0.5148	0.2397	0.0125	-0.0171	0.2914

Table 2. Compared with the existing results.

task. It is shown that extracting them simultaneously is beneficial to obtain music emotion information from different perspectives, and the PCC and RMSE changes of Arousal are not significant.

4.4.3 Comparison with the Existing Models

We compare the DAMFF to other DMER methods [9, 16–18] published in recent years. They differ from us in that [18] takes DEAM2014 [39] as the dataset, which consists of 744 songs. [16–18] take RMSE as the evaluation metrics, and [9] translates numerical-type V-A values to binary representation and independently predict emotion for each 0.5s.

In this paper, we reproduce the models mentioned above on the DEAM2015 and MER1101 datasets. All models’ performance is evaluated with the same experimental configurations, i.e., the same dataset, evaluation metrics, and metric calculation method. Table 2 shows the results of the experiments. On the MER1101 dataset, our model is superior to the others in all three metrics. On the DEAM2015 dataset, our model shows powerful recognition ability for arousal, but the valence slightly outperforms the previous models, which may stem from the less consistent valence annotations [15]. We believe predicted valence values on the DEAM2015 dataset are relatively incapable of evaluating DMER since the predicted CCC value number in valence driven from all models is near zero. Experiments show that our model can perform well in emotion recognition on different datasets, especially in the arousal dimension. Overall, valence values are more impoverished in both datasets than arousal values, indicating that predicting valence is more challenging. This is also consistent with the conclusions of most works.

Model	Arousal			Valence		
	CCC ↑	PCC* ↑	RMSE* ↓	CCC ↑	PCC ↑	RMSE ↓
DAMFF	0.4223	0.6856	0.1494	0.1115	0.2004	0.2595
w/o Fusion Strategy	0.4097	0.6869	0.1563	0.1074	0.1722	0.2707
w/o Channel Attention	0.4061	0.6740	0.1494	0.1071	0.1904	0.2650
w/o Spatial Attention	0.4177	0.6819	0.1518	0.1009	0.1874	0.2720
w/o DAFF	0.3982	0.6813	0.1562	0.0977	0.1693	0.2670

* The result of the significance test (Student’s t test) show that there is no significant difference between the results of this metric.

Table 3. Ablation experiments of arousal and valence on the MER1101 dataset.

4.4.4 Ablation Study

To investigate the role of various modules, we constructed four ablation modules. Among them, “w/o Fusion Strategy” directly inputs the result of the SCAM module into BiLSTM, which explores the role of fusion strategy. In addition, the influence of dual attention is studied using “w/o Channel Attention”, “w/o Spatial Attention”, and “w/o DAFF”. Table 3 shows the experimental results on the MER1011 datasets. The results show that: 1) the non-linear fusion strategy of the attention mechanism better aggregates the multi-scale context and performs better; 2) the attention mechanism increases the weights of emotional features, which is helpful for emotion recognition. At the same time, dual attention is better than single attention, indicating that spatial and channel attention mechanisms learn and emphasize *what* and *where* affect-salient features, effectively improving CNN features. In summary, we conclude that fusing multi-scale convolutional features from spatial and channel dimensions is more conducive to capturing key emotional features, which is more evident on the CCC metric.

5. CONCLUSION

This paper proposes a novel Dual Attention-based Multi-scale Feature Fusion (DAMFF) network, which extracts multi-scale convolutional features from spectrograms and exploits the dual-attention mechanism to capture important channel and spatial information. The network adopts the fusion mechanism that aggregates multi-scale context information, effectively improving CNN features’ expressive ability. The music emotion dataset MER1101 we developed contains 1101 music audio with 16 genres, 5 languages and a balanced distribution of emotion labels. Experimental results show that our model outperforms the comparison methods on the CCC metric on both MER1101 and DEAM2015 datasets. Furthermore, our model has substantial prediction capabilities in terms of arousal and comparable results in terms of valence.

The prediction of the valence dimension is still challenging in DMER. In the future, we will focus on developing more effective techniques, such as pre-training audio features for improving the recognition performance of valence.

ABSTRACT

Taking long-term spectral and temporal dependencies into account is essential for automatic piano transcription. This is especially helpful when determining the precise onset and offset for each note in the polyphonic piano content. In this case, we may rely on the capability of self-attention mechanism in Transformers to capture these long-term dependencies in the frequency and time axes. In this work, we propose *hFT-Transformer*, which is an automatic music transcription method that uses a two-level hierarchical frequency-time Transformer architecture. The first hierarchy includes a convolutional block in the time axis, a Transformer encoder in the frequency axis, and a Transformer decoder that converts the dimension in the frequency axis. The output is then fed into the second hierarchy which consists of another Transformer encoder in the time axis. We evaluated our method with the widely used MAPS and MAESTRO v3.0.0 datasets, and it demonstrated state-of-the-art performance on all the F1-scores of the metrics among *Frame*, *Note*, *Note with Offset*, and *Note with Offset and Velocity* estimations.

1. INTRODUCTION

Automatic music transcription (AMT) is to convert music signals into symbolic representations such as piano rolls, Musical Instrument Digital Interface (MIDI), and musical scores [1]. AMT is important for music information retrieval (MIR), its result is useful for symbolic music composition, chord progression recognition, score alignment, etc. Following the conventional methods [1–15], we estimate the frame-level metric and note-level metrics as follows: (1) *Frame*: the activation of quantized pitches in each time-processing frame, (2) *Note*: the onset time of each note, (3) *Note with Offset*: the onset and offset time of each note, and (4) *Note with Offset and Velocity*: the onset, offset time, and the loudness of each note.

For automatic piano transcription, it is important to analyze several harmonic structures that spread in a wide range of frequencies, since piano excerpts are usually polyphonic. Convolutional neural network (CNN)-based methods have been used to aggregate harmonic structures as acoustic features. Most conventional methods apply multi-layer convolutional blocks to extend the receptive field in the frequency axis. However, the blocks often include pooling or striding to downsample the features in the frequency axis. Such a downsampling process may reduce the frequency resolution [6]. It is worth mentioning, many of these methods use 2-D convolutions, which means the convolution is simultaneously applied in the frequency and time axes. The convolution in the time axis works as a pre-emphasis filter to model the temporal changes of the input signals.

Up to now, recurrent neural networks (RNNs), such as gated recurrent unit (GRU) [16] and long short-term memory (LSTM) [17], are popular for analyzing the temporal sequences of acoustic features. However, recently some of the works start to use Transformer [18], which is a powerful tool for analyzing sequences, in AMT tasks. Ou et al. [2] applied a Transformer encoder along the time axis and suggested that using Transformer improves velocity estimation. Hawthorne et al. [3] used a Transformer encoder-decoder as a sequence-to-sequence model for estimating a sequence of note events from another sequence of input audio spectrograms. Their method outperformed other methods using GRUs or LSTMs. Lu et al. [19] proposed a method called SpecTNT to apply Transformer encoders in both frequency and time axes and reached state-of-the-art performance for various MIR tasks such as music tagging, vocal melody extraction, and chord recognition. This suggests that such a combination of encoders helps in characterizing the broad-scale dependency in the frequency and time axes. However, SpecTNT aggregates spectral features into one token, and the process in its temporal Transformer encoder is not independent in the frequency axis. This inspires us to incorporate Transformer encoders in the frequency and time axes and make the spectral information available for the temporal Transformer encoder.

In addition, we usually divide the input signal into chunks since the entire sequence is often too long to be

Figure 1. hFT-Transformer (N: number of frames in each processing chunk, M: length of margin, F: number of frequency bins, P: number of pitches)

dealt at once. However, this raises a problem that the estimated onset and offset accuracy fluctuates depending on the relative position in the processing chunk. In our observation, the accuracy tends to be worse at both ends of the processing chunk. This motivates us to incorporate extra techniques during the inference time to boost the performance.

In summary, we propose *hFT-Transformer*, an automatic piano transcription method that uses a two-level hierarchical frequency-time Transformer architecture. Its workflow is shown in Figure 1. The first hierarchy consists of a one-dimensional (1-D) convolutional block in the time axis, a Transformer encoder in the frequency axis, and a Transformer decoder in the frequency axis. The second hierarchy consists of another Transformer encoder in the time axis. In particular, the Transformer decoder at the end of the first hierarchy converts the dimension in the frequency axis from the number of frequency bins to the number of pitches (88 for piano). Regarding the issue of the location dependent accuracy fluctuation in the processing chunks, we propose a technique which halves the stride length at inference time. It uses only the result of the central part of processing chunks, which will improve overall accuracy. Finally, in Section 4, we show that our method outperforms other piano transcription methods in terms of F1 scores for all the four metrics.

A `PyTorch` implementation of our method is available here ¹.

2. RELATED WORK

Neural networks, such as CNNs, RNNs, generative adversarial networks (GANs) [20], and Transformers have been dominant for AMT. Since Sigtia et al. [4] proposed the first method to use a CNN to tackle AMT, CNNs have been widely used for the methods of analyzing the spectral dependency of the input spectrogram [2, 6–10, 12–15]. However, it is difficult for CNNs to directly capture the harmonic structure of the input sound in a wide range of frequencies, as convolutions are used to capture features in a local area. Wei et al. [5] proposed a method of using harmonic constant-Q transform (CQT) for capturing the harmonic structure of piano sounds. They first applied a 3-Dimensional CQT, then applied multiple dilated convolutions with different dilation rates to the output of

CQT. Because the dilation rates are designed to capture the harmonics, the performance of *Frame* and *Note* accuracy reached state-of-the-art. However, the dilation rates are designed specifically for piano. Thus, the method is not easy to adapt to other instruments.

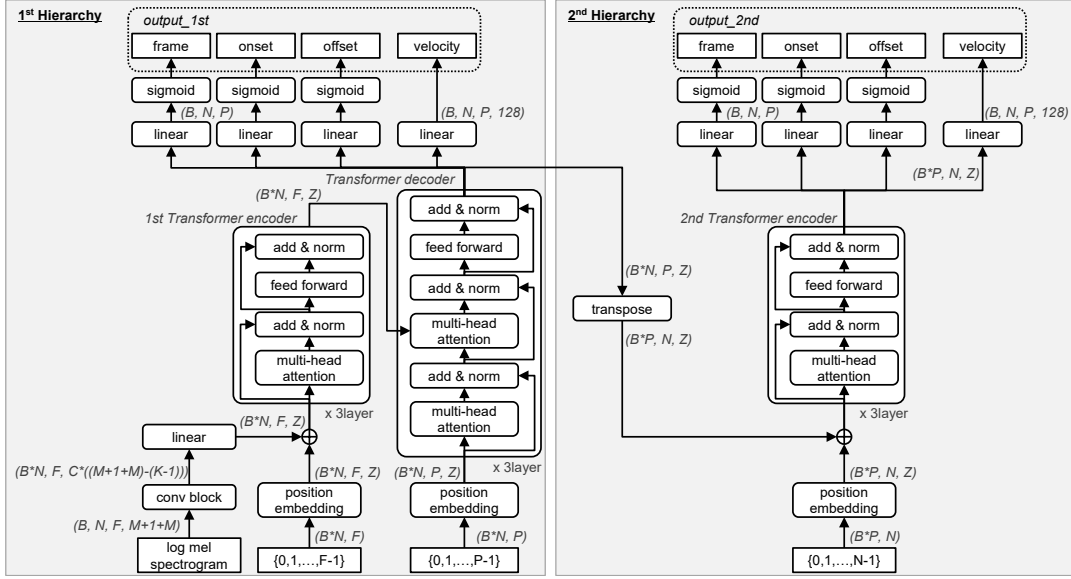

For analysis of time dependency, Kong et al. [6] proposed a method that uses GRUs. Howthorner et al. [7], Kwon et al. [8], Cheuk et al. [9], and Wei et al. [5] proposed methods that use bi-directional LSTMs for analysis. Ou et al. [2] used a Transformer encoder to replace the GRUs in Kong et al.’s method [6], and showed the effectiveness of the Transformer. Usually, the note onset and offset are estimated in each frequency and time-processing frame grid, then paired as a note for note-level transcription by post-processing algorithms such as [6]. However, compared to heuristically designed algorithms, end-to-end data-driven methods are often preferred. For example, Keltz et al. [10] applied a seven-state hidden Markov model (HMM) for the sequence of attack, decay, sustain, and release to achieve note-level transcription. Kwon et al. [8] proposed a method of characterizing the output of LSTM as a five-state statement (onset, offset, re-onset, activate, and inactivate). Hawthorne et al. [3] proposed a method of estimating a sequence of note events, such as note pitch, velocity, and time, from another sequence of input audio spectrograms using a Transformer encoder-decoder. This method performs well in multiple instruments with the same model [11]. Yan et al. [12] proposed a note-wise transcription method for estimating the interval between onset and offset. This method shows state-of-the-art performance in estimating *Note with Offset* and *Note with Offset and Velocity*. However, the performance in estimating *Frame* and *Note* is worse than that of Wei et al.’s method [5].

3. METHOD

3.1 Configuration

Our proposed method aims to transcribe N frames of the input spectrogram into N frames of the output piano rolls (*frame*, *onset*, *offset*, and *velocity*) as shown in Figure 1, where N is the number of frames in each processing chunk. Each input frame is composed of a log-mel spectrogram having size $(F, M + 1 + M)$, where F is the number of frequency bins, and M is the size of the forward margin and that of the backward margin. To obtain

¹ <https://github.com/sony/hFT-Transformer>

Figure 2. Model architecture of hFT-Transformer

the log-mel spectrogram, we first downmix the input waveform into one channel and resample them to 16 kHz. Then, the resampled waveform is transformed into a mel spectrogram with `transforms.MelSpectrogram` class in the `TorchAudio` library [21]. For the transformation, we use *hann* window, setting the window size as 2048, fast-Fourier-transform size as 2048, F as 256, padding mode as *constant*, and hop-size as 16 ms. The magnitude of the mel spectrogram is then compressed with a log function.

3.2 Model Architecture and Loss Functions

The model architecture of our proposed method is shown in Figure 2. We first apply a convolutional block to the input log-mel spectrogram, the size of which is $(B, N, F, M+1+M)$ where B is the batch size. In the convolutional block, we apply a 1-D convolution in the $M+1+M$ dimension. After this process, the data are embedded with a linear module.

The embedded vector is then processed with the first Transformer encoder in the frequency axis. The self-attention is processed to analyze the dependency between spectral features. The positional information is designated as $[0, 1, \dots, F-1]$. These positional values are then embedded with a trainable embedding. These are processed in the frequency axis only, thus completely independent to the time axis (N dimension).

Next, we convert the frequency dimension from F to the number of pitches (P). A Transformer decoder with cross-attention is used as the converter. The Transformer decoder calculates the cross-attention between the output vectors of the first Transformer encoder and another trainable positional embedding made from $[0, 1, \dots, P-1]$. The decoded vectors are then converted to the outputs of the first hierarchy with a linear module and a sigmoid function (hereafter, we call these outputs *output_1st*).

Regarding the loss calculation for the outputs, *frame*, *onset*, and *offset* are calculated with binary cross-entropy,

and *velocity* is calculated with 128-category cross-entropy. The losses can be summarized as the following equations:

$$L_{\text{bce}}^{<m>} = \sum_{n=0}^{N-1} \sum_{p=0}^{P-1} l_{\text{bce}}(y_{n,p}^{<m>}, \hat{y}_{n,p}^{<m>}), \quad (1)$$

$$L_{\text{cce}}^{\text{velocity}} = \sum_{n=0}^{N-1} \sum_{p=0}^{P-1} l_{\text{cce}}(y_{n,p}^{\text{velocity}}, \hat{y}_{n,p}^{\text{velocity}}), \quad (2)$$

$$L = L_{\text{bce}}^{\text{frame}} + L_{\text{bce}}^{\text{onset}} + L_{\text{bce}}^{\text{offset}} + L_{\text{cce}}^{\text{velocity}}, \quad (3)$$

where $< m >$ is the placeholder for each output (*frame*, *onset*, and *offset*), l_{bce} and l_{cce} denote the loss function for binary cross-entropy and categorical cross-entropy, respectively, and y and \hat{y} denote the ground truth and predicted values of each output (*frame*, *onset*, *offset*, and *velocity*), respectively. Although it is intuitive to apply the mean squared error (MSE) for *velocity*, we found that using the categorical cross-entropy yields much better performance than the MSE from a preliminary experiment.

Finally, the output of the converter is processed with another Transformer encoder in the time axis. The self-attention is used to analyze the temporal dependency of features in each time-processing frame. A third positional embedding made from $[0, 1, \dots, N-1]$ is used here. Then, similar to the first hierarchy, the outputs of the second hierarchy are obtained through a linear module and a sigmoid function. We call these outputs of the second hierarchy as *output_2nd* hereafter. The losses for the *output_2nd* are evaluated in the same way as those for *output_1st*. These losses are summed with the coefficients $\alpha_{1\text{st}}$ and $\alpha_{2\text{nd}}$ as follows:

$$L_{\text{all}} = \alpha_{1\text{st}} L_{1\text{st}} + \alpha_{2\text{nd}} L_{2\text{nd}}. \quad (4)$$

Although both outputs are used for computing losses during training, only *output_2nd* is used in inference. As Chen et al. [22] suggested that the performance of their method of calculating multiple losses outperformed the method

Figure 3. Estimation error (Eqn (5)) on location in each time-processing frame

that uses single loss only, it hints us that utilizing both *output_1st* and *output_2nd* in training has the potential to achieve better performance.

3.3 Inference Stride

As mentioned in Section 1, chunk-based processing is required because the input length is limited due to system limitations, such as memory size and acceptable processing delay. We found that the estimation error tends to increase at certain part within each processing chunk. This can be demonstrated by evaluating the error for each instance of time n within the chunks:

$$error_n^{<m>} = \frac{1}{IP} \sum_{i=0}^{I-1} \sum_{p=0}^{P-1} (y_{i,n,p}^{<m>} - \hat{y}_{i,n,p}^{<m>})^2, \quad (5)$$

where $<m>$ is the placeholder for each output (*frame*, *onset*, *offset*, and *velocity*), and I is the number of processing chunks over the test set. The result using our proposed model trained using the MAESTRO training set (described in Section 4) is shown in Figure 3. Here, the error $error_n^{<m>}$ is calculated using the MAESTRO test set. In the figure, we observe a monotonic decrease for *frame* and a similar but much weaker trend for *onset* and *offset*. However, for *velocity*, no such trend can be observed. This hints us to use only the middle portion of a processing chunk as the output to reduce the error rate. We call this as the half-stride strategy, since a 50% overlap is required for processing chunks, as shown in Figure 4 (B).

4. EXPERIMENTS

4.1 Datasets

We use two well-known piano datasets for the evaluation. The MAPS dataset [23] consists of CD-quality recordings and corresponding annotations of isolated notes, chords, and complete piano pieces. We use the full musical pieces and the train/validation/test split as stated in [4, 7]. The number of recordings and the total duration in hours in each split are 139/71/60 and 8.3/4.4/5.5, respectively. The MAESTRO v3.0.0 dataset [13] includes about 200 hours of paired audio and MIDI recordings from ten years of the International Piano-e-Competition. We used the

Figure 4. Inference stride: (A) full stride, (B) half stride

train/validation/test split configuration as provided. In each split, the number of recordings and total duration in hours are 962/137/177 and 159.2/19.4/20.0, respectively. For both datasets, the MIDI data have been collected by Yamaha Disklaviers concert-quality acoustic grand pianos integrated with a high-precision MIDI capture and playback system.

4.2 Model Configuration

Regarding our model architecture depicted in Figure 2, we set N as 128, M as 32, F as 256, P as 88, the CNN channels (C) as 4, size of the CNN kernel (K) as 5, and embedding vector size (Z) as 256. For the Transformers, we set the feed-forward network vector size as 512, the number of heads as 4, and the number of layers as 3. For training, we used the following settings: a batch size of 8, learning rate of 0.0001 with Adam optimizer [24], dropout rate of 0.1, and clip norm of 1.0. ReduceLRonPlateau in PyTorch is used for learning rate scheduling with default parameters. We set α_{1st} and α_{2nd} as 1.0, which were derived from a preliminary experiment (see Section 4.6).

We trained our models for 50 epochs on MAPS dataset and 20 epochs for MAESTRO dataset using one NVIDIA A100 GPU. It took roughly 140 minutes and 43.5 hours to train one epoch with our model for MAPS and MAESTRO, respectively. The best model is determined by choosing the one with the highest F1 score in the validation stage.

In order to obtain high-resolution ground truth for *onset* and *offset*, we followed the method in Kong et al. [6]. We set J , the hyper-parameter to control the sharpness of the targets, to 3. Also, the label of *velocity* is set only when an *onset* is present. We set the threshold as 0.5, which means if the *onset* is smaller than 0.5, the *velocity* is set as 0.

4.3 Inference

At inference time, we use *output_2nd* as the final output. We set the threshold for *frame* as 0.5. For note-wise events (*onset*, *offset*, and *velocity*), the outputs in each pitch-frame grid are converted to a set containing note-wise onset, offset, and velocity following Kong et al.'s *Algorithm 1* [6] in five steps shown below:

Step 1. onset detection: find a local maximum in *onset* with a value at least 0.5. Then calculate the precise onset time using the values of the adjacent three frames [6].

Step 2. velocity: If an onset is detected in Step 1, extract the *velocity* value at the frame. If the value is zero, then

Table 2. Evaluation results on MAESTRO v3.0.0 test dataset

Figure 5. Example of conversion from grid-wise values to note-wise values

discard both onset and velocity at this frame.

Step 3. offset detection with *offset*: find a local maximum in *offset* with a value at least 0.5. Then calculate the precise offset time using the values of the adjacent three frames [6].

Step 4. offset detection with *frame*: choose the frame that is nearest to the detected onset which has a *frame* value below 0.5.

Step 5. offset decision: choose the smaller value between the results of Step 3 and 4.

An example is shown in Figure 5. The *onset* is 4.003, and the *velocity* is 61. For *offset*, the direct estimation from *offset* is 4.043, and that estimated via *frame* is 4.064. Thus, we choose 4.043 as *offset*. Finally, we obtain a note with {*onset*: 4.003, *offset*: 4.043, *velocity*: 61} in the output.

4.4 Metrics

We evaluate the performance of our proposed method with frame-level metrics (*Frame*) and note-level metrics (*Note*, *Note with Offset*, and *Note with Offset & Velocity*) with the standard precision, recall, and F1 scores. We calculated these scores using `mir_eval` library [25] with its default settings. The scores were calculated per recording, and the mean of these per-recording scores was presented as the final metric for a given collection of pieces, as explained

in Hawthorne et al. [7].

4.5 Results

Tables 1 and 2 show the scores on the test sets of MAPS and MAESTRO datasets. The numbers of parameters in these Tables are referred from [5, 10]. For the MAPS dataset, our proposed method outperformed the other methods in F1 score for all metrics. For the MAESTRO dataset, our proposed method outperformed the other methods in F1 score for *Note*, *Note with Offset*, and *Note with Offset & Velocity*. Furthermore, our method with the half-stride strategy which is mentioned in 3.3 outperformed other methods in all metrics. In contrast, the two state-of-the-art methods for MAESTRO, which are Semi-CRFs [12] and HPPNet-sp [5], performed well only on a subset of the metrics.

The results suggest that the proposed two-level hierarchical frequency-time Transformer structure is promising for AMT.

4.6 Ablation Study

To investigate the effectiveness of each module in our proposed method, we trained various combinations of those modules using the MAPS training set and evaluated them using the MAPS validation set. The variations are shown in Table 3. In this study, we call our proposed method *I-F-D-T*, which means it consists of the *I-D* convolution block, the first Transformer encoder in the *Frequency* axis, the Transformer Decoder, and the second Transformer encoder in the *Time* axis. Table 4 shows evaluation results for each variation.

Second Transformer encoder in time axis. To verify the effectiveness of the second Transformer encoder, we compared the *I-F-D-T* and the model without the second Transformer encoder (*I-F-D-N*). For the *I-F-D-N* model, we use `output_1st` in both training and inference stages as the final output. The result indicates that the second Transformer encoder improved *Note with Offset* performance, in

Model	1st-Hierarchy			2nd-Hierarchy		Output
	Convolutional block	1st Transformer encoder	Converter	2nd Transformer encoder		
1-F-D-T†	1-D (time axis)	Frequency axis	Transformer Decoder	Time axis	output_2nd	
1-F-D-N	1-D (time axis)	Frequency axis	Transformer Decoder	n/a	output_1st	
2-F-D-T	2-D	Frequency axis	Transformer Decoder	Time axis	output_2nd	
1-F-L-T	1-D (time axis)	Frequency axis	Linear	Time axis	output_2nd	

Table 3. Model variations for ablation study (†: the proposed method, hFT-Transformer)

Model	Params	Frame			Note			Note w/ Offset			Note w/ Offset&Velocity		
		P(%)	R(%)	F1(%)	P(%)	R(%)	F1(%)	P(%)	R(%)	F1(%)	P(%)	R(%)	F1(%)
1-F-D-T†	5.5M	93.61	88.71	91.09	98.81	94.81	96.72	86.18	82.81	84.42	77.47	74.55	75.95
1-F-D-N	3.9M	92.85	87.49	90.09	99.01	93.24	95.95	82.67	78.06	80.23	73.89	69.90	71.78
2-F-D-T	6.1M	75.49	61.08	67.52	97.03	19.68	31.10	64.07	13.28	20.88	42.11	8.57	13.50
1-F-L-T	3.4M	93.71	88.42	90.99	99.11	92.90	95.79	85.77	80.56	82.98	71.66	67.32	69.34

Table 4. Evaluation results of ablation study on MAPS validation dataset

which the F1 score is 84.42 for 1-F-D-T and 80.23 for 1-F-D-N. This shows the effectiveness of the second Transformer encoder as it provides an extra pass to model the temporal dependency of acoustic features, which is presumably helpful in offset estimation.

Complexity of convolutional block. To investigate how the complexity of the convolutional block affects the AMT performance, we compared the 1-F-D-T model and the model that replaces the 1-D convolutional block with a 2-D convolutional block (2-F-D-T). Surprisingly, the result shows that the performance of the 2-F-D-T model is significantly worse than that of the 1-F-D-T model. This is probably because the two modules working on the spectral dependency do not cohere with each other. The 2-D convolutional block may over aggregate the spectral information thus resulting into an effectively lower frequency resolution. Then, the Transformer encoder can only evaluate the spectral dependency over an over-simplified feature space, causing the performance degradation.

Converter. We used a Transformer decoder to convert the dimension in the frequency axis from F to P . In contrast, almost all of the existing methods used a linear module to achieve this. We compared the performance of the 1-F-D-T model to a model with the Transformer decoder replaced with a linear converter (1-F-L-T). The result indicates that the 1-F-D-T model outperformed the 1-F-L-T model in F1 score for all four metrics. Especially, the difference in *Note with Offset and Velocity* is large (75.95 for the 1-F-D-T model and 69.34 for the 1-F-L-T model in F1 score). This suggests that using a Transformer decoder as converter is an effective way of improving the performance, although the side effect is the increase of model size.

We also investigated how the coefficients for the loss functions, α_{1st} and α_{2nd} in Eqn (4), affect the performance. We investigated six pairs of coefficients of loss functions ($\alpha_{1st}, \alpha_{2nd}$) in Eqn (4), i.e., (1.8, 0.2), (1.4, 0.6), (1.0, 1.0), (0.6, 1.4), (0.2, 1.8), and (0.0, 2.0), for the 1-F-D-T model. Figure 6 shows the F1 scores of *frame*, *onset*, *offset*, and *velocity* evaluated on the MAPS validation set in each epoch. These results indicate that the (1.0, 1.0) pair

Figure 6. Performance of 1-F-D-T model trained with six-pairs of coefficients of loss functions

yields the best score. It also shows that the training converges faster when α_{1st} is larger than α_{2nd} . Importantly, if we omit the *output_1st*, which is the case when training with the pair (0.0, 2.0), the training loss did not decrease much. Therefore, the F1 score stays around 0% and thus cannot be seen in Figure 6. This suggests that it is crucial to use both losses, *output_1st* and *output_2nd* in our proposed method.

5. CONCLUSION

In this work, we proposed *hFT-Transformer*, an automatic piano transcription method that uses a two-level hierarchical frequency-time Transformer architecture. The first hierarchy consists of a 1-D convolutional block in the time axis, a Transformer encoder and a Transformer decoder in the frequency axis, and the second hierarchy consists of a Transformer encoder in the time axis. The experiment result based on two well-known piano datasets, MAPS and MAESTRO, revealed that our two-level hierarchical architecture works effectively and outperformed other state-of-the-art methods in F1 score for frame-level and note-level transcription metrics. For future work, we would like to extend our method to other instruments and multi-instrument settings.

6. ACKNOWLEDGMENTS

We would like to thank Giorgio Fabbro and Stefan Uhlich for their valuable comments while preparing this manuscript. We are grateful to Kin Wai Cheuk for his dedicated support in preparing our github repository.

ABSTRACT

A descriptive transcription of a violin performance requires detecting not only the notes but also the fine-grained pitch variations, such as vibrato. Most existing deep learning methods for music transcription do not capture these variations and often need frame-level annotations, which are scarce for the violin. In this paper, we propose a novel method for high-resolution violin transcription that can leverage piece-level weak labels for training. Our conformer-based model works on the raw audio waveform and transcribes violin notes and their corresponding pitch deviations with 5.8 ms frame resolution and 10-cent frequency resolution. We demonstrate that our method (1) outperforms generic systems in the proxy tasks of violin transcription and pitch estimation, and (2) can automatically generate new training labels by aligning its feature representations with unseen scores. We share our model along with 34 hours of score-aligned solo violin performance dataset, notably including the 24 Paganini Caprices.

1. INTRODUCTION

Automatic music transcription (AMT) is a core task in Music Information Retrieval that aims to convert a musical performance into some form of symbolic notation. While general-purpose AMT systems have recently seen substantial progress with deep learning [1–5], instrument-specific systems usually perform better, e.g., for piano [6–9], vocals [10, 11], guitar [12–14], and drums [15–17]. Despite the prominence of the violin in Western classical music and other traditions, a specialized high-precision violin transcription system that applies the recent advances in deep learning does not exist. In this paper, we aim to transcribe violin performances into a descriptive music notation [18]. As opposed to a prescriptive transcription, whose aim would be to produce an easily understandable score from which a musician can perform according to stylistic conventions of Western classical music writing, a descrip-

Figure 1: Our method transcribes violin recordings sampled with 44.1 kHz waveform into MIDI with a 5.8 ms time- and 10-cent frequency-resolution pitch bends.

tive transcription has an analytical purpose, aiming at notating high-precision pitch modulations along the notes.

Most typical AMT systems employ audio-to-MIDI transcription where each note event is represented with semitone resolution in the 12-tone equal temperament (12-TET). However, cognitive studies show that even the Western classical violinists heavily deviate from the 12-TET in favor of Pythagorean tuning and just intonation [19, 20]. Furthermore, the violin also plays a central role in many other traditions that do not employ the Western 12-TET [21]. Considering playing styles such as the vibrato and glissando that involve pitch modulations, a higher frequency resolution than the conventional 12-TET is required for violin transcription. An important step towards transcription outside the 12-TET was introduced by Bittner et al. [1] with an instrument-agnostic AMT system, which employs MIDI pitch bends to represent performances with 33-cent frequency resolution. However, adapting their approach to violin transcription remains to be a challenge since 33-cent frequency resolution is still too high compared to a violinist’s intonation precision [20].

A further main challenge in violin transcription is the lack of frame-level annotated training data. To cope with the absence of frame-level annotations, Weiß and

Peeters [22] employ sequence-level targets and a variant of the Connectionist Temporal Classification (CTC) loss for multipitch estimation. However, this strategy is sensitive to the segment duration (stable until segment lengths of 60 seconds) and, therefore, still requires some form of weak alignment. While some works explore data augmentation for frame-level supervised models through additional unlabeled [4] or pseudo-labeled [5] data, recent AMT methods are mostly trained using frame-level annotations [1, 3, 8, 9]. In some cases, obtaining such annotations is feasible through electronic music instruments, e.g., Disklavier. For example, the MAESTRO [23] dataset, with 200 hours of virtuoso piano performances and respective note labels captured with 3 ms frame resolution, enabled significant improvements for piano transcription.

In case electronic music instruments are unavailable, a common approach for obtaining automatic frame-level annotations is employing audio-to-score alignment (ASA), which found application in score following [24, 25]. ASA itself is not a technology developed for creating training datasets for AMT systems, and it has been reported that inaccurately aligned datasets may even worsen the result [2]. The intertwined nature of ASA and transcription can also be viewed from another aspect. For example, Kwon et al. [26] showed that frame and onset features of an AMT system work as robust feature representations for ASA. To our knowledge, the only deep-learning-based transcription system that integrates ASA into AMT is the recent work by Maman and Bermano [2], which utilizes ASA with chroma representations obtained from AMT frames.

As the main contribution of this paper, we propose a novel AMT system specifically tailored for descriptive violin transcription¹ regarding two crucial aspects: 1) We represent pitch deviations such as vibrato, glissando, or intonation choice by incorporating fine-grained pitch representations into the transcription. While borrowing our note postprocessing system and the MIDI pitch bend representations from Bittner et al. [1], we build a conformer-based model that works on the raw audio waveform and further improves the pitch bend estimation through note-constrained Viterbi pitch tracking. 2) We acquire frame-level annotations for violin transcription by considering simultaneous transcription and alignment in a joint framework, similar to the work by Maman and Bermano [2]. Following the findings from the music synchronization literature, we also incorporate activation-function-based features in the alignment [27, 28].

In order to benchmark our descriptive violin transcription method, we consider the proxy tasks of transcription and pitch estimation and compare our model with general-purpose baselines. As a side contribution, we also release a 34-hour dataset of solo violin recordings, with automatically aligned MIDI and note-constrained multi-f0 tracks obtained using our descriptive violin transcription system.

The remainder of this paper is organized as follows: in Section 2, we introduce our Multi-Stream Conformer (MUSC) model for AMT that processes an audio wave-

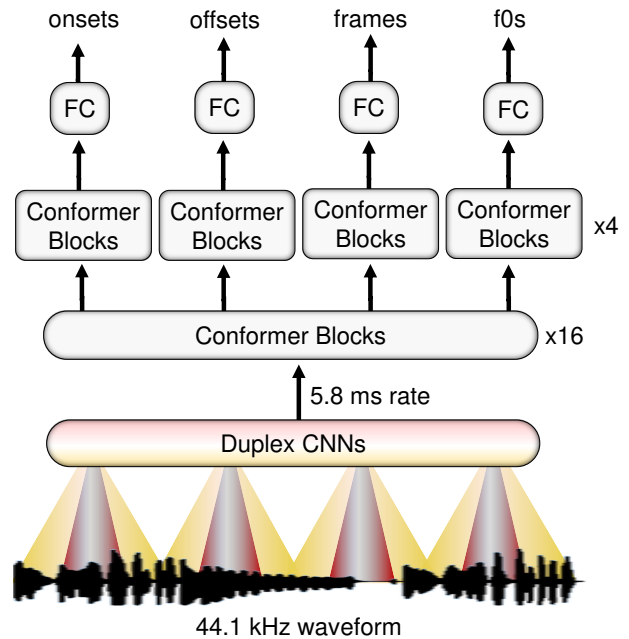

Figure 2: The Multi-Stream Conformer architecture converts raw audio sampled with 44.1 kHz into four feature representations with a frame rate of 5.8 ms.

form into four musical representations. In Section 3, we describe our strategy for learning without frame-level annotations. In Section 4, we introduce how we simultaneously annotate a novel violin transcription dataset while training our model. In Section 5, we compare our descriptive violin transcription model against general-purpose transcription and pitch estimation baselines. Finally, we conclude in Section 6 with prospects on future work.

2. MULTI-STREAM CONFORMER

We propose a Multi-Stream Conformer (MUSC) that processes the raw audio waveform into four streams that estimate onset, offset, semitone-level pitch frames (denoted as frames as in the AMT literature), and high-resolution f0 frames as shown in Figure 2. The raw audio waveform sampled with 44.1 kHz is converted into 256-dimensional features with a hop size of 5.8 ms through duplex CNNs. Then, these features pass through the Conformer blocks to estimate the four representations. The resulting representations can be either used for MIDI transcription with pitch bends as in Figure 1, or for frame-level dataset annotation for training (see Section 3).

2.1 Duplex CNNs

We borrow the basic CNN structure from the first two layers of the CREPE [29] pitch estimator, except for zero padding. We remove the zero padding in the convolutional layers so that the duplex CNNs can access to the information at the borders of the window with varying receptive fields. With the raw audio in 44.1 kHz as the input, the duplex CNNs independently summarize the waveform into 128-dimensional frames with a hop length of 5.8 ms.

¹<https://github.com/MTG/violin-transcription/>

Figure 3: A closer look at the Duplex CNNs.

The standard CNN (shown in red in Figure 3) analyzes the frame with the CREPE configuration, resulting in a receptive field of 26 ms. The dilated CNN (depicted in yellow within Figure 3) incorporates double the number of dilations and strides per layer, ultimately leading to a receptive field of 118 ms. Thanks to the dilations and strides, the sampling rate for the dilated CNN is subsequently reduced to 22.05 kHz, and 11 kHz. Thus, it effectively analyzes a smoother version of the signal. The 128-dimensional outputs of the individual CNNs are then stacked into a 256-dimensional representation and pass through a simple fully-connected layer before the main Conformer stream.

2.2 Conformer Blocks

Due to the direct analogy between music transcription and speech recognition, we adopt the Conformer [30], a state-of-the-art automatic speech recognition (ASR) model, as the base block of MUSC. We directly employ conformer blocks from the Conformer encoder (M version) as described by Gulati et al. [30], i.e., with four attention heads, a depthwise convolution size of 32, and an encoder dimension of 256. For the main stream, we repeat the conformer blocks 16 times as in Conformer (M). Then, we employ separate conformer blocks for each of the onset, offset, frame, and f0 streams with four conformer blocks per representation. The total number of conformer blocks we utilize in the multi-stream conformer architecture is 32.

2.3 Feature Representations

Our method is based on transforming weak labels into frame-level features that are used both as training targets and alignment features. The feature representations encompass the violin pitch range from $F\sharp 3$ to $E8$, i.e., 58 bins for the onsets, offsets, and note frames, which work on semitone resolution, and 580 bins for the f0s, which work on 10-cent resolution. More precisely, we use a fixed sequence duration of three seconds and convert the audio waveform into 512×58 dimensional onset, offset, and (note) frames, and 512×580 dimensional f0 frames.

Figure 4: Constraint region for the Viterbi pitch tracking.

We train the model to predict strong onset, offset, and frame labels that are generated from iterative score alignments. We employ Gaussian label smoothing for onset, offset, and f0 features. For the onsets and offsets, we smooth the feature representations with a standard deviation of 4 ms. Following Kim et al. [29], we also blur the f0 features with a 12-cent standard deviation.

Note that the high-precision f0 features are not included in the score, hence cannot be inferred from the alignment. For the f0 features, we train the model to predict pseudo-labels generated by the TAPE model [31] in the first iteration. Then, we use our model’s predictions as pseudo f0 labels. The polyphonic multipitch information are also encoded in the f0 representations. We employ constrained Viterbi pitch estimation (see Section 2.5) for generating pseudo-f0 labels for the polyphonic segments.

2.4 Note postprocessing

In the original Conformer paper [30], which is designed for ASR, the output of the encoder is proceeded by a decoder that uses an external language model to generate the word sequence. A natural adoption of this strategy to our scenario would require onsets, offsets, and frames to be fed into a language model that is specialized in the violin repertoire. However, employing a decoder is not viable since violin repertoire remains a low-resource language, and training decoders with such limited data is prone to overfitting. Instead, we experiment with postprocessing techniques from open-source AMT libraries and adopt the one² from Bittner et al. [1]. We leave improving the post-processing stage as an open question for further studies.

2.5 Constrained Viterbi Pitch Estimation

Previous studies have shown that score information [32] and the continuity principle of pitch perception [33] can be used for refining the f0 estimation. We apply continuity constraints within note sections to detect the pitch bends with higher accuracy. First, we define the constraint region on the f0 matrix from the note onset, offset, and 200 cents around the note frequency as shown in Figure 4. We calculate the Viterbi path within the note boundaries by utilizing the constraint region as observation probabilities and f0 transition probability matrix $\mathbf{S} \in \mathbb{R}^{21 \times 21}$ covering the

² https://github.com/spotify/basic-pitch/blob/main/basic_pitch/note_creation.py

Figure 5: The proposed high-resolution violin transcription model only requires piece-level labels for learning as it can generate frame-wise labels using its own onset, offset, and frame feature representations.

200 cents around the note frequency. For each consecutive time instant, \mathbf{S} allows smooth transitions with a Gaussian standard deviation of 25 cents, i.e., $2.5 f_0$ states:

$$s_{ij} = \frac{\exp\left(-\frac{1}{2} \left(\frac{j-i}{(25/10)}\right)^2\right)}{(25/10)\sqrt{2\pi}},$$

for $i, j \in [1 : 21]$, where s_{ij} denotes the state transition probabilities in the 10-cent resolution f_0 matrix.

Since Viterbi algorithm has a complexity of $O(n^2)$, applying the pitch tracking within the constrained region also improves the runtime speed compared to Viterbi without note constraints. Moreover, applying Viterbi within note constraints allow detecting multiple f_0 s.

After per-note Viterbi paths are calculated, the frame-wise pitch predictions are obtained through the regional weighted averaging method from Kim et al. [29] to deter the f_0 estimates through further interpolations.

3. LEARNING FROM WEAK LABELS

Our proposed method enables learning from weak labels, which involve pairs of violin recordings and their publicly-available scores. The learning procedure consists of four phases. First, we create initial audio-score alignments using music synchronization techniques. Second, we use the aligned audio-score pair for the first round of training. Third, we recompute the alignment using the estimated features. Fourth and finally, we finetune our model using the finer features learned by the model.

To create the initial audio-score alignments, we use dynamic time warping (DTW), which is a well-known tech-

nique for music synchronization [34–36]. Conventional methods for music synchronization typically use DTW and chroma features as the input representation [32, 37], whereas the integration of additional activation functions, e.g., onsets, beats, downbeats, has proven to enhance the synchronization accuracy [27, 28]. Since we deal with violin transcription in this paper, we follow the alignment method in [28], which deals with a similar scenario, i.e., audio-to-audio synchronization of string quartets. Inspired by their combined synchronization approach, we first incorporate beat, downbeat, and onset activation functions alongside chroma features to generate the initial audio-score alignments. The inclusion of activation functions results in a grid-like structure in the DTW cost matrix, which guides the alignment through activation cues that point to note onsets or other musical events. At the same time, chroma features account for the harmonic and melodic information.

Following the setting in [28], we use a sample rate of 22.05 kHz and a feature rate of 50 Hz to create the alignments. As this feature rate (20 ms) is coarser than the model’s frame resolution (5.8 ms), we apply linear interpolation to create labels. Note that we cannot evaluate the synchronization accuracy of the training data since we do not have any annotations for these. Using these target labels obtained from the initial alignment, which can possibly be inaccurate, we train our model for one epoch in the first training phase.

Following the first training phase, we obtain the four learned representations, onset, offset, semitone-level frames, and high-resolution f_0 frames for each audio-score pair. To acquire finer and more accurate labels, we run a novel synchronization stage. We recompute the alignment with the refined features, estimated semitone-level frame representations, and the activation with the stacked onset and offset features (see Section 2.3). Note that the feature rate we use in the alignment is the same as the MUSC features (hop size of 5.8 ms). Using the labels obtained from synchronization, we finetune our model using early stopping.

Our iterative training strategy resembles the approach by Maman and Bermano [2]. Their approach starts with training the transcription model with synthetic data and then creating the initial alignments with the features estimated by this model and involves three training iterations: first on synthetic data and two more iterations to finetune the model on the target dataset. In contrast, we start from a robust ASA and complete the training process in two iterations.

4. DATASET AND TRAINING

In this section, we describe our dataset that we use for the training and our training procedure. The weakly-labeled dataset consists of 120 scores and 34 hours of solo violin performances. We also provide automatic score alignments and frame-level pitch bends that are generated by our joint data curation and training process.

	#s	#p	#r	dur
Paganini, Op. 1	24	10	235	13:00
Wohlfahrt, Op. 45	60	6	506	11:36
Kayser, Op. 20	36	8	280	09:48
Total	120	22	1021	34:24

Table 1: Dataset statistics. #s: number of scores, #p: number of distinct players, #r: number of recordings, dur: total recording duration in hh:mm.

4.1 Dataset Statistics

Our dataset comprises public scores of 96 etudes which are included in the Violin Etudes dataset [38], i.e., Wohlfahrt Op. 45, and Kayser Op. 20. We also extend these scores with additional 24 etudes/caprices by Paganini Op. 1. In contrast to the Violin Etudes dataset, which only includes monophonic recordings, the recordings in our dataset include a mix of monophonic and polyphonic etudes. We collect multiple versions of these etudes from YouTube and automatically match and align them using the method described in Section 3. For the Paganini Op. 1 score, we noticed that performers do not always follow the repeat signs. To ensure better alignments, we automatically expand each repetition pattern individually and select the one that best matches the recording based on the alignment distance. As the most extreme case, we found four different repetition patterns for the Paganini Op. 1 No. 23, which we label as Op01-23, Op01-23-a, Op01-23-b, and Op01-23-c in the dataset, respectively.

The dataset we provide includes original YouTube links, annotated start and end timestamps, and aligned MIDI files containing multi-pitch bends. These resources can be utilized to generate expressive performances featuring vibrato. Moreover, for each etude and caprice, we provide at least five performances, which can be utilized for audio-to-audio synchronization and comparative studies. Table 1 summarizes the dataset statistics.

4.2 Training Details

Using Adam optimizer and a learning rate of $1e-3$, we train the model to minimize the binary cross entropy (BCE) loss for the onset, offset, frame, and f_0 s:

$$\mathcal{L} = \mathcal{L}_{\text{onset}} + \mathcal{L}_{\text{offset}} + \mathcal{L}_{\text{frame}} + \frac{\mathcal{L}_{f_0}}{10}.$$

In addition to Gaussian label smoothing as described in Section 2.3, we weight positive onset and offsets with 9 to balance the sparse matrices. Furthermore, we also observe that weighting the \mathcal{L}_{f_0} by $1/10$ helps in increasing the stability of the training.

Since our dataset includes several versions per piece, we do not employ further data augmentations. We train the model using a batch size of 16 and a fixed sequence duration of three seconds (512 frames). We employ (80 – 20) train-validation splits and consider each sample with the etude no $\equiv 3 \pmod{5}$ for the validation set.

After training for one epoch on the dataset obtained with initial alignments and pseudo f_0 labels, we realign

the dataset with the model’s onset, offset, and frame features and apply constrained Viterbi tracking for the f_0 labels. Using the new labels estimated by the model, we train the model further, applying early stopping.

5. EXPERIMENTS

While we aim at the task of descriptive violin transcription with high-resolution pitch bends, there is no previous work on which we can directly compare with. Therefore, we compare our model with general-purpose baselines for the closely-related proxy tasks of transcription and pitch estimation. We provide our experimental results on the violin tracks of two manually-annotated and corrected datasets, i.e., URMP [39] and Bach10 [40].

5.1 Test Datasets

The URMP dataset [39] is a multimodal dataset that includes 44 performances in various chamber ensemble settings. The dataset was annotated with the help of the Tony melody transcription software [41], which utilizes the pYIN [33] algorithm for the initial f_0 estimates and applies a hidden Markov model for note quantization. The note onsets, offsets, and f_0 s are then manually corrected. For our evaluation, we use all the violin tracks from the URMP dataset. We note that one of our transcription baselines, the MT3 [3] model, was trained using this dataset. Since we employ our tests in the entirety of the violin tracks, the tests include the training samples of the MT3.

Our second test dataset, Bach10 [40], comprises 10 four-part chorales played by a violin, clarinet, tenor saxophone, and bassoon quartet. The ground-truth f_0 annotations in the dataset were estimated first using the YIN [42] algorithm and then corrected manually. The dataset also includes note annotations derived from the beat times that are manually-annotated by musicians. However, the manual correction for offset times is not included in the dataset. For our evaluation, we use all the violin tracks from the Bach10 dataset. We note that the Bach10 dataset was included in the training of one of our baselines in pitch estimation, i.e., CREPE [29].

5.2 Evaluation Metrics

As a proxy to descriptive violin transcription, we evaluate our method’s transcription and pitch estimation performance separately using the common `mir_eval` metrics, and compare with general-purpose baselines. For the transcription, we provide our results with Precision P, Recall R, F1-score F1, and F1-score without offset $F1_{\text{no}}$ using the default thresholds. Namely, for P, R, and F1, a note is considered correct its pitch is within 50 cents, the onset is within 50 ms and the offset is within 20% of the note’s duration. We also include an additional measure, $F1_{\text{no}}$, where a note is considered correct if the onset is within 50 ms without considering the offset. For the pitch estimation experiments, we used the Raw Pitch Accuracy (RPA) metric with two thresholds: the standard RPA50 metric, which considers the estimate accurate if it is within 50

	URMP				Bach10			
	P	R	F1	F1 _{no}	P	R	F1	F1 _{no}
MUSC	86.5	83.1	84.6	93.0	65.0	64.8	64.8	77.0
MT3	79.1	87.1	82.2	88.9	54.2	51.5	52.7	62.0
BP	58.8	67.9	62.8	83.3	33.6	43.2	37.6	57.5

Table 2: Violin transcription results (%) comparing MUSC with two general-purpose AMT methods. Tests are conducted on all violin stems from the datasets. Bach10 represents the fair evaluation in a dataset unseen to all models. URMP was involved in the training dataset of the MT3, whereas it is unseen to both BP and MUSC.

	URMP				Bach10			
	P	R	F1	F1 _{no}	P	R	F1	F1 _{no}
Iter1	84.6	82.5	83.6	92.9	63.1	63.5	63.2	75.3
Iter2	86.5	83.1	84.6	93.0	65.0	64.8	64.8	77.0

Table 3: Violin transcription results (%) before (Iter1) and after (Iter2) fine-tuning the proposed MUSC model with the iterative alignment.

cents, and the RPA10 metric, which has a more strict 10-cent threshold.

5.3 Results

We compare MUSC with two recent general-purpose AMT baselines: Our first baseline is the Basic Pitch [1] (*BP*), which is a lightweight model for instrument-agnostic AMT. The postprocessing method of BP is optimized for F1_{no}, and MUSC also shares the same postprocessing script with their default parameters. The second baseline we consider for transcription is the MT3 [3], which is a multi-instrument transcription model that predicts instrument labels alongside transcription. Since we only test on violin recordings, we combine their output without the instrument labels for fair evaluation.

Table 2 summarizes the results for the transcription experiments. At a first glance, the proposed violin-specific model MUSC outperforms MT3 and BP on both datasets, indicating that it is a more effective method for violin transcription. Even though the training set of MT3 included the test samples in the URMP dataset, MUSC yields the best F1-score value among the three AMT systems. Furthermore, the performance gap between MUSC and MT3 is greater for the Bach10, which was not included the training set of any method. The results indicate that the all the models yield rather poor scores on the Bach10 dataset when evaluated using the conventional P, R, and F1 metrics. Since the offsets in the Bach10 dataset are not manually-corrected, the F1_{no} scores can be viewed as a better indicator of the transcription performance for this dataset.

We also compare our model’s transcription performance before and after fine-tuning with alignments generated using its own feature representations. The Table 3 shows that some of the improvements in our model’s transcription performance can be attributed to the iterative training strategy.

For the pitch estimation experiments, we compare MUSC with four well-known pitch estimators: the pre-

	URMP		Bach10	
	RPA50	RPA10	RPA50	RPA10
MUSC	98.3	89.0	98.3	86.9
vMUSC	98.6	89.4	98.4	87.0
CREPE	96.4	87.2	98.6	88.1
vCREPE	97.3	88.4	98.6	88.1
YIN	95.3	88.4	97.1	81.7
pYIN	97.2	88.6	97.4	80.3
SWIPE	97.2	89.3	97.7	84.3

Table 4: Violin Raw Pitch Accuracy (RPA, %) results. Note that the training set of CREPE involved the Bach10 dataset. vMUSC and vCREPE contain an additional Viterbi decoding stage.

trained CREPE model [29] from its official repository³, pYIN [33], and YIN [42] from librosa⁴, and SWIPE [43] from the libf0 library⁵. We use the same F#3 (min) to E8 (max) frequency range for a fair evaluation.

Table 4 summarizes the pitch estimation results. First, all the pitch estimators achieve high accuracies on both datasets. For the URMP dataset which is unseen to all the models, vMUSC (MUSC with Viterbi decoding) outperforms the common state-of-the-art pitch estimators in terms of RPA50 and RPA10. For the Bach10 dataset, which is included in the training samples of the pre-trained CREPE model, the CREPE expectedly yields the best RPA values. Note that even though our model was not trained with these test samples from Bach10, MUSC remains to be competitive (e.g., 98.4% versus 98.6% RPA50 in Bach10).

6. CONCLUSION

In this paper, we introduced MUSC, an AMT system tailored for violin transcription through high-precision pitch bend estimation, and the capability of learning from piecewise weak labels. We showed that, by only utilizing 120 scores, we were able to obtain state-of-the-art transcription and pitch estimation results for the violin. We also shared our descriptive violin transcription dataset to the MIR community. In the future, we will focus on improving the note postprocessing and alignment stages of the MUSC in order to specialize better for the string repertoire, and use it as a large-scale dataset curation tool for strings music, ethnomusicology, and music education research. We believe that the descriptive music transcription capabilities of the MUSC will accelerate the research in music education, ethnomusicology, and expressive performance generation.

ABSTRACT

We propose Polyffusion, a diffusion model that generates polyphonic music scores by regarding music as image-like piano roll representations. The model is capable of controllable music generation with two paradigms: *internal* control and *external* control. Internal control refers to the process in which users pre-define a part of the music and then let the model infill the rest, similar to the task of masked music generation (or music inpainting). External control conditions the model with external yet related information, such as chord, texture, or other features, via the cross-attention mechanism. We show that by using internal and external controls, Polyffusion unifies a wide range of music creation tasks, including melody generation given accompaniment, accompaniment generation given melody, arbitrary music segment inpainting, and music arrangement given chords or textures. Experimental results show that our model significantly outperforms existing Transformer and sampling-based baselines, and using pre-trained disentangled representations as external conditions yields more effective controls.¹

1. INTRODUCTION

Diffusion models [1, 2], as a new class of generative models, have been successful in generating high-quality samples of image data and beyond. They achieve state-of-the-art sample quality on a number of image generation benchmarks [3, 4], and also show strong results for the generation of various media such as audio [5, 6], video [7–9], and text [10, 11].

Symbolic music generation, a task very different from audio generation, has highly discrete outputs and is often described in terms of constraint optimization problems [12, 13]. Despite the improvement of deep music genera-

Figure 1: The forward and reverse process of the proposed diffusion model trained on piano roll representations. The red dot at the front of each note denotes its onset; the green bar following it denotes its sustain. Notice that the image axes are swapped for proper visualization.

tive modeling [14, 15], symbolic music generation still suffers from the lack of controllability and consistency at different time scales [16]. In our study, we experiment with the idea of using diffusion models to approach controllable symbolic music generation.

Inspired by the high-quality and controllable image generation that diffusion models have achieved in computer vision, we devise an image-like piano roll format as the input, and used a UNet-based diffusion model to stepwise denoise a randomly sampled piano roll, as illustrated in Figure 1. We show in our experiments and demos that our design provides excellent generation results.

Besides unconditional generation, the model also accepts two categories of controls, namely internal control and external control:

- **Internal Control (Inpainting):** By masking out part of the given piano roll, we can specify the remaining area to be generated, thus implicitly conditioning the generation to fit in the masked part. We regard this strategy as a generalized music inpainting method.
- **External Control (Conditional Generation):** By adopting the cross-attention mechanism of Latent Diffusion [17], we can explicitly control the music generation on given external conditions such as chords and textures. They are first encoded into latent representations using pre-trained, disentangled variational autoencoders (VAEs), and then fed into the backbone UNet of the diffusion model to condition the denoising process. We show that the generated music complies with the given conditions well. We also add classifier-free guidance to control the variance of the generation.

These controls of diffusion models enable us to unify a wide spectrum of creative music tasks that previously require separate modeling and training. In this paper, we showcase the following scenarios:

- **Melody generation given accompaniment** by generation with the accompaniment part being masked out.
- **Accompaniment generation given melody** by generation with the melody part being masked out.
- **Arbitrary music segment inpainting** by generation with any time segments being masked out.
- **General music arrangement given chords or textures** by conditioning on external chord or texture signals.

2. RELATED WORK

We review three realms of related work: 1) music inpainting, which is related to our internal control method, 2) conditioned music generation with external signals, which is related to our external control method, and 3) recent progress on diffusion-based modeling in the music domain.

2.1 Music Inpainting

Music inpainting is a controlled music generation task that regulates the generation with pre-defined musical contexts. We see various studies on polyphonic music inpainting. For example, DeepBach [18] develops a context-aware recurrent neural network (RNN) capable of inpainting missing notes for chorales in the style of Bach. Coconet [19] uses blocked Gibbs sampling to repeatedly rewrite a masked music score. Chang et al. [20] achieve variable-length music score inpainting. Music SketchNet [21] and MusIAC [22] introduce various controls to the inpainting task under VAE-based and Transformer-based framework respectively. Comparatively, diffusion models naturally possess the inpainting ability via masked generation [23], and there is no need to train or fine-tune a task-specific model for inpainting.

Though the current inpainting tasks mostly apply masks over a continuous period of time, the inpainted area, in theory, can be any note in the score (any area of a piano roll). In this study, we show that our image-like representation enables both part-wise and time-wise inpainting. The former refers to inpainting melody or accompaniment part given the other part, while the latter refers to infilling notes falling in arbitrary time segments.

2.2 Music Generation Conditioned on External Signals

External control signals are also one of the mainstream methods to control the music generation process. Common scenarios include generating music given chords [18, 24–26], lyrics [27], and other relevant features such as note density and voicing numbers [28].

Our study focuses on polyphonic score generation controlled by external chords and textures. In particular, the

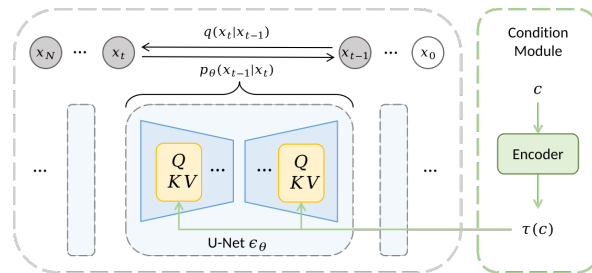

Figure 2: The model structure with an additional condition module for external control. Each UNet unit ϵ_θ applies one denoising step during the reverse process. External condition signals are encoded by pre-trained encoders and fed into the cross-attention layers, which are represented by the yellow squares in the UNet unit.

“control by texture” task has great practical value in both music arrangement and composition style transfer [29], while very few existing models could realize this function.

2.3 Diffusion Models for Music Generation

Recently, we have seen several attempts to introduce diffusion models to symbolic music tasks. Mittal et al. [30] generate monophonic music by training a diffusion model on the latent representations learned by MusicVAE [31]. Cheuk et al. [32] brings diffusion models to the music transcription task by adapting the piano roll format into the DiffWave [5] structure. It is relevant to our study as the model can also output piano rolls. However, the model focuses on transcription instead of generation by relying on a ground-truth spectrogram as its control. In general, for symbolic music generation, conditioning diffusion models on external controls is still an area to be explored.

3. METHODS

3.1 Data Representation

Our image-like piano roll representation is a 2-channel *binary* tensor $x \in \mathbb{R}^{2 \times T \times P}$. The generation task targets 8-bar (32-beat) long music segments, with 1/4 beat as the time step, resulting in $T = 128$ time steps per sample. We use a MIDI pitch range 0...127, resulting in $P = 128$ pitch bins. Each entry $x(c, t, p)$ represents whether there is a note onset (for $c = 0$) or sustain (for $c = 1$) at time step t and MIDI pitch p .

3.2 Diffusion Model

Diffusion models [1, 2] are latent-variable models comprised of a forward (diffusion) process which gradually disrupts the structure of data x_0 and a reverse (denoising) process that learns to recover the original data x_0 from the noisy input. In our study, x_0 denotes the clean piano roll. The forward process iteratively adds Gaussian noise in N diffusion steps:

$$q(x_t|x_{t-1}) = \mathcal{N}(x_t; \sqrt{1 - \beta_t}x_{t-1}, \beta_t I) \quad (1)$$

$$q(x_{1:N}|x_0) = \prod_{t=1}^N q(x_t|x_{t-1}) \quad (2)$$

where $\beta_1, \beta_2, \dots, \beta_N$ are a series of variance scheduling parameters. The reverse process requires the model to parameterize a Markov chain that iteratively reconstructs the piano roll x_0 from a corrupted input $x_N \sim \mathcal{N}(0, I)$.

$$p_\theta(x_{t-1}|x_t) = \mathcal{N}(x_{t-1}; \mu_\theta(x_t, t), \sigma_\theta(x_t, t)) \quad (3)$$

$$p_\theta(x_{0:N}) = p(x_N) \prod_{t=1}^N p_\theta(x_{t-1}|x_t) \quad (4)$$

During training, we optimize the model parameters ϵ_θ by minimizing the following target:

$$L(\theta) = \mathbb{E}_{x_0, \epsilon, t} \left[\left\| \epsilon - \epsilon_\theta(\sqrt{\alpha_t}x_0 + \sqrt{1 - \alpha_t}\epsilon, t) \right\|^2 \right] \quad (5)$$

where t is uniformly sampled from $[1, N]$ and $\epsilon \sim \mathcal{N}(0, I)$, $\alpha_t := 1 - \beta_t$, $\bar{\alpha}_t := \prod_{s=1}^t \alpha_s$. As shown in Figure 2, our unconditional model structure is based on [2], an image-oriented diffusion model using a 2-D UNet as its backbone ϵ_θ .

3.3 Internal Control (Inpainting)

Internal control refers to the use of the music notes themselves to regulate and influence the generation process, and we regard music inpainting as a means of internal control.

Specifically, we denote the given piano roll sample as s and the mask as m . At each step t during inference sampling, the fixed area of the image is diffused with the forward process $q(s_t|s) = \mathcal{N}(s_t; \sqrt{\alpha_t}s, (1 - \alpha_t)I)$ and put together with the denoising sample s_{t-1} . Algorithm 1 [23] shows the detailed implementation of this inpainting process.

Algorithm 1 Inpainting Process

Input: inpainting mask m , original sample s , $x_N \sim \mathcal{N}(0, I)$

- 1: **for** $t = N, \dots, 1$ **do**
 - 2: $\epsilon_1, \epsilon_2 \sim \mathcal{N}(0, I)$ if $t > 1$, else $\epsilon_1 = \epsilon_2 = 0$
 - 3: $y = \sqrt{\alpha_t}s + \sqrt{1 - \alpha_t}\epsilon_1$ if $t > 1$, else s
 - 4: $x_{t-1} = \mu_\theta(x_t, t) + \sigma_\theta(x_t, t)\epsilon_2$
 - 5: $x_{t-1} = x_{t-1} \odot (1 - m) + y \odot m$
 - 6: **end for**
 - 7: **return** x_0
-

3.4 External Control (Conditional Generation)

External control means using external signals to condition the generation process. We aim to incorporate a general strategy that does not place strong assumptions on the *format* of input control signals. To this end, we use the cross-attention mechanism [33] for conditional generation introduced by Latent Diffusion [17] since it is insensitive to the dimension of the condition signals. We also adopted the strategy used by Rombach et al. [17], which augments the backbone UNet structure with cross-attention layers that map condition signals into the UNet intermediate latent representations.

Formally, to preprocess the external musical signal c , we introduce a corresponding encoder τ that projects c to a latent representation $\tau(c)$. The encoder τ is pre-trained and fixed during diffusion model training. The cross-attention layers then map $\tau(c)$ to the intermediate layers of the UNet (as shown in Figure 2). The conditional training objective is

$$L_{\text{cond}}(\theta) := \mathbb{E}_{x_0, c, \epsilon, t} \left[\left\| \epsilon - \epsilon_\theta(\sqrt{\alpha_t}x_0 + \sqrt{1 - \alpha_t}\epsilon, t, \tau(c)) \right\|^2 \right] \quad (6)$$

We use classifier-free guidance (CFG) [34] to enable both conditioned and unconditioned generation by controlling the intensity of the condition signals during sampling. We refer readers to [34] and [35] for details on CFG.

4. CONTROLLABLE MUSIC GENERATION

In this section, we present four general musical applications our model empowers with internal and external controls: 1) melody generation given accompaniment, 2) accompaniment generation given melody, 3) arbitrary music segment inpainting, and 4) music arrangement given chords or textures. For each application, we provide non-cherry-picked generated samples as a case study. We also refer readers to our demo page for more examples.

4.1 Melody Generation Given Accompaniment

This task is achieved by internal control — to pre-define the accompaniment part and let the model infill the upper melody. Figure 3(a) shows an example of pop song melody generation given the accompaniment. We see that the melody is consistent with the underlying chords of the given accompaniment, and maintains an overall consistent rhythmic pattern, except for a 16th-note jump at the beginning of the 3rd bar.

4.2 Accompaniment Generation Given Melody

Similarly, given a lead melody, we can inpaint its corresponding lower accompaniment. Figure 3(b) shows an example, in which we see that the generated chord sequence suits the key (E minor) of the melody well, realized by a consistent arpeggio texture. The generated counter-melody also fills in the gaps between melody onsets well.

4.3 Arbitrary Music Segment Inpainting

The common scenario of music inpainting, also called music infilling [20], is to generate a music segment that fills in the gap between given past and future contexts. For our model, this task can be fulfilled by masking out the full pitch range of selected bars for inpainting.

Figure 3(c) shows an example of the inpainting process of the 3rd, 4th, 5th, and 7th bars, given the rest as fixed contexts. In the example, the model is capable of generating a full cadence connecting the 7th and the 8th bar, and also a nice applied chord in the non-diatonic progression Gm-Adim-B♭m connecting the 5th and the 6th bar.

We also extend the problem setup and let the diffusion model generate *long-term* music by iteratively inpainting

Figure 3: Generated samples in various tasks of controllable music generation. The generated parts are marked in blue. These examples have corresponding hearable demos on the demo page.

the future given the past. Figure 3(d) shows an example of a 24-bar generation based on a 4-bar prompt. The model generates 4 bars during each inference and finishes the process with five iterations. We see that the generated music contains a smooth chord progress, with a key modulation towards the end. The long-term textural structure is coherent, however lacking a consistent music theme.

4.4 Music Arrangement Given Chords or Textures

Inspired by the *chord-texture* disentanglement work [13, 29], we choose these two factors as the external condition signals for polyphonic generation. In our context, chords refer to the harmonic information, and textures refer to the rhythmic information. The latent chords and textures are encoded using pre-trained VAEs and cross-attended with the backbone UNet.

Beat-wise chords are first extracted by rule-based meth-

ods [36, 37], in which we adopted a 36-D chord representation consisting of a 12-D one-hot root encoding, a 12-D one-hot bass encoding and 12-D multi-hot chroma encoding. We then use a chord VAE [13] to extract a 512-D representation for each 8-bar chord sequence. For texture conditioning, we encode each 2-bar segment with the pre-trained texture encoder in [13] and then concatenate four encoded 256-D representations into a 1024-D vector as an 8-bar texture representation.

Figure 3(e) demonstrates an example of polyphonic music generation conditioned on chords. In the example, the accompaniment and the melody are mostly chord notes, with a certain degree of non-chord passing and neighboring tones that increase the interestingness of the song.

To show the complex combinations of conditions that the model can handle, we showcase a “texture-specified melody generation” for a given accompaniment segment as an example of the combination of internal and external

controls. As shown in Figure 3(f), We generate the melody part of a given accompaniment segment conditioned on the encoded texture representations of a given melody line. The result preserves a similar rhythmic pattern and fits the tonality of the new accompaniment.

5. EXPERIMENTS

5.1 Dataset and Training

We train our model using the POP909 dataset [38], a pop song dataset containing around 1K MIDI files. We only keep the pieces with 2/4 and 4/4 meters and cut them into 8-bar music segments with 1-bar hopping size, which results in 64K samples in total. The dataset is randomly split into the training set (90%) and validation set (10%) on a song level. The training samples are randomly transposed to all 12 keys for data augmentation.

The classifier-free guidance technique stated in Section 3.4 combines unconditional and conditional training. We adopt the implementation of DDPM and cross-attention layers in [39]. With 1K total diffusion steps, the model converges around 50 epochs (200K steps) on Adam Optimizer [40] with a constant learning rate $5e-5$.

To turn the generated 2-channel piano roll representations into MIDI files, we round them to $\{0, 1\}$ and neglect notes without an onset. In practice, the generation process of 160 8-bar samples report zero invalid notes.

5.2 Evaluation

To validate the generation quality and control effectiveness of our model, we conducted both objective and subjective evaluations on 5 tasks: (1) unconditional generation, (2) accompaniment generation, (3) segment inpainting, (4) chord-conditioned generation, and (5) texture-conditioned generation. Tasks 2-3 focus on the evaluation of internal controls, and tasks 4-5 focus on external controls. Table 1 summarizes the evaluation method for each task.

5.2.1 Evaluation Metrics

Objective metrics: To objectively measure the music quality for all 5 tasks, we use the averaging overlapped area of pitch distribution (\mathcal{D}_P) and duration distribution (\mathcal{D}_D) from [41], which measure the distribution similarity of pitch and duration between the generated samples and ground truth. Additionally, we introduce *chord distance* (CD) [41] and *onset distance* (OD) to evaluate the efficacy of external control. These metrics measure the ℓ_2 distance of chord (for task 4) and onset distribution (for task 5) between the generated samples and the chord/texture condition.

Subjective metrics: Subjective metrics include *creativity* (C), *naturalness* (N), and *musicality* (M), which provide a perceptive evaluation complementing the objective musical quality metrics. To demonstrate the efficacy of internal control, we pick accompaniment generation as an example and add a *fitness* (F) metric to evaluate how well the generated parts fit in with the given melody.

5.2.2 Baseline models

We use two types of models as our baselines:

Transformer models: As suggested in the polyphonic representation disentanglement study [13], applying a Transformer on disentangled latent codes yields better results than raw token predictions. Following [13], we train a Transformer to predict the chord and texture representations from melody representations. For unconditional generation (task 1), we sample the latent spaces of the first 2-bar melody and then predict its accompaniment and the following content. For accompaniment generation (task 2) and external conditioning (tasks 4-5), the melody (task 2), chord (task 4), or texture (task 5) latent representation is directly encoded as the condition for the Transformer. We adopt the XLNet-based model proposed in [20] for the music segment inpainting task (task 3).

Sampling-based models: We adopt the VAE-based disentanglement model in [13] and generate music segments by sampling the latent spaces. For unconditional generation (task 1), we sample from the chord and texture latent spaces of the first and the last 2 bars, then linearly interpolate the middle latent codes to form a coherent 8-bar segment. For inpainting (task 3), we also use linear interpolation on latent codes to infill the missing bars. For external conditioning (tasks 4-5), the chord (task 4) or texture (task 5) latent component is directly encoded from the given condition.

5.3 Comparative Results

We calculate the average of each objective metric on 160 generated samples for each task. As shown in Table 2, Polyffusion and its variations achieve the highest objective scores in tasks 1-4. For controllability, our model yields competitive results on segment inpainting and chord-conditioned generation. For the texture-conditioned generation task, our model does not perform as well as the baseline but is capable of preserving the general musical texture, since the baseline model is explicitly trained on texture reconstruction targets, while the texture condition of our model only serves as a hint for the generation.

We also show the effectiveness of classifier-free guidance in Table 2. With a guidance scale of 5, the model (Polyffusion-S5) shows improved controllability on both chord conditioning and texture conditioning. Notably, a large guidance scale for chord conditions negatively impacts the \mathcal{D}_D metric. We speculate that this is because notes regular in length provide clearer chord context, which can be noticed in the guidance demos.

For subjective evaluation, we invite participants to rate the generation quality via a double-blind online survey. Our survey consists of 4 groups of samples of unconditional generation and accompaniment generation, respectively. Each group contains a ground-truth piece, generated samples by Polyffusion and all baselines with random orders. 36 participants completed our survey. Each participant rated 4 random groups on average based on a 5-point scale. The evaluation results are shown in Figure 4 and 5. The height of each bar represents the mean rating,

Sampling	0.86	0.90	N/A	N/A	0.89	0.91	0.86	0.90	0.70	0.91	0.93	0.20

Table 2: The objective evaluation and ablation study results. The statistics of generation, accompaniment generation and segment inpainting are identical for three Polyffusion models (hence gray-out for the latter two models) since they share the same internal control method.

Figure 4: Subjective evaluation for unconditional generation.

Figure 5: Subjective evaluation for accompaniment generation.

and the error bars are MSEs computed by within-subject ANOVA [42]. We report a significantly better performance (p-value < 0.05) of Polyffusion than baseline models in *naturalness* and *musicality* for both tasks and in *fitness* for accompaniment generation. Interestingly, Polyffusion even outperforms the ground truth on the *creativity* metric.

5.4 Ablation Study

We perform an ablation test on the use of VAE encoders for condition signals. For both chord conditioning and texture conditioning, we remove the corresponding pre-trained encoders. The ablated model of chord conditioning uses concatenated 36-D chord vectors as the condition signals. The ablated model of texture conditioning uses a modified piano roll representation [13]. Both models are trained with the same settings as the proposed model. Table 2 shows that the ablated models (Polyffusion-A) perform worse than the proposed models on the controllability metrics (CD & OD), showing the advantage of using disentangled latent representations as condition signals for diffusion models.

6. CONCLUSION AND FUTURE WORK

In this paper, we propose a diffusion model for polyphonic symbolic music generation. We show that an image-like piano roll representation is effective for modeling the musical context for a high-quality score generation. We specify two methods for controllable generation: internal control via masked generation, and external control via conditioning using cross-attention. Experiments show that our method achieves higher quality and controllability compared to the Transformer and sampling-based baselines on both internal and external control tasks.

We regard the diffusion framework as a prospective direction for future work on controllable music generation, since it achieves fine-grained controls over high-quality generation and enables a wide spectrum of arrangement applications. Currently, our generation is limited to quantized music scores without performance features. We plan to extend this methodology to expressive performance modeling. Several new controls can also be introduced to facilitate human-AI co-creation of symbolic music, e.g., hierarchical structure controls (e.g., music segment labels) and multimodal controls (e.g., text descriptions).

ABSTRACT

This paper introduces a new corpus, CoCoPops: The Coordinated Corpus of Popular Musics. The corpus can be considered a “meta corpus” in that it both extends and combines two existing corpora—the widely-used McGill Billboard corpus and the RS200 corpus. Both the McGill Billboard corpus and the RS200 contain expert harmonic annotations using different encoding schemes and each represent harmony in fundamentally different ways: Billboard using a root-quality representation and the RS200 using Roman numerals. By combining these corpora into a unified format, using the well-known `**kern` and `**harm` representations, we aim to facilitate research in computational musicology, which is frequently burdened by corpora spread across multiple encoding formats. The format will also facilitate cross-corpus comparison with the large body of existing works in `**kern` format. For a 100-song subset of the CoCoPops-Billboard collection, we also provide participant ratings of continuous valence and arousal ratings, along with the RMS (Root Mean Square) signal level and associated timestamps. In this paper we describe the corpus and the procedures used to create it.

1. INTRODUCTION

In 2011, Burgoyne et al. [1] introduced a dataset that would have a lasting influence in the ISMIR community: the McGill Billboard corpus, a set of expert harmonic analyses of commercial pop songs. This dataset—and the Harte [2] standard for encoding chord symbols that it adopted—has become a standard in the MIR community, for example, being used as training and testing data in the MIREX competition for Audio Chord Estimation since 2008. Around the same time, Trevor de Clercq and David Temperley independently created another rock music dataset—the RS200 corpus—which would ultimately consist of 200 harmonic *and* melodic transcriptions [3, 4]; Though perhaps less well known in the MIR community, their corpus has been the basis for several computational

musicology papers [4]. While other datasets of popular-style music harmony have been released (e.g., Isophonics [2]), the Billboard and RS200 datasets stand out for their use of experts to encode the annotations, the rigor of their sampling methodologies, and the detail of their procedural documentation.

The field of computational musicology suffers from perennial data scarcity [5]; What few symbolic corpora exist are largely biased towards Western classical music [6], which is relatively easy to digitize due to its basis in notated scores. Unlike classical music, popular music must generally be transcribed from audio recordings, with melody transcription being a particularly time-consuming task. Although more open-source data can be found (e.g., crowd-sourced arrangements from www.musescore.com) and MIR algorithms for tasks such as source separation and automatic transcription are improving, both procedures are prone to high levels of error that is undesirable for either computational music analysis or training machine learning models [6]. The RS200 is still the only major corpus of expert melodic transcriptions of popular music; the pairing of these melodic transcriptions with harmonic analyses affords sophisticated analysis of tonality in popular music.

In this paper we present a corpus which extends the Billboard corpus to include expert-transcribed melodies for a sizable subset of the original corpus (214 songs presently). By adding melodic transcriptions to an existing corpus of harmonic annotations (the Billboard corpus), we create a dataset fully comparable to the RS200. We also translate both the Billboard and RS corpora into humdrum data formats, creating two comparable datasets which together form a super-corpus we call the Coordinated Corpus of Popular Music (CoCoPops). In addition to melodic and harmonic transcriptions, CoCoPops includes entirely new annotations of rhyme schemes in both subcorpora and continuous valence and arousal ratings in a 100-song subset. Like the When In Rome project [7], CoCoPops aims to facilitate musicological and MIR research by making a large body of data available in a consistent, standard format. In the sections that follow, we describe in detail the original two datasets that CoCoPops is built on, the procedures we used to generate new data, and the content of CoCoPops.

2. BACKGROUND

2.1 The McGill Billboard Corpus

The McGill Billboard [1] corpus contains annotations of 739¹ unique songs, all sampled from the Billboard Hot 100 charts between 1958 (when Billboard magazine began publishing this chart) and 1991. The authors used a stratified sampling procedure to gather as representative a sample as possible, sampling a (roughly) equal number of songs from each of three “eras” (60s, 70s, 80s) while also accounting for chart position (1–100).

The McGill Billboard transcription process involved a team of more than two dozen people, included “auditions to identify musicians with sufficient skill to transcribe reliably and efficiently,” and cost upwards of \$20,000 [1]. The process included creating manual annotations of the chords, formal sections (e.g., verse, chorus), phrases (loosely defined), key(s), and meter in each sampled song, conducted by two independent annotators. A third “meta-annotator” compared the two versions for differences and combined them into a single, final transcription.

The McGill Billboard chord annotations are encoded using the representation scheme proposed by Harte in 2005 [8] and later expanded and revised in 2010 [2]. This representation uses a syntax that is common in popular music lead sheets, where chords are represented as a root note with a set of intervals above the root, with the most common chord types given a list of shorthand symbols (e.g., C:maj, A:7). The McGill annotations are encoded in plain-text files with line breaks representing new phrases, each line tagged with the dominant instrument (or vocals) in that phrase. An example of an original file from the McGill Billboard corpus is shown in Figure 1.²

2.2 The RS200 Corpus

The Rolling Stone corpus was first described in a paper published in 2011 [3], initially dubbed the RS5x20 cor-

pus. This original 100-song corpus (RS5x20) contained harmonic annotations of the top 20 songs listed, for each of five decades from the 1950s through the 1990s, on Rolling Stone magazine’s list of the “500 Greatest Songs of All Time” (as first published in 2004). The corpus was later expanded to 200 songs (the RS200 corpus), and also added melodic transcriptions for each song [4], making it the first public corpus of expert melodic transcriptions of popular music. Since the remaining 400 songs on Rolling Stone’s list were not chronologically balanced, the second set of 100 songs was chosen based on rank position alone. While the Billboard charts are based on commercial sales, the Rolling Stone list was based on votes from experts (specifically, “172 rock stars and leading authorities”). Although one may suspect that these two corpora would substantially overlap, in fact there are only fifteen songs in common.

The RS200 annotations are spread over multiple separate files per song: one with the timestamps, two with the harmonic analyses (one per annotator), another with the melody transcription, and (for an 80-song subset) a fifth with lyrics. Unlike the Billboard corpus, the RS200 chords are annotated using Roman numerals; Similarly, the melody transcriptions are encoded as scale-degree annotations, with direction markers to clarify octave and contour. Rhythmic durations are not encoded at all, only the timing of note onsets: each measure of music is divided into regular steps representing metric positions, with notes placed at steps indicating onsets and dots representing empty steps. The number of steps per measure is dynamic, depending on the meter and the lowest metric position needed to represent onsets in that measure. For instance, a measure that contains only one note that arrives on the second half of the first beat (e.g., the “and of 1”) requires division into eighth notes, so that measure will have eight steps with only a note at the fourth step and the rest dots. However, a measure with only a single note that lands on the downbeat can be represented with just one token. Sample files from the RS200 corpus can be seen in Figure 2.

2.3 Related Work

The most closely-related work to ours is another extension to the McGill Billboard corpus by Christopher White et al. [9], which adds timbral and textural annotations to the entire Billboard corpus. Annotators of this corpus listened to the songs and notated “all moments of change” within each track according to three broad categories: the “domain” of change (such as the instrument group, harmony, lyrics, texture, etc.); the “genera” of each change within the relevant domain (such as a change to “solo” within a texture category); and an “event type” which solely denotes one of three options: a change, entry, or exit. We intend to work with the authors for a future release of CoCoPops to incorporate this textural and timbral information as well.

A major drawback of both the Billboard and Rolling Stone samples is their overwhelming bias towards music from before 1991. Two recent projects have sought to right this imbalance by creating corpora of more modern popular music to complement the Billboard sample: White et

¹ Note that a small subset has been withheld from the public to serve as testing data for the MIREX competition.

² A separate set of mirex text-files includes only the chords, but with a timestamp for every chord.

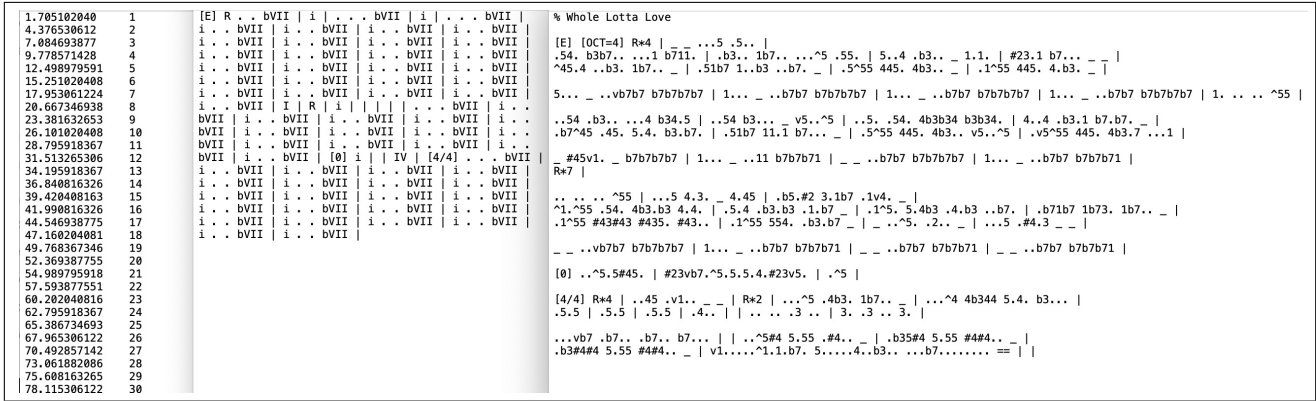

Figure 2. Sample annotation files from the RS200 corpus (“Whole Lotta Love,” Led Zeppelin). The image shows three files overlaid on top of each other from left to right: timestamps of each measure, key and chord annotations, and melody transcription.

al. [10] introduce the “Millennial corpus,” a dataset of expert melodic transcriptions of twenty five popular songs written between 2015 and 2019. Beach and Arthur [6] created a much larger corpus of popular songs with annotations, although their annotations are derived algorithmically from the audio, and are quite noisy.

Our aim to combine two existing corpora into a single, homogeneous dataset is inspired by Mark Gotham’s “when in Rome” project [7], which merges and reformats several existing classical corpora with Roman numeral annotations into a single collection in a common format. Our project to gather valence and arousal data for the Billboard sample was similarly inspired by the DEAM dataset: a dataset containing dynamic annotations of valence and arousal for 1,809 non-copyrighted (Creative Commons license) songs and song excerpts [11]. The majority of these annotations are of short excerpts ($\approx 45_s$) across numerous musical styles (folk, world, jazz, instrumental, pop); however, the dataset also includes ratings for 56 complete songs, which provide the most valuable information, according to the creators [11]. In addition, the quality of the audio recordings (and the musical content) in the DEAM sample is highly variable, as these recordings do not represent professionally published works. Our valence- and arousal-ratings for 100 complete, successful, commercial recordings will serve as a useful complement to the DEAM sample.

3. CORPUS OVERVIEW

The CoCoPops corpus consists of two collections: the Billboard and RS200 subcorpora. Each collection contains one file per song. In the CoCoPops-Billboard collection, all 739 of the original McGill Billboard files have an equivalent humdrum file. The contents of each file, however, vary: All 739 files contain all the originally encoded information (chords, keys, formal section labels, timestamps, phrase information) from the original McGill dataset, but all converted to humdrum format, and with a significant number of corrections (see Section 5). At present, 214 out of the 739 files include new expert melodic and lyric tran-

scriptions, as well as an encoding of the rhyme scheme; 100 of those 214 songs also contain continuous user ratings of valence and arousal, as well as rolling RMS (root mean square) amplitude values of the audio, to approximate the changing sound level of the music—both sampled at a rate of 2_{Hz} . A sample CoCoPops-Billboard file is shown in Figure 3. In the CoCoPops-RS200 collection, each file contains the information originally spread over separate files—e.g., melody, harmony, time stamps, lyrics—in a single humdrum file. Unlike the original Billboard annotations which used Harte’s encoding scheme (i.e., root+quality), the RS200 were originally annotated with Roman numerals. To facilitate analysis, we provide both types of harmonic annotations in both collections. In addition, since the original RS200 contained two independent transcriptions of the harmony, each CoCoPops-RS200 file includes two Roman numeral annotations (i.e., two `**harm` spines) side-by-side. Eighty of the files also include lyrics and syllable stress information.

The humdrum syntax is a plain-text format for representing musical information, organized into tab-delineated columns—called “spines”—representing different streams of data [12] (see www.humdrum.org for more information). Within the general humdrum syntax, various specific representation schemes can be defined³: Two of the most common representation schemes include the widely-known `**kern` representation of pitch information, the `**silbe` representation of lyrics, and the `**harm` representation of harmonic information in Roman-numeral format. Other relevant representations for the present collections include `**harte`—a humdrum representation for root+quality-style harmonic annotations (near-identical to the original annotation scheme used in the McGill Billboard corpus. This scheme is based on the syntax proposed by Chris Harte [2, 8] and the humdrum representation is described in Arthur et al. [13]); and `**rhyme`—a representation for rhyme schemes [14].

In the following sections we describe our procedures for gathering new data (e.g., melodic transcriptions), and

³ Chapter 18 of the Humdrum User Guide illustrates how to create new humdrum representations.

how we converted the preexisting datasets into humdrum formats.

4. MELODY TRANSCRIPTION

In the early stages of our project, we worked with four collaborators⁴ to define transcription guidelines which could be applied consistently. We elected to transcribe only vocal parts, with focus on the “lead” vocal melody in each song—however, we agreed to encode important vocal harmonies or other “backing” vocals as needed. The vocal performances in the sample are often challenging to transcribe, including unpitched or quasi-pitched vocals, “blue” notes, glissandi, loose rhythms, and syncopation. Our goal was to create readable transcriptions using conventional musical syntax (beat positions, durations, notes) rather than mechanical, empirical terms (milliseconds, F0, etc.). This requires significant interpretation and quantization; However, we took care to not over-simplify melodies such that they became melodic reductions. Our transcriptions generally interpret rhythms using a 16th-note grid, but triplets and 32nd-notes are used sparingly at slow tempos; Similarly, pitches are encoded in standard western pitch categories (e.g., C#5, B4), ignoring most glissandi and blue notes. However, many vocal performances simply cannot be faithfully represented in traditional score categories: as such, we included provisions for indicating, as needed, unpitched or approximate pitch, “free” or approximate rhythms, glissandi, and blue notes—the complete details of these encodings are documented directly in the CoCoPops repository.

Ultimately, ten individuals contributed to our 214 melodic transcriptions: 94 transcriptions by the authors; 40 transcriptions by our four early collaborators, all graduate students in music performance or theory; 10 transcriptions by three (paid) undergraduate music students; and 70 tran-

scriptions by one (paid) professional jazz performer, also a graduate student in jazz performance at the time. When transcribers were uncertain of their transcriptions, a second transcriber would collaborate on the final version. We gave our paid transcribers detailed instructions and have personally vetted and edited all transcriptions for consistency. The complete transcription guidelines are provided in the supplementary materials.

The exact audio files used for the original McGill transcriptions are not publicly available; for our transcriptions we accessed targeted songs via YouTube, taking care to confirm that each recording was the correct Billboard Hot 100 single. Unfortunately, some of the original McGill transcriptions do *not* match the targeted single, instead matching an album version, live version, or some other version of the same song; In a few cases, we could not find any recording that clearly matched the transcription. To improve consistency, we elected to modify the harmonic transcriptions for sixteen tracks to match the correct, single version from the Hot 100 chart. In most cases, these versions were very similar but slightly longer or shorter; in a few cases, the alternate version was in a different key or contained other significant differences. For these sixteen altered versions, the original timestamps were discarded and replaced with corrected timestamps in the correct single version, as available on YouTube. The CoCoPops repository includes files with links to each song’s reference recording on YouTube, as well as MusicBrainz MBIDs for our 214-song melodic transcription subset.

5. CONVERTING EXISTING DATA

To create the new data, we converted the preexisting Billboard and RS data into humdrum format. During this process, we noted some errors in the Billboard transcriptions, which we corrected in our new data. Our expertise (education/credentials) in music performance and analysis is comparable to the original transcribers’. Most of these er-

⁴ Thanks to Hubert Léveillé Gauvin, Gary Yim, Dana DeVlieger, Lissa Reed.

rors are unambiguous—for instance, a measure of music missing or a clear change of key that is not indicated. In only a few cases our “corrections” might be considered debatable. All errors and corrections are documented in our corpus repository. Each file in CoCoPops also includes a wealth of meta-data, including track information—title, original artist, release date, etc.—and sampling information, like the rank on the Rolling Stone 500 list and chart position on the Billboard Hot 100.

5.1 Billboard Data

We created a custom R script to convert the original Billboard corpus files (available at ddmal.music.mcgill.ca/research) into a humdrum representation. The harmonic annotations are encoded in a `**harte` spine with the timestamps in a `**timestamp` spine. Along with the `**harte` representation, we also include a `**harm` spine in each file: the humdrum standard for representing Roman numerals. Whereas the original harmonic transcriptions focus on the literal pitch-content played by rhythm-section instruments (ignoring vocal parts), Roman numerals represent harmony at a higher level of abstraction, incorporating the broader tonal context. This means that, for example, open-fifth “power chords” are interpreted as major or minor triads (numerals) based on the key, context, and vocal melody. For illustration, the original transcription of the track “I’m Going Down,” by Bruce Springsteen, consists entirely of two repeated patterns: `A:5-E:5-F#:5-D:5` and `A:maj-E:maj-F#:min-D:maj`. We interpret both of these patterns as `I-V-vi-IV`. To create this `**harm` information, we wrote an R script to parse each file and replace under-specified chords (like `C5`) with the full triad expected given the key-signature and/or explicit triads indicated on the same root in the same song. This process was effective in the vast majority of cases; however, for songs with ambiguous modality we identified the triad manually. The harmonic rhythm is also indicated in the `**harm` spine using standard humdrum rhythmic duration tokens.

The original McGill data includes two, parallel, formal encodings: named sections (e.g., verse, chorus) and abstract letters (e.g., AABA). These parallel encodings are not redundant, as the transcribers used letters to indicate more abstract repetition (mainly of chord progressions)—for example, a guitar solo section which reuses the chord progression from the verse will be labeled “solo”, but use the same letter designation (e.g., A) as the verse. We encode both formal representations, independently, in hierarchical <https://www.humdrum.org/guide/ch20/>: Abstract formal labels are encoded in interpretation records of the form `*>Letter>A`; formal names are encoded in separate records of the form `*>Label>Verse`. Phrases in the music (originally represented with line breaks) are indicated by the presence of the token `newline` in a `**phrase` spine, with a parallel `**leadinstrument` spine for lead-instrument annotations.

Transcribers worked in music notation software of

their choice (e.g., MuseScore, Sibelius) transcribing pitch, rhythm, and lyrics. The transcription was then exported into musicXML format. We wrote a Haskell program to parse musicXML scores into humdrum notation (`**kern` for pitch/rhythm, and `**silbe` for lyrics), and align this information with the already generate humdrum data described in the previous paragraphs. When transcribers included more than one vocal part for a song, each part appears as a separate pair of spines (`**kern` and `**silbe`) in the humdrum file.

5.2 Rolling Stone Data

The RS200 dataset is available at rockcorpus.midside.com, with data for each song encoded in four or five separate files—Figure 1 shows three such files. In addition, David Temperley provided us with files indicating the hierarchical structure built into their original transcriptions, which can be interpreted as formal labels. We created a Haskell program to parse these files and generate a single humdrum-syntax file for each track.⁵ In some cases, we had to correct inconsistencies between harmonic and melodic transcriptions—e.g., music notated as 4/4 in the harmonic analysis but 12/8 in the melodic transcription. Each humdrum file created includes two `**harm` spines, representing Temperley and de Clercq’s separate harmonic transcriptions, labeled with comment tokens ‘!D.T.’ or ‘!T.d.C.’ respectively. The RS200’s original step-sequencer-like approach to rhythm transcription is faithfully encoded using humdrum’s “timebase” function where `*tb` interpretations indicate the duration of each step. For the 80-song subset with lyrics, a `**silbe` spine indicates the lyric alongside a `**stress` spine to indicate three levels of lexical/prosodic stress.

The original RS200 transcriptions indicate only tonal center (tonic), not mode, which can be ambiguous in popular music [3]. For consistency with the Billboard data, the key in each `**harm` spine is indicated as either major or minor, depending on what would be the most likely interpretation. The RS200 melodic transcriptions *do* include key-signature-like indications of raised/lowered scale degrees. Using these scale indications and the humdrumR package [16], we were able to convert the original scale-degree representation to `**kern` in the final dataset.

6. VALENCE AND AROUSAL SUBSET

In addition to the musical data itself, we gathered continuous-response ratings of perceived valence and arousal, in a 100-song subset of the Billboard data. Valence and arousal are the two core dimensions of Russell’s circumplex model of affect [17], and, while perhaps limiting [18, 19], has been used widely in both music perception research [18, 20] and music emotion recognition (MER) [21–23]. We focused on valence and arousal due to their simplicity (i.e., only two variables) and ubiquity

⁵ Though the `music21` Python library [15] includes a parser for the RS200 harmonic transcriptions, it was easier to assure consistency and alignment between melodic, harmonic, lyrical, and formal information by using a single custom parser.

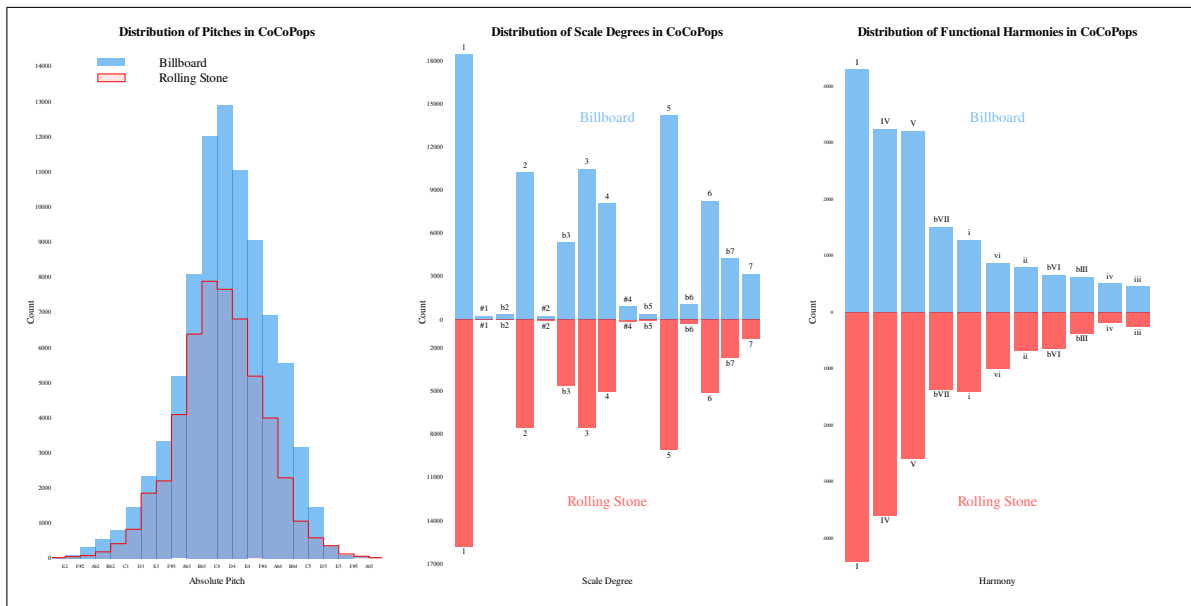

Figure 4. Left: distribution of absolute pitches in each corpus. Middle: distribution of 15 most common scale degrees in each corpus. Right: distribution of ten most common functional harmonies in each corpus (11 in total), sorted by rank in the Billboard data. (Only Temperley’s harmonic annotations are counted; Immediate repetitions of a chord are not counted.)

in the literature, though it is acknowledged that there are likely additional, overlooked dimensions such as tension and power [24]. Since arousal is highly correlated with sound level, we also include the rolling RMS values for each track in an `**rms` spine.

6.1 Perceptual Data

Perceptual data was gathered in a human-subject experiment, approved by Georgia Tech’s Institutional Review Board (protocol H22086). Eighty participants took part in our experiment, each paid \$15 for their time. All participants were students at Georgia Tech, and were mainly non-music majors. Experiments took place in person, in a sound-attenuated booth using professional-quality loudspeakers set at the same fixed sound-level for all participants. Participants used a physical slider (Monogram Creative) to make their continuous ratings, with the slider position sampled every 500_{ms}.

The concepts of valence and arousal were explained to each participant in simple terms: arousal being how calm-energetic they perceived the music to be at any given moment, and valence being the polarity (negative-positive) of the music [25]. Participants were instructed to rate what they perceived the music to express, not necessarily what they themselves felt. Since continuously tracking valence and arousal simultaneously is challenging, we had participants rate each independently—the same approach taken for the DEAM dataset [11]. The authors of the DEAM project also reported an increase in the usability (i.e. variation) [11] of the ratings when they used full songs as opposed to shorter clips; Accordingly, participants in our experiment listened to the full songs. To encourage sustained engagement and attention throughout the experiment, we had each participant rate only ten songs. Participants were

randomly assigned to rate valence in five songs and arousal in the other five, with the order of tasks counterbalanced. Ultimately, each of the 100 songs was independently rated for valence and arousal by eight different participants (four for valence and four for arousal). The full experiment took approximately forty minutes.

Files in the 100-song subset include independent `**valence`, `**arousal`, and `**rms` spines. The four independent arousal and valence ratings are encoded in the same spine, in space-separated humdrum sub-tokens.

7. SUMMARY

The CoCoPops corpus includes complete melodic and harmonic data for 398 unique popular songs released between 1949 and 2002. 95% of songs (379) come from the years 1956–1991 with more than half (203) from the years 1965–1980. The corpus includes 145,822 note onsets (86,215 in the Billboard subset), 37,010 chord changes (19,682 in the Billboard subset), and 63,809 words in the lyrics (48,018 in the Billboard subset). Figure 4 shows the distributions, in each subcorpus, of three fundamental pitch parameters—absolute pitch height, scale degree, and the ten most frequent Roman numerals. Though the two subcorpora originate in data generated by different sampling criteria and different measurement/encoding procedures (see Section 5), these distributions are nonetheless broadly similar, highlighting the potential value of treating these two separate subcorpora as a single united corpus.

The CoCoPops dataset is hosted at github.com/Computational-Cognitive-Musicology-Lab/CoCoPops, shared under a CC-BY-4.0 license. Many further methodological and encoding details are included in the repository files, as well as our recommendations about the usage, distribution, and citation of the data.

ABSTRACT

The research field of music therapy has witnessed a rising interest in recent years to develop and employ computational methods to support therapists in their daily practice. While Music Information Retrieval (MIR) research has identified the area of health and well-being as a promising application field for MIR methods to support health professionals, collaborations with experts in this field are as of today sparse. This paper provides an overview of potential applications of computational music analysis as developed in MIR for the field of active music therapy. We elaborate on the music therapy method of improvisation, with a particular focus on introducing therapeutic concepts that relate to musical structures. We identify application scenarios for analysing musical structures in improvisations, introduce existing analysis methods of therapists, and discuss the potential of MIR methods to support these analyses. Upon identifying a current gap between high-level concepts of therapists and low-level features from existing computational methods, the paper concludes further steps towards developing computational approaches to music analysis for music therapy in an interdisciplinary collaboration.

1. INTRODUCTION

The use of music technology in the context of health and well-being is becoming increasingly important, in line with a growing interest in eHealth in medicine. Music's affordances such as emotion regulation [1], motor coordination [2], and social interaction [3], enable a broad range of therapeutic applications. They feed into research on developing music technology for various contexts of music therapy (MT) such as for supporting motor and cognitive rehabilitation through musical biofeedback [4] and through music-based applied games [5, 6], or through digital musical instruments developed for specific patient groups [7]. For a broad overview on different use cases of music technology for music therapy we refer to [8].

One of the main application fields envisioned for music technology in the context of health and well-being is the

support of data analysis from therapeutic sessions, including analysis and visualizations of musical structures. The computational analysis of musical structures has been one of the main research topics of music information retrieval (MIR) over the past decades. While MIR has identified the health context as one of its future challenges [9], there exist only few attempts to employ MIR methods for the analysis of musical structures in the context of MT to date [10–15]. The goal of this paper is to provide an introduction and overview on how MIR methods for computational music analysis can be of use for active music therapy (employing music making), specifically for analysing musical improvisations from therapy sessions to support music therapists.

The contributions of this paper are threefold: First, it provides an overview of the different contexts in which music therapists analyse musical material from improvisations, and of their analytical approaches (Section 2). Second, it identifies and describes different scenarios in MT which can benefit from computational methods on music analysis. (Section 3). Third, it identifies a current gap between high-level concepts of therapists and low-level features of current computational approaches, and concludes collaboration perspectives for MIR and MT researchers on developing computational approaches to musical structure analysis of clinical improvisations (Section 4).

2. OVERVIEW ON MUSIC THERAPY

2.1 What is music therapy?

The American Music Therapy Association describes music therapy (MT) as "the clinical and evidence-based use of music interventions to accomplish individualized goals within a therapeutic relationship by a credentialed professional who has completed an approved music therapy program" [16]. In a music intervention, therapists create musical experiences in a holistic manner involving the patient's cognition, emotion, movement and social interaction, to approach issues faced by their patients. Music therapists theorize that musical processes are correlated with psychological processes [17, 18]: a musical change can indicate a change in the patient's inner state or in the interrelation between the patient and others. For instance, if a patient with ADHD learns to focus during MT, or a patient with Parkinson learns to have more control over their body while playing music, these improvements can be generalizable to other areas in their lives, because of the interdependence of human functioning [17]. For an overview on the

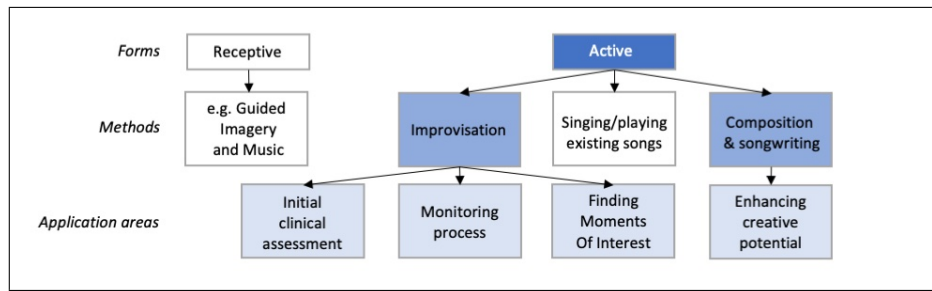

Figure 1. Main forms and methods of music therapy with application areas for computational music analysis. This paper focuses on the areas depicted by coloured blocks.

various affordances of music for therapeutic use, and clinical and non-clinical contexts of music intervention see [8].

2.2 Active music therapy

MT is divided into active (music making) and receptive (music listening) MT [19], see Figure 1. A common receptive method is called *Guided Imagery and Music* (GIM) [20], in which the patient listens to music in a relaxed state. The therapist guides the patient in bringing up the imagery that emerges from their inner process in response to the music, to explore their inner conflicts.

In active MT, creative methods such as improvisation, composition and songwriting are employed, as well as recreative methods such as singing an existing song. Creative methods are used to unravel underlying psychological patterns [21]. For instance, if the patient acts mainly as the follower in the interaction with the therapist during a musical improvisation (i.e. only the therapist initiates changes in the music), this behaviour can help to unravel interaction patterns and corresponding associations in daily life interactions of the patient.

In improvisation methods, the patient plays or sings music that they are creating themselves, either alone, with the therapist or in a group. This paper focuses on the setting of therapist and patient playing together. During a MT session, the therapist is focused on creating the music together with the patient (and the verbal evaluation of it), using musical interventions, such as changes in one or more musical parameters like timbre, dynamics, or timing, to encourage changes in the playing style of the patient. After the session, the therapist listens to the recording of the session and seeks to answer questions such as: In what way does the patient interact? Where did it feel like we were in a flow together (instead of the patient just playing for themselves) and what type of intervention caused this? In which musical parameters is the patient very rigid and what interventions change that? The therapist then seeks to draw parallels to other aspects of the patient’s life and could ask the patient in the next session if the way they interact and react to the music is the same in other situations in their life. After this verbal reflection, these habits can be further explored when improvising again. In this way, therapist and patient try to slowly break out of typical habits in the process of consecutive MT sessions.

In composition methods, the patient uses their impro-

visations to subsequently compose music. This could be done for example by starting with a musical improvisation, then selecting from the improvisations the parts or motifs the patient finds most interesting to use in a composition, then improvising again using these motifs, and so forth, hence employing an iterative approach. This fosters interpersonal trust through a joint process working towards an explicit artistic product [22]. In song writing, the use and analysis of lyrics is important, in composition the focus is on using musical parameters and structure.

2.3 Analysis of music therapy improvisations

There exist many different approaches to analyse MT sessions. In some of them, therapists analyse only the behaviour of the patient, and not the created music. Approaches that do analyse musical structures are called *music-centered approaches*, such as the Nordoff-Robbins method [23, 24] and the so-called *psychodynamic approach* [25]. This paper focuses on the psychodynamic approach, which suggests that producing music can help accessing the unconscious mind such that the patient’s underlying issues will surface within a musical improvisation. While analysing musical structures can be useful in all MT methods and approaches, e.g. in receptive methods pattern discovery could be helpful to investigate whether specific patterns contribute to what patients prefer to listening to in specific contexts, we will focus in this paper on active, creative MT methods (see Figure 1).

Bruscia, one of the pioneers for analysis of MT improvisations (MTI), created the so-called *Improvisation Assessment Profiles* (IAPs) [26], for which the therapist fills out questionnaires based on their observations. The IAP consists of six different profiles (called *Autonomy*, *Integration*, *Tension*, *Variability*, *Saliency* and *Congruence*). For example, the Autonomy profile explores the intermusical relationship between patient and therapist, which could show that the patient is a leader or a follower, where the patient does or does not initiate changes in the music when playing together. The therapist can observe this relationship in different musical dimensions, such as in rhythm, melody, or harmony, but also in lyrics [27]. The Tension profile shows how much tension is created through different aspects of the music, relating to questions such as: is the tempo or modality calm, or tense [28]? For a detailed description of Variability, Saliency, and Congruence, we refer to [17, 28].

Therapists typically do not use all profiles and dimensions, but focus on one profile and fill out the questionnaire for all musical dimension or analyse one musical dimension in all six profiles [10]. They choose the profile and parameters based on the context: for instance, with MT for a child with ADHD, it could be relevant to analyse the presence of hyper-activity and how this changes over time, for which the therapist could use the Tension profile.

The profiles describe high-level concepts from Bruscia [17] that require fine-grained descriptions on how they might relate to concepts of musical structure for MIR researchers. For instance, when can a tempo be described as tense? According to [10, 29, 30], there exists a variety of other methods for analysing MTI, see e.g. [24, 31–33], which all address various high-level MT concepts (such as autonomy or tension). In general, these analyses are carried out by the therapist after the MT session by listening to the recorded music, using different analytical methods and the implicit musical knowledge of the therapist. There exists no systematic research on how music therapists use the different music analysis methods in their practice, as music analysis methods in MT are a particularly under-researched area according to [34].

3. APPLICATION AREAS OF COMPUTATIONAL MUSIC ANALYSIS IN MT IMPROVISATIONS

Computational methods for music analysis can be employed for several areas within the MT domain. In this section, we describe for the creative methods within active MT (namely improvisation, composition and songwriting) the following different application areas: initial clinical assessment; monitoring process; finding of so-called Moments of Interests; and enhancing the creative potential of patients within composition processes.

3.1 Psychological Assessment

Psychological assessment is the collection and analysis of information of a patient, resulting in hypotheses about the nature and causes of a patient's personality, condition, resources and potentials. In the context of MTI, the information includes musical data.

Initial clinical assessment. Hypotheses which are formed in the psychological assessment are used to determine an effective treatment program [10], considering the skills the patient currently has and what kind of therapy would fit them. Data gathered in the psychological assessment during the first therapy session is used to determine if the patients' symptoms are consistent with the diagnostic criteria for a specific mental disorder [35]. Computational analyses of the improvisations in the first therapy session can support the initial clinical assessment. For instance, computationally analysing musical timing parameters of clinical improvisations can be promising in diagnosing Borderline Personality Disorder [14].

Monitoring process. Therapists use the data gathered with psychological assessment in later stages of the therapy for monitoring the process of the patient during treat-

ment, such as for detecting any form of progress or development of the patient. One existing approach for assessing this process is the so-called *microanalysis* [30] which focuses on small changes in social, musical, and emotional behaviour and experiences within one MT session. A computational tool could assist in performing the microanalysis on the musical content on aspects such as identifying musical dimensions of the patient's improvisations that, for instance, contain many repetitions for assessing the degree of rigidity in the playing style; identifying aspects of interventions of the therapist that caused changes in the patient's playing style on a micro level; determining the dimensions which had the greatest influence on the musical change observed in the improvisation. Gathering these insights over different sessions helps to establish what is typical of a patient's improvisational style and how it changes over time as a result of the therapeutic interventions.

Moments Of Interest. Effects of MT are often seen in specific moments within one musical improvisation session. When carrying out psychological assessment, therapists seek to identify these specific moments which can be turning points in the development of a patient. The focus of the therapist's analysis is to identify the so-called *Moments of Interest* (MOIs) [21], though there exist many other terms for MOIs, such as meaningful moments [36], pivotal moments [37], and present moments [38].

MOIs are chosen by therapists based on what they recognise as an important change [30]. It could be a mistake (e.g. patient accidentally plays an unintentional note), a mis-attunement between therapist and patient (e.g. patient does not listen to the therapist's playing which leads to unsynchronized notes), a refreshing new harmonic chord, etc. The musical events right after this moment are also of interest, since the therapist notices if the change leads indeed to something new within the improvisation (e.g. if a moment of interaction occurs between patient and therapist where they dissolve the mistake or continue on the new chord). MOIs are not described by one single form of musical change, different musical elements could be of importance in the identification of MOIs for individual diseases and patients. For instance, for patients with psychosis it could be an important change if they stop playing repetitively [39], and for borderline patients it could be an important change if they start alternating between leading and following the therapist in the improvisation [40].

3.1.1 Case study: playing styles for psychosis patients

A specifically interesting example for the potential application of computational music structure analysis, is the identification of different playing styles within MTI of patients with psychosis, including the finding of specific MOIs, namely *Moments of Synchronicity* (MOS). The spectrum of different playing styles as identified in [41] ranges from so-called *sensorial play* to *complete musical form*. In between arise Moments of Synchronicity.

Sensorial play describes a style consisting of repetitive and monotonous, or chaotic and fragmented play, with a lack of phrasing, silences and dynamics. This style is typ-

ical for patients with psychosis who are perceptually and emotionally detached from their improvisation and are not really engaging in the music, leading to an absence of interaction between patient and therapist. Typical characteristics of sensorial play are, e.g., random playing (tonal and atonal), and a significant lack of variation.

Musical form denotes a playing style that is situated on the other end of the range of observed playing styles in patients with psychosis compared to sensorial play. It arises from an inter-subjective phenomenon between patient and therapist, where both engage in a musical interaction. They experience being autonomous and equal, and are able to introduce their own new musical ideas to the improvisation. It is characterized as an improvisation where dynamical differentiation, pulse, phrasing, pauses, repetition, variation, rhythmic and melodic themes, and especially interaction between players can be observed. A clear beginning, ending and development can be identified.

Moments of Synchronicity (MOS). For patients with psychosis, the goal is to progress from sensorial play to musical form during several therapy sessions. In between, MOS between patient and therapist need to be established. These are short moments where both players have a shared feeling of an autonomous and free playing style, constituting a moment of musical interaction. Often MOS are fuelled by interventions from the therapist. In these moments, attunement/synchronicity in the musical parameters of the patient and therapist can be observed and some variation, dynamics and phrasing emerge. A pulse, combined with accents in the meter, are shared. MOS enrich the therapeutic relationship, creating moments of trust, which enable the patient to take more risks in the music playing, which in turn leads to changes in the patient. MOS are the most basic form of a MOI; after these first interactions, new interactions can emerge (see [41,42] for a detailed descriptions of the playing styles and MOS).

In sum, MOS denote specific MOIs for patients with psychosis, marking their transition from sensorial play to musical form. Recognizing these different playing styles identified by the extent as to how much musical structures are present in a MTI, delivers an interesting case study for MIR on musical structure analysis and pattern discovery.

3.2 Enhancing the creative potential for composing

The composition methods for enhancing the creative potential of patients as part of active music therapy (see Figure 1) offer a particularly interesting field of application for automatic pattern discovery. For creating compositions, patients start with improvising music. Afterwards, the patient and therapist listen to the music together and seek to find parts that the patient would like to use for composing their own musical piece. The therapist writes down the motifs they hear in musical notation, which can be time consuming. A pattern discovery tool could be used to identify and highlight all moments where the patient repeated their motifs, and preferably these motifs could be automatically transcribed to musical notation so that in the next phase of the composition these motifs could be used immediately.

4. DEVELOPING MIR METHODS FOR MT

4.1 Existing Computational Approaches in MT

A number of computational approaches have been developed to support psychological assessment in MTI, which we summarize in this section. According to [10,12], Computer Aided Music Therapy Analysis System (CAMTAS) was the first attempt to organize and analyse audio and video data specifically from MT. Developed during the mid-90s, it was used for uploading recorded data and playing back audio and video files simultaneously. Another annotation tool, the so-called Music Therapy Analysing Partitura (MAP) [29], helps to annotate events in MT based on therapist's manual transcriptions. The therapist can annotate the auditory material from a session, including the music itself, but also e.g. talking, silence, crying, and laughing, using a visual format with fixed graphical codes, allowing the therapist to view the content of one improvisation or over a whole session. Both CAMTAS and MAP rely on manual work by the therapist without any automatic detection of events from music recordings, hence using these tools is rather time-consuming [10].

Computational tools for MTI which analyse the musical content are the Music Therapy Logbook [12] and the Music Therapy Toolbox (MTTB) for MatLab [15,27,43]. The Music Therapy Logbook was developed in collaboration between MIR and MT researchers. It can be used to gather evidence of changes in a patient's and therapist's use of music over time for psychological assessment. In a proof-of-concept study using simulated MTI where one expert would improvise in the role of the patient and the other as the therapist [12], existing MIR techniques e.g. for the detection of tempo changes or the identification of rhythmic patterns, have been employed. It was tested whether computational methods can assist in evaluating whether therapist's tempo changes are effective in increasing the patient's tempo flexibility. While it was possible to identify, for instance, call and response type of play between therapist and patient, it was concluded that addressing higher-level concepts about musical interactions with computational means has yet to be fully explored in the future.

The MTTB tool takes MIDI files of therapist and patient as input and automatically extracts musical features, which it outputs into graphs depicting both the therapist and patient over time. The musical features in the MTTB are based on the Autonomy profile of the IAP [27] described in section 2.3. For instance, the density graph is calculated by averaging the number of notes played in a given time window. Since theory suggests that increasing musical density is a sign of increased arousal and therefore increased emotional and physiological density [44], density should be clinically relevant [43]. By manually reading and interpreting the two graphs of the therapist and patient, the role-relationship can be determined for the feature. A pilot study [45] investigated how the MTTB could support clinical assessment from improvisations when combined with subjective experiences of the participants, delivering first insights on how this tool might be used in the future

for investigating Bruscia's improvisation techniques, such as imitation and synchronisation through specific musical parameters. The MTTB is still under development.

For monitoring the process of patients over several therapy sessions with computational methods, the concept of *Musical Profiling* was introduced in [10], comprising three parts: *Typical Performance* for establishing a patient's individual typical playing style, *Temporal Evolution* for measuring the changes in different features in the improvisations over some time or over different sessions, and *Individual Tendencies*, measuring relations between features that are specific to that patient. In a case study with 6 participants, they used e.g. averages of the features of duration, note count, tempo, pulse clarity, dynamic centroid, and pitch centroid, to characterize a typical performance. The Musical Profiling concept is intended to contribute to establishing a systematic method of measuring and representing musical processes in improvisations in order to formalize assessment methods. To the best of our knowledge, this concept has not yet been set into practice.

In sum, there exist promising first steps in developing computational approaches to support the psychological assessment of the therapist when analysing clinical improvisations. They are not yet ready for use in clinical practice. Linking high-level MT concepts (such as moments of interest, tension, salience) to elements of the musical structure that can be extracted with computational features from the music, is as of today not a solved problem (see [11, 46] for studies on linking computational features to clinical improvisations). Moreover, from the perspective of their practical use, tools like MATLAB are not easy to use for all music therapists, and while MIDI is useful in the MT research context, most clinical contexts work with audio.

4.2 Musical structure analysis and pattern discovery

For analysing the musical content of clinical improvisations, MIR methods for musical structure analysis [47–51] as well as pattern discovery [52–64] could be of potential use in the different application fields within MT described in section 3. Techniques to identify coherent segments using concepts such as homogeneity, novelty, repetition, or regularity, developed in music structure analysis [47, 48], might be useful for describing structures emerging in clinical improvisations. Pattern discovery methods could support the identification of different playing styles such as sensorial play or musical form, taking into account the amount and kind of repetition and variation in musical patterns identified. However, these methods have been developed for different scenarios and styles, such as for popular music, jazz, classical music or folk songs. It needs to be explored in how far these techniques need to be adapted for improvisations in the MT context; e.g. in [13] it has been shown that repeated musical patterns identified in MTI were rather different from patterns typically investigated in musicological analyses of compositions and corpora.

Apart from the difference in the musical material, the analysis process of music therapists differs from musicological investigations of compositions. Typically, the

therapist has participated in the improvisation and analyses afterwards the recorded musical material, taking into account their own experience during the improvisation, which might already steer the attention to certain elements of the structure. This is different from a musicological analysis of musical material that has been produced by other musicians (or musical novices).

For adapting MIR methods to the context of MT, the typical high-level concepts addressed by music therapists need to be investigated and deconstructed collaboratively in order to establish how these concepts are manifested in musical features and structures that can be described by computational means. Proof-of-concept studies such as [10, 12] provide a promising start into applying MIR features for analysing MTI. Yet, in order to develop meaningful computational features for the working context of therapists, their implicit knowledge employed in analysing clinical improvisations needs to be made more explicit. One example is given in [34] employing interviews with therapists to determine implicit and explicit knowledge in music analysis of MTI. Working towards the explicating of this implicit knowledge through collaboration would also contribute to establish how much agreement exists between different therapists using the same terminology and analysis methods. This constitutes an important step not only for developing computational methods, but also in developing assessment methods that support the development of evidence-based methods in MT.

4.3 Collaboration perspectives for computational approaches to musical structure in MT improvisations

In MIR, there exists a strong tradition of collaboration with domain experts on investigating specific musical concepts for enabling computational modeling, such as on Leitmotifs [65–67], on cadences [68–70], on similarity of folk songs belonging to a tune family [71, 72], or on melodic schemata and patterns of a certain musical style [54, 55, 72–74]. The establishment of data sets and annotations of experts regarding these concepts has been a crucial factor for enabling collaboration. We expect this to be a necessary step also for developing computational approaches to music analysis for MTI. In the following we indicate examples for the envisioned collaboration for the applications described in section 3.

Initial clinical assessment. For developing computational methods for the analysis of improvisations within the initial clinical assessment, data sets and descriptions of typical playing styles for specific patient groups need to be established. For instance, an overview of which profiles and musical dimensions therapists typically select for specific patient groups within their manual assessment using IAPs, could serve as a starting point for explicating therapists' knowledge on how to describe playing styles using musical features. In the future, once computational methods have been established, they could support therapists to initially scan *all* profiles with the help of computation, instead of manually selecting a few, ensuring that nothing has been overlooked before concentrating on selected aspects.

Monitoring process. Comparing improvisations from different sessions in order to monitor the therapeutic process requires a data-rich approach to musical structure for which computational methods are specifically apt. The concept of Temporal Evolution within Musical Profiling [10] is a first step to monitor process, using low-level musical features such as note count or pitch centroid. For getting closer to the MT practice, the high-level concepts of music analysis in MT need to be connected to appropriate models in MIR, such as identifying recurring patterns and the amount of repetitiveness and variation observed in these patterns, and the comparison of features over time.

Finding MOIs and identifying playing styles. For an overview on envisioned steps in the collaboration between MIR and MT researchers on identifying MOIs as important changes in the therapeutic process, we refer to the discussion in [8] on the creation of datasets and annotations, and the use of automatic pattern discovery and information theory. For the specific case of MOS as a progress from sensorial play to musical form (see Section 3.1.1), the identification of emerging synchronicity in the musical parameters of patient and therapist requires the modeling of musical structure as emerging from an interaction. For instance, MIR models on rhythm and meter could be adapted for detecting the establishment of a shared pulse in MOS, requiring a data collection with improvisations exhibiting different degrees of stability and variability in temporal structures with annotations on MOS as identified by therapists. For distinguishing different playing styles, such as sensorial play and musical form as described in section 3.1.1, computational methods for identifying musical structure, repetition and variation along different musical dimensions, can be employed.

Enhancing the creative potential of patients for composing. Automatic pattern discovery has been successfully employed in MIR for the automatic generation of music [75, 76]. For supporting the composition method as part of active MT, pattern discovery could assist in enhancing the creativity of the patient in the iterative process of generating a composition from improvisations. For discovering appropriate motifs in the patient's improvisations, the methods need to be able to find non-exact matches that might be perceptually meaningful. Appropriate visualization methods for displaying identified matches could support patients in choosing which matches they consider meaningful to work with. Automatic music generation systems such as [77] could be used to explore whether they might support enhancing the patient's creativity in MT (see the discussions in [78] on AI and musical creativity, and [8] on automatic music generation specifically for MT).

We conclude the following steps for establishing the collaboration between MIR and MT on developing computational methods for music analysis of improvisations:

- Investigate music analysis methods of therapists and create data sets with clinical improvisations and music analytic annotations from therapists. Using simulated therapy sessions as in [12, 45] letting therapists imitate typical playing styles of patients is a first step, yet its usefulness

is limited by providing only stereotypical examples.

- Establish a catalogue of typical intervention methods of therapists in clinical improvisations as a first step on finding appropriate musical features for developing analytical methods to musical interactions in MTI.
- Explore computational approaches from MIR for the automatic detection of musical structures in MTI; start with assessing existing MIR features, and determine suitable adaptations for supporting therapists' analytical concepts. Taking into account the granularity of music information required, determine in which contexts symbolic and/or audio formats are appropriate.
- Initiate case studies: For exploring the emergence of musical structures in MTI, identifying different playing styles of patients with psychosis as in Section 3.1.1 can provide a particular interesting starting point for collaboration once datasets are established, since these playing styles are well described in the MT literature.
- Assess how much therapists (dis)agree in their individual intervention and analysis styles. Investigating the agreement between therapists requires the building of dedicated annotation tools and methods to measure agreement between annotators, such as in [79–82].
- Assess how the intuitive knowledge of the music therapist on their subjective experience in the improvisation can be combined with and enhanced by the objective analysis of the musical material through computation, to support therapists in their daily work, and to further establish evidence-based treatments in MT.
- Consider aspects of usability, including considerations from HCI, for developing appropriate tools for the daily practice of therapists; see [8, 42] for some general considerations on developing tools for MT.

5. CONCLUSION

Clinical improvisation from music therapy provide interesting and novel musical data for developing MIR methods for music structure analysis and pattern discovery, aiming to support therapists in their daily work. Interdisciplinary efforts between MIR and MT researchers need to be invested to close the gap between high-level concepts of music analysis used by therapists, and low-level features of current computational approaches to analyse MTI. Investigating music analysis methods employed by therapists, including the explication of therapists' implicit musical knowledge and the assessment of the agreement between different therapists, constitutes a crucial step for developing computational tools for MT. Specifically important herein is the establishing of data sets with clinical improvisations for different application areas, such as for initial clinical assessment, including different patient groups and catalogues of typical interventions of therapists. Creating these data sets through interdisciplinary efforts will not only prepare the ground for the appropriate computational modeling of music structures in MTI, but also to a better understanding of music analysis methods in MT, ultimately contributing to ongoing research on establishing evidence-based methods in MT.

ABSTRACT

Timbre transfer techniques aim at converting the sound of a musical piece generated by one instrument into the same one as if it was played by another instrument, while maintaining as much as possible the content in terms of musical characteristics such as melody and dynamics. Following their recent breakthroughs in deep learning-based generation, we apply Denoising Diffusion Models (DDMs) to perform timbre transfer. Specifically, we apply the recently proposed Denoising Diffusion Implicit Models (DDIMs) that enable to accelerate the sampling procedure. Inspired by the recent application of DDMs to image translation problems we formulate the timbre transfer task similarly, by first converting the audio tracks into log mel spectrograms and by conditioning the generation of the desired timbre spectrogram through the input timbre spectrogram. We perform both one-to-one and many-to-many timbre transfer, by converting audio waveforms containing only single instruments and multiple instruments, respectively. We compare the proposed technique with existing state-of-the-art methods both through listening tests and objective measures in order to demonstrate the effectiveness of the proposed model.

1. INTRODUCTION

Timbre is an extremely important perceptual aspect of music, yet it is hard to both model and define. The concept of musical timbre can be defined as the perceived characteristics of a musical sound that are different from pitch and amplitude contours [1].

Timbre Transfer concerns the task of converting a musical piece from one timbre to another while preserving the other music-related characteristics. While this operation is not trivial, it is of extreme interest for several applications, from the development of plugins to be used in Digital Audio Workstations (DAW) to enabling the possibility of playing sounds corresponding to not widely available musical instruments.

In this paper, we present DiffTransfer, a technique for timbre transfer which is tested both between single and multiple instruments and is based on a continuous Denoising Diffusion Implicit Model (DDIM) with deterministic sampling [2], a modified version of Denoising Diffusion Probabilistic Models (DDPMs) that are trained using the same procedure, but allow for faster sampling times. Specifically, in [2] it was empirically shown that DDIMs allow for $10 \times -50 \times$ faster wall-clock time performances with respect to DDPMs.

In order to be able to convert one timbre into another, we use a procedure similar to the recently proposed image-to-image technique Palette [3]. Specifically, we use as input to the diffusion model the noise and condition it with the chosen input timbre spectrogram, then, through the denoising procedure, the model learns to reconstruct spectrograms of the desired timbre. We consider the scenario where the timbre-transfer task is *paired*, which means that the desired and input spectrograms have the same melodic/harmonic content, but differ in terms of timbre.

We experiment both with the possibility of converting between tracks containing only single instruments and also mixtures of instruments, with no prior separation step, while making no modifications to the model in order to take into account both configurations.

In order to demonstrate the effectiveness of the proposed model, we compare DiffTransfer with state-of-the-art techniques, both through objective measures and by performing a user-based listening test. The source code and audio excerpts can be found at <https://luccacoma.github.io/DiffTransfer/>.

2. RELATED WORK

Several types of timbre Transfer techniques have been proposed in the literature. In [4] a CycleGAN [5] is applied in order to perform an unpaired transfer using the Constant-Q transform and the audio is then recovered through a WaveNet [6] model. In [7] an attention-based architecture is applied in order to convert mel spectrograms, which are then inverted through a MelGAN architecture [8]. Gaussian mixture-based variational autoencoders are applied [9] in order to learn a latent space where pitch and timbre representations are disentangled.

Another class of methods, instead, extracts musical parameters such as pitch and loudness from the input audio tracks and performs the transfer by resynthesizing sound

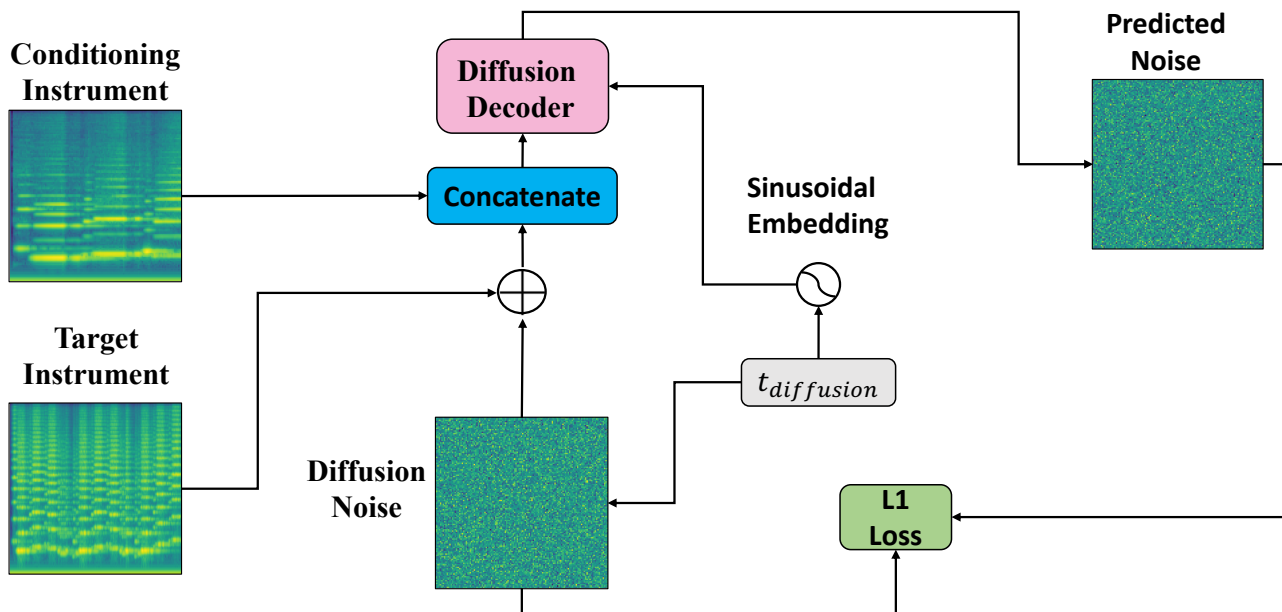

Figure 1: Training scheme of the proposed DiffTransfer technique. The target instrument spectrogram is summed with noise following a simplified cosine schedule. The decoder, conditioned on the conditioning instrument spectrogram and on the sinusoidal embedding representing the current time instant estimates the added noise. The decoder parameters are estimated by computing the L1 loss between the ground truth and the estimated diffusion noise.

through a network that has learned to generate tracks with the desired timbre. The most known example of these techniques is the Differentiable Digital Signal Processing (DDSP) [10] model. Other similar techniques were proposed such as [11], where a hierarchical model is used in order to reconstruct the signal at increasing resolutions. Recently there have been proposed also models that directly work on the audio waveform such as [12], where music pieces are translated to specific timbre domains. The only model that, to the best of our knowledge and except for the one proposed in this paper, is tested on multi-instrument timbre transfer without any source separation pre-processing is the Music-STAR network, presented in [13]. In Music-STAR a WaveNet autoencoder [14] is trained by applying teacher-forcing [15] to the decoders in order to recover the desired timbre.

Denosing Diffusion Probabilistic Models (DDPMs) [16] have recently become the latest state-of-the-art for what concerns deep learning-based generation fastly replacing Generative Adversarial Networks (GANs) [17] and Variational Autoencoders [18], due to their easier training procedure and increased quality of the produced results.

DDPMs have been successfully applied to a wide variety of image-related tasks such as generation [19] and translation [3].

More recently, DDPMs have been also used for audio-related tasks. In [20] a diffusion model is applied in order to convert midi tracks to spectrograms, while in [21] a text-to-music diffusion model is proposed. DDPMs have also been applied to symbolic music generation [22], speech synthesis [23] and singing voice extraction [24].

While DDPMs have extremely powerful generation capabilities they suffer from slow sampling times. To ameliorate

this issue, recently Denosing Diffusion Implicit Models (DDIMs) [2], which allow for faster sampling times and were recently applied to image inpainting [25].

3. PROPOSED MODEL

In this section, we describe the proposed DiffTransfer technique for timbre transfer. Instead of working directly with raw audio signals, we convert them into log mel-scaled spectrograms, due to their easier handling by deep learning models. We then propose a model that, given as input the spectrogram corresponding to the conditioning instrument, generates the corresponding target spectrogram that would have been obtained by playing the same piece of music with the target instrument. Operatively we achieve this through a conditional continuous-time DDIM, which learns to denoise the target instrument spectrogram, while conditioned on the input instrument spectrogram, as depicted in Fig. 1. At inference time, the model is fed with the input conditioning instrument concatenated with Gaussian noise and generates the corresponding target spectrogram. We retrieve the audio signal by applying to the log mel spectrograms the SoundStream¹ model [26], provided by [20] where it was trained on a custom music dataset.

In the following, we’ll provide a brief overview of the DDIM framework and notation used in this paper, in order to make the tractation as compact as possible, for additional and more thorough formulations, we refer the reader to [2] and [3]. We aim at giving a general overview of the process and we’ll use a slight abuse of notation to describe the diffusion process using the continuous time framework,

¹ <https://tfhub.dev/google/soundstream/mel/decoder/music/1>

in order to make it more similar to the more common literature regarding DDPMs and DDIMs.

3.1 Diffusion Decoder

We adopt a procedure similar to the Palette [3] image-to-image translation technique in order to train the timbre transfer decoder as a Denoising Diffusion Implicit Model (DDIM) [2]. Broadly speaking, DDIMs work by learning how to generate data from noise in a two-part procedure. The first part is denoted as the *forward process*, where Gaussian noise $\gamma \sim \mathcal{N}(0, 1)$ is subsequently added to the input until it is indistinguishable from the former. The second part consists of the *reverse process* where a decoder learns how to invert the forward process, effectively reconstructing data from the noise. DDIMs can be seen as a generalization of DDPMs that shares the same training procedure, however, they differ in the modeling of the reverse process, by using a non-markovian diffusion process, which allows for faster generation times.

3.1.1 Forward Process

Let us define \mathbf{X} and \mathbf{Y} as the log mel spectrograms corresponding to the conditioning and target instruments, respectively. We choose a continuous diffusion time [27–29] in order to be able to change the number of desired sampling steps. If we consider T steps, then the diffusion time can be defined as $t \in \{0, 1\}$, where consecutive times are separated by $\Delta_t = 1/T$. Then, the forward process is defined similarly to the case of DDPMs by subsequently adding noise to the target spectrogram for T steps

$$q(\mathbf{Y}_t | \mathbf{Y}_{t-\Delta_t}) = \mathcal{N}(\mathbf{Y}_t, \sqrt{(\alpha_t)} \mathbf{Y}_{t-\Delta_t}, \beta_t \mathbf{I}),$$

$$q(\mathbf{Y}_{1:T} | \mathbf{Y}_0) = \prod_{t=1}^T q(\mathbf{Y}_{t-\Delta_t}) \quad (1)$$

where α and β are parameters defined by a simplified cosine schedule [30].

3.1.2 Reverse Process

In the case of DDIMs, the reverse diffusion process is operated by introducing an additional distribution p_θ , where a sample $\mathbf{Y}_{t-\Delta_t}$ can be generated from a sample \mathbf{Y}_t as

$$\mathbf{Y}_{t-\Delta_t} = \sqrt{\beta_{t-\Delta_t}} \left(\frac{c - \sqrt{\beta_t} \gamma_\theta^{(t)}(\mathbf{Y}_t, \mathbf{X})}{\sqrt{(\alpha_t)}} \right) + \sqrt{1 - \alpha_{t-\Delta_t} \cdot \gamma_\theta^{(t)}(\mathbf{Y}_t, \mathbf{X})}, \quad (2)$$

, where γ is the noise estimated by a network with parameters θ . The noise at time t $\gamma_\theta^{(t)}$ is estimated by a network that is conditioned also on the input timbre spectrogram \mathbf{X} , similarly to the formulation proposed in Palette [3].

3.1.3 Training Procedure

The denoising process is operated through a U-Net architecture which is conditioned on \mathbf{X} and trained to predict the added noise in order to minimize the L1 loss

$$\mathbb{E} = \|\gamma_\theta^{(t)}(\mathbf{Y}_t, \mathbf{X}) - \gamma\|_1, \quad (3)$$

where γ is the true perturbation, while $\gamma_\theta^{(t)}(\mathbf{Y}_t, \mathbf{X})$ is the estimate of the noise added to the target spectrogram at time t , conditioned on the input spectrogram \mathbf{X} .

3.2 Architecture

The decoder architecture is based on a U-Net model. The building element is made of residual blocks, in each of these the input is processed by (i) a 2D convolutional layer with swish activation, followed by batch normalization and by (ii) a convolutional layer with no activation. Both convolutional layers have kernel size 3. The output of this procedure is then summed with the residual, which is obtained by processing the input with a convolutional layer with kernel size 1.

The encoder part of the network consists of 3 downsampling blocks, each consisting of 4 residual blocks having filter sizes 64, 128, 256. The output of each downsampling block is followed by average pooling, with pool size 2 in order to compress the dimension of the spectrograms. The last block of the encoder is followed a self-attention block.

The bottleneck obtained through the encoder is processed by a residual block with 512 filters and is then processed by the decoder, which is a specular version of the encoder. The only difference lies in the use of transposed convolutions in order to create upsampling layers needed to increase the dimension of the features.

The last downsampling layer of the encoder, the bottleneck and the first upsampling layer of the decoder are followed by self-attention.

3.3 Deployment

The proposed model takes as input spectrograms of a fixed size, therefore audio tracks longer than the ones used for training need to be sliced accordingly.

The decoder takes as input the conditioning spectrogram \mathbf{X} and the diffusion noise and retrieves an estimate of the latter, which can then be subtracted in order to obtain an estimate of the desired output timbre spectrogram $\hat{\mathbf{Y}}$. The output waveform y can then be obtained by feeding the pre-trained SoundStream model with $\hat{\mathbf{Y}}$.

4. EXPERIMENTS

In this section, we describe experiments performed with the aim of demonstrating the capabilities of the proposed DiffTransfer technique both in the single-instrument and multi-instrument application scenarios.

In Fig. 3 we show an example of input, generated and ground-truth spectrograms, obtained via the DiffTransfer model when converting from a Clarinet to Strings.

4.1 Dataset

In order to train the model we considered the StarNet dataset [31], which contains a set of tracks that are played with two timbre-domains, namely strings-piano and vibraphone-clarinet. The dataset consists of roughly 22 hours of audio. We used the reduced version of the dataset,

Figure 2: Deployment scheme of the proposed DiffTransfer technique. The decoder is fed with Gaussian noise and with the conditioning instrument spectrogram. The noise estimate provided by the decoder is then subtracted from the input noise in order to provide an estimate of the desired target spectrogram, from which the audio is estimated via the SoundStream model [20, 26].

where tracks are resampled to 16000 Hz and converted them to mono. In order to perform the evaluation, we use the same ten tracks considered in [13], in order to ease the comparison with their model.

4.2 Techniques Under Comparison

We consider two baselines in order to compare the performances of the proposed DiffTransfer architecture. For what concerns the single-instrument timbre transfer task, we consider the Universal Network [12] fine-tuned on the StarNet dataset as done in [13]. For what concerns the multi-timbre task, we consider the mixture-supervised version of the Music-STAR network proposed in [13]. We perform three different types of timbre transfer tasks: *single*, where only single instruments are converted, *single/mixed* where the separate conversions of single instruments are mixed in order to create the desired mixture track and *mixture*, where the mixture is directly converted. These nomenclatures are used just to ease the presentation of the results, we would like to point out that, for what concerns the DiffTransfer architecture, no specific changes are required for the various types of applications, except for the choice of desired input data.

4.3 Experiment Setup

The Universal Network and Music-STAR architectures are trained with the procedure described in [13]. The DiffTransfer network is trained for 5000 epochs using a batch size of 16, with the AdamW optimizer [32] with learning rate $2e - 5$ and weight decay $1e - 4$. The epoch that minimizes the $L1$ noise prediction loss is chosen in order to retain the model used to compute the results. We train a total of six models, performing the following timbre transfer conversions: vibraphone to piano, piano to vibraphone,

clarinet to strings, strings to clarinet vibraphone/clarinet to piano/strings and piano/strings to vibraphone/clarinet.

The network input features are computed by first applying the Short-Time Fourier Transform (STFT) with a Hann window of size 0.020 s and 50% overlap to normalized audio tracks. Then the log mel spectrogram is computed over 128 bins corresponding to the range of 0 – 16000 Hz. We do not feed the entire audio tracks as input to the network, instead, during each epoch we extract 128 frames from the log mel spectrogram, corresponding to ≈ 2 s. Each spectrogram slice is normalized between -1 and 1 before being given as input to the network and the output spectrograms are denormalized before being fed to the SoundStream model in order to recover the audio waveform. Since the tracks considered for the test are of length 10 s and the model gets as input a fixed 128 frames spectrogram we slice the conditioning spectrogram before feeding into the model and we keep the input noise fixed for all slices, in order to ensure consistency in the generation. All spectrogram slices are normalized in the range $[-1, 1]$ and denormalized before being fed to the SoundStream decoder.

4.4 Objective Evaluation

We evaluate the model objectively in order to analyze the perceptual similarity and content preservation capabilities of the generated tracks with respect to the ground truth audio.

In order to evaluate the perceptual similarity, we compute the Fréchet Audio Distance (FAD) [33] using the VG-Gish embeddings [34], through a PyTorch implementation². FAD is a reference-free metric for music enhance-

² <https://pypi.org/project/frechet-audio-distance/>

Figure 3: Example of Timbre Conversion log mel Spectrograms using the DiffTransfer architecture, obtained when converting Clarinet (a) to Strings (b). The ground truth Strings spectrogram is shown in (c).

ment algorithms, which views the embeddings as a continuous multivariate Gaussian and is computed between the real and generated data as

$$\text{FAD} = \|\mu_r - \mu_g\|^2 + \text{tr}(\Sigma_r + \mu_g - 2\sqrt{\Sigma_r \Sigma_g}), \quad (4)$$

where (μ_r, Σ_r) and (μ_g, Σ_g) are the mean and covariances of the embeddings corresponding to the real and generated data, respectively. Similarly to [20], we compute FAD in order to analyze the perceptual similarity between the generated audios with respect to the ground truth one, corresponding to the original StarNet dataset.

To understand the content-preservation capabilities of the model, following [35], we compute how the pitch contours of generated ground truth audio tracks are dissimilar, by calculating the mismatch between two sets of pitches A and B through the Jaccard Distance

$$\text{JD}(A, B) = 1 - \frac{|A \cap B|}{|A \cup B|}, \quad (5)$$

where a lower value corresponds to a lower mismatch and thus to a higher degree of similarity between the generated pitch contours. Pitch contours are computed using a multi-pitch version of the MELODIA [36] as implemented in the Essentia library [37], rounding pitches to the nearest semitone. We report the values obtained by computing the metrics on the test dataset in Table 1.

Objective Evaluation		
Method	FAD ↓	JD ↓
Universal Network (single)	7.09	0.53
DiffTransfer (single)	2.58	0.28
Universal Network (single/mixed)	10.47	0.64
DiffTransfer (single/mixed)	4.73	0.46
Music-STAR (mixture)	8.93	0.57
DiffTransfer (mixture)	4.37	0.38

Table 1: Objective Evaluation of the proposed DiffTransfer Method compared to the baselines, in terms of Fréchet Audio Distance (FAD) and Jaccard Distance (JD). Results are averaged over all participants and over all the tracks considered for each part of the test.

4.5 Subjective Evaluation

In order to evaluate subjectively the timbre transfer capabilities, we perform a listening test with 18 human participants. The web page of the test is available at ³. The test was split into two parts corresponding to the single and multiple instrument application scenarios, respectively.

During the single instrument part of the test, the users listened to four tracks, corresponding to the four types of conversions performed, namely: clarinet to strings, strings to clarinet, piano to vibraphone, vibraphone to piano. Each example consisted of two conditions, one obtained via the DiffTransfer model and the other through the Universal Network.

In the second part of the test, concerning multiple instrument timbre transfer, a total of four tracks were considered, two for the conversion from vibraphone/strings to piano/strings waveforms and two for the reverse conversion. Each example consisted of four conditions, namely DiffStar (single/mix), Universal Network (single/mix), DiffStar (mixture) and Music-STAR (mixture).

Both the order of conditions and the order of examples in each separate part of the test were randomized.

The participants were asked to rate the conditions in terms of similarity with respect to the reference track on a 5 elements Likert scale where 1 corresponds to bad and 5 to excellent. We report the results obtained through the listening test in Table 2.

4.6 Discussion

By briefly inspecting both the objective and subjective results, reported in Table 1 and 2, respectively, it is clear how the proposed DiffTransfer model outperforms the Universal Network and Music-STAR baselines both for what concerns the single and multiple timbre transfer tasks.

When considering single timbre results, DiffTransfer is able to achieve significantly better performances in terms of FAD, Jaccard Distance and Perceived Similarity, with respect to the Universal network. The gap between the two methods becomes even more evident when considering the

³ <https://listening-test-ismir-ttd.000webhostapp.com/>

Subjective Evaluation	
Method	Similarity
Universal Network (single)	1.82
DiffTransfer (single)	3.68
Universal Network (single/mixed)	1.69
DiffTransfer (single/mixed)	3.78
Music-STAR (mixture)	2.89
DiffTransfer (mixture)	3.80

Table 2: Objective Evaluation of the proposed DiffTransfer Method compared to the baselines, in terms of perceived similarity with respect to the ground truth on a Likert scale from 1 (Bad) to 5 (Excellent). Results are averaged over all test tracks.

single/mixed case, i.e. when single timbre transfer tracks are mixed in order to form the desired mixture audio.

For what concerns the Music-STAR method, the gap with respect to DiffTransfer remains high in terms of FAD, but becomes less noticeable when considering JD and the perceived subjective similarity.

5. CONCLUSION

In this paper, we have presented DiffTransfer a technique for both single- and multi-instrument timbre transfer using Denoising Diffusion Implicit models. The novelty of the proposed approach lies in the fact that in addition to being, to the best of our knowledge, the first application of diffusion models to timbre transfer, it is the first model to be tested in order to perform single and multi-timbre transfer, without varying the architecture depending on which application is chosen. We compared the proposed model with state-of-the-art Universal Network and Music-STAR baselines through both objective evaluation measures and a listening test, demonstrating the better capabilities of the proposed DiffTransfer approach.

Future works will involve increasing the audio quality of the generated audio, by taking into account the consistency of subsequent generated spectrograms. Furthermore, we plan on modifying the model in order to be able to perform unpaired timbre transfer, which greatly eases the dataset requirements and applicability of the technique.

CORRELATION OF EEG RESPONSES REFLECTS STRUCTURAL SIMILARITY OF CHORUSES IN POPULAR MUSIC

ABSTRACT

Music structure analysis is a core topic in Music Information Retrieval and could be advanced through the inclusion of new data modalities. In this study we consider neural correlates of music structure processing using popular music—specifically choruses of Bollywood songs—and the NMED-H electroencephalographic (EEG) dataset. Motivated by recent findings that listeners’ EEG responses correlate when hearing a shared music stimulus, we investigate whether responses correlate not only within single choruses but across pairs of chorus instances as well. We find statistically significant correlations within and across several chorus instances, suggesting that brain responses synchronize across structurally matched music segments even if they are not contextually or acoustically identical. Correlations were only occasionally higher within than across choruses. Our findings advance the state of the art of naturalistic music neuroscience, while also highlighting a novel approach for further studies of music structure analysis and audio understanding more broadly.

1. INTRODUCTION

Music structure analysis (MSA)—the task of dividing and labelling songs into perceptually salient segments [1]—is a core topic of Music Information Retrieval (MIR) and has been approached through a variety of data types including audio representations, lyrics, and perceptual annotations. For example, choruses of popular songs are often easily recognizable by music listeners, and can be detected from audio due to both their placement throughout a song and their intrinsic features [2]. While much progress has been made in this area, there may be new approaches and data modalities that could advance it even further.

MIR studies have come to involve brain data, particularly electroencephalography (EEG) [3]. EEG has been used to predict stimulus labels, decode musical attributes such as beat and tempo, and even reconstruct music. EEG inter-subject correlation (ISC), which captures neural synchronization of audience members experiencing a com-

plex, real-world stimulus [4], has also advanced music neuroscience research. We leverage and extend this approach to investigate MSA.

We focus on responses to four Bollywood songs written in the popular form—specifically their choruses, due to their salience and tendency to repeat with a high degree of similarity. Importantly, while past EEG-ISC studies have considered responses among listeners experiencing the same stimulus (e.g., one chorus instance), we ask for the first time whether neural responses also synchronize *across* instances of structurally similar content (i.e., pairs of choruses). Moreover, by using a dataset containing two response trials from each participant, we can investigate correlations both across and within participants. In sum, we address the following research questions:

RQ 1 *Does music structure similarity translate to measurable similarity among responses?* In other words, do brain responses synchronize across structurally matched musical segments, even when those segments are contextually unique (in their placement within the song) and also often acoustically unique from one another? Here we expect structural similarity to produce statistically significant EEG correlations both within and across a song’s choruses.

RQ 2 *Even if responses are similar across chorus instances, are individual choruses still uniquely experienced?* This question extends RQ1 to investigate whether EEG responses are more correlated within, versus across, chorus instances. We predict that within-chorus EEG correlations will be higher than across-chorus correlations.

RQ 3 *Are a listener’s neural responses more similar to themselves than to responses from other listeners?* Understanding whether reliable measures of music structure similarity can be obtained from single listeners can motivate the design of future studies. We expect EEG correlation with one’s own data will be higher than correlation with the data of other listeners, due to individual differences in perception and EEG characteristics.

We report small but often significant correlations that align with previous published research. Moreover, within-chorus correlations do not systematically outperform across-chorus correlations. While preliminary, our findings suggest that this novel application of EEG correlation may capture structural similarity during music listening, which may motivate future MSA studies.

2. RELATED WORK

2.1 MSA and Chorus Analysis

MSA involves recognizing and labelling non-overlapping musical segments based on musical similarity [1]. Over the years, MSA has come to involve specific features, similarity representations, and algorithms [5]. One sub-topic of MSA is chorus identification; here, choruses have often been identified based on repetition and contextual cues using measures of similarity [6] and Markov models [7], as well as chroma features and image processing filters [8]. Some systems have also used segment length and positioning to identify choruses [6, 8]. Independently of context, Van Balen et al. looked at intrinsic content features that might distinguish choruses [2]. Their “Chorusness” variable, a probability measure of how likely a segment may be labelled as a chorus by an independent annotator, highlights audio features (e.g., higher loudness and roughness) that qualify the particular salience of choruses.

MSA remains a challenging task due, for example, to ambiguities around defining similarity as well as subjectivity and interpretation of annotations [1, 9]. In their 2020 overview article, Nieto et al. called for “richer human labels in upcoming MSA datasets” [1]; we propose that brain data may fit this call.

2.2 MIR and EEG

The growing use of decoding and signal-based approaches and complex, naturalistic (real-world) stimuli in neuroscience has increased that field’s relevance to the more applied field of MIR. Kaneshiro & Dmochowski have suggested that MIR and neuroscience researchers might augment their gains through collaboration, highlighting EEG as a particularly relevant response type for MIR due to its high temporal resolution, non-invasiveness, whole-brain coverage, and relative portability and low cost [3].

EEG studies addressing MIR topics include using classification to predict which stimulus elicited an EEG response [10, 11] or which stream a listener attended to in a polyphonic stimulus [12–15]. Other tasks include EEG-based tempo detection/classification [16–18], onset detection [19], and music reconstruction [20]. EEG has been mapped to time-varying music or audio features using Canonical Correlation Analysis (CCA) [21] or deep-CCA [22]; by correlating EEG with semantic music vectors [23]; or using MEG—the magnetic analogue of EEG—and temporal response functions to decode surprisal [24]. In recent studies, Ofner and Stober examined EEG responses at automated segmentation boundaries [25], and Sangnark et al. performed music preference classification on EEG responses to choruses with and without lyrics [26]. However, we know of no study to date that has assessed *similarity* among EEG responses to repeated structural segments.

2.3 Neural Correlation

A particularly relevant approach for the current study involves the correlation of neural responses to a shared stim-

ulus, often termed inter-subject correlation (ISC). Hasson et al.’s 2004 seminal functional magnetic resonance imaging study showed that real-world stimuli (e.g., movie excerpts) can synchronize neural responses across audience members, and that the timing and location of synchronized activity identifies stimulus-evoked brain activity [27]. This data-driven approach, reducing the need for controlled stimuli and a priori event markers, facilitated the use of complex stimuli in neuroscience. In 2012, Dmochowski et al. introduced an EEG implementation which first optimizes the data for ISC [4]. Often referred to as “Correlated Components Analysis (CorrCA)” [4] or “Reliable Components Analysis (RCA)” [28], this optimization applies a relative eigenvalue decomposition to compute multiple spatial filters in which across-trials variance relative to within-trials variance (i.e., ISC) is maximized.

Recent studies involving music have shown that EEG-ISC is modulated by listener expertise [29], musical tempo [30], temporal stimulus manipulations [30, 31], and salient musical events [31]. Auditory studies have reported small but significant group-mean ISC ($0.01 < r < 0.02$) in RC1, the maximally reliable spatial component. Repetition, explored through repeated listens of full excerpts, sometimes but not always results in lower ISC on repeated listens [29, 30]. However, the topic of repeating structural elements *within* a song has not yet been addressed.

2.4 Music-EEG Datasets

The acquisition and preparation of EEG data for analysis requires specialized expertise and sizeable investments in recording apparatus [3]. A key factor supporting MIR-EEG research is the growing number of open EEG datasets released with the intent for re-use by other researchers. Datasets vary in stimuli, stimulus manipulations, participant samples, listening tasks, additional response types, and EEG platforms used. Shorter stimuli are used in the MIIR dataset, comprising perceived and imagined responses to 12 excerpts 6.9–16.0 seconds in length [32] and the MAD-EEG dataset involving 78 solo, duet, or trio stimuli, each around six seconds long [14]. Datasets involving slightly longer excerpts include the DEAP dataset, with 40 one-minute excerpts from music videos [33]; MUSIN-G, with 12 excerpts, 100–132 seconds in length, from various genres [34]; and NMED-M, containing five-minute excerpts of various versions of a minimalist work [31]. Finally, a few datasets use complete musical works as stimuli: NMED-H includes four Bollywood songs [35], NMED-T uses 10 EDM-style songs [36], and NMED-E includes a cello concerto movement [37].

3. METHODS

3.1 EEG Dataset and Stimuli

Among the available datasets, we chose to work with NMED-H (Naturalistic Music EEG Dataset—Hindi) [35] as it used full-length pop (Bollywood) songs with repeating choruses as stimuli. Specifically, we work with the four “Intact” songs of the dataset: “Ainvaiy Ainvaiy”, “Daaru

Figure 1. Analysis overview. The NMED-H dataset contains EEG responses recorded while 48 participants listened to four full-length Bollywood songs. We used RCA to compute a spatial EEG component in which ISC was maximized, and used the stimulus audio and lyrics to identify chorus segmentation boundaries to further epoch the EEG. For each song, correlations were performed within and across choruses, as well as between choruses and segments epoched at random.

Desi”, “Haule Haule”, and “Malang”. Each song is around 4 min 30 sec in length and contains between 3 and 5 choruses as illustrated in color in Fig. 1. The stimuli were assumed to be new to the participants, who did not understand the Hindi-dialect song lyrics. We used the pre-processed, 125-channel EEG data sampled at 125 Hz with average reference; each song contained 24 trials from 12 unique participants (48 participants total) as each participant had listened to their assigned song twice.

3.2 EEG Analyses

To analyze the EEG, we followed an established procedure of spatial filtering followed by correlation calculations (Fig. 1). We used a publicly available RCA implementation¹ to compute a single spatial filter across all four songs. We computed RCA across entire song durations and not just chorus segments, as our permutation testing procedure involved segments sampled from throughout each song (see § 3.3). We then analyzed the vectorized form of single EEG trials from only the maximally reliable component RC1, as previous studies have shown that that component explains most of the ISC in EEG responses to music [30, 31]. Thus, the response data for each song was a time-by-trial matrix, with 24 trials from 12 participants for each song and a variable number of time samples per song.

To identify and segment song choruses, we first identified structural segment boundaries at the measure level using lyrics.² Next, we used a publicly available beat-tracking algorithm [38] to identify audio sample indices of the boundaries and converted those time stamps to the sampling rate of the EEG to segment the EEG accordingly.

Correlations were performed on a per-song basis, in two broad categories. *Within-chorus correlations* involved pairwise correlations among response trials from a single chorus instance, producing a symmetric matrix whose diagonal (being 1) was excluded from further analysis. *Across-chorus correlations* involved the cross-correlation of two matrices, each representing a different chorus instance. These correlations produced asymmetric matrices, since no response vector was ever correlated with itself.

Each correlation also involved both *intra*-subject correlations (IaSC) of non-identical trials from the same participant and *inter*-subject correlations (ISC) of trials from different participants. As illustrated in Fig. 2, with 24 trials per song comprising two listens from each of 12 participants, within-chorus correlations produced for each participant one IaSC value (first listen and second listen) and 22 ISC values, excluding the diagonal. Across-chorus correlations produced for each participant four IaSC values (reflecting two distinct chorus instances \times two distinct listens) and 88 ISC values. For each calculation, we computed mean correlations at the participant as well as the group level.

3.3 Statistical Analyses

We assessed statistical significance over distributions of per-participant results ($N = 12$). For RQ1 we used permutation testing: Each analysis was performed over 1000 pairs of segments of the same length as the true chorus segments, but with one segment epoched from a random start time in the song. The 1000 results served as the null distribution against which we compared the true result to compute the p-value. For RQ2 and RQ3 we used nonparametric Wilcoxon signed-rank tests to account for variable standard deviations of the sampling distributions caused by the discrepancy in the number of samples in each group (i.e., IaSC versus ISC; within- versus across-chorus). We performed one-sided tests in accordance with our expected results (RQ2 H_1 : *within* > *across*; RQ3 H_1 : $I_aSC > ISC$). We corrected for multiple comparisons using False Discovery Rate [39] on a per-song basis for RQ1 and RQ3 and on a per-song, per-condition basis for RQ2. We report statistically significant results (‘***’, ‘**’) and also indicate but do not summarize marginally significant results (‘*’) for this first exploratory analysis.

4. RESULTS

4.1 Individual Correlations

We correlated vectors of spatially filtered, single-trial EEG on a per-song basis, both among responses to single choruses as well as across pairs of different choruses. The re-

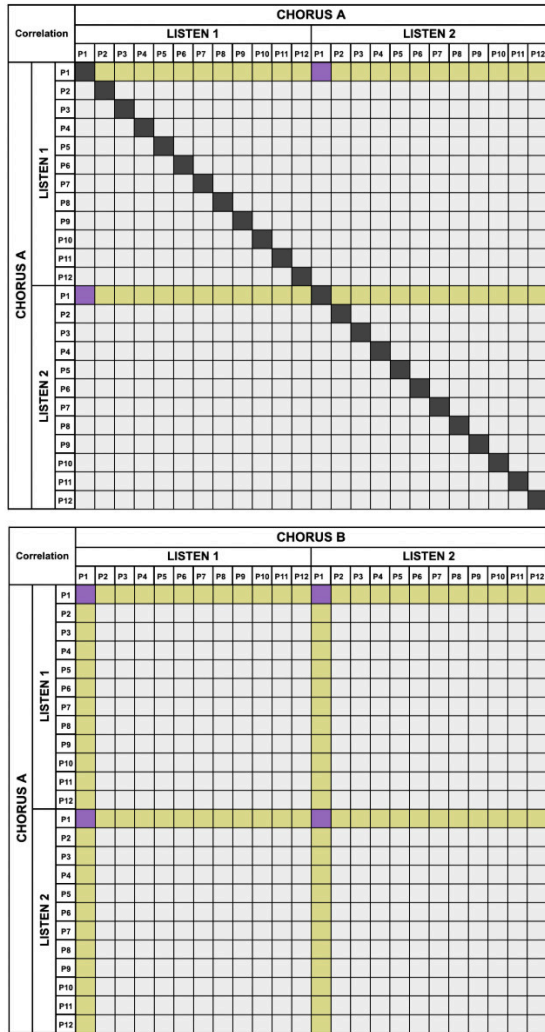

Figure 2. Illustration of IaSC and ISC matrix elements for Participant 1 of 12; each participant heard their assigned stimulus twice. **Top:** Within-chorus correlation produces a symmetric 24×24 matrix. The same IaSC correlation appears twice (purple), along with 22 unique ISC correlations (yellow). **Bottom:** Across-chorus correlation produces an asymmetric matrix with four unique IaSC correlations (2 choruses \times 2 listens) and 88 unique ISC correlations.

sulting correlation matrices could then be partitioned into correlations from the same participant (IaSC) and different participants (ISC). Results are visualized in Fig. 3 and provided numerically in Tab. 1. After multiple comparison correction, 10 of 15 within-chorus IaSC and 2 of 22 across-chorus IaSC were statistically significant (“**” or “***”). For ISC, 14 of 15 within-chorus calculations and 12 of 22 across-chorus correlations were significant. IaSC distributions tended to have larger variance than ISC distributions, both at the participant level for single analyses (Fig. 3) and across the group means (Tab. 1).

4.2 Within- versus Across-Section Correlations

We assessed whether within-chorus correlations— involving identical musical content and context—were higher than across-chorus correlations, which are struc-

turally similar but not identical. Tab. 2 summarizes the statistical significance of each comparison. After correcting for multiple comparisons, within-chorus IaSC was found to exceed across-chorus IaSC 7 times, while within-chorus ISC was higher than across-chorus ISC 4 times. Significant (and marginally significant) results most often implicated the first chorus of a song.

4.3 Intra- versus Inter-Subject Correlation

For our last analysis, we assessed whether IaSC—being computed from the same listener’s data—would exceed ISC. Contrary to our expectations, one-sided Wilcoxon signed-rank tests revealed that after multiple comparison correction, IaSC did not exceed ISC for any within- or across-chorus correlation.

5. DISCUSSION

MSA has leveraged various representations—e.g., audio, lyrics, human annotations—to model human perception of musical structure. In this study we have answered the call for new forms of human response data to inform this task [1] and explored perception of repeated structure segments using brain data. Specifically, we assessed whether EEG responses to repeating choruses of four Bollywood songs were significantly correlated.

We found that EEG responses within and across choruses of a song were often significantly correlated, particularly for ISC. While small, these ISCs are on par with those reported in previous auditory EEG studies [30,31,40]. Correlating across choruses contrasts with past ISC research, which considered correlation only among responses to a single stimulus. That precedent may be due to those studies using predominantly narrative stimuli, such as movies or speeches, which generally do not include repeated segments. But for music, repetition is often integral to structure, from brief melodic motifs to large-scale elements [41]. The present use of ISC to assess music structure similarity is also a departure from its previous application to index brain states of attention and “engagement” in relation to attributes of stimuli (e.g., narrative tension, temporal coherence) [4, 30, 31] or participants (e.g., trained versus untrained musicians) [29]. Future research could consider data from spatial components beyond RC1 and further explore relationships between EEG correlation, music structure, and repetition to index both content similarity and listener engagement with repeated content.

We found that within-chorus correlation occasionally but not consistently exceeded across-chorus correlation; future research is needed to elucidate the role of acoustical or contextual differences across chorus instances in this result. Notably, within-chorus correlation most often exceeded across-chorus correlation in a song’s first chorus. Past studies have shown that EEG-ISC often drops upon repeated exposures to full stimuli [4, 29, 30], and music-discovery engagement has been shown to be highest for first choruses compared to subsequent instances [42]. While this might lead one to expect higher ISC during

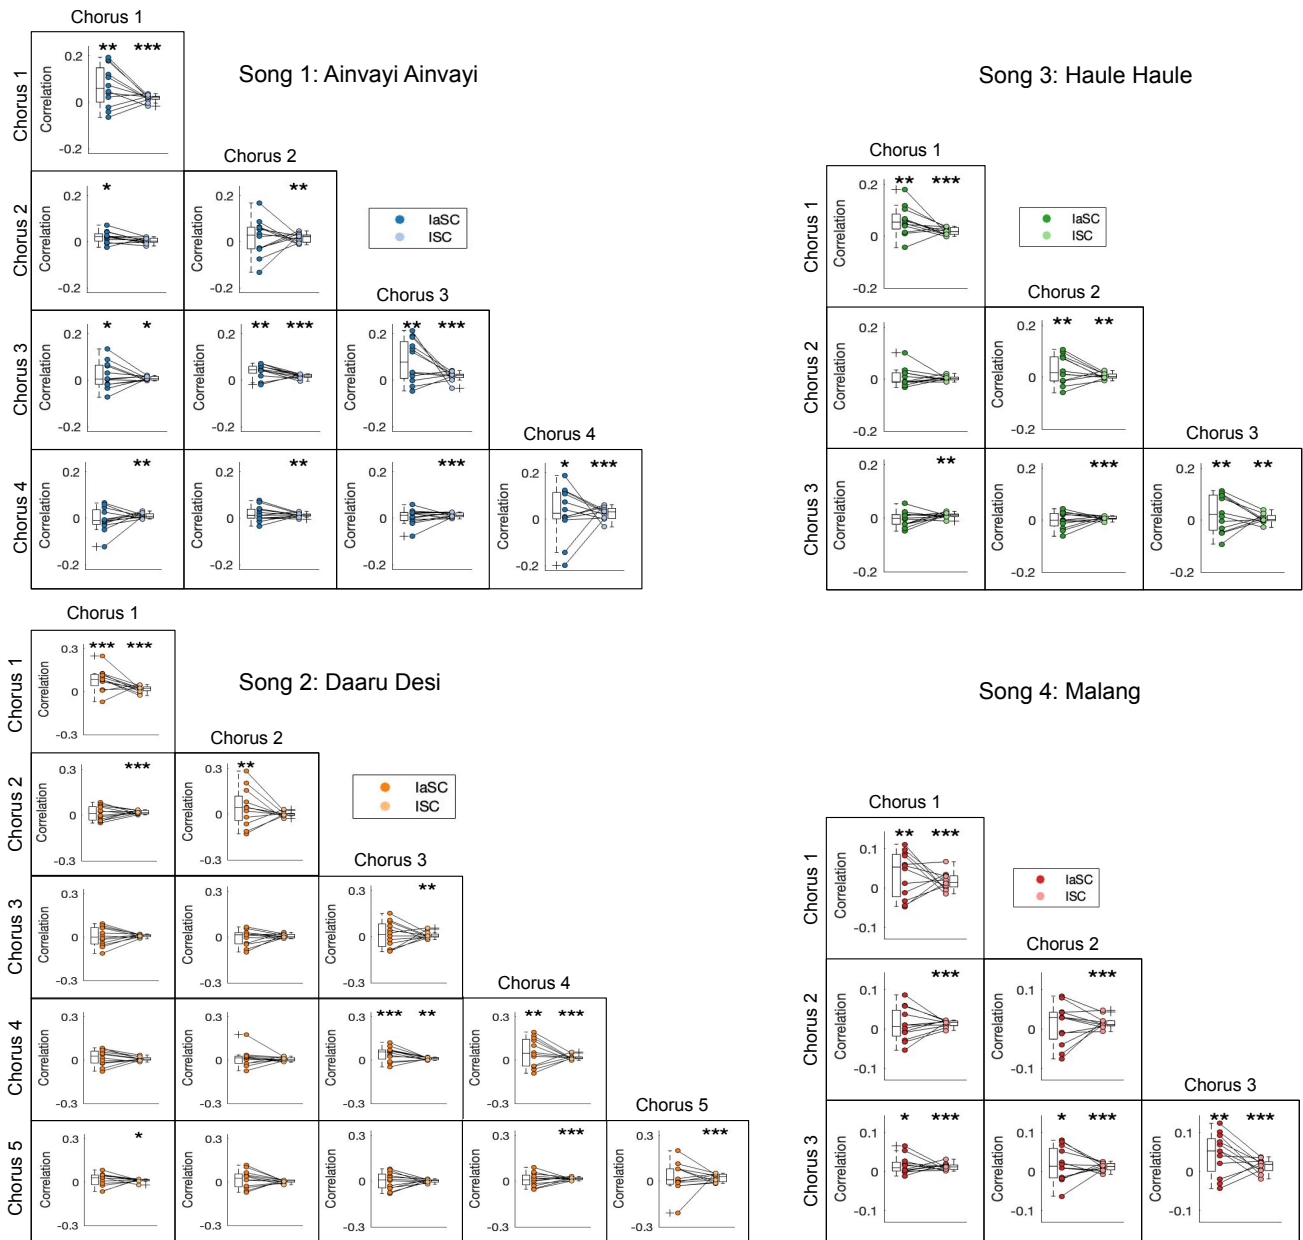

Figure 3. EEG correlations within and across choruses of four Bollywood songs. Each plot shows a distribution of intra- (IaSC) and inter- (ISC) subject correlation values across the 12 participants assigned to that song. Statistical significance of each correlation is denoted as $p = 0$ *** 0.01 ** 0.05 * 0.10 for FDR-corrected p-values.

the first chorus, current results do not suggest that within-chorus correlation drops as a song progresses. However, it may be that listeners have a unique perceptual experience of first choruses relative to other choruses.

Our expectation that IaSC would exceed ISC was not supported by the data. The large variance of IaSC relative to ISC, and greater number of significant ISC results despite lower group means, suggests that ISC ultimately provided a more stable estimate of neural correlation. Whether this is due to IaSC comprising fewer correlations, or an advantage of correlating across a heterogeneous sample of listeners, can be further investigated to inform future study designs.

This study contributes a first step toward using EEG data for MSA. While we focused on establishing similar-

ity of neural responses among pre-identified repeating segments, and not detection of repeated segments or segment boundaries, our findings lay a foundation for multiple avenues of future work. For instance, a multimodal MSA framework could incorporate EEG measures of similarity alongside music content representations and human annotations. Other EEG-ISC analysis configurations may also prove useful for MSA: For instance, Dauer et al.’s finding that ISC computed over short time windows peaked during salient musical events including structural segment boundaries [31] is worth exploring further. Returning, too, to established connections between ISC and engagement, using ISC to identify highly engaging portions of songs could inform audio thumbnailing. Finally, while the present work leveraged an existing dataset, future studies could be de-

signed to address specific MSA questions with newly collected EEG data. In all, we do not propose that EEG should or could replace existing data modalities for MSA, but rather highlight potential insights from EEG that may complement other existing approaches and inputs.

5.1 Limitations

We acknowledge limitations of this work. First, while we report multiple significant results, they do not imply generalizability: The correlations are small, and our findings—while promising—are not conclusive across all calculations. Next, we chose NMED-H as a ready-to-use EEG dataset of responses to popular songs containing repeated choruses. But the small stimulus set of four songs also hinders generalization, and future confirmatory studies should

utilize a larger song set. We note that the original design of NMED-H specified that participants not be familiar with the songs or the language of their lyrics [35]. This too may limit generalizability, as more familiar or lyrically understandable songs may result in different EEG correlations.

Another main limitation is that while the song choruses crucially elicited the EEG data, they were only treated as repeating segments, and we did not consider nuances of placement or content attributes of individual choruses. Yet such features are known to impact perceptual and neural responses to choruses [26]. Thus, future research should consider finer-grained characterizations of music segments treated as structurally similar. One concrete next step could involve cross-modal comparisons of music similarity—for instance, whether similarity measures derived from audio, lyrics, or human annotations predict neural similarity.

Lastly, we trained RCA once over all available trials. Future work should incorporate cross-validation—iteratively optimizing the RCA spatial filter on training data and then applying it to holdout test trials—into the analysis pipeline to avoid overfitting.

6. CONCLUSION

MSA is an MIR topic with rich applications in audio thumbnailing, motif-finding, music summarization, music recommendation, and automatic music generation. Aiming to expand the scope of data modalities that may inform this task, we have contributed a first look at structural repetition using brain data. We used a publicly available EEG dataset and analyzed single-trial responses to choruses from four Bollywood pop songs by computing intra- and inter-subject correlations within and across choruses. We find that neural responses do often synchronize to a significant extent, which suggests that similarity among repeated choruses may translate to neural similarity. These findings motivate future studies of music similarity perception and highlight EEG data as a promising input to multi-modal MSA systems.

CHROMATIC CHORDS IN THEORY AND PRACTICE

Mark R. H. Gotham
Durham University

ABSTRACT

‘Chromatic harmony’ is seen as a fundamental part of (extended) tonal music in the Western classical tradition (c.1700–1900). It routinely features in core curricula. Yet even in this globalised and data-driven age, 1) there are significant gaps between how different national ‘schools’ identify important chords and progressions, label them, and shape the corresponding curricula; 2) even many common terms lack robust definition; and 3) empirical evidence rarely features, even in discussions about ‘typical’, ‘representative’ practice. This paper addresses those three considerations by: 1) comparing English- and German-speaking traditions as an example of this divergence; 2) proposing a framework for defining common terms where that is lacking; and 3) surveying the actual usage of these chromatic chord categories using a *computational* corpus study of *human* harmonic analyses.

1. INTRODUCTION

Different traditions for teaching music theory come with divergent terminology. These gaps often correspond to national trends (or ‘schools’) and to the different languages used. As always with language, these gaps can take several forms. Some terms may be *shared* by the two languages, so no translation is needed. Other times, a term is present *in one language only*; this inclusion may indicate an importance for the term/concept on one side of this divide and not the other. More complex still, two languages may have some terms with *partially overlapping* meaning.

There are significant gaps between English- and German-speaking terminology for chromatic harmony, despite so much shared historical heritage. Even the distinction of ‘chromatic’ from ‘diatonic’ betrays an English-language stance. Section §1.1 introduces something of a frame for this comparison and §2 discusses three interesting case-studies of ‘canonical’ terms. The focus is on chords that are either *intrinsically* chromatic (Augmented Sixths, §2.2), or chromatic against their diatonic *context* (Neapolitan Sixths, §2.1; Modal Mixture, §2.3). We leave to one side what is sometimes called ‘functional chromaticism’ (the ‘secondary’/‘applied’ chords involved in tonicisation/modulation – see [1, Part 5]) though the final section (§5) briefly considers some relevant chord *progressions*.

Figure 1. A ‘Tonnetz’ diagram of tonal space. Major and minor triads in the key of *C major* are grey; those in *C (natural) minor* are in blue, and the ‘Neapolitan’ is purple.

Moreover, a closer look reveals that even some of the apparently core concepts in chromatic harmony are only vaguely defined. For example, although ‘modal mixture’ is common (at least in US-English music theory), no source sets out comprehensive criteria for inclusion in this category. Section §3 addresses this, seeking to establish not so much a single, definitive answer, but a *framework* to deal with the various issues involved.

Finally, having established the (range) of terms that German- and English-speaking scholars elevate as important, and clarified the meaning of some, §4 provides an initial overview of the relative *usage* of these chords in the ‘When in Rome’ repository: a meta-corpus of all Roman numeral analyses that human annotators have encoded in computational formats [2]. In doing so, we gain insight into how common these chords are, at least in the repertoires covered and the view of those human analysts.

Clearly, sheer *usage* is not the only relevant consideration for the *significance* of a chordal category — many subjects are interesting partly because of their rarity. In any case, all such discussions, and any claims about ‘general practice’, need a basis in this kind of empirical evidence. The clarity that evidence brings may prompt a review of our existing practice (how we categorise these chords, and/or how much time we devote to them in our curricula and wider musical practice). It may also clarify the extent to which that attention is based on the frequency of occurrence as opposed to some other factor, like how *explainable* the concept is in terms of a particular theory.

1.1 Textbooks, Terminology, and Tradition

We begin with that slippery notion of a ‘tradition’. While it is hard to pin down exactly what this means in practice,¹ the contents of widely circulated textbooks provide

¹ For more on the question of ‘representativeness’, see [3].

one kind of insight into what is ‘typically taught and commonly known’ in a given context. Among the issues here is the privileging of contexts in which textbooks are common (broadly speaking, the US), and lack of sensitivity to more flexibly amassed materials, particularly in a changing world with ever more materials shared ever more accessibly online.² Then again, many of these online materials and apps continue to reflect what is described here in terms of textbooks. And I implicate myself in this: see, for example, the chapter listings and content of the ‘Open Music Theory’ (OMT) textbook [5] which (incidentally) serves throughout this paper as a go-to resource for further reading, with links to relevant chapters provided.

1.1.1 English-language (hereafter ‘Anglophone’)

On the Anglophone side we benefit from two surveys of the ‘core curriculum’ in American music theory teaching, including information about the textbooks typically used [6, 7]. The more recent of these surveys finds that 91.89% (238/259) respondents include ‘Chromatic harmony’ in their core curriculum (see Table IV-1), with 1 or 2 semesters being the ‘most commonly reported lengths of time for teaching’ this content (p.202, Table IV-9), and that 79.92% use textbooks/anthologies (Table IV-10).

These surveys also appear to indicate that the preference for *which* textbook to use changes quickly,³ but that *what* those textbooks cover remains largely the same: they consistently cover the same canonical collection including at least the so-called ‘Neapolitan sixths’, ‘Augmented sixths’, and ‘Modal Mixture’.⁴

Click on those terms above for OMT chapters about them, and click here for a summary of these chords in a musical score that you can view, play and more online (no login required). That rendering is relatively typical of the simple, purportedly ‘prototypical’ ways these chords are set out in textbooks. (Naturally, we will discuss here just how prototypical they really are.)

1.1.2 German-language (hereafter ‘DACH’)

As no equivalent survey existed for the DACH side,⁵ we conducted one anew in mid-2022.⁶ Specifically, we asked anyone teaching chromatic harmony at a German-speaking tertiary education institution to answer basic questions about the textbooks and terminology they know and use. Please refer to that study for a thorough report on the method and results of the survey. This paper refers to only the most salient results as relevant for present purposes, as discussed in the following sections.

² On the growing adoption of technological alternatives see the ‘What Do Musicologists Do All Day’ (WDMAD) surveys (2014-15, [4] and 2021-22, forthcoming) which investigate ‘the use of technology in the work of music researchers in the widest sense’ (including teaching).

³ I.e., there is little overlap between the 2000 and 2017 results.

⁴ Increasingly, many also refer to the common-tone diminished sevenths, (for which see §5) though they often package this more deeply e.g., within the ‘Rise of Symmetrical Harmony in Tonal Music’ [1].

⁵ ‘DACH’ is an abbreviation/acronym for Germany, Austria and Switzerland. These are the main areas of German-speaking today and where all the institutions approached for the survey are situated.

⁶ The written report is forthcoming (Feilen, Schnauss and Gotham).

2. THREE CANONICAL CATEGORIES

2.1 Similar usage: the ‘Neapolitan sixth’

The ‘Neapolitan sixth’ appears routinely in both languages. It is interesting to note the status of this chord in relation to the *Funktions-* and *Stufentheorie* approaches to harmony which capture much of the core divide between DACH and Anglophone approaches (respectively).

The Neapolitan can be seen as a simple, one-semi-tone modification to the minor subdominant.⁷ In *Funktions-* *theorie*, such small transformations typically indicate close harmonic relations, leading to maps of tonal space like the *Tonnetz* of figure 1 which shows how the Neapolitan sits alongside diatonic chords, especially in minor.⁸ (We will return to the minor-specific aspect *in practice* in §4). *Stufentheorie*, by contrast, typically describes the Neapolitan in terms of a modification of the second degree (bII^6). This is clearly relegated to a subsidiary position, a ‘chromatic’ chord outside the main, ‘diatonic’ set.⁹

Notwithstanding the different theoretical frames, the Neapolitan presents relative close Anglophone-DACH agreement: not only is there agreement on which pitches are involved, but both typically relate this chord to the ‘subdominant’ (both), or more loosely to ‘predominant’ function (Anglophone). Despite the Anglophone notion of bII^6 , the close relation to ‘iv’ (‘s’) is often emphasised, and likewise it is common in DACH to eschew the possible *Funktions-*only explanation in favour of the symbol s^n that further emphasises the proximity to the subdominant.

Anglophone and DACH traditions also share most of the definitional incompleteness, notably terms of whether to admit: other *inversions* (e.g., 53) and other *tones* (e.g., seventh chords such as 653). DACH theory often *does* admit the 53 configuration of this chord, and reserves a special name for it: the *verselbständigter*. It is noteworthy that, despite being rather sparing in its use of special terms for individual chords, DACH considers the Neapolitan worthy not only of one term, but two.¹⁰ Both Anglophone and DACH theories lack an explicit consensus on whether the Neapolitan may have a seventh.

2.2 Divergent terms: Augmented-sixth chords

The Anglophone convention for teaching Augmented-sixth chords identifies (at least) three forms that have been given spurious national labels: the ‘Italian sixth’ (63), the ‘French’ (643), and the ‘German’ (653). Those labels seem

⁷ This can be viewed as the *Mollsubdominantgegenklang* (sG), though see the following text on s^n . The *-gegenklang* transformation is the same as the *-gegenparallel* and better known in Anglophone contexts as the *leittonwechsel* or ‘leading-tone exchange’.

⁸ Although this common visual analogy for tonal ‘space’ is familiar to Anglophone music theory, is much more closely related to the *Funktions-* *mentality*. The earliest, recognisable form seems to be from Euler [8] (yes, the mathematician) but the best known exposition of this idea and ‘space’ is that of Riemann [9] (no, not the mathematician).

⁹ DACH can also express this chromatic alteration (*hoch-* and *tief-* *alterierte*), but usually does so a last resort where other theory fails.

¹⁰ One of the earliest recorded Anglophone uses of this term treats a middle line in which the chord is explicitly built on the subdominant scale degree (‘Fa’, i.e., 4) and ‘is never inverted’, apparently meaning that, unusually, this 63 form is not to be considered ‘inverted’ [10].

to have originally been proposed (c.1800) based on their usage in the repertoire. For example, [11] explicitly links these chords to the music of those nations.¹¹

Leaving until §4 the question of whether these national labels have anything to do with repertoire usage, there is an Anglophone/DACH division in the terms themselves which may perhaps be telling. DACH emphasises a single category for which the recognised term is *übermäßiger Quintsextakkord*. This explicitly refers to the 653 form — the one that Anglophone theory calls the ‘German’ sixth.

This also indicates opposing ways of handling augmented sixth chord categories: Anglophone traditions not only use 3 categories, but tend to start with the ‘Italian’ (63) as the prototype (at least in the pedagogical sense) and then *add* tones to build the French (643) and German (653); DACH, by contrast, starts with the 653 and would need to *remove or modify* from there.¹²

These differences aside, there is broad Anglophone-DACH agreement on the composition of the chords. The eponymous augmented sixth interval is needed (and spelt as such), and there is a strong focus on both the *inversion* that sees the lower note of that interval in the bass and the *voice-leading* whereby this interval expands ‘out’ to a perfect octave on the dominant (♯5).

2.3 Anglophone only: ‘Modal Mixture’

Most Anglophone textbooks offer a short definition of ‘modal mixture’ (a.k.a. ‘borrowing’) as the use of a chord that is not diatonic in the key specified, but would be in the parallel (German: *variant*) major / minor and can therefore be thought of as a ‘mixture’ of major and minor modes, or a ‘borrowing’ from the one to the other. Some coverage of this topic is present in all the Anglophone textbooks surveyed, usually with a dedicated chapter.

No DACH equivalent appears in German textbooks. Equivalents do sporadically appear in DACH analysis scholarship with terms such as *Dur-moll-Austauschbarkeit*, (or simply *Austauschbarkeit*, literally ‘exchange’), but this term cannot be assumed knowledge in the classroom or beyond.¹³

Despite the ubiquity of the term ‘mixture’ in Anglophone textbooks, it is particularly under-defined and never fully unpacked to account for all in-/exclusions. This is perhaps understandable in a pedagogical context where the increased clarity must be weighted against the corresponding complexity, but as a field, we clearly need a framework for robust definition. The following, dedicated section §3 provides such a framework.

¹¹ Callcott appears to have inherited the term ‘Italian’, noting that it ‘has been termed’ the Italian. There’s no direct reference, though nearby mention of Rousseau suggests that may be at least one of his sources. Callcott seems to introduce the other two ‘nationalities’.

¹² Click here for a modern, online example of this DACH pattern, and see also Biamonte’s account of this chord, including DACH sources dating back to Marpurg 1755 [12].

¹³ Incidentally, it is not self-evident that this ‘mixture’ is indeed a mixture of distinct parts, as opposed to a unified entity. For instance, another school of thought (historically of German-origin, now more common in Russian music theory) sees the major mode with b6 as a single ‘harmonic major’ scale. See [13] for the progress of this idea from Hauptmann, via Iogansen, Liadov, and Rimsky-Korsakov to modern Russian theory.

3. DEFINING MODAL MIXTURE

In a major context, the subdominant is also major (‘IV’ or ‘S’). Probably the most common chord identified in terms of modal mixture is the minor variant of this subdominant (‘iv’ or ‘s’). So in C major, for example, we would have <F-A \flat -C> in place of <F-A-C>.

But what if this mixture chord had a seventh, so not simply <F-A \flat -C>, but <F-A \flat -C-E \flat >, or <F-A \flat -C-E>? The first case, <F-A \flat -C-E \flat > seems like a very good candidate: the additional borrowing from the minor of E \flat further strengthens the case for mixture. The same can’t be said for <F-A \flat -C-E> as E belongs to C major exclusively and arguably counts *against* the notion of mixture.¹⁴ So **should cases of clear non-mixture be excluded?**

If we admit the <F-A \flat -C-E> as a case of modal mixture, then what do we have to say about the case of <F-A-C-E \flat >? Is that equivalent? Now the E \flat is borrowed, but the A is arguably not depending on the type of minor mode. **What minor form are we talking about when we speak of mixture?** Some accounts seem to hint at the natural minor, but then every raised leading-tone chord (V, V7, viio, ...) would count as cases of mixture in minor.

Should the case of <F-A-C-E \flat > depend on whether it is cast as IV \flat 7 or as V \flat VII? That is, **should secondary/applied chords be handled differently** as a case of ‘functional’ chromaticism or (put another way) as diatonic elements in a new key area? Does this depend on whether that secondary tonality is realised by a subsequent **tonicisation or modulation**? This question opens a second set of possible criteria: in addition to questions about the chord’s *content*, we now must also consider its *context*.

Speaking of context, **does the so-called ‘Picardy Third’ count?**¹⁵ And arguably related to both content and context, (and certainly relevant to applied chords) is the question: **does pitch spelling matter?** Were our <F-A-C-E \flat > chord spelt as <F-A-C-D \sharp >, apart from potentially leading analysts to describe it differently, should that spelling itself have a bearing on the status of mixture? Is the minor third mixed only when spelt as such, or is it to be handled as a pitch class, and thus admitting the enharmonic equivalent of a raised second degree (♯2)?

Altogether, these musical questions capture something of the ambiguity in defining modal mixture, and the need for greater clarity in what ‘counts’. They also suggest the need to create a *framework* for category membership, rather than clear-cut rules applicable in all contexts.

Realising this, functionality at ‘When in Rome’ enables user-defined answers to any of the questions raised above, while also providing default settings and proposing a system for grading the *relative* strength of mixture, both in terms of the chord *content* and of the surrounding chord *context*.

¹⁴ Note we are talking specifically about how relatively *mixed* these chords are, not how *chromatic*.

¹⁵ This term stands for the practice of ending a minor key passage with a major tonic as the final chord. (Click here for the modal mixture chapter of OMT, including an example of the ‘Picardy Third’.) It is extremely common, at least in some repertoire contexts.

3.1 Which pitches, which minor?

In working towards a relative gradation of mixture (which may be paired with strict requirements/exclusions), we begin with an account of how *each pitch* can add to or detract from the mixture status. This necessarily also involves the question of ‘which minor’, a conundrum which often complicates matters of definition in tonal music.

Many definitions of modal mixture restrict themselves to natural minor specifically (minor $\hat{6}$ and $\hat{7}$), yet they do not describe V in minor as a mixture, despite the raised $\hat{7}$ clearly belonging to major and not the chosen minor form. Tones’ mixture status can be organised in a few categories: *clearly* indicative of one mode and not the other; *possible* indication of mixture; and *neutral/shared*. The following categorisation is logically guided, but only one (set of) opinion(s). Users of this framework are free to re-allocate the status of these pitches (within reason).

3.1.1 Clear (non-)mixture: m3, M3, m6

Tones strongly indicate (non-)mixture when they clearly belong in either the host mode or the parallel mode but not both. The clearest example is scale degree $\hat{3}$. The minor third (m3) is a clear case of mixture when it appears in major (hereafter min→maj mixture) and non-mixture when in minor. Likewise, vice versa, for the major M3: this is a clear case of mixture in minor (hereafter maj→min) and non-mixture in major. (Again, these comments are separate from the *context* caveats discussed elsewhere, e.g., concerning the ‘Picardy Third’.)

The minor sixth (m6) in major is almost as clear: it is not in the major scale and does belong to both natural and harmonic minors, as well as the descending melodic minor form. Only the ascending melodic minor misses this pitch. When in Rome defaults suggest the inclusion of m6 as a case of *clear* mixture, in the definition framework, while enabling theorists to categorise it instead as a case of *possible* mixture if they prefer for a specific repertoire/task.

3.1.2 Possible mixture: M6, m7, M7

Some tones offer a lower level of *possible* mixture due to their considerably more ambiguous status. When in Rome proposes the major sixth degree (M6) for this category as it is more strongly associated with major, though it can be reached in one melodic minor form (ascending). M6 may therefore indicate *possible* maj→min mixture.

Likewise, the minor seventh degree (m7) may indicate min→maj mixture: it does not feature in major, but it is also not as strongly indicative of minor mode as m6 is, appearing only in natural and descending melodic forms.

Finally, as discussed, the major seventh degree (M7) arguably indicates maj→min mixture, though raised leading-tones are too common in tonal music to support this as a chromatic category.

3.1.3 Neutral (1, 2, 4, 5) and ‘chromatic’ ($\sharp 1$, $\sharp 4$)

Neutral tones belong to both major and minor forms equally. This group includes scale degrees 1, 2, 4, and 5 along with any tones excluded from the above categories.

That leaves tones which may be called ‘chromatic’ in the sense that they do not belong to either mode. We can confidently populate this category with degrees $\sharp 1$ and $\sharp 4$. If the user asserts that spelling matters, then the chromatic category also hosts enharmonics (like $\sharp 2$, discussed above).

3.2 Metrics and/or Categories

If we accept the notion some chords are more strongly indicative of mixture than others, largely because of the relative status of the tones, then we may wish to explicitly weight that relative strength, note by note. For example, *clearly* mixed tones might attract twice the weight (2) of *possible* mixture (1), with *neutral* values at 0. *Chromatic* tones are perhaps the most ambiguous. When in Rome defaults to a value of -1 , because their clearly chromatic status often detracts from their candidacy for mixture.

For instance, to return to the above example cases of min→maj mixture: the strength of mixtures like $\flat VI$, $\flat VII$, and $iv7$ derives from that fact that they all feature the m6 and m3, and all avoid any detractors. The weighting values above would grade each of these at 4, twice the strength of chords like iv with only the m6 (no m3, but also no detractors) at 2. The pros and cons of an ambiguous chords combining m6 and M3 would effectively balance out.

One asset of this weighting-by-tone metric is its flexibility: it enables any chord to be assessed, including modifications like added/altered tones, and it can handle the enharmonic question separately. Context can be handled either categorically (e.g., excluding all secondaries) and/or with further weightings. For instance, the status of mixture may be enhanced when it is bookended by clearly *non-mixed* chords as in I-iv-I (T-s-T). Again, see ‘When in Rome’ for a demonstration.

4. IN PRACTICE (CORPUS STUDY)

All of the above discussion – ‘national’ category variants, graded definitions, and more – would benefit from comparison with the actual usage in practice. For instance, if a chord is *not* commonly used in a particular style but *is* commonly taught in courses purporting to represent that style, then we need to be clear on the reasons why.

Part of the difficulty of establishing robust definitions of the chords above comes from the fact that a robust definition of the ‘chord’ itself is challenging. Western classical notation includes information about which *pitches* to play, and when, but has no explicit statements on how they connect as *chords*.¹⁶ It differs in this (and other) respects from leadsheets, for example, where it *is* typical to include chord symbols.¹⁷ While many explicit algorithms for automatic harmonic analysis have been proposed, none really approaches the quality of a human expert. And arguably the best automatic analysis systems to have emerged in recent years are those based on machine learning, which derive, in turn, learns from the *computer* encodings of *human* expert analyses discussed here [14].

¹⁶ Baroque figured bass is arguably a partial exception: given the bass note and figuring, you have something like a chordal analysis.

¹⁷ Though they are not key-relative like Roman numerals.

The assessment of chordal usage ‘in practice’ here is based on that data, and specifically the ‘When in Rome’ repository, which provides a synthesis of all those *computer* encodings of *human* analyses for Western classical music using Roman numerals.

As with all analysis, this is inherently subjective; while the score source material may have editorial ambiguities that evade the notion of ‘ground truth’, this is all the more so in analytical commentary on that source. Then again, the harmonic analyses are our subject of interest, and so this subjectivity is not only inevitable, but also desirable.

Once the analyses have been encoded in a suitable format (legible to human and machine alike), although there are still operational decisions to make, the process of extracting them is readily implemented and interpreted. The operational decisions include filters for more or less detailed versions of the chords used as best befits the research question at hand. For example, it is sometimes necessary to *retain* inversion information, while at other times it is best to report on aggregated data *excluding* inversion.

Every such option is fully, openly implemented in extensively documented and tested code at ‘When in Rome’ to allow maximum re-use and adaptation for future research. Moreover, that repository presents the percentage usage per basic chord type in dedicated files, separated both by sub-corpus and for major-*versus*-minor contexts.

From this alone, we can assess the relative usage of our ‘canonical’ chords. Any such survey highlights the extreme predominance of basic tonic and dominant function chords (c.75% of the total). Chromatic chords are certainly marginal in relation to this, but we are more concerned here with how common the chromatic chords are *relative to each other*. Figure 2 provides an example of the summative data and visualisations provided on ‘When in Rome’, in this case for the example of Augmented Sixth chords in the lieder sub-corpus, divided (as discussed) into separate data for major-*versus*-minor tonal contexts.

In addition to the source repo, anyone interested can interact with this data on OMT’s chromatic harmony anthology (click here) where instances of these chromatic chord types can be browsed in sortable tables, in their full score context, and in few-bar excerpts.

4.1 Results for the Three Chromatic Categories

For each of the three ‘canonical’ chromatic categories discussed above, this section provides some high-level observations from the evidence of the corpus, and it considers the implications these observations might have for reviewing our attitudes to those chords.

The **Neapolitan sixth** is used relatively little. The main use cases in the lieder sub-corpus are ‘bII6’ and ‘bII65’ in minor (c.0.5%). Another c.0.4% accounts for the other Neapolitan candidates in minor, and there is very little use in major contexts at all. Other corpora broadly bear out this trend, and with even less usage of the seventh chords. Even here in the lieder, many of the ‘bII65’ sevenths cases occur in progressions against an inverted pedal, potentially suggesting a possible sub-category for this specific device.

Figure 2. Augmented sixths chords in the Lieder corpus.

The fact that Neapolitans are so commonly taught is somewhat contrary to the evidence of usage, perhaps prompting a review of the importance attributed to them, especially in the ‘category light’ DACH tradition.

Augmented sixth chords are much more common. For instance, in the lieder the ‘German’ (653) in minor alone accounts for over 1.5%, and thus more than all the possible Neapolitans in both modes. Within the augmented sixth category, it is notable that the ‘German’ (653) is so much more common than the other forms, and that all forms are much more common in the minor mode context. The DACH practice of concentrating teaching and terminology of *augmented sixths* on the 653 form arguably receives support from this usage-in-practice evidence.

Modal mixture is much more common still, but very unevenly so. The kinds of strong candidates for mixture described above occur relatively infrequently, for instance, with only ‘bVI’ making a short-list of top-10 cases (c.0.1%). Much (c.10x) more common are moderate mixtures like i (c.1.2%) and iv (c.1.0%). This extremely varied extent of usage reinforces the need for a distinction between types or grades of *relative* mixture strength.

It is perhaps also notable that the ‘other’ chromatic chord categories discussed (Augmented and Neapolitan sixths) feature among the most common cases of possible ‘mixture’. They all pose a strong case for mixture, (especially the ‘German’ which features both of the main mixed tones), but they also have the detraction of chromatic notes (at least $\sharp 4$ for the Augmented Sixths; $b 2$ for Neapolitans). This may prompt a review or clarification of categories which, in turn, speaks to wider issues such as the ‘French’ sixth’s status in relation to tritone substitution (again, see [12]), the ‘bebop’ dominant seventh with diminished fifth, and even some secondary dominants.

5. PROGRESSING TO CHORD PROGRESSIONS

This brief paper has set out some of the musical, computational, and even national/institutional issues at stake in defining chromatic chords and commenting on their use in practice, focussing on three individual chromatic chords.

Clearly this is only an initial step towards developing recommendations for how to define chords and describe ‘general’ practice in a given repertoire.

There is plenty of opportunity for future work, not least in growing the datasets (their sheer scale, repertoire coverage, and range of analytical perspectives), and in widening the range of both chordal categories and the languages/‘schools’ considered. Another clear next step is to expand the remit from individual *chords* to chord *progressions*. This is not so clear-cut a distinction as it may seem.

We close with some examples. Once again, all of the logic discussed here is implemented in the When in Rome repository, and examples are presented in both the ‘Anthology’ section of that repo, and in the more browsing-friendly format of the OMT harmony anthology.

5.1 Chord or progression? The Case of the ‘Cto7’

Some chromatic cases sit ambiguously between ‘chord’ and ‘progression’. As discussed, mixture is arguably an example: we certainly have to take account of the modal context (iv is diatonic in minor but mixture in major) and we may also chose to have additional contextual requirements such as the elimination of secondary dominants that resolve, and/or of the ‘Picardy Third’ endings.

The common-tone diminished seventh chord (‘Cto7’) presents an example that nudges further into the realm of progressions. Once again, we describe a single chord, though certainly need a wider contextual view. Here the chord’s construction as a fully diminished seventh is required, but only a small part of the definition which otherwise relies on the context of at least the following chord. Almost certainly required is a common-tone with the *following* chord ... which is not a suspension.¹⁸ Not usually required, (though potentially strengthening the case) is use of a common-tone with the *preceding* chord. And the case is arguably stronger still if the preceding and following chords are the same, indicating more of a *prolongation*.

5.2 Anglophone/DACH Progressions

The comparison of Anglophone and DACH traditions can, of course, continue to chord progressions. The ‘Cto7’ does not feature in DACH traditions, though a related form known in Anglophone circles as the ‘Omnibus’ does have a relative in the DACH concept of the *Teufelsmühle* [15].

Not yet at the textbook level, Lewandowki [16] recently proposed a category pair for *fallender Quintanstieg* (hereafter, fQ) and *aufsteigender Quintfall* (hereafter, aQ) both of which see pairs of fifth in the same direction, separated by a step in the opposite direction. For example, D-A-C-G would be an instance of the fQ, while G-C-A-D would be a case of the aQ.

Instances of these progressions can be extracted by any corpus, functional or otherwise.¹⁹ Filtering When in

¹⁸ The progression of viio7/V to the cadential 64 is common, but a weak candidate for the Cto. It is excluded by most definitions (e.g., on OMT), though it may be significant as an historical origin for this progression.

¹⁹ As the labels are not dependent on key-context or RN labelling, it is reasonable to include pop examples here (as Lewandowki does). For

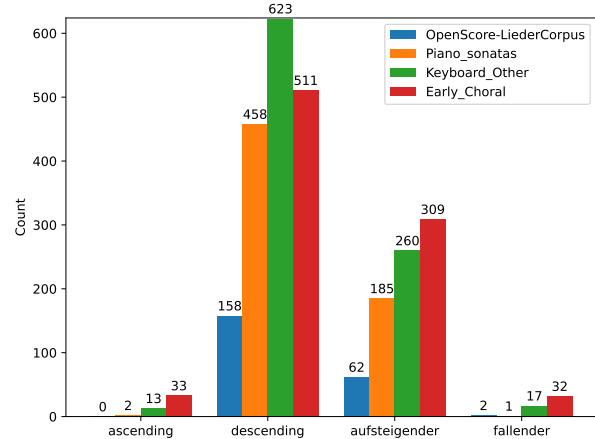

Figure 3. Fifth progressions by category and corpus.

Rome for the minimal, 4-chord instances of each shows that the aQ is much (c.20x) more common than the fQ across all corpora (RHS of fig.3). The better known pattern of rising/falling cycles of fifths are related in that they also feature pairs of fifths a step apart. Filtering for 4-grams of these progressions reveals a similar, and even more extreme (c.50x) preference for one direction (falling) over the other (rising). So once again, while we may seem to have a class of equal schema *in theory*, the usage *in practice* highlights an imbalance that arguably needs including at the outset of teaching these materials.

5.3 Beyond the Anglophone-DACH Comparison

We close with an example progression originating in another language, and with the additional constraint of having an expected *position* for its usage, thus further expanding the *context* we need to assess.

‘Partimenti’ treatises originating in 18th-century Italy have enjoyed a renewed interest from music theorists in recent years [17]. This method centres on prototypical, schematic patterns that can serve as the basis of composition (including improvisation). The schema are typically defined by their bass and melodic lines, their harmony, and their position both in relation to the metre and the large-scale form.²⁰ Harmonic analysis data captures all of this except the melodic line. For example, most aspects of the *Quiescenza* are captured by progressions like I-V7/IV-IV-V-I,²¹ and by the expected position at the *end* (coda) of a work. These textbooks provide repertoire examples, and there are certainly cases in the meta-corpus (which includes a sub-corpus of Corelli Trio Sonatas) that fit.

However, counter-examples are also easy to find and an initial survey of overall usage finds no tendency towards end-section emphasis in any sub-corpus, including the Corelli.²² Once again, the data suggests that it is time for a thorough re-evaluation of schematic associations passed pedagogically from one generation to the next.

example, the fQ (D-A-C-G) is the chord progression of TLC’s *Waterfalls*.

²⁰ Click here for examples in the relevant section of OMT.

²¹ Again, the code sets out how to catch all and only the relevant cases.

²² The code includes functionality for plotting usage-by-position.

6. ACKNOWLEDGEMENTS

Thanks to all who have contributed to the (rather long) gestation of these ideas. Clearly the international aspect reflects my time working in several countries. Thanks to all colleagues and students for the exchanges! For mixture especially, I have canvassed opinions from the (computational) music theory community since around 2020, on music21 (as part of creating the `.isMixture()` method here), on Twitter (here), and elsewhere (several public talks). Thanks to all who engaged with this ... or even simply heard me out!

ABSTRACT

Intra-opus repeated pattern discovery in polyphonic symbolic music data has challenges in both algorithm design and data annotation. To solve these challenges, we propose BPS-motif, a new symbolic music dataset containing the note-level annotation of motives and occurrences in Beethoven’s piano sonatas. The size of the proposed dataset is larger than previous symbolic datasets for repeated pattern discovery. We report the process of dataset annotation, specifically a peer review process and discussion phase to improve the annotation quality. Finally, we propose a motif discovery method which is shown outperforming baseline methods on repeated pattern discovery.

1. INTRODUCTION

Repetition is ubiquitous in music. Computational discovery of repeated patterns in music data has been long discussed in the field of music information retrieval (MIR). Aside from its importance in music analysis [1], the role of repeated pattern discovery has also been noticed in music classification [2,3] and generation [4,5]. The definition of a pattern is multi-fold. Generally speaking, a pattern refers to a group of notes that serves a musically important role and occurs multiple times in a piece of music. Repeated patterns are known by various names, such as motifs, themes, phrases and sections, depending on their specific musical function. The goal of the *repeated pattern discovery* problem is then to find the relevant patterns (depending on the intended task) and all of their occurrences within the provided musical data.

Compared to other music analysis tasks (e.g., harmony analysis) on polyphonic symbolic music data, repeated pattern discovery is relatively less discussed due to mainly two challenges. First, searching for all the possible candidates of repeated patterns is costly and redundant [6]. The computational complexity of the algorithm is high, while the discovered patterns often have little musical significance [7]. Second, repetition is a non-exact attribute of music. A large pattern can be potentially divided into

small ones; whether a note group constitutes a meaningful repeated pattern also depends on the subjective views regarding repetition, similarity, and musical importance. As a result, human-annotated datasets that comprehensively identify all the available patterns and all of their occurrences remains in a quite limited scale.

In this paper, we propose a new dataset, BPS-motif, to improve the scalability of music pattern discovery research. The BPS-motif dataset contains the note-level annotation of motives and their occurrences in the first movements of Beethoven’s Piano Sonatas (BPS). This is an extension of the many previous musical annotations on BPS, such as the functional harmony, phrase and section annotation provided in the Beethoven Piano Sonata Functional Harmony (BPS-FH) dataset [8]. We are specifically interested in annotating the *motivic* units in the melody parts of each piece of music, which could be complementary to the more *thematic* annotation (e.g., phrases and sections) provided in the BPS-FH dataset. We expect that the proposed dataset can enrich not only multi-task MIR research but also novel computational music analysis tasks.

Besides, as another contribution of this paper, we also propose a simple yet effective algorithm for repeated pattern discovery. Different from previous works which emphasized the equal translations among notes, we emphasize the contextual relationships among short segments of notes. We demonstrate that the proposed algorithm not only outperform several baselines on the BPS-motif dataset, but also on the JKU-PDD dataset [9], the most widely used dataset for the discovery of repeated themes and sections. In other words, the proposed algorithm is competitive for finding both motivic and thematic patterns.

The rest of this paper is organized as follows. Section 2 gives a background introduction and a survey of previous works on the datasets and methods for repeated pattern discovery. In Section 3, we introduce the dataset and our proposed annotation process. In Section 4, we introduce the proposed motif discovery algorithm and demonstrate its evaluation results. Conclusions are made in Section 5.

2. RELATED WORK

2.1 Repeated pattern discovery datasets

The datasets for repeated pattern discovery are built mostly for the interest in computational music analysis research. Complete annotation of repeated patterns should incorporate all the note groups (each note in pitch-onset part) that

constitute 1) the patterns of interest and 2) the occurrences of each pattern. Usually, a music piece contains more than one pattern, and each pattern should repeat (i.e., occur more than twice). The occurrences of a pattern may not be the same; one occurrence can be an exact copy of, or a variation from another occurrence that belongs to the same pattern. The music data can be either monophonic or polyphonic, and can be in either symbolic or audio format. The annotation can be either *intra-opus* or *inter-opus* [10]. In the former case, the analysis focuses on how a piece of music is broken down into pattern occurrences by having occurrences of a pattern within one music piece [7, 10]. In the latter case, the analysis focuses on the evolution of common elements in a corpus, by having occurrences of a pattern in different pieces of music. It should be noted that the annotation in inter-opus datasets can be limited to only a small set of patterns, while intra-opus datasets need a comprehensive set of patterns and occurrences and is hard to build; see Table 1 and the discussion below.

Table 1 presents the datasets for both inter-opus and intra-opus pattern discovery. In the Saraga dataset, Srinivasamurthy *et al.* annotated 4,571 temporal occurrences from 1,067 *characteristic melodic phrases*, a musical unit related to the *rāga*, over 170 audio recordings [11]. Krause *et al.* performed large-scale leitmotif classification in audio recordings by annotating the time intervals of 10 leitmotifs in Richard Wagner’s four-opera cycle *Der Ring des Nibelungen* and achieve a large scale of occurrence over 16 versions of recordings [12].¹ In the MTC-ANN dataset, Kranenburg *et al.* categorized 93 patterns in 360 monophonic folk tunes and annotated 1,657 occurrences [13]. Finkensiep *et al.* considered 20 types of *schemata* and annotated 244 events in Mozart’s piano sonatas [14]. In the MIREX campaign of *Discovery of Repeated Patterns and Themes*, Collins *et al.* firstly compiled an organized, open-source intra-opus pattern discovery dataset containing 165 occurrences in five pieces and this dataset has been widely discussed in the follow-up research works. It should be noted that, among these datasets, only the JKU-PDD dataset is for intra-opus pattern discovery but its size is smallest among all (only five pieces of music).

Aside from the above-mentioned datasets, it is still worth mentioning the datasets for *pattern matching* [15], such as the Dig That Lick dataset for Jazz music [16] and the Theme Finder for Classical music [17]. These datasets support pattern retrieval tasks with known query, but they neither support pattern discovery research nor provide the annotation of pattern occurrences explicitly.

2.2 Repeated pattern discovery methods

For symbolic music data, there are three major approaches to implementing the repeated pattern discovery algorithms: 1) string-based approach which represents music data as one-dimensional pitch sequence and finds repeated patterns with sub-string matching [18, 19]; 2) geometry-based approach which represents music data as multi-dimensional point sets (usually onset-pitch pairs in two-

	format	usage	#ps	#ptns	#ocrs
[11]	poly audio	inter	170	1,067	4,571
[12]	poly audio	inter	11	10	2,403
[13]	mono symbolic	inter	360	93	1,657
[14]	poly symbolic	inter	54	20	244
[9]	poly symbolic	intra	5	32	165
Ours	poly symbolic	intra	32	263	4,944

Table 1: Comparison of several open-source musical repeated pattern datasets including the saraga dataset [11], The *Ring* (one performance version) [12], MTC-ANN [13], Schemata [14], JKU-PDD [9], and BPS-motif (ours). The number of pieces (#ps), the number of individual patterns (#ptns), and the number of occurrences (#ocrs) are listed. The data formats can be monophonic (mono) or polyphonic (poly), audio or symbolic. The type of annotation can be inter-opus (inter) or intra-opus (intra).

dimensional space) and retrieves the translatable subsets (see discussion below) as repeated patterns [20–22]; 3) feature-based approach which extracts or learns features from music data, and retrieves patterns with clustering or classification of the features [14, 23–25].

While the string-based approach falls limited in representing polyphonic music [22], research efforts on pattern discovery have been more emphasized on the geometry-based approach. In the geometry-based approach, we consider a music piece \mathbf{D} with N notes and \mathbf{d} denotes a note. We have $\mathbf{D} := \{\mathbf{d}_i\}_{i=1}^N$, where $\mathbf{d}_i := (o_i, p_i)$ denotes the i th note, and o_i, p_i denote its onset and pitch value, respectively. In the discussion of the structure induction algorithm with translational equivalence classes (SIATEC) [20], two subsets (i.e., two patterns) \mathbf{m} and \mathbf{n} in \mathbf{D} are translatable (denoted as $\mathbf{n} \equiv \mathbf{m}$) if there exists a vector \mathbf{v} such that the translation function $f(\mathbf{d}, \mathbf{v}) : \mathbf{m} \rightarrow \mathbf{n}; \mathbf{d} \mapsto \mathbf{d} + \mathbf{v}$ is bijective. All the patterns translatable with respect to \mathbf{m} form a translational equivalence class (TEC) of \mathbf{m} in \mathbf{D} , that means

$$\text{TEC}(\mathbf{m}, \mathbf{D}) := \{\mathbf{n} : \mathbf{n} \equiv \mathbf{m}, \mathbf{n} \subseteq \mathbf{D}\}. \quad (1)$$

A *maximal translatable pattern* (MTP) is the largest pattern translatable by a translatable vector \mathbf{v} [20]:

$$\text{MTP}(\mathbf{v}, \mathbf{D}) := \max_{|\mathbf{d}|} \{\mathbf{d} : \mathbf{d} \in \mathbf{D} \text{ and } \mathbf{d} + \mathbf{v} \in \mathbf{D}\}, \quad (2)$$

where $|\mathbf{d}|$ is the number of notes in \mathbf{d} . SIATEC is then an algorithm which finds all the TEC of the available MTPs in \mathbf{D} . A survey and comparative study can be found in [26].

In the feature-based approach, machine learning techniques are usually applied; features are processed by clustering for the pattern discovery task (when a query is not given), and by classification for the pattern matching task (when a query is given) [15]. For example, in [23], agglomerative clustering over the wavelet transform of the pitch sequence data was used for pattern discovery in melodies. In [14], music schema recognition was performed by extracting the schema candidates using a skip-gram model and then a binary classification on the rhythm

¹ There are in total 38,448 occurrences if counting the 16 versions.

and pitch features over the candidates. It is also noted that the feature-based approach has also been widely discussed in the repeated pattern discovery of audio. In [24], Nuttall *et al.* adopted matrix profile, a time-series-based motif discovery method [27], on the predominant pitch contours to extract the characteristic melodic phrases from audio [11]. Krause *et al.* utilized recurrent neural networks (RNN) to classify over 30,000 leitmotifs over different performances of *Der Ring des Nibelungen* [25].

3. DATASET

3.1 Overview

The BPS-motif dataset contains the annotation of motives in the first movements of Beethoven’s 32 piano sonatas. An annotation unit contains a group of motif notes and the corresponding motif label. The motif labels are sorted in alphabetical order: the motif that occurs first in the music piece is labeled as *A*, the secondly occurred motif is labeled as *B*, the thirdly occurred one is *C*, and so on. The group of notes which are the *j*th occurrence of the motif *A* in *D* is annotated as $\mathbf{m}_{A,j}$, $\mathbf{m}_{A,j} \subset \mathbf{D}$, $j \in \mathbb{Z}_{\geq 0}$. All the occurrences of this motif are annotated with *A*. Further information, such as the start time and end time of each motif occurrence, and the non-motif notes (i.e., the notes which do not belong to any motif) can be directly derived. The dataset is available at: https://github.com/Wiilly07/Beethoven_motif.

Over the 32 music pieces, we labeled 263 distinct motives with 4,944 occurrences in total (see Table 1). These occurrences contain 36,652 notes, which is 28.87% of the total number of 126,943 notes. For each piece of music, the number of motives ranges from 2 to 13 (average 8.22 motives), and the number of occurrences ranges from 41 to 290 (average 154.5 occurrences). On average, a motif contains 7.41 notes and spans 5.30 crochet beats. The pitch ranges of the motives are mostly within two octaves.

To facilitate the annotation process, we only consider the repeated patterns in melodic notes; that means, all the annotated motives are constrained to be a monophonic note sequence. For example, in Figure 1a, although the first beat of the first measure contains three notes (i.e., B3, D4, G4), only G4 is included in the the annotated motif \mathbf{A}_0 . However, there can be multiple motives which are fully or partly overlapped in time; see the demonstration in Figure 1c (the red and blue boxes represent two overlapped motives).

3.2 Data format

We basically followed the data format adopted in the BPS-FH dataset. First, all the articulation symbols and grace notes were omitted (see Figure 1a). Second, pickup was filled when needed (see Figure 1b and the following discussion). Repeat signs are also unfolded when needed.

We take a crotchet beat as the unit time step (i.e., the duration of a crotchet is 1 in our note annotation and is 1 second in MIDI) to represent the data. Two types of timestamps are recorded. The *score time* takes the pickup measure as negative while the *MIDI time* fills the pickup

(a) Grace note removal/ taking the monophonic motif

(b) Filling the pickup measure

(c) Annotating overlapped motives

Figure 1: Examples of annotated motives. From (a) to (c), the three demonstrated excerpts are from Beethoven’s Piano Sonata No. 20, No. 1, and No. 5, respectively. The notes bounded by a colored box form a motif occurrence.

measure and defines the beginning of the measure as 0. For example, in Figure 1b, the score time of the C4 note at the beginning is -1 while the MIDI time is 3. Both the score time and the MIDI time unfolds the repeat signs so the timestamps increase monotonically. Similarly, at the measure level, the *score measure number* is the measure number counted on the score sheet (the pickup measure is measure 0, with repeat signs), while the *MIDI measure number* takes the pickup measure (if there is) as measure 1 and unfolds the repeat signs. Two types of pitch number are recorded: the MIDI pitch (in MIDI number) and the morphetic pitch number [28].

For each piece of music, we provide annotation data in different formats for users to retrieve the motif events in different ways. The file formats include:

1. A multi-track MIDI file that records the motif notes. Temporally overlapped motives are recorded in different tracks. There are at most four tracks in our annotation of this dataset.
2. A list of all the notes. Each note has the labels of 1) onset time (in score time), 2) MIDI pitch number, 3) morphetic pitch number, 4) note duration (in

Figure 2: Motives and occurrences labeled in Beethoven’s Piano Sonata No.1 in F minor. From top to bottom shows the annotation of section intervals, subsection intervals, phrase intervals, the time when a new motif occurs (with motif labels), and the piano roll of the music piece marked with motif and non-motif notes. In the bottom subfigure, different motives are specified by different colors. Motif occurrences are marked with a black bounding box. Non-motif notes are in gray color.

Figure 3: Assessment results (Q1 to Q4) regarding the data annotation from the seven reviewers. The results were collected before the discussion phase.

crotchet beats), 5) staff number (integers from zero for the top staff), 6) MIDI measure number, and 7) motif (e.g., a note is annotated as *A* if it is part of *A*). The notes without motif labels are non-motif notes.

3. Individual note lists of each motif occurrence. These lists are provided for users to better retrieve each occurrence. The labels in these lists are the same as the ones in the list of all notes.
4. A list describing the properties of motif occurrences. Each motif occurrence has the labels of 1) the start time and end time (in both score time and MIDI time), 2) the duration of the occurrence, 3) the measure number where the motif start (in both score measure and MIDI measure), 4) the “start beat” of the motif start, and 5) time signature.

We also provide the PDF scoresheets with the annotator’s manual annotations and notes. These scoresheets are for reference only because they are the raw annotations and may not be the same as the annotation of our final version; see Section 3.3 for more details about the annotation process. The note lists and the score time are compatible with the BPS-FH dataset, therefore annotation of more thematic units (e.g., theme, sub-section and phrase) can be retrieved from the BPS-FH dataset. To better see our annotation result, Figure 2 illustrates the hierarchical musical structures

with motives of Beethoven’s Piano Sonata No. 1, combining the section, subsection and phrase labels in BPS-FH, and the motif labels in BPS-motif.²

3.3 Annotation process

There are a few challenges in the data annotation process. First, as mentioned, identifying of musical motifs and their repetitions or variations in a piece of music is not straightforward. Ambiguity arises from multiple factors. For example, some repeated patterns may not be considered as valid musical motifs, a motif may not always be the smallest unit of a repeated pattern, and the similarity or difference between two such sequences can also be subject to human interpretation. Besides, while experienced musicians can read the scoresheet and mark the motifs directly by hand on it, converting such hand-drawing annotations into database formats still requires lots of efforts.

Our proposed approach to build the BPF-motif dataset incorporates three parts: annotation, review, and score typing. First, two annotators (the first and the second authors) manually annotate the motives on the scoresheet. Each piece is annotated by one annotator. Then, we invite external reviewers to review annotated scoresheets. Also, the reviewer helps us digitize the manual annotation. In the review process, we design a review form to let the reviewers assess the overall quality of annotation and also provide their suggested annotation if they hold different opinions. The review form contains the following questions:

1. (Q1) Are the annotations reasonable? (3: totally reasonable; 2: mostly reasonable; 1: unreasonable)
2. (Q2) Are the annotations coherent with your opinion? That means, if you were the annotator, will you

² It should be noted that there are still some annotation inconsistency between the BPS-FH and BPS-motif datasets. For example, in Figure 2, the phrase *c* is constructed only with the motif *D*, while the phrase *c'''* is constructed only with the motif *H*. This means that while the annotator of BPS-FH considered *c'''* as simply a variation of *c*, the annotator of BPS-motif considered them being different (and are thereon constructed with different motives).

Figure 4: Two segments (light gray and light purple regions) and their common structure. The crosses indicate notes, and the set of vectors in a segment represents its structure. Blue vectors denote the common structure which exists in both segments. The dashed gray arrows represents non-motivic notes within the two segments.

also have the same annotations as ours? (3: totally coherent; 2: mostly coherent; 1: incoherent)

3. (Q3) Are the annotations consistent (i.e., did we hold consistent criteria annotating the data)? (3: totally consistent; 2: mostly consistent; 1: inconsistent)
4. (Q4) In which way your opinions are different from ours? (a: we took multiple motives into one (*undersegmentation*); b: we divided a motif into many (*oversegmentation*); c: we took some non-motif patterns as motives (*overlabeling*); d: we omitted some musically important motives (*underlabeling*)) Choose one even you totally agree to our annotation.
5. (Q5) If you hold different opinions on our annotation and think we should revise them, leave your comments explicitly. Your comments can be, for example, “the motif *E* in Sonata No. *x* should be further divided into *F* and *G*” (describe what *F* and *G* are); “the motif *H* in Sonata No. *y* can be considered as a variation of *B* and should be merged,” etc.

Seven reviewers were invited to review the annotations. The reviewers are all from composition background and are good at using computer scorewriters. Each reviewer was assigned from 3 to 7 pieces (according to the length of the music piece) for review, then they answered the above questions and provided their suggested annotations on a co-edited document. During the review and discussion phase, the reviewers also need to convert the manual annotation on the score into the symbolic form using the scorewriter MuseScore. This confirms that they had carefully read the annotation, and also speed up the process of building the dataset. After the reviewers typed the scores of the annotated motives, we can directly convert it to MIDI and the final annotation data.

The reviewer’s assessment results are shown in Fig. 3. From Q1 to Q3, it is shown that no reviewer reported our annotation as unreasonable, incoherent to their thoughts, or self-inconsistent. However, over half of the reviewers did point out a few annotation they considered problematic. We discussed with the reviewers regarding those issues and revised them such that all the annotations are

Algorithm 1 Find Common Structure

21:  end for
22:  return  $\mathbf{M}$ 
23: end function

```

acceptable for the reviewer. The result of Q4 shows that reviewers tend to say our annotations are oversegmented. This however fits our needs because doing this provides extra flexibility to the dataset; researchers who are interested in longer repeated patterns can simply merge our annotations. On the other hand, it is hard to retrieve short motivic patterns from undersegmented annotation.

4. MOTIF DISCOVERY

4.1 Algorithm

We regard a motif as a short pattern recurring with little change in its structure. In other words, the relative positions of the notes in a motif will be almost fixed. We therefore find motifs by detecting *common structures* in short musical segments. The idea of the proposed algorithm is presented in Figure 4 and Algorithm 1. Formally, let Δt denote a threshold of time interval, and $\mathbf{D} := \{\mathbf{d}_i\}_{i=1}^N$ a musical piece composed of N notes sorted in ascending order, with $\mathbf{d}_i = (o_i, p_i)$ being a two-dimensional vector indicating the onset and pitch number of the i th note. For \mathbf{d}_i , we first aggregate its context \mathbf{C}_i and create a segment \mathbf{S}_i . The derived segments are then compared pairwise to obtain common structures. By representing a segment as a set of *vectors* (see Figure 4 and Line 3–12 in Algorithm 1), the common structure of any two segments (i.e., the blue arrows in Figure 4) can be obtained by collecting vectors which exist in both segments (Line 18).

As the pairwise comparisons between segments (Line 15–19) will result in various types of common structures, we retrieve a representative pattern and all its occurrences by finding the “most common” structure (i.e., the com-

(b) Repeated pattern discovery on the JKU-PDD dataset

Table 2: Evaluation of pattern discovery algorithms. The subscripts *est*, *occ*, and *thr* indicate the *establishment*, *occurrence*, and *three-layer* measurements, respectively. The averaged runtime is in minutes.

mon structure that occurs the most times) in \hat{S} with the MOST_COMMON operation (Line 20). Finally, motifs are acquired by filtering out non-motivic patterns in \mathbf{M} heuristically. In this work, we set $\Delta t = 12$ crotchet beats.

The proposed algorithm differs from the SIA family in two aspects. First, the SIA family aggregates notes of a pattern by detecting equal *translations* among notes, while our algorithm finds patterns by identifying common structures, or *contextual relationships*, among small segments. Second, the SIA family computes maximal translatable patterns (MTP) and subsequently find their occurrences, whereas our algorithm establishes a small pattern and all its occurrences at the same time. Our approach is promising in that the contextual comparisons between segments help identify motifs which are small and recurring. The code of the proposed algorithm is available at https://github.com/Tsung-Ping/motif_discovery.

4.2 Evaluation

We evaluate the motif discovery algorithm on the proposed dataset (with an averaged number of 3937 notes per piece) as well as the JKU-PDD dataset (1284 notes in average) [9] using standard metrics for pattern discovery. The *establishment measurement* (*est*) shows the capability of an algorithm to recognize patterns rather than to find all occurrences of a pattern. The *occurrence measurement* (*occ*), on the contrary, emphasizes the ability to find all occurrences of a pattern. The *three-layer measurement* (*thr*) is a comprehensive evaluation combining aspects of both the establishment and occurrence measurements. Each of the three measurements are specified in terms of precision, recall, and F1 score.³ The *averaged runtime* on each dataset will also be measured to give a rough sketch of the time complexity. We compare the proposed algorithm with three methods from the SIA family, i.e., SIATEC [20], COSI-

ATEC [21], and SIATECCompress [21].⁴ All algorithms were implemented in Python programming language.

The evaluation results are summarized in Table 2. Generally, our algorithm performs consistently across datasets despite that the two datasets are composed of distinct types of musical patterns, i.e., *motivic* (the proposed) versus *thematic* (the JKU-PDD), which differ with each other mainly in the size. Our algorithm is superior to the baselines in all the three establishment measures, indicating that our method can identify more existences of the ground-truth patterns than the other algorithms. Besides, our algorithm is competent in the other two measurements, with at least one best performance in each measurement. Specifically, the R_{occ} measure shows that the patterns retrieved by our algorithm are more complete (i.e., discovering more occurrences of a pattern) with respect to the ground-truth patterns, and the F_{thr} measure suggests that our method has better capability to recognize salient patterns in music, especially the motivic ones. Finally, the runtime measurement indicates that our algorithm can achieve a better performance on the pattern discovery tasks at a moderate computational cost, which is 4.2 (resp. 2.7) times slower than the SIATEC on the proposed (resp. JKU-PDD) dataset.

5. CONCLUSION

We have demonstrated a dataset for repeated pattern discovery of polyphonic symbolic data and a motif discovery algorithm. Our data annotation clearly demonstrates the hierarchical structure of music. The proposed motif discovery algorithm has been shown outperforming the baseline methods on various repeated pattern discovery problems. These findings suggest a direction for developing repeated pattern discovery algorithms, and also evoke further investigation on music structure analysis, novelty analysis, and repeated pattern discovery algorithms.

ABSTRACT

Multi-pitch estimation (MPE), the task of detecting active pitches within a polyphonic music recording, has garnered significant research interest in recent years. Most state-of-the-art approaches for MPE are based on deep networks trained using pitch annotations as targets. The success of current methods is therefore limited by the difficulty of obtaining large amounts of accurate annotations. In this paper, we propose a novel technique for learning MPE without any pitch annotations at all. Our approach exploits multiple recorded versions of a musical piece as surrogate targets. Given one version of a piece as input, we train a network to minimize the distance between its output and time–frequency representations of other versions of that piece. Since all versions are based on the same musical score, we hypothesize that the learned output corresponds to pitch estimates. To further ensure that this hypothesis holds, we incorporate domain knowledge about overtones and noise levels into the network. Overall, our method replaces strong pitch annotations with weaker and easier-to-obtain cross-version targets. In our experiments, we show that our proposed approach yields viable multi-pitch estimates and outperforms two baselines.

1. INTRODUCTION

Music transcription, i. e., converting music audio recordings into score representations, is a fundamental task in music information retrieval (MIR). As a subtask of transcription, one may estimate the pitches active at different points in time throughout a recording of polyphonic music, yielding a piano roll representation (without considering instrumentation, note values, or other score-based information). This goal is commonly referred to as multi-pitch estimation (MPE). Recent years have seen significant advances in MPE systems, mainly due to the use of deep learning models [1–6]. These models are typically trained with large amounts of aligned pitch annotations as targets, see also Figure 1a. Creating such annotations may involve an enormous effort. In particular, manually anno-

Figure 1: Systems for multi-pitch estimation are typically trained using pitch annotations (a), which are cumbersome to create. In this work, we propose to use different versions of a piece as surrogate targets (b), which are much easier to obtain. In both scenarios, a network input (I) is passed through convolutional layers, producing an output (O), which is compared to one or several targets (T) using some loss function (\mathcal{L}).

tating pitch activity in every frame of an audio recording would be prohibitively time consuming. Many datasets are thus annotated using semi-automatic methods like score–audio synchronization (e. g., [7]), which introduces annotation errors. Because of this, systems that can learn pitch estimation without large amounts of pitch annotations are highly desirable.

In this paper, we propose a novel approach for learning MPE without pitch annotations. As our key idea, we use different versions (i. e., recorded performances) of a musical piece as surrogate targets. To this end, we leverage cross-version music datasets, which contain several versions per piece. Such datasets are especially common for Western classical music, where the same compositions are regularly performed by different musicians. Each version exhibits unique timing, artistic expression, and varying acoustic conditions. All versions, however, are based on the same musical score and thus contain the same combinations of pitches. We therefore hypothesize that a deep network may produce pitch estimates by learning the commonalities between different versions of a piece.

In our approach, we train a deep network that takes a time–frequency representation of one version as input, and whose output minimizes a certain distance to time–frequency representations of other versions. This core idea is illustrated in Figure 1b. Since versions vary in length and the timing of pitch events may be different, we require a distance measure that temporally aligns the network output to the representations of other versions. To do so within a deep learning setting, we use a differentiable variant of dynamic time warping called SoftDTW [8]. Apart from the fundamental frequencies of pitches played, all recorded versions of a piece contain overtone structures and ambient noise. To increase the validity of our hypothesis and to encourage the network to capture nothing but pitches, we incorporate knowledge about overtones and noise using additional fixed processing blocks.

Overall, our proposed approach replaces the need for strong pitch annotations (which are frame-wise, binary, and difficult-to-obtain) with weaker cross-version targets (not temporally aligned, real-valued, and easy-to-obtain).

In summary, we make the following contributions: We propose a novel approach for weakly supervised MPE that does not require pitch annotations, based on the hypothesis that pitch estimation can be learned from multiple versions. We further propose to incorporate extra layers for simulating overtones and noise levels to ensure that our hypothesis holds. Finally, as a proof of concept, we show qualitatively and quantitatively that our approach can be used for MPE and outperforms two baselines. To aid reproducibility, we release code and trained models for our approach.¹

The remainder of this paper is structured as follows: In Section 2, we discuss related work on pitch estimation. In Section 3, we describe our proposed approach. Section 4 covers the experimental setup, while Section 5 contains our results. Section 6 concludes the paper with an overview of possible directions for future work.

2. RELATED WORK ON MULTI-PITCH ESTIMATION

The majority of work on MPE and music transcription in general has focused on supervised training schemes, where a dataset of music recordings with aligned pitch annotations is given. Most recent papers utilize deep learning models that are trained with pitch targets using standard cross-entropy loss functions [1–5]. Often, these works focus on piano music, where annotations can be obtained using MIDI recording technology built into certain types of pianos [9]. We refer to [6] for an overview of music transcription research.

Some works have explored pitch estimation from data without aligned pitch annotations. Weiß and Peeters [10] proposed to utilize weakly aligned annotations, where there may be temporal deviations between recorded performance and annotations. This scenario is also explored in [11]. However, in both cases, pitch annotations are required for the entire training dataset. Gfeller et al. [12] in-

roduced a self-supervised approach for pitch estimation, where a network learns to predict the relative differences between pitch-shifted, monophonic recordings. Their approach requires only a small amount of data with pitch annotations, but does not deal with polyphonic scenarios. Berg-Kirkpatrick et al. [13] describe a system for MPE on piano recordings that does not use pitch annotations. Their approach solves an optimization problem, with constraints motivated by the sound production process in pianos. In contrast, the method we propose in this paper utilizes several versions of a musical piece and could be used for recordings with arbitrary instruments.

3. PROPOSED METHOD

We now describe our proposed approach for learning MPE using cross-version alignment. Here, we assume that we have multiple corresponding recorded versions for each musical piece in the training set. Let us denote the set of all corresponding versions for one piece by $\mathcal{V} = \{V_1, V_2, \dots\}$. Furthermore, given a version $V \in \mathcal{V}$, we write $\text{InputRep}(V)$ for the audio representation of V that our network takes as input.¹

Given an input $\mathbb{I} = \text{InputRep}(V)$, we formulate MPE as the problem of producing a binary piano roll $\tilde{\mathbb{M}} \in \{0, 1\}^{B \times N}$ that matches the pitch annotations $\mathbb{A} \in \{0, 1\}^{B \times N}$ for that input. Here, B denotes the number of pitch bins, while N is the number of time frames in the input. In the supervised case, deep networks for MPE produce a real-valued output $\mathbb{O} \in [0, 1]^{B \times N}$ that is optimized using the binary cross-entropy loss \mathcal{L}_{BCE} with $\mathbb{T} = \mathbb{A}$ as targets (where the loss is averaged over all time–pitch bins). The final pitch predictions $\tilde{\mathbb{M}}$ are obtained from \mathbb{O} by applying a threshold τ . This threshold is often set to a fixed value (e. g., $\tau = 0.4$ in [7]) or optimized on a validation dataset [14]. This supervised approach to MPE, which crucially relies on the aligned pitch annotations \mathbb{A} , is illustrated in Figure 1a. In the following, we will refer to it with the shorthand Sup .

Our proposed approach, illustrated in Figure 1b, also takes an input representation $\mathbb{I} = \text{InputRep}(V)$ for some version $V \in \mathcal{V}$. As before, our network yields a real-valued output $\mathbb{O} \in [0, 1]^{B \times N}$. However, rather than using pitch annotations \mathbb{A} , we utilize a surrogate target $\mathbb{T} = \text{TargetRep}(V')$ based on another version $V' \in \mathcal{V} \setminus \{V\}$. We choose a time–frequency representation $\text{TargetRep}(V') \in [0, 1]^{B \times N'}$ as target that is normalized in the range $[0, 1]$ and has the same number of bins B as \mathbb{O} , but a potentially different number of time frames N' , due to the temporal differences between versions.¹ As explained in the introduction, \mathbb{T} contains the same combinations of pitches as \mathbb{I} .² Intuitively, if \mathbb{O} is close to the target representations of all versions $\mathcal{V} \setminus \{V\}$, we hypothesize that \mathbb{O} must correspond to pitch estimates for \mathbb{I} . We

¹ Details of InputRep and TargetRep are provided in Section 4.

² Here, we assume that there are no structural differences between versions, i. e., performers do not deviate from the score. Versions performed in different keys can be handled through pitch shifting, see Section 4.

Figure 2: Detailed overview of the proposed cross-version alignment (CVA) method, see also Figure 1b. Before applying the alignment loss ($\mathcal{L}_{SoftDTW}$), the intermediate output of the network (M) is optionally extended using a simple overtone model ($+Ov$) and a bias value ($+B$) to address background noise. The final output O can thus arise from different configurations (e. g., $O = M$, $O = M+Ov$, \dots). Importantly, the MPE output of the system (\tilde{M}) is computed based on the intermediate representation M , rather than the output O .

refer to our proposed approach with the shorthand CVA (for “cross-version alignment”).

Note that we cannot directly apply a loss on time–pitch bins here (as in the supervised case), since O and T are not temporally aligned. For this reason, we use the differentiable alignment loss $\mathcal{L}_{SoftDTW}$ in our approach, see Section 3.1. Furthermore, our hypothesis may fail to apply, since recorded versions of a piece contain overtone structures and background noise in addition to the pitches played. We thus extend our approach to account for these properties of music recordings in Section 3.2.

3.1 Differentiable Alignment

In order to perform temporal alignment between O and a target representation T in a differentiable fashion, we use the SoftDTW loss [8]. SoftDTW is a differentiable approximation of the classical dynamic time warping algorithm that is often used to align music sequences [15]. SoftDTW has originally been introduced for one-dimensional time series but has also been adopted for computer vision tasks like action recognition in video recordings [16, 17]. Within MIR, SoftDTW has previously been used in the context of music synchronization [18] and MPE [11]. In [11], the authors showed that SoftDTW can be used to replace strongly aligned (i. e., frame-wise) pitch annotations with weakly aligned pitches without a major impact on MPE performance. Nevertheless, their approach requires pitch annotations for training.

In our case, we crucially rely on the ability of SoftDTW to align real-valued sequences such as time–frequency representations of audio. In contrast, a commonly used alternative loss function called connectionist temporal classification (CTC) can only handle discrete target sequences. To compute $\mathcal{L}_{SoftDTW}$, one needs to choose a local cost function (for comparing individual frames of the time–frequency representations) and set a temperature hyperparameter called γ (which determines the approximation quality of SoftDTW). Here, we use the cosine distance for comparing frames, which exhibited high training stability in our experiments. We further set $\gamma = 0.1$, which corresponds to a good approximation of DTW.

As a drawback, the time and space complexity of SoftDTW is quadratic in the lengths of the input sequences. We thus train on short input excerpts (see Section 4).

3.2 Overtone and Noise Model

Aside from differentiable alignments, our proposed approach utilizes fixed processing layers that simulate overtone structures and background noise. In this way, our method follows the analysis-by-synthesis paradigm [19], where one estimates parameters from an audio recording (pitches, in our case) by re-synthesizing the input. Choi and Cho [20] utilized this idea for unsupervised drum transcription. Their network consists of a transcription stage and a fixed sample-based drum synthesizer. The transcription network is trained by minimizing a reconstruction loss on the synthesizer output. In recent years, such systems have become more popular due to the release of the differentiable digital signal processing (DDSP) library [21], which has been used, e. g., in the context of unsupervised monophonic pitch estimation [22]. In contrast to these works, our proposed approach utilizes cross-version data.

A full overview of our CVA approach is given in Figure 2. We explicitly add overtones (denoted by $+Ov$) and background noise ($+B$) to an intermediate output M of our network via dedicated layers. In this way, the network may learn a sparser and more piano roll-like representation M , since overtones and noise are added afterwards. Crucially, the final MPE results \tilde{M} are obtained from M , before overtones and noise are applied. The output O , used for alignment with the cross-version targets, depends on the model configuration used. For example, $O = M+Ov+B$ if all modules are used, $O = M+Ov$ if only overtones are added, etc. In the basic system without extensions, $O = M$.

Here, we opt for very simple overtone and noise models that serve to indicate the potential of our core idea. We estimate the relative amplitudes of different harmonics from a small internal dataset of single-note piano recordings. The resulting estimates, used for our overtone model, are illustrated in Figure 3. We keep these values fixed for all subsequent experiments. To apply this fixed overtone model within our network in a differentiable fashion, we sum up pitch-shifted versions of M . For each harmonic h , we shift M along the vertical axis by a number of semitones corre-

Figure 3: Amplitudes for the overtone model (+Ov) employed in our proposed approach.

sponding to h (e.g., 12 semitones for $h = 2$). We then weight the shifted representation with the amplitude estimated for h (see Figure 3). The final output is obtained by summing the resulting representations for all h .³ To address the overall noise level in the target \mathbb{T} , we add a fixed bias term of $\delta = 0.2$ after applying the overtone model. As a result of this additional processing, we may obtain outputs larger than 1. We therefore clip all values outside the interval $[0, 1]$ (corresponding to the value range of the target representations \mathbb{T}) to get the final output \mathbb{O} .

4. EXPERIMENTAL SETUP

4.1 Model, Representations, and Training

In this work, we focus on demonstrating the potential of our cross-version approach compared to traditional, fully supervised training for MPE. Thus, we do not propose complicated network architectures that require extensive tuning. Instead, we use a relatively small convolutional neural network for extracting the representation \mathbb{M} from \mathbb{I} . For InputRep and TargetRep, we use time–frequency representations based on the constant-Q transform (CQT), which provides a frequency axis corresponding to semitones. Note that we cannot train on entire (several minutes long) recordings in a single step. Instead, our training batches contain short input excerpts and we use state-of-the-art music synchronization techniques [23] to find the corresponding sections in other versions.

Concretely, we use the network architecture, input representation, and training setup from [10] (we refer to their paper for details). Their network consists of five convolutional layers with musically motivated kernel shapes and roughly 50 000 learnable parameters. The network takes a magnitude harmonic CQT (HCQT [24]) of an audio excerpt as InputRep, containing $N = 500$ frames computed with a hop size of 512 from waveforms at 22 050 Hz (i.e., an excerpt of 11.6 seconds length). The network produces outputs \mathbb{M} of the same length, with a pitch axis containing $B = 72$ bins (corresponding to the semitones from C1 to B6). The final layer of the network contains a sigmoid activation, such that all values in \mathbb{M} are restricted to the interval

³ Equivalently, the overtone model can be understood as a frame-wise convolution in pitch direction, with a kernel based on the amplitudes in Figure 3.

$[0, 1]$. For TargetRep, we use magnitude CQTs where the center frequencies of different bins correspond to the same $B = 72$ semitones. Column-wise max-normalization is applied on \mathbb{T} , such that the target values are also in $[0, 1]$.

We train our network by minimizing the SoftDTW loss over all training excerpts until the validation loss has stopped improving for 12 epochs. In each training step, we compute the loss on a batch of 16 inputs. Each input excerpt is based on some version $V \in \mathcal{V}$ and aligned to the corresponding excerpt in one randomly selected target version $V' \in \mathcal{V} \setminus \{V\}$. We use the Adam optimizer with a learning rate of 0.001, which is reduced whenever the validation loss has not improved for three epochs. Finally, we employ an efficient CUDA implementation of the Soft-DTW recursions by Maghumi et al. [25].⁴

4.2 Dataset and Split

To train our cross-version approach, we require a dataset containing multiple versions per piece. For testing, we additionally require aligned pitch annotations for the recordings. We opt for using the Schubert Winterreise Dataset (SWD, [26]) for training, which contains nine versions of the 24 songs in the cycle “Winterreise” composed by Franz Schubert (in total, roughly 11 h of audio). Each song constitutes one unique musical piece. The recordings consist of a tenor or baritone singer accompanied by piano. There are no structural differences between versions. Thus, all recordings for a piece contain the same combinations of pitches up to transposition (a global pitch shift), since some musicians chose to perform some songs in different keys. When training our CVA approach, we ensure that input and target version are in the same key by appropriately shifting the target CQT representation according to the key annotations given in the dataset.

We train and evaluate our model using a challenging split where the train and test sets contain both different versions and different songs. We choose songs 1–13 for training, 14–16 for validation, and 17–24 for testing. Furthermore, versions HU33 and SC06 are used for testing, while the remaining seven versions are used for training and validation. Such a split is also referred to as a “neither split”, since neither the same versions nor songs appear during training and testing [27]. This split avoids over-optimistic evaluation due to confounders such as the “album effect” [28].

4.3 Baselines

Aside from the supervised baseline Sup , which is trained using strong pitch annotations, we compare our proposed CVA approach to two additional baselines. With these, we aim to evaluate our hypothesis that cross-version targets are useful for learning MPE-like representations (see

⁴ Note that, within one batch, the targets \mathbb{T} may have different lengths. In order to benefit from parallelization across the batch dimension, we therefore rescale the targets \mathbb{T} to a common length $N' = 500$ (a trick referred to as W4 in [11]). This did not affect results negatively in early experiments. Note that rescaling is not equivalent to temporally aligning inputs and targets.

Scenario	CS	AP	$\tau = 0.4$		$\tau = \tau^*$	
			F	Acc.	F	Acc.
CQT	0.585	0.410	0.443	0.287	0.450	0.292
AE	0.588	0.500	0.336	0.203	0.511	0.345
CVA	0.632	0.589	0.585	0.416	0.592	0.423
CVA+Ov	0.664	0.639	0.553	0.384	0.623	0.455
CVA+B	0.633	0.563	0.560	0.392	0.592	0.424
CVA+Ov+B	0.682	0.646	0.625	0.458	0.627	0.460
Sup	0.748	0.753	0.700	0.543	0.703	0.546

Table 1: Results for multi-pitch estimation on the Schubert Winterreise Dataset for the baselines and different configurations of our proposed approach.

Section 3). For the CQT baseline, we take the target representations of our test recordings (which are normalized to have values in the range $[0, 1]$) and obtain multi-pitch estimates by directly thresholding these magnitude CQTs with τ . This learning-free baseline was previously proposed in [10] and, like CVA, does not require pitch annotations. Furthermore, we consider a second baseline that is very similar to CVA but does not utilize cross-version targets. Therefore, for each input excerpt, we choose the same version $V \in \mathcal{V}$ for both \mathbb{I} and \mathbb{T} . Thus, the network needs to effectively recreate its input, similar to an auto-encoder. We refer to this baseline with the shorthand AE. Intuitively, we expect CQT and AE to yield similar results. However, AE allows us to verify that any improvements observed for CVA stem from the cross-version targets and not from the model architecture or training setup. Note that Sup and AE use the same network architecture as CVA.

4.4 Evaluation Metrics

We evaluate the multi-pitch estimates of our proposed approach and all baselines using standard metrics on the test set. For this, we utilize the strongly aligned pitch annotations provided in the test data. As metrics, we use the cosine similarity (CS) between predictions and annotations, averaged over all frames and files in the test set. Furthermore, we compare the average precision (AP, computed as the area under the precision-recall curve), F-measure (F), and the accuracy (Acc.) metric introduced in [29]. For these measures, we average over all pitches. Note that F and Acc. are evaluated on \tilde{M} and thus depend on the threshold τ , while CS and AP are threshold-free evaluation metrics that directly compare M and A .

5. RESULTS

The main results of our study are summarized in Table 1. Rows correspond to different baselines or configurations of our proposed approach. We write +Ov when adding overtones and +B when including the bias term to account for background noise. Our model including all proposed modules is thus referred to as CVA+Ov+B. Columns contain the evaluation metrics. For the thresholding-based metrics F and Acc., we provide both results based on a fixed threshold ($\tau = 0.4$) and a threshold chosen to optimize F on the validation set ($\tau = \tau^*$).

Figure 4: F-measures on the test set for different MPE approaches, depending on the choice of threshold τ . Markers show the optimal threshold τ^* as determined on the validation set.

Our proposed approach CVA outperforms the two baselines CQT and AE across all metrics, demonstrating the effectiveness of using different versions of a piece to capture pitches in M . For example, $CS = 0.632$ for CVA compared to $CS = 0.588$ for AE, and $AP = 0.589$ for CVA compared to $AP = 0.410$ for CQT. Furthermore, our proposed overtone and noise models are effective. By adding overtones (CVA+Ov), we can further increase AP from 0.589 to 0.639. Adding a fixed bias term (CVA+B) does not yield improvements by itself. However, by combining both modules (CVA+Ov+B), we achieve the best results for our approach, further increasing AP to 0.646 and CS to 0.682.

Despite these encouraging results, there remains a gap between the best results for our proposed approach and those for the supervised baseline Sup. We emphasize again that—unlike CVA—Sup requires strong pitch annotations for training.

5.1 Impact of Threshold τ

When using the standard value of $\tau = 0.4$ for thresholding M , our CVA approach also outperforms both baselines in terms of F-measure and accuracy (e.g., $F = 0.553$ for CVA+Ov compared to 0.443 for CQT).

A fixed threshold may be sub-optimal, especially for methods that are not explicitly trained for MPE. When evaluating using the optimized threshold τ^* , we observe increased results for all approaches. CVA and its extensions continue to outperform the two baselines. The F-measure for CVA+Ov, for example, further increases to $F = 0.623$. For that model, the optimal threshold as determined on the validation set is $\tau^* = 0.28$. In this case, our method requires at least a few pitch annotations to determine τ^* and is no longer relying solely on the cross-version targets.

Figure 4 further demonstrates the impact of the parameter τ . F-measures (vertical axis) are shown for different MPE approaches (colored lines), depending on the choice of τ (horizontal axis). Markers indicate τ^* . As shown in this figure, a poor choice of τ may strongly affect test results. Moreover, τ^* as found using the validation set may not always give the highest scores on the test set. For in-

Figure 5: Qualitative results on a test excerpt from SWD.

stance, a choice of $\tau = 0.5$ would yield an even higher F-measure of 0.634 for CVA+OV+B.

5.2 Training Stability

The metrics reported in Table 1 are computed from a single training run per method. When repeating the experiment, results may deviate slightly due to random network initialization, dataset shuffling, or dropout. For CVA+OV+B, we repeat the experiment five times and find low standard deviation σ in results ($\sigma(\text{CS}) = 0.004$, $\sigma(\text{AP}) = 0.009$, $\sigma(\text{F}) = 0.008$, and $\sigma(\text{Acc.}) = 0.009$ for $\tau = \tau^*$).

5.3 Qualitative Results

To complement the quantitative evaluation, we also provide qualitative results on an exemplary excerpt in Figure 5. The first row shows an input excerpt (I) and corresponding pitch annotations (A), while the remaining rows

show multi-pitch estimates before (M) and after thresholding (\tilde{M} , computed using $\tau = \tau^*$).

For CQT and AE, the resulting M correspond to the input representation and thus lead to poor multi-pitch estimates.

When training our approach without overtones or noise model (CVA), the output representation M emphasizes the fundamental frequencies of many of the actual pitches being played. However, M also contains a lot of energy from overtone structures and background noise. As a consequence, the resulting \tilde{M} contains many spurious pitch predictions, especially for higher pitches.

With +OV and +B, we see a reduced impact of overtones or background noise in M, respectively. In both cases, many erroneous predictions remain after thresholding. By including both modules (CVA+OV+B), we obtain a promising representation that bears visual resemblance to the results for Sup. We also observe fewer spurious activations in \tilde{M} compared to the basic CVA. Overall, the proposed extensions are effective in encouraging the model to produce MPE predictions in M.

6. CONCLUSION

In this paper, we presented a novel approach for MPE that does not require pitch annotations for training. Instead, our method utilizes multiple versions of the same musical piece as surrogate targets. We train a network that takes a time–frequency representation of one version as input and minimizes an alignment-based distance to time–frequency representations of other versions. We hypothesized that this would result in outputs corresponding to pitch estimates. We further incorporate knowledge about overtones and noise levels into our system to support this hypothesis and improve results. In our experiments, we showed that our approach outperforms two baselines and that our proposed extensions to the model are effective. Overall, our work demonstrates the use of weak cross-version targets to replace strong pitch annotations.

This paper serves as a proof of concept for our core idea, which could be extended in future work. First, better results may be obtained by utilizing larger model architectures and bigger training datasets than in the present study. Here, we also abstained from excessive model and hyperparameter tweaking. In the future, larger and more extensively tuned models may close the gap between fully supervised approaches and the proposed cross-version training. Second, one may extend our approach to align one input excerpt to multiple versions simultaneously within the same training step (rather than choosing one target version at a time). This may further regularize the model output. Finally, future work may explore more elaborate synthesis models that could replace the simplistic overtone and noise models used here. For example, one may incorporate knowledge about the sound production processes of different instruments into the network [13]. In this context, results might also be improved by estimating the synthesis parameters (e. g., amplitudes of the overtone model) from the input recording, rather than using fixed processing steps.

ABSTRACT

We present the *Batik-plays-Mozart* Corpus, a piano performance dataset combining professional Mozart piano sonata performances with expert-labelled scores at a note-precise level. The performances originate from a recording by Viennese pianist Roland Batik on a computer-monitored Bösendorfer grand piano, and are available both as MIDI files and audio recordings. They have been precisely aligned, note by note, with a current standard edition of the corresponding scores (the New Mozart Edition) in such a way that they can further be connected to the musicological annotations (harmony, cadences, phrases) on these scores that were recently published by [1].

The result is a high-quality, high-precision corpus mapping scores and musical structure annotations to precise note-level professional performance information. As the first of its kind, it can serve as a valuable resource for studying various facets of expressive performance and their relationship with structural aspects.

In the paper, we outline the curation process of the alignment and conduct two exploratory experiments to demonstrate its usefulness in analyzing expressive performance.

1. INTRODUCTION

Music performance is a complex and nuanced activity that involves the interplay of various expressive features such as timing, dynamics, and articulation. Expressive performance research in music information retrieval (MIR) focuses on modeling expressive aspects of music performance by analyzing how performers use nuances in timing, dynamics, articulation, and other expressive features to convey their musical intentions, with the aim of developing computational models that can analyze, recognize, or synthesize expressive performances [2].

Recent research in this field for Western classical piano has focused on data-driven approaches both for performance generation [3,4] and data creation in the form of

large-scale MIDI performance data transcribed from audio recordings [5,6]. While such data corpora can be useful for comparative performance analyses and related tasks (e.g., performer identification, performance style transfer), they lack the necessary precision and alignment information (with the underlying musical score) required to precisely map expressive intentions and parameters to underlying score features.

Compared to these large-scale transcribed MIDI datasets, precise MIDI data (as recorded on computer controlled grand pianos such as the Yamaha Disklavier or Boesendorfer SE/Ceus series) along with their corresponding score alignment is somewhat limited in quantity and size [7–9]. The performances in such datasets are typically sourced from advanced piano students or piano competitions, whereas the digital scores are often obtained from open-source, user-curated online libraries such as MuseScore¹.

Regarding the performance-to-score alignment, one would ideally want to have note-by-note correspondence information; unfortunately, in the case of the largest of these datasets [7], score-performance alignments are only given at a rather coarse level of beats. Score annotations conveying structural information such as underlying harmony or phrases are even more scarce.

To address these limitations, we introduce the *Batik-plays-Mozart* dataset², in which we provide a set of expert performances of 12 complete Mozart piano sonatas (36 distinct movements) in MIDI format by concert pianist Roland Batik, precisely aligned, at a note-by-note-level, to a standard edition (the New Mozart Edition) of the score, thereby linking the performance information to a previously published dataset [1] of expert annotations of the scores in terms of harmony, cadence, and phrase structure. To the best of our knowledge, this is the first corpus of its kind, combining high quality digital score and structural annotations with expert performances in recorded MIDI format. We report two preliminary experiments to demonstrate the benefits of having precise performance–score–structure annotation alignments.

The remainder of this paper is organised as follows: Section 2 presents a list of comparable expressive performance datasets currently publicly available. Section 3 de-

scribes the data origins, the used data formats, and the curation process. Section 4 gives an overview of the dataset, and Section 5 describes two preliminary experiments to demonstrate the benefits of performance–score–structure annotation alignments. Finally, Section 6 concludes the paper with some remarks for future work.

2. RELATED WORK

Several piano performance datasets have been published in the context of expressive performance analysis and performance rendering. While recently published datasets are considerably larger than *Batik-plays-Mozart*, they provide performance recordings solely in the form of MIDI transcribed from audio recordings [5, 6] or do not include a high-quality digital score ground truth [11]. Despite the encouraging results demonstrated by recent transcription models, they often introduce inaccuracies, such as incorrect note fragmentation, missed note onsets, and falsely identified notes [12]. Similarly, certain expressive performance aspects such as (micro-)timing and tempo can only be measured given either a temporal or note-wise score-performance mapping [2]. Nevertheless, these datasets remain useful for various related tasks such as symbolic music generation, music transcription and tagging, or high-level comparative performance analysis.

Table 1 presents an overview of comparable piano performance datasets currently publicly available, for which precise (recorded) MIDI data, score-performance alignments and/or musicological annotations are available. Among these datasets, ASAP [7] stands out as the most extensive one, both in terms of musical pieces and performer range, with 1,068 performances beat-aligned to 222 scores, each annotated with key and time signature. In comparison to ASAP, all other publicly accessible datasets are significantly smaller: The Vienna 4x22 corpus [8] contains 22 different performances for excerpts of four different pieces, each aligned on a note level and provided in MusicXML³, MIDI and audio format. The CrestMuse PEDB v2.0 [9] provides 35 pieces note-aligned to 411 performances, with scores provided in MusicXML and MIDI and performances in MIDI and WAV. The dataset also contains phrase structure annotations, however, merely in the format of PDF and plain text files, somewhat limiting their (re)usability.

The MazurkaBL dataset [10] consists of a corpus of 44

Chopin Mazurkas with MusicXML scores that have been beat-aligned to 2000 performances. The performances themselves are not provided (neither as MIDI nor as audio); only beat positions and corresponding loudness values are given, along with the positions of tempo/dynamics markings in the score.

3. CURATION PROTOCOL AND FILE FORMATS

3.1 File origins

The MIDI performance files originate from a performance of twelve Mozart piano sonatas by Viennese concert pianist Roland Batik on a computer-controlled Bösendorfer SE290 grand piano, the predecessor of the CEUS model. The Bösendorfer SE series measures each individual keystroke and pedal movement precisely, with onset and offset times being captured at a time resolution of 1.25ms. Hammer velocity values are captured in a proprietary file format, and converted and mapped to the 128 dynamics MIDI values (see [13] for conversion details). The audio recordings corresponding to those MIDI files can be purchased commercially⁴.

These MIDI performance data were originally aligned manually, on a note-to-note level, to a symbolic encoding of the score produced by our team [14, 15]. In order to make it possible to link the performance data in an unequivocal way to the musicological score annotations provided in the *Annotated Mozart Sonatas* dataset by Hentschel et al. [1], we decided to replace our score encoding in the alignments entirely by the score notes as given in their dataset, which link to their annotations directly via absolute temporal score position. The scores in the *Annotated Mozart Sonatas* dataset conform to the New Mozart Edition⁵ and are given in MuseScore format, with the harmony, phrase and cadence label annotations provided in tabular format, as tab-separated values (TSV) files.

3.2 The match alignment format

We provide the alignment between the above-mentioned score and performance files in the match file format [16], a file format for symbolic music alignment in a human-understandable textual form. It is structured sequentially, and the alignment information is given at the level of individual notes.

⁴ <https://www.gramola.at/products/9003643987012>

⁵ <https://dme.mozarteum.at/DME/nma/start.php?l=2>

³ <https://www.musicxml.com/>

Figure 1. Visual illustration of the alignment process. Each step in the alignment process is numbered according to the textual description in Section 3.3. Steps marked * indicate manual correction / post-processing. Elements highlighted in green are combined in the new alignment match files.

The encoded alignment is complete in the sense that all performance and all score notes are captured. Each performance and each score note is represented with their respective note ID, and their respective alignment can be recorded with one out of three potential tuples: 1. A *match* between score note and performance note, i.e., $(score_id, performance_id)$, 2. a *deleted* score note $(score_id,)$ which represents a score note omitted in the performance, or 3. an *inserted* performance note $(, performance_id)$, which marks a performed note for which there is no corresponding score note.

Following this alignment encoding, each line in a match file corresponds to either a *match*, a *deletion* or an *insertion*. Additional lines express (sustain or soft) pedal information, or encode meta information about the musical piece and performer. While the performance part in match corresponds to a lossless encoding of a corresponding performance in MIDI format, the score part captures essential information including onset, offset and duration in beats, and pitch, pitch spelling, and octave information for each score note.

3.3 Curation protocol

To create note-level score-to-performance alignments, encoded in the match file format, between the performance MIDI data by pianist Roland Batik and scores and musicological annotations by Hentschel et al. [1], we follow the workflow as outlined below (see Fig. 1):

1. **Retrieve information from old alignment.** Given an old alignment file, we use `partitura` [17] to re-

trieve a score and performance representation which we parse into score and performance note arrays, `sna_o` and `pna_o`, to sequentially capture each (notated and performed) note with a unique note ID. In addition we retrieve a score-to-performance alignment, `align_o`, in the encoding format explained above (i.e., a list of note ID tuples expressing either a match, deletion or insertion).

2. **Retrieve score note array from MusicXML.** In the next step, we convert the annotated MuseScore format scores provided by Hentschel et al. [1] to MusicXML, assign unique note IDs to each note, and convert this score representation into a second score note array (`sna_s`).
3. **Unfold score note array.** We update the score note array obtained from MusicXML, `sna_s`, by unfolding it in accordance to the repetition structure found in the performance note array, `pna_o`.⁶
4. **Create score-score alignment.** In this step, we create a score-to-score alignment (`align_s`) by matching each note in the two score note arrays `sna_o` and `sna_s` using its pitch, onset and duration information in beats. Any notes in `sna_o` and `sna_s` not matched automatically need to be aligned manually. Missed alignments at this stage can occur due to:

- **Score mistakes.** These reflect mistakes in the score (e.g., a missing note, incorrect pitch, octave, missing modifier, missing repetition or ending markings) and require a manual correction of the score file.
- **Differing score versions.** For certain sonata movements, the notated score provides an alternative score version reflecting the first edition (“Erstdruck”) for certain segments of a piece, expressing the composer’s impromptu ornamentation.⁷ For the current dataset, such ornamented versions exist in K.284iii, K.332ii, K.457iii.
- **Double-voiced score notes.** These occur frequently in notated music, and describe a score note that is notated doubly in two different voices but corresponds to one performed note.
- **Grace notes.** Grace notes in notated music can occur in multiple forms to reflect different types of ornaments such as trills, acciaccature, mordents, turns etc. Depending on the ornament type and the underlying score encoding format, this may result in several notes occurring at the same (notated) onset (and hence

⁶ To reflect the same note occurring in a repeated segment, a suffix is added to the ID to reflect the number of occurrence, i.e. for a note with ID `n14`, the repeat structure unfolding is expressed as `n14-1` for the first, and `n14-2` for the second occurrence, respectively.

⁷ <https://www.henle.de/en/music-column/mozart-piano-sonatas/>

Figure 2. An example of a cadenza within a piano sonata starting in measure 198 in KV333, 3rd movement.

with zero duration) to ensure a regular measure according to the time signature of that piece. Without onset and duration information, these notes must then be manually aligned to their corresponding performed notes.

- **Cadenza and *ad libitum* measures.** Both cadenza measures and those marked *ad libitum* correspond to irregular measures, that is, measures that contain more beats than indicated in the time signature (see Fig. 2). Digitally encoded, the notes in such measures are commonly notated without duration to allow for error-free parsing, and thus share the same beat onset and need to be aligned manually.

5. Update score-performance alignment. Here we update the score note IDs in the old alignment (`align_o`) according to the score-score alignment (`align_s`) to create new score-performance alignments, `align_n`. For each alignment in `align_o`, we then need to ensure the validity of the original alignment type (match, insertion or deletion). In particular, for notes in the original score note array (`sna_o`) that could not be aligned to notes in the MusicXML-based score note array (`sna_s`), we consider two cases:

- If the note in `sna_o` corresponds to type ‘match’ in `align_o`, the alignment type for the formerly matched performance note is changed accordingly into an insertion.
- If the note in `sna_o` corresponds to type ‘deletion’ in `align_o` (i.e., a score note that was not performed), it is discarded in `align_n`.

Notes in `sna_s` that could not be aligned with notes in `sna_o`, on the other hand, are recorded as type ‘deletion’ in `align_n`.

6. Create match files. Using the updated performance-to-score alignment `align_n`, we

create new match files, and manually add attributional information (e.g., ‘diff_score_version’, ‘voice_overlap’) to score notes to reflect edge cases described in step 4.

4. DATASET OVERVIEW

The *Batik-plays-Mozart* dataset contains performances by pianist Roland Batik of twelve Mozart sonatas (see Table 2 for the list of sonatas), corresponding to approx. 102,400 played notes and 223 minutes of music, for which the performances are provided in MIDI, musical scores in MusicXML, and the alignment in match file format. Approximately 98,300 (95.36%) of all performed notes are aligned with a corresponding score note, the remaining 4,100 (4.44%) represent insertions (reflecting mostly ornaments). Roughly 200 score notes have been omitted in the performances.

For each performance, we also provide the performance note arrays, which capture each played note with its note ID along with onset and duration information in seconds and MIDI ticks, as well as velocity and pitch information. Likewise, the dataset includes the score note array (unfolded according to the repeats as played by the pianist and reflected in the alignment), which captures each score note with its (MusicXML) note ID (including repeat suffixes, where applicable), onset and duration information in terms of beats (reflecting the time signature), and quarter notes (reflecting a “normalized” score time unit), and pitch and voice information.

We link our aligned score note arrays to the musicological annotations in [1] via their temporal position in the following way: In the second version⁸ of the dataset, each annotation label for harmonies, cadences, and phrases is unequivocally referenced to a temporal score position represented in terms of quarterbeats and measure number, where the first expresses the distance of the label from the beginning of the piece in quarter note units. We leverage these two temporal parameters to link each note-aligned score note array by first reducing it to its shortest form (without any unfolded repeats), aligning it temporally with the musicological annotations, and eventually unfolding it according to the performed repetition structure.

5. DATASET DEMONSTRATIONS

This section presents two simple examples of the kinds of studies that are made possible by our dataset. The first is motivated by a directly related study in the Annotated Mozart Sonata corpus paper [1]; the second shows how precise performance alignments permit more detailed investigations relating to cadences and their performance.

5.1 Global tempo and harmonic density

In a first study, we replicate the second experiment in Hentschel et al. [1], aimed at investigating the relationship

⁸ https://github.com/DCMLab/mozart_piano_sonatas

Sonata	Performed Notes	Duration (min)	Match Notes	%	Insertion Notes	%	Deletion Notes	%

Table 2. List of sonatas in the *Batik-plays-Mozart* dataset. The bottom row represents the sum in all columns except for those expressing percentages, for which the mean is shown.

between tempo and harmonic change rate. The basic question asked in [1] was whether the rate at which the harmony changes in a piece is correlated with the piece’s typical performance tempo. Their study involved determining the average (median) performance duration of each sonata movement from 6 complete commercial sonata recordings, and correlating harmonic label density (rate of harmonic labels in their annotations, per performance time unit) with average overall performance tempo (number of quarter notes per performance time unit). We repeat the same experiment with our pianist’s performances and our alignment files instead of 6 pianists’ audio recordings.

We apply the same procedure as in [1], unfolding the score according to the repeat structure of the piece in order to calculate the actual piece length (in terms of quarter notes). The only difference is that we do this according to the repeats actually performed by the pianist (which are expressed in our match files, thus omitting the need for a dedicated “unfolding” step), whereas [1] seem to have assumed that all repeats were played by all pianists.

Comparing our results (Fig. 3) to Fig. 10 in [1], we see a similar general trend, in the form of a roughly linear increase in harmonic label density with performed tempo (slope = .43, $r = .75$, compared to .48 and .80, respectively, in [1]).⁹ However, we also immediately see a marked difference in the performance tempo distribution: in [1], Fig. 10, there is a relatively large cloud of points (sonata movements) with conspicuously high tempos of 180–200 (quarters per minute), which does not appear in our plot, and which we believe may point to a systematic problem in their way of estimating playing tempo: assuming that all notated repeats are played out by the performers leads them to overestimate the tempo in all cases where some or a majority skipped some repeats.¹⁰

⁹ Note that we have a somewhat smaller set of points, because we only have 12 of the 18 sonatas in our dataset.

¹⁰ Of course, the authors explicitly acknowledge the problem: “Also, some of the initial assumptions might have to be revisited. For example, the extreme outlier suggesting a tempo of 239 quarter notes per minute is due to the fact that for this particular piece – the first movement of K. 533/494 – there seems to be a convention among pianists to repeat the first part of the piece, but not the second (as the score would suggest), which of course reduces the performance duration.” [1] (p.76), but a comparison

Figure 3. Correlation between global tempo (as measured in quarter notes per minute) and harmony label density

We thus see an immediate advantage of our more precise performance-aligned corpus: the match files naturally give correct tempo and score duration information, being based as they are on score-performance alignments that reflect the actual repeat structure played by our performer. Still, we can say that our results support and confirm the overall hypotheses proposed there, showing a more or less linear relationship between harmonic label density and global performance tempo.

5.2 Performance of different cadence types

Our data permits much more detailed investigations into relationships between structural aspects of a piece, and how these are translated into performance decisions by a pianist. As a simple example, we investigate variations in local tempo before various types of cadences. Specifically, we compare the local tempo prior to a cadence annotation across different tempo classes for authentic (perfect and imperfect, i.e., PAC and IAC) and half cadences (HC), and differentiate between the cases when a cadence falls on either a downbeat or a weak beat. The hypothesis to be tested

with our distribution implies it might be more severe than expected.

Figure 4. Comparison of local timing strategies one quarter note before and after authentic and half cadence labels, over different tempo classes (in increasing tempo from top to bottom), for cadences falling on a downbeat (left) or weak beat (right). Colour identifies cadence type, line style notated tempo class.

here is that a performer will tend to shape cadences differently, in terms of tempo, depending on their type and degree of ‘finality’.

To compute the local tempo curves, we consider a uniform window spanning one quarter note each preceding and following a cadence label.¹¹ For each score-note-aligned performed note in that window, we define the local tempo via the *beat period* (*BP*), which we calculate as the ratio of the inter-onset-interval (IOI) between the current *performed* onset and the subsequent one, and the IOI between the current *notated* onset and subsequent one. We exclude grace notes and their corresponding performed notes from this calculation in order to remove outliers.

Next, we perform time-wise interpolation on these tempo curves to obtain beat period values at eighth note intervals within the window. Given that we are most interested in the local timing strategy immediately before a label (that is, an eighth note before the label position), we discard those curves where that particular time point is interpolated. Following this procedure, we obtain a total of 3,540 local tempo values (corresponding to 708 curves), of which 251 (7.09%) values are interpolated.

Figure 4 shows the mean of local tempo curves across different tempo classes, for cadence labels annotated on a downbeat (left) and on a weak beat (right), respectively. For both authentic and half cadence types, the differences in local tempo diminish with increasing global tempo for both downbeat and weak beat cadences. Likewise, the tempo profiles tend to flatten out with increasing global tempo, suggesting that the pianist takes more liberty, in terms of expressive timing, in slow pieces. For this reason, we focus our analysis on the *adagio* tempo class, the slowest tempo (the solid line plots in Fig. 4).

The influence of the beat level on the local tempo for half cadences seems to be negligible, with the local beat period decreasing slightly prior to the cadence (causing an

increase in local tempo, i.e. an *accelerando*), regardless of whether it falls on a downbeat or weak beat. For authentic cadences, we can see a substantial difference in expressive tempo depending on whether or not the label falls on a downbeat: for authentic cadences falling on a downbeat, the mean tempo curve for the *adagio* tempo class corresponds mostly to what one would expect (i.e., a very clear *ritardando* in preparation of the cadence) based on the underlying harmonies and their notion of tension and release. Interestingly, this *ritard* seems to continue somewhat after the resolution into the tonic, suggesting a lengthening of the tonic arrival. For weak-beat authentic cadences, a similar significant preparation or anticipation is largely missing.

6. CONCLUSION AND FUTURE WORK

We have presented *Batik-plays-Mozart*, a piano performance dataset linking professional Mozart piano sonata performances to expert-labelled musical scores, at the level of notes. The resulting dataset is the first of its kind to combine professional performances in precise, recorded MIDI with curated musical scores and expert musicological and structural annotations [1] at this level of detail.

We presented two preliminary experiments, intended to demonstrate the benefits of having such precise, note-aligned performance–score–structure annotation data for studying expressive features and their relation to the underlying musical structure.

Our plan for future work includes the transcription of the remaining six sonatas of the Mozart piano sonatas corpus from audio recordings by the same pianist, and their subsequent alignment to the musical scores using state-of-the-art transcription and alignment models. By doing so, we hope to advance our understanding of the differences between transcribed and recorded MIDI, and to evaluate the potential benefits of incorporating an alignment step to improve the quality of transcription.

¹¹ In the *Annotated Mozart Sonatas Corpus* [1], cadence labels are placed at the onset of the final target harmony (e.g., *I/i* for authentic cadences).

7. ACKNOWLEDGMENTS

We wish to express our gratitude to pianist Roland Batik for his gracious permission to publish the detailed measurements of his performances. We also want to thank the authors of the *Annotated Mozart Sonatas Corpus* for their tremendous efforts, and for permitting us to link our data to theirs. This work receives funding from the European Research Council (ERC), under the European Union’s Horizon 2020 research and innovation programme, grant agreement No. 101019375 (*Whither Music?*). The LIT AI Lab is supported by the Federal State of Upper Austria.

ABSTRACT

Generating a stereophonic presentation from a monophonic audio signal is a challenging open task, especially if the goal is to obtain a realistic spatial imaging with a specific panning of sound elements. In this work, we propose to convert mono to stereo by means of predicting parametric stereo (PS) parameters using both nearest neighbor and deep network approaches. In combination with PS, we also propose to model the task with generative approaches, allowing to synthesize multiple and equally-plausible stereo renditions from the same mono signal. To achieve this, we consider both autoregressive and masked token modelling approaches. We provide evidence that the proposed PS-based models outperform a competitive classical decorrelation baseline and that, within a PS prediction framework, modern generative models outshine equivalent non-generative counterparts. Overall, our work positions both PS and generative modelling as strong and appealing methodologies for mono-to-stereo upmixing. A discussion of the limitations of these approaches is also provided.

1. INTRODUCTION

Single-channel monophonic (mono) signals are found in multiple situations, such as historical recordings or current ones made with a single microphone (e.g., field recordings, amateur band rehearsals, etc.). Even recordings made with two or more microphones that are not spaced enough or that do not have enough directivity may be better treated by downmixing to mono (e.g., mobile phone recordings). Furthermore, many processing algorithms, including modern deep neural network algorithms, cannot yet or are simply not designed to handle more than one channel. Unlike these scenarios, the most common listening experiences, either through loudspeakers or headphones, involve two-channel stereophonic (stereo) signals. Hence the usefulness of mono to stereo upmixing.

Classical approaches to produce a pseudo-stereo effect from a mono signal are based on decorrelation. Ini-

tial approaches used time delays and complementary filters [1], although all-pass filters [2] are commonly used nowadays, together with multi-band processing to improve the effect [3–5]. Instead of multi-band, estimation of foreground/background time-frequency tiles can also be performed [6]. Decorrelation approaches, however, only provide a mild stereo effect, with limited width, and cannot spatially separate individual elements in the mix. To overcome the latter, researchers have considered source separation approaches [7–9]. The main idea is that, if individual elements or tracks are available, those can be panned to any location, producing a more realistic spatial image. Nevertheless, this approach presents several drawbacks: firstly, even the best-performing source separation algorithms produce artifacts [10], which can be highly audible in the stereo render; secondly, current separation algorithms are very restrictive in the number and types of elements they can separate [11], thus considerably limiting their application in real-world spatialization tasks; thirdly, after elements or tracks are separated, it remains to be seen how can they be automatically panned in a realistic manner (cf. [12]), which is the reason why separation-based approaches usually involve user intervention in the panning stage [7–9].

Music is a paradigmatic example where, apart from stereo capture, artists and engineers massively exploit the stereo image to serve a creative artistic intent. Instrument panning is a fundamental part of music mixing, and achieving the right balance requires musical sensibility as well as technical knowledge [13]. However, apart from some style conventions, the stereo image of a music mix is a highly subjective construct: given a set of input tracks, there are many plausible stereo renditions from which selecting the final mix is practically only a matter of artistic choice. Hence, we posit that this is a perfect ground for modern deep generative models [14]. However, to our surprise, we only found one work using deep neural networks for mono-to-stereo [15], with very limited generative capabilities.

In this work, we propose the use of machine learning techniques and parametric stereo (PS) decoding [16,17] for converting mono to stereo. PS is a coding technique that allows to transmit a stereo signal through a mono signal plus side information that, with enough bit rate, can be used to recover an almost transparent version of the original stereo content. By leveraging machine learning techniques, we generate (or invent) plausible versions of PS parameters in situations where side information is not available. These

parameters can then be used to decode an existing mono signal into a plausible stereo one. We propose two variants of PS generation: one based on a classical nearest neighbor approach [18] and another one based on deep generative modeling. For the latter, we consider both common autoregressive modeling [19] and more recent masked token modeling [20], and show that there can be noticeable differences between the two. We use subjective testing to compare the proposed approaches and show that PS generation can produce results that are more appealing than considered competitive baselines. We also introduce two objective evaluation metrics and discuss the limitations of both PS and generative approaches for mono-to-stereo.

2. PARAMETRIC STEREO

PS exploits the perceptual cues that are more relevant to our spatial perception of sound, namely the fact that directional sources produce interaural level and phase (or time delay) differences, and the fact that diffuse sound fields manifest as decorrelated signals at the two ears. These cues effectively describe how a mono signal is mapped to the left and right stereo channels, and can be measured using three quantities or parameters [16, 17]: interchannel intensity differences (IID), interchannel time differences (or, equivalently, phase differences), and interchannel coherence or correlation (IC). PS parameters are computed in frequency bands, to reflect the frequency-dependent nature of the spatial properties of stereo content, and also on a frame-by-frame basis, to reflect the time-varying nature of frequency cues and spatial images. An important observation is that PS is capable of capturing spatial attributes that are perceptually relevant and re-instate those without changing signal levels, tonality, or other artifacts that may arise from methods that operate on audio signals directly. In this work, for compactness and ease of implementation, we choose to use the two-parameter approach by Breebaart et al. [17], which models IID and IC without interchannel phase differences, accepting that this two-parameter approach is not providing the best possible quality of PS coding. We now overview this PS coding strategy and introduce the main notation of the article.

2.1 Encoding

Given two complex-valued spectrograms expressed as complex matrices \mathbf{X} and \mathbf{Y} , where rows represent frequency bins and columns represent frames, we define the band-based cross-spectrogram function

$$\rho(\mathbf{X}, \mathbf{Y}) = \mathbf{B} (\mathbf{X} \odot \mathbf{Y}^*),$$

where \odot denotes elementwise multiplication, $*$ denotes elementwise complex conjugate, and \mathbf{B} is a matrix with ones and zeros that is used to sum frequency bins according to a certain frequency band grouping (using matrix multiplication). In this work, we use the same spectrogram settings and banding as in [17]: frames of 4,096 samples for 44.1 kHz signals, 75% overlap, a Hann window, and

34 bands which are approximately distributed following equivalent rectangular bandwidths.

Given the two complex spectrograms \mathbf{L} and \mathbf{R} corresponding to the left and right channels of a stereo signal, we can compute the IID using

$$\mathbf{P}^{\text{IID}} = 10 \log_{10} (\rho(\mathbf{L}, \mathbf{L}) \oslash \rho(\mathbf{R}, \mathbf{R})),$$

where \oslash denotes elementwise division. The IC is similarly derived from the cross-spectrogram following

$$\mathbf{P}^{\text{IC}} = \text{Re} \{ \rho(\mathbf{L}, \mathbf{R}) \} \oslash \sqrt{\rho(\mathbf{L}, \mathbf{L}) \odot \rho(\mathbf{R}, \mathbf{R})},$$

where $\text{Re}\{\}$ extracts the real part of each complex value and the square root is applied elementwise. Notice that the use of the real part instead of the absolute value allows to retain information on the relative phase of the two signals that would otherwise be lost. We finally quantize \mathbf{P}^{IID} and \mathbf{P}^{IC} by discretizing each matrix element. To do so, we use the same non-uniform quantization steps as in [17]: 31 steps for IID and 8 for IC. We denote the quantized versions as \mathbf{Q}^{IID} and \mathbf{Q}^{IC} .

To facilitate subsequent operation, and to prevent potential prediction mismatches between IID and IC, we join both parameters and treat them as one. For \mathbf{P}^{IID} and \mathbf{P}^{IC} , we concatenate them in the frequency axis and form a single matrix \mathbf{P} . For \mathbf{Q}^{IID} and \mathbf{Q}^{IC} , we fuse them elementwise into individual integers using the amount of IC quantization steps. This way, $\mathbf{Q}_{i,j} = 8 \cdot \mathbf{Q}_{i,j}^{\text{IID}} + \mathbf{Q}_{i,j}^{\text{IC}}$ (note that we can recover back $\mathbf{Q}_{i,j}^{\text{IID}}$ and $\mathbf{Q}_{i,j}^{\text{IC}}$ using the division and modulo operators).

2.2 Decoding

To decode the above PS encoding, we perform a mixing between the available mono signal and a decorrelated version of it. We decorrelate a mono signal \mathbf{S} by applying a cascade of 4 infinite impulse response all-pass filters and obtain \mathbf{S}^{D} (this all-pass filter is an enhanced version of the basic one proposed in [17] thanks to transient detection and preservation, which avoids time smearing). After that, we can decode the estimated left and right channels $\hat{\mathbf{L}}$ and $\hat{\mathbf{R}}$ by carefully mixing \mathbf{S} and \mathbf{S}^{D} . We can do so with

$$\begin{aligned} \hat{\mathbf{L}} &= \mathbf{M}^a \odot \mathbf{S} + \mathbf{M}^b \odot \mathbf{S}^{\text{D}}, \\ \hat{\mathbf{R}} &= \mathbf{M}^c \odot \mathbf{S} + \mathbf{M}^d \odot \mathbf{S}^{\text{D}}, \end{aligned}$$

using mixing matrices \mathbf{M} , which are computed from the coded PS parameters \mathbf{P}^{IID} and \mathbf{P}^{IC} . The exact calculation of mixing matrices \mathbf{M} is straightforward to obtain by adapting to matrix notation the formulation in [17], to which we refer for further detail and explanation.

3. PARAMETRIC STEREO GENERATION

We now explain the proposed approaches for PS generation. All of them share the above encoding-decoding formulation, either using the quantized or unquantized versions. During training, stereo signals are used to compute input downmixes $\mathbf{S} = (\mathbf{L} + \mathbf{R})/2$ and target PS parameters \mathbf{P} or \mathbf{Q} (hence the proposed approaches aim at producing

$\hat{\mathbf{P}}$ or $\hat{\mathbf{Q}}$). Note that, in the case of the generative models we consider, one has to additionally input contextual PS parameters in a teacher-forcing schema [21]. We also want to note that, since they are quite common practice, it is not in the scope of the current work to provide a detailed explanation of existing generative models (instead, we refer the interested reader to the cited references). In all proposed approaches, we tune model hyperparameters by qualitative manual inspection in a preliminary analysis stage. PS specifications are predefined and correspond to the ones mentioned in Sec. 2. Neural network approaches use Pytorch’s [22] defaults and are trained with Adam for 700 epochs using a batch size of 128 and a learning rate of 10^{-4} , with warmup cosine scheduling.

3.1 Nearest neighbor

The first approach proposes to impose the PS parameters of existing, similar stereo fragments to individual mono frames using a nearest neighbor (NN) algorithm [18]. We call the approach PS-NN. The idea is to retrieve frame-based PS parameters using mono frame sequences, and to use the sequence of those retrieved parameters to decode the mono input. At training time, we randomly select a song, randomly extract an $N = 20$ frame spectrogram \mathbf{S} and its corresponding parameters \mathbf{P} , and compute a key-value vector pair (we here use the magnitude spectrogram). The key vector is formed by framewise averaging the energy in each band,

$$\mathbf{k} = \frac{1}{N} \sum_{j=1}^N \mathbf{B} \mathbf{S}_{:,j}, \quad (1)$$

and the value vector corresponds to the PS parameters of the last frame, $\mathbf{v} = \mathbf{P}_{:,N}$, which allows for a fully-causal schema. We repeat the process half a million times and store all pairs in a nearest neighbor structure. At test time, for every frame of the input mono signal, we compute an average as in Eq. 1, query the nearest neighbor structure, retrieve the $\hat{\mathbf{v}}$ vector of the closest neighbor (using Euclidean distance), and assign it as the predicted PS parameter for that frame. This way, we obtain a sequence of estimated PS parameters $\hat{\mathbf{P}}$.

In preliminary analysis, we observed that PS-NN produced a high-rate ‘wobbling’ effect between left and right (that is, panning was rapidly switching from one channel to the other) and presented some temporal inconsistencies (that is, sources were unrealistically moving with time, even within one- or two-second windows). To counteract these effects, we implemented a two step post-processing based on (i) switching the sign of $\hat{\mathbf{P}}_{:,j}^{\text{IID}}$ if the Euclidean distance to $\hat{\mathbf{P}}_{:,j-1}^{\text{IID}}$ was smaller, and (ii) applying an exponential smoothing on the columns of $\hat{\mathbf{P}}$ with a factor of 0.95. This post-processing substantially reduced the aforementioned undesirable effects.

3.2 Autoregressive

The second approach proposes to model PS parameters with a deep generative approach based on an autoregres-

sive (AR) transformer [19]. We call the approach PS-AR. Our architecture is composed by 7 transformer encoder blocks of 512 channels, with 16 heads and a multilayer perceptron (MLPs) expansion factor of 3. We use sinusoidal positional encoding at the input, and add a two-layer MLP with an expansion factor of 2 at the output to project to the final number of classes (which is 31×8 tokens times 34 bands per frame, see Sec. 2.1). The input is formed by a projection of the mono spectrogram \mathbf{S} and the teacher-forcing information \mathbf{Q} into a 512-channel activation \mathbf{H} ,

$$\mathbf{H} = \phi(\mathbf{S}) + \sum_{i=1}^B \xi_i(\mathbf{Q}_{i,:}), \quad (2)$$

where ϕ is a two-layer MLP with an expansion factor of 2, $B = 34$ is the number of bands, and ξ_i is a learnable per-band token embedding (which includes the mask token, see below). We train the model with weighted categorical cross-entropy, using the weight

$$w = 1 + \lambda \sigma \left([\mathbf{P}^{\text{IID}}]_{\pm\epsilon} \right) + \sigma(\mathbf{P}^{\text{IC}}), \quad (3)$$

calculated independently for every element in the batch. In Eq. 3, $\sigma(\mathbf{X})$ corresponds to the elementwise standard deviation of \mathbf{X} , $\lambda = 0.15$ compensates for different magnitudes, $[\]_{\pm\epsilon}$ corresponds to the clipping operation, and $\epsilon = 20$ is a threshold to take into account the little perceptual relevance of IIDs larger than 20 dB [23]. In preliminary analysis, we observed that using w qualitatively improved results, as it shall promote focus on wider stereo images and more difficult cases.

PS-AR follows a PixelSNAIL recursive approach [24], starting with the prediction of lower frequency bands, then higher frequency bands, and moving into the next frame once all bands are predicted. To efficiently exploit the past context, all input sequences have full-sequence teacher-forcing except for the upper frequency bands of the last frame, which are masked consecutively and uniformly at random during training [24]. At test time, we sample recursively, following the same masking strategy and using a temperature hyperparameter $\tau = 0.9$. In addition, we employ classifier-free guidance [25] with a hyperparameter $\gamma = 0.25$. For that, we use the approach in [26], which modifies the conditional logits \mathbf{U}^{cond} with unconditional ones $\mathbf{U}^{\text{uncond}}$ such that

$$\mathbf{U} = (1 + \gamma) \mathbf{U}^{\text{cond}} - \gamma \mathbf{U}^{\text{uncond}}. \quad (4)$$

To have both a conditional and an unconditional model within the same architecture, following common practice, we randomly replace $\phi(\mathbf{S})$ in Eq. 2 by a learnable dropout token 10% of the time.

3.3 Masked token modeling

The third approach proposes to model PS parameters with a deep generative approach based on masked token modeling (MTM) [20]. We call the approach PS-MTM. The architecture, loss, inputs, and outputs of the model are the same as in PS-AR, including the cross-entropy weights

(Eq. 3) and classifier-free guidance (Eq. 4). The only difference is the masking approach and the sampling procedure, which implies different hyperparameters for the testing stage (we use $\tau = 4.5$ and $\gamma = 0.75$, but now the temperature τ has a different meaning as explained below).

MTM generates patch representations \mathbf{Q} with quantized elements $\mathbf{Q}_{i,j}$ which are dubbed as tokens (in our case the matrix \mathbf{Q} has dimensions $B \times N$, with N being the number of considered audio frames; the maximum number of tokens in $\mathbf{Q}_{i,j}$ is 31×8 , as defined in Sec. 2.1). During training, the teacher-forcing input \mathbf{Q} is masked uniformly at random, and only the ground truth elements corresponding to the masked positions are used to compute the cross-entropy loss at the output. The number of elements to mask is also selected at random following a cosine schedule [20] (this specifically includes the case where all patch elements are masked). During sampling, patch representations are formed with 50% overlap, using no masking for the first half of the patch, similar to [26].

MTM sampling is an iterative process that achieves orders of magnitude speedups compared to autoregressive modeling (in our case PS-MTM uses 20 steps for a 3 s hop, while PS-AR requires $B = 34$ steps for just a single audio frame of a few milliseconds). MTM iteratively samples a masked patch, performs predictions with classifier-free guidance [26], chooses the predictions with the highest logit score for the next iteration (they will become unmasked and fixed), and reduces the percent of masked tokens following the same scheduling as in training until no masked elements remain [20]. Differently from training, the masking used in sampling is not random, but based on logit scores (lowest ones become masked), and noise is added to logit scores to promote diversity [20, 26]. In our case, we employ Gaussian noise with zero mean and a standard deviation τ , which becomes our redefined temperature parameter.

4. EVALUATION

To train and evaluate all approaches we use a collection of professionally-recorded stereo music tracks at 44.1 kHz. We consider 419,954 tracks for training and 10 k for evaluation, and randomly extract a 10 s chunk from each track. During training, we sample 6 s patches from those and perform data augmentation using a random gain and also randomly switching left and right channels.

4.1 Baselines: regression and decorrelation

In addition to the original stereo and its mono downmix, we consider two additional baselines to compare with the previous approaches. The first baseline corresponds to an ablation of the deep generative approaches, and tries to answer the question of whether a generative component is needed or convenient for the task. Thus, the baseline consists of a neural network with the exact same configuration as PS-AR or PS-MTM, but substituting the generative part by standard regression with mean-squared error [18]. We term this baseline PS-Reg, and note that it could be con-

sidered an enhanced modern version of the approach of Chun et al. [15], using PS.

It is interesting to mention that, in preliminary analysis, we observed that PS-Reg accurately estimated IC values, but consistently failed to predict IIDs. The predicted IIDs had minimal deviation from zero, which can be attributed to the probability distribution function of IID values being centered around zero with equally plausible deviations to the right and to the left. This was an early indication that the one-to-many mapping of IID prediction cannot be correctly handled by regression methods, and that the task would be better served by a generative approach.

The second baseline we consider corresponds to a variant of classical decorrelation approaches. Here, the decorrelation is implemented by means of an all-pass filter network enhanced by (i) detection and preservation of transients, and (ii) a frequency-dependent mix between original and decorrelated signals to achieve a frequency-dependent IC. We term this baseline Decorr, and we note that it could be considered an improved modern version of the approaches [1–6].

4.2 Objective measures

To the best of our knowledge, there are no objective measurements for plausible stereo renderings nor suitable PS prediction scores. Due to the highly creative/subjective nature of the task, common error measurements may not be appropriate. Therefore, as a way of measuring progress, we propose to use a couple of metrics inspired from the literature on generative modeling (cf. [14]). The first metric we consider is the minimum error on a large sample basis, E_{\min} . Given a large sample of generated PS parameters ($K = 128$ for a single audio excerpt), E_{\min} chooses the minimum error with respect to the ground truth:

$$E_{\min} = \min_k \left[\sum_{i,j} \delta \left(\mathbf{P}_{i,j}, \hat{\mathbf{P}}_{i,j}^{(k)} \right) \right],$$

where δ is a suitable error function. The idea is that if we allow the model to generate many samples for every input, in the limit of very large K one of them should come close to the ground truth. For PS parameters, we use absolute errors, weight the IID to compensate magnitudes with IC, and take into account some perceptual relevance for IID as in Sec. 3.2 and Eq. 3:

$$\delta(x, y) = \begin{cases} \lambda |[x]_{\pm\epsilon} - [y]_{\pm\epsilon}| & \text{for IID,} \\ |x - y| & \text{for IC.} \end{cases}$$

The second metric we consider is the Fréchet distance on the PS parameter space, D_F . Given a pool of PS parameters \mathcal{P} and a K times larger pool of generated parameters $\hat{\mathcal{P}}$, assuming Gaussian distributions, D_F is computed as

$$D_F = \left| \mu(\mathcal{P}) - \mu(\hat{\mathcal{P}}) \right|^2 + \text{Tr} \left\{ \sigma(\mathcal{P}) + \sigma(\hat{\mathcal{P}}) - 2\sqrt{\sigma(\mathcal{P})\sigma(\hat{\mathcal{P}})} \right\},$$

Figure 1. Preference results for the items included in the subjective test (Sec. 4.3). Markers indicate average values and vertical bars indicate the 95% confidence interval associated to them.

where $\text{Tr}\{\}$ denotes the matrix trace and μ and σ correspond to the mean vector and the covariance matrix over frames, respectively. The Fréchet distance has become a standard measure in generative modeling where, instead of the PS parameters used here, activations of pre-trained classification networks are used. We will see that it is also able to provide some informative cues in our task (Sec. 5).

4.3 Subjective evaluation

Given the creative/subjective nature of the task, the best way to measure performance is through subjective testing. In this study, we ran a preference test with 24 listeners on 7 song excerpts of 10 s from the test set. To select those excerpts, we ranked the test excerpts based on w (Eq. 3) and randomly selected them from the top quartile. When doing so, we manually verified that the selected excerpts covered distinct musical genres and ensured that a PS-decoded version did not exhibit significant coding degradation (this way, we prime the listener to focus on the stereo image instead of potential artifacts introduced by our implementation of PS, Sec. 2).

The test consisted in providing a rating between 0 and 100 to 7 approaches: the three proposed ones, the two baselines, the mono downmix, and the original stereo signal (professional mix, non-coded). Mono and stereo signals provide us with intuitive bounds for the analysis of preference, and also serve us to discard non-expert listeners. Indeed, we found that the task is quite hard for non-experts, who provided many inconsistent ratings when asked to evaluate an appropriate balance between the width and the clarity of the mix. We used the most obvious of those inconsistencies to discard listeners from the test, namely the fact that they rated mono (input) over stereo (professional mix) in one or more occasions. Half of the users (12) did not incur into such inconsistency and were considered reliable enough to derive conclusions from their ratings. To compensate for differences in subjective scales, we normalized excerpt preference tuples between 0 and 1 (that is, we normalized the ratings for the 7 approaches independently per audio excerpt and listener). To measure statistical significance, we used pair-

wise Wilcoxon signed-rank tests and applied the Holm-Bonferroni adjustment for multiple testing with $p = 0.05$. The Wilcoxon signed-rank test is appropriate for our case as it is non-parametric and designed for matched samples.

5. RESULTS

In Fig. 1 we depict the average listener preference for each item and approach. Initially, we see that the pattern differs depending on the test item. For some items, the proposed approaches are preferred over the baselines (e.g., Electro1, Jazz1, and Latin3) while, for some other items, differences between approaches are less clear (e.g., Rock1 and Soul2). All approaches seem to be preferred above the mono signal, except for baseline approaches with Electro1. Noticeably, in some situations, preference for some of the proposed approaches even overlaps with the original stereo (e.g., Electro1, Latin3, and Soul2). The case of Soul2 shows an example where considered approaches are almost as preferred as the original stereo, whereas the case of Jazz1 shows an example where considered approaches are still far from the professional mix.

Despite the different preferences on individual excerpts, upon further inspection we see that a clear pattern emerges when considering all items: proposed approaches rank better than mono and the considered baselines (Fig. 1, right). In Table 1 we confirm that, on average, PS-AR is preferred over the baseline approaches and that, in turn, PS-NN and PS-MTM are preferred over PS-AR. In Table 2, we report statistically significant differences between PS-NN/PS-MTM and the baseline approaches, but not between PS-AR and the baseline approaches (and neither between PS-AR and PS-NN/PS-MTM nor between PS-NN and PS-MTM). Overall, the results show that a generative approach to PS prediction can become a compelling system for mono-to-stereo. The performance of PS-NN is a nice surprise that was not predicted by the objective metrics, which otherwise seem to correlate with listener preference (Table 1; perhaps PS-NN does not follow the trend because it is not a generative approach).

Besides quality, another aspect worth considering is

Approach	$E_{\min} \downarrow$	$D_F \downarrow$	Preference \uparrow
Mono	0.104	20.89	0.090 ± 0.042
PS-Reg	0.069	8.11	0.451 ± 0.066
Decorr	0.093	8.32	0.457 ± 0.064
PS-AR	0.074	0.62	0.527 ± 0.060
PS-NN	0.089	3.08	0.582 ± 0.057
PS-MTM	0.068	0.59	0.608 ± 0.050
Stereo	0.000	0.03	0.908 ± 0.042

Table 1. Results for the objective (E_{\min} , D_F) and subjective (Preference \pm 95% confidence interval) evaluations.

	PS-Reg	Decorr	PS-AR	PS-NN	PS-MTM	Stereo
Mono	✓	✓	✓	✓	✓	✓
PS-Reg		✗	✗	✓	✓	✓
Decorr			✗	✓	✓	✓
PS-AR				✗	✗	✓
PS-NN					✗	✓
PS-MTM						✓

Table 2. Pairwise statistical significance for the case of all test items (12 subjects times 7 excerpts, see Sec. 4.3). The obtained p -value threshold is 0.0053.

speed. In Table 3 we observe that PS-AR, as anticipated, is orders of magnitude slower than the other approaches, to the point of making it impractical for real-world operation. Decorr, PS-Reg, and PS-NN are faster than real-time on CPU and PS-MTM is not. However, one should note that with PS-MTM we can easily trade off sampling iterations at the expense of some quality reduction (see [20, 26]). PS-NN may dramatically improve speed if we consider the use of fast nearest neighbor search algorithms or even hash tables, which make this approach very interesting for real-world deployment (note we deliberately made PS-NN comparable in size to the other approaches, see Table 3).

6. DISCUSSION

Despite the good results obtained above, the subjective test reveals that, for some of the considered excerpts, there is still a gap between professional stereo mixes and the proposed approaches. We hypothesize that this gap is due to (i) limitations of the considered PS encoding, and (ii) the difficulty of the task itself. Regarding (i), we suspect that part of the low subjective scores of PS-based approaches is due to the audio distortions and tonal artifacts introduced by the PS decoding. Thus, we hypothesize that using a commercial implementation of PS coding (or perhaps even learning end-to-end the coding operation) could yield better results. Besides, we think that the fact that PS is defined in a banded domain poses a challenge to PS generation approaches, namely that individual bands are panned but approaches do not have an explicit notion of instrument or ‘entity’. Indeed, we sometimes observe individual entities being panned into two different positions simultaneously (e.g., for the same instrument, we may get some frequencies panned to the left and some to the right, which is an uncommon stylistic decision). A potential solution to this

Approach	Learnable parameters	RTF \downarrow	
		CPU	GPU
Decorr	0	0.25	n/a
PS-Reg	30.1 M	0.32	0.21
PS-NN	34.0 M [†]	0.82	n/a
PS-MTM	34.5 M	5.81	0.33
PS-AR	34.5 M	255.87	8.38

Table 3. Number of learnable parameters and average real-time factor (RTF). Superscript [†] indicates an estimation of 0.5 M key-value pairs with $B = 34$ bands (Sec. 3.1). RTFs are measured on a Xeon(R) 2.20 GHz CPU and on a GeForce GTX 1080-Ti GPU.

problem could be to add better (or more) inputs to the models, together with more capacity, with the hope that they achieve a better understanding of what is a source before panning it. Along this line, it would be perhaps interesting to include some techniques used in the context of source separation with neural network models [11]. Regarding (ii), another issue we sometimes observe is with the temporal consistency of panning decisions, with an instrument appearing predominantly in one channel but then moving (without much artistic criterion) to the other channel after 10 or 20 s. Handling temporal consistency is a transversal problem across all generative models, typically handled by brute force (that is, more receptive field and/or larger models) or by some form of hierarchical or recurrent processing. Nonetheless, it is still an open issue, especially in the case of really long sequences like audio and music.

In addition to the limitations inherent to the technology, there are also some shortcomings in the test methodology. The subjective tests were conducted using headphones, whereas stereo images are typically created and mixed in a studio using professional loudspeaker monitoring. This implies that when critically evaluating the proposed approaches on a professional setup, additional subtleties might be discernible. Another methodological challenge was that often users had difficulty in evaluating multiple test excerpts according to the stated evaluation criteria. A potentially contributing factor to it was the absence of a standardized test methodology for multiple preference testing without a reference.

7. CONCLUSION

In this work we study methods to convert from mono to stereo. Our proposal entails (i) the use of PS for mono to stereo upmixing and (ii) the synthesis of PS parameters with three machine learning methods. We also introduce (iii) the use of modern generative approaches to the task and propose two variants of them. We additionally (iv) overview and adapt an existing PS methodology and (v) propose two tentative objective metrics to evaluate stereo renderings. The three proposed approaches outperform the classical and the deep neural network baselines we consider, and two of such approaches stand out with a statistically significant difference in the subjective test.

8. ACKNOWLEDGMENTS

We thank all the participants of the listening test for their input and Gautam Bhattacharya and Samuel Narváez for preliminary discussions on the topic.

ABSTRACT

Recent developments in MIR have led to several benchmark deep learning models whose embeddings can be used for a variety of downstream tasks. At the same time, the vast majority of these models have been trained on Western pop/rock music and related styles. This leads to research questions on whether these models can be used to learn representations for different music cultures and styles, or whether we can build similar music audio embedding models trained on data from different cultures or styles. To that end, we leverage transfer learning methods to derive insights about the similarities between the different music cultures to which the data belongs to. We use two Western music datasets, two traditional/folk datasets coming from eastern Mediterranean cultures, and two datasets belonging to Indian art music. Three deep audio embedding models are trained and transferred across domains, including two CNN-based and a Transformer-based architecture, to perform auto-tagging for each target domain dataset. Experimental results show that competitive performance is achieved in all domains via transfer learning, while the best source dataset varies for each music culture. The implementation and the trained models are both provided in a public repository.

1. INTRODUCTION

As the time passes by, more and more pre-trained models are being made available in the MIR field. These models can be used in a variety of tasks by providing informative deep audio embeddings for music pieces. In correspondence with publicly available datasets, the vast majority of these models are trained on the so called “Western”¹ musical tradition [1]. While studying world, folk, or traditional music, that fact arises two research questions; on the one hand what is the potential of these models when they

¹ we use the term “Western” to denote music styles which mostly originate from Western cultures, including pop, rock, and Western classical.

are being used in the realm of a different culture and on the other hand how capable can a model be when trained on a specific music tradition on providing meaningful audio embeddings.

There are several experimental setups one can employ in order to derive answers to the above questions. By taking into account the importance of the auto-tagging task in the MIR field [2], it becomes clear that transferring knowledge between domain-specific models to perform this task may lead us to valuable insights. Automatic content-based tagging aims to predict the tags of a music piece given its audio signal. The audio signal includes the acoustic characteristics and some of them are responsible for the occurrence of a tag in a piece, forming a multiple instance problem [3].

A variety of models have been proposed to cope with the automatic tagging of music pieces. They can be divided, according to the input data they process, into the ones that utilize time-frequency representations and the others that accept the raw audio signal. In the first category, CNN-based models which are adopted by the computer vision field can be found, such as VGG-ish [4] as well as specifically developed architectures for music, like Musicnn [5]. A Transformer-based architecture was recently proposed in [6] called Audio Spectrogram Transformer (AST). Regarding the models that process audio, the TCNN [7] and the Wave-U-Net [8] architectures are being commonly used. For the purposes of our study, it is essential to use models of the same category with respect to the input they accept and, thus, we selected the ones that process time-frequency representations because of their popularity in the MIR field.

While using deep neural networks, transfer learning of a trained model can lead to a significant performance improvement on the target domain, compared to one that starts from a random state in the parameters space [9]. Typically, the weights of the target domain model are initialized with the ones of a pre-trained model and then fine-tuning is applied. During this step, one has to determine which of the layers will be trainable and which ones will be kept frozen [10]. In general, it is not clear which part of the network should be allowed to be trained in the target task and, thus, experimentation with different setups is necessary. Standard methods include the fine-tuning of the whole network, as suggested in [11], as well as only the last few layers or a part of the network, as in [12]. We

experiment with both setups to derive valuable insights on knowledge transfer across domains.

Even though under-represented in general, datasets from specific music cultures are evident in the MIR field and a set of the aforementioned methods have been used to perform several tasks. In [13] a classification of Indian art music was conducted using deep learning models while automatic makam recognition in Turkish music was carried out in [14, 15]. With respect to Western music, there are several research works performing auto-tagging via deep learning models, as in [16] and [17].

In this paper, we incorporate a mosaic of different cultures by including six datasets from Western to Mediterranean and Indian music. Three music audio embedding models, two that mainly consist of convolutional layers and a Transformer-based architecture, are utilized on both single-domain and transfer learning experimental setups for music tagging. Results indicate that any model, despite the music culture that it is trained on, has the potential to adapt to another and achieve competitive results. When comparing the contributions of cross-domain knowledge transfers, we notice that they vary for each music culture and we suggest which one is the best candidate to outperform the single-domain approach. To the authors' knowledge, this is the first study which attempts to explore whether existing music audio embedding models can be used to transfer or learn representations for non-Western cultures. For reproducibility, we share the implementation in a public repository².

2. DATASETS

The selection of the datasets is a prominent theme in the current study and it is constrained by the available corpora that reflect different music cultures. By basing our intuition on the location of each culture, we pursue to include three distinct geographic regions each one represented by two corpora.

Even though spread in several continents, we consider the “West” as a single entity and utilize the MagnaTagATune [18] and FMA-medium [19] datasets that mainly belong to this culture. The second region is the eastern Mediterranean represented by the traditions of Greece and Turkey in our study with Lyra [20] and Turkish-makam [21] datasets. The Indian subcontinent is also incorporated with Hindustani and Carnatic corpora [22], corresponding to the music traditions of the Northern and Southern areas of India respectively.

2.1 MagnaTagATune

MagnaTagATune [18] is a publicly available dataset that is commonly used for the auto-tagging problem in the MIR field. It consists of more than 25,000 audio recordings, summing to 210 hours of audio content at total. Each audio recording is annotated with a subset of the unique 188 tags. Typically, only the top 50 most popular tags are used, which include annotations about genre, instruments

and mood. In Table 1, the most frequent tags for MagnaTagATune are presented along with the ones of the other datasets.

2.2 FMA-medium

The Free Music Archive [19] is an open and easily accessible dataset that is used for evaluating several tasks. It contains over 100,000 tracks which are arranged in a hierarchical taxonomy of 161 genres. In order to keep the durations of the datasets balanced whenever possible, and to include genres belonging to Western music styles, we use FMA-medium that consist of 25,000 tracks of 30 seconds each. That means that its total duration is 208 hours, almost equal to the one of MagnaTagATune. With regards to the metadata, we include the top-20 hierarchically related genres of the music pieces.

2.3 Lyra

Lyra [20] is a dataset for Greek traditional and folk music that comprises 1570 pieces and metadata information with regards to instrumentation, geography and genre. Its total duration is 80 hours which makes it the only dataset with duration less than 200 hours in our study. We incorporate the top-30 tags retrieved from columns “genre”, “place” and “instruments” to form our multi-label classification setup.

2.4 Turkish-makam

The Turkish makam corpus [21, 23] includes thousands of audio recordings covering more than 2,000 works from hundreds of artists. It is part of CompMusic Corpora³ [24] which comprises data collections that have been created with the aim of studying particular music traditions. Using Dunya [25] and the related software tool⁴, we were able to get access to 5297 audio recordings, summing in 359 hours, along with their metadata. In order to keep the dataset sizes similar, we set a maximum audio duration equal to 150 seconds which reduced the total length to 215 hours. For the tags, the top-30 most popular with regards to “makam”, “usul” and “instruments” information have been included.

2.5 Hindustani

The Hindustani corpus [22] is also part of CompMusic Corpora. It includes 1204 audio recordings, with a total duration of 343 hours, covering a plethora of artists and metadata categories. By setting the maximum audio duration to 780 seconds, the size of the dataset has been decreased to 206 hours for the needs of our study. Furthermore, information about “raga”, “tala”, “instruments” and “form” has been used to form the labels of each piece. The top-20 most frequent tags have been incorporated to our study as the target of the classification models.

2.6 Carnatic

The Carnatic corpus [22] comprises 2612 audio recordings, summing in more than 500 hours of content. As with the previous datasets, by setting a maximum duration cut equal to 330 seconds, the total duration has been decreased to 218 hours. Identical to Hindustani, the top-20 most popular annotations regarding “raga”, “tala”, “instruments” and “form” have been included for the metadata.

3. METHOD

In this section, the models which are used for the purposes of this study are first presented. We, then, describe how transfer learning is utilized to infer similarities between the music cultures by employing knowledge from the domain adaptation field.

3.1 Models

3.1.1 VGG-ish

All of our models use the mel-spectrogram as their input, a commonly used feature for MIR tasks such as automatic tagging [26]. This selection enables the utilization of CNN-based architectures which have been successfully used in computer vision tasks. The Visual Geometry Group (VGG) network [27] and its variants consist of a stack of convolutional layers followed by fully connected layers.

We use a VGG-ish architecture, similar to the one implemented by the authors in [28], that is a 7-layer CNN, with 3×3 convolution filters and 2×2 max-pooling, followed by two fully-connected layers. It accepts mel-spectrograms that correspond to short chunks of audio as its input, with duration equal to 3.69 seconds.

3.1.2 Musicnn

Musicnn [17] is a music inspired model that uses convolutional layers at its core. Its first convolutional layer consists of vertical and horizontal filters in order to capture timbral and temporal features respectively. These features are, then, concatenated and fed to 1D convolutional layers followed by a pair of dense layers that summarize them and predict the relevant tags. Similar to VGG-ish, it uses

mel spectrograms from short audio chunks at its input with duration 3 seconds.

3.1.3 Audio Spectrogram Transformer

As its name indicates, Audio Spectrogram Transformer (AST) is a purely attention-based model for audio classification [6]. Based on the Transformer architecture [29], AST splits the input mel-spectrogram to 16×16 patches in both time and frequency dimensions that are, in turn, flattened to 1D embeddings of size 768 using a linear projection layer. A trainable positional embedding is also added to each patch embedding so that the model will capture the spatial structure of the input 2D spectrogram. The resulting sequence is fed to the Transformer, where only the encoder is utilized since AST is designed for classification tasks. The output of the encoder is followed by a linear layer that predicts the labels. As the authors that introduced the architecture suggest, we set a specific cut to the input length of the AST model that is equal to 8 seconds in all our experiments.

3.2 Transfer Learning

The purpose of transfer learning is to improve the performance of the models on target domains by transferring knowledge from different but related source domains [30]. In the field of MIR, both transferring feature representations to the target domain from a pre-trained model on a source task [31] as well as learning shared latent representations across domains [32] have been proposed in the past. Yet, these methods have not been applied to non-Western music datasets neither by adapting an existing model to them nor by studying to what end these cultures can be valuable source domains for widely developed models, two aspects which are both studied in this work.

According to the categorization conducted by the authors in [33], these methods belong to *parameter sharing* category of the model-based transfer learning techniques. In the deep learning realm, it is, thus, common to use a trained network for a source task, share its parameters and in turn fine-tune some or all layers to produce a target network. While following this method, one expects it to lead to better results when the participating domains are similar

Model	VGG-ish		Musicnn		AST	
Metric / Dataset	ROC-AUC	PR-AUC	ROC-AUC	PR-AUC	ROC-AUC	PR-AUC
MagnaTagATune	0.9123	0.4582	0.9019	0.4333	0.9172	0.4654
FMA-medium	0.8889	0.4949	0.8766	0.4473	0.8886	0.5024
Lyra	0.8097	0.4806	0.7391	0.4042	0.8476	0.5333
Turkish-makam	0.8696	0.5639	0.8505	0.5299	0.8643	0.5669
Hindustani	0.8477	0.6082	0.8471	0.6016	0.8307	0.5786
Carnatic	0.7392	0.4278	0.7496	0.4182	0.7706	0.4394

Table 2. ROC-AUC and PR-AUC scores of the models on single domain auto-tagging tasks.

to each other. Indeed, by studying the prior work on domain adaptation, one will find that the main strategy consists of minimizing the difference between the source and target feature distributions, when transferring representations from a labeled dataset to a target domain where labeled data is sparse or non-existent [34, 35].

By adapting the above rationale to our study, where the participating domains are all rich in labeled data, we expect that when applying transfer learning by parameter sharing, the more the similarity between the participating domains the better the performance of the target domain on its supervised learning task.

In order to study to what end this hypothesis stands in computational musicology with deep neural networks, we utilize the previously presented models which are widely used in the MIR field and consist of different cores, namely convolutional layers (VGG-ish and Musicnn) and a Transformer module (AST). Having the models trained on each single dataset, we apply all the cross-domain knowledge transfers for each architecture by fine-tuning only the output layer as well as the whole network. We then aggregate the results across the models seeking to derive insights with regards to the similarities between the domains as well as specifying which source is the best candidate for each target dataset.

4. EXPERIMENTS

As already mentioned, we use mel spectrograms as the input of all our models. In order to convert the audio recordings of the datasets to this representation, we use Librosa [36] to re-sample them to 16 kHz sample rate. Then, 512-point FFT with a 50% overlap is applied, the maximum frequency is set to 8 kHz and number of Mel bands to 128. Our intention, in this study, is not the optimization of the performance of the single-domain tasks but rather studying the knowledge transfer across the domains. So, we keep our training setup as close as possible to the literature, at each single domain task, in order to have a sanity check for the implementation.

For VGG-ish and Musicnn models, we use a mixture of scheduled Adam [37] and stochastic gradient descent (SGD) for the optimization method, identical to what the authors at [28] have used. The batch size is set to 16 and the learning rate to $1e - 4$ for both models while the maximum number of epochs are 200 for VGG-ish and 50 for

Musicnn. With regards to the AST model, we follow the setup proposed in [6], namely batch size 12, Adam optimizer, learning rate scheduling that begins from $1e - 5$ and is decreased by a factor of 0.85 every epoch after the 5th one as well as pre-trained on Imagenet Transformer weights.

All our models accept a fixed size audio chunk at their input but need to predict song-level tags. During the evaluation phase, we aggregate the tag scores across all chunks by averaging them to acquire the label scores for the whole audio. We use the area under receiver operating characteristic curve (ROC-AUC), a widely used evaluation metric on multi-label classification problems and the area under precision-recall curve (PR-AUC), a suitable metric for unbalanced datasets [38].

During transfer learning, we initialize all parameters of the target model, except for the output layer, from each source dataset and (i) allow only the output layer to be trained and (ii) train the whole network. In both settings, we use the same hyper-parameters and evaluation procedure with the single-domain setups across all datasets for each model architecture.

5. RESULTS

The performance of the three models on all single-domain tasks can be seen in Table 2. The performance of the Musicnn and VGG-ish models on MagnaTagATune is similar to the reported metrics in [28], which indicates the validity of our implementation. In general, the AST model shows the best performance followed by VGG-ish and then Musicnn. This result should not be taken into account solidly, because no hyper-parameter tuning has been taken place for each domain and in order to keep the duration of the training to less than 24 hours for each task, the number of epochs for Musicnn was significantly less than VGG-ish. On the other hand, one should consider that the AST [6] and VGG-ish [28] models may, indeed, perform better for limited time resources.

In Table 3, one can see the ROC-AUC scores in all single-domain and cross-domain setups. The rows are the source datasets while the columns are the target datasets. A sub-table is constructed for each model architecture and for a transfer from domain A to B , the result of the fine-tuning of only the output layer ('output') as well as all the layers ('all') are reported. The single-domain setup is

Table 3. ROC-AUC scores (%) when applying transfer learning using the models VGG-ish, Musicnn and Audio Spectrogram Transformer. Rows are the source domains and columns the target domains. After initializing the network with the parameters of the trained (at the source dataset) model, fine-tuning on the output layer as well as on the whole network is applied. The diagonal values (under the “all” columns) correspond to the respective single-domain models (no transfer learning) where the experimentation with only the output layer trainable has no meaning.

when source and target is the same dataset and, thus, only training of the whole network has meaning. The table is better parsed column-wise, e.g., by inspecting the results of VGG-ish model on MagnaTagATune when transferring knowledge from the other domains at the upper-left pair of columns in the table.

In order to aggregate all the cross-domain knowledge transfers, we follow the subsequent procedure: for each target task that consists of a specific model, target dataset and fine-tuning method, min-max normalization is applied to the $N - 1$ transfer learning results, where N is the number of all datasets. The previous step leads to the construction of $M \times F$ matrices, M the number of the models and F the number of fine-tuning methods, where rows are the source domains, columns the target domains and diagonal elements are empty. Each cell has a value in the range $[0, 1]$, as a result of the normalization step, while the value 1 corresponds to the knowledge transfer that led to the best performance in the target domain. By calculating the element-wise mean of the produced $M \times F$ matrices, we reach to the result that can be seen in Figure 2.

6. DISCUSSION

The results indicate that knowledge transfer both from Western to non-Western cultures and the opposite can be

beneficial when deep learning models are used to perform automatic music tagging. Indeed, by inspecting Table 3, the general take-home message one should acquire is that regardless of the model architecture, all datasets have the potential to contribute as a source to a target domain by providing their deep audio embeddings. To investigate how valuable knowledge transfers from widely used datasets to non-Western music cultures can be, we focus on the last four datasets, i.e., the last eight columns of the table, and parse the two first rows, corresponding to MagnaTagATune and FMA datasets, at each model architecture. For instance, we notice that for Lyra, when Musicnn is used and fine-tuning only of the output layer is applied, the model coming from MagnaTagATune has the greater ROC-AUC score, namely 71.79%. Additionally, the AST model trained on the FMA-medium dataset, outperforms the others when totally fine-tuned to the Turkish-makam dataset, scoring 87.43%.

In order to study the inverse transfer direction, we center our interest to the first four columns of the entire table. Even though MagnaTagATune and FMA are almost always the best source for each other, the deep audio embeddings provided by the other datasets achieve competitive performance. For example, when MagnaTagATune is the target domain and fine-tuning is restricted to the output layer of the network, we observe that transferring from Turkish-

Figure 1. Average, over the three models, ROC-AUC scores of all cross-domain transfers when fine-tuning of the output layer is applied. The highest bar at each group corresponds to the respective single-domain model.

	MagnaTag-ATune	FMA-medium	Lyra	Turkish-makam	Hindustani	Carnatic
MagnaTag-ATune	—	0.89	0.9	0.54	0.64	0.49
FMA-medium	1.0	—	0.44	0.59	0.48	0.6
Lyra	0.17	0.37	—	0.39	0.39	0.59
Turkish-makam	0.35	0.19	0.52	—	0.44	0.37
Hindustani	0.11	0.36	0.55	0.49	—	0.53
Carnatic	0.25	0.05	0.11	0.66	0.54	—

Figure 2. Cross-cultural music transfer learning results. Rows correspond to the source datasets and columns to the target datasets. The value of each cell (knowledge transfer) is normalized and averaged across all models and fine-tuning methods.

makam leads to a performance that is comparable to the best source (FMA-medium) for all models.

By considering all cross-domain knowledge transfers, one can specify the best candidate to provide a trained model, with a specific architecture, for each target dataset. We, thus, notice that the model that is transferred from Hindustani outperforms the others at the Carnatic dataset, when fine-tuning on the whole Musicnn architecture is applied. A holistic picture of the cross-cultural music transfer learning is depicted in Figures 1 and 2.

In Fig. 1 the scores of all cross-domain transfers when fine-tuning the output layer, can be seen, averaged across the three models. The uniformity of the performances of different sources at each target dataset can be examined. We, thus, recognize that the most unbalanced performances are spotted on the Lyra target domain, a result that is probably related to the smaller size of this dataset compared to the others. By exploring Fig. 2 in a column-wise fashion, we observe that for MagnaTagATune as the tar-

get domain, FMA-medium is the best source with a value equal to 1. This means that in all transfer learning setups, this source performed better than the others in this domain.

Both figures show that MagnaTagATune and FMA-medium perform consistently well across the domains, something that possibly indicates their appropriateness for the auto-tagging task. However, as we move to the Eastern cultures, we notice that their contribution is somehow decreased and other domains tend to contribute similarly or even more in those targets. The values at Fig. 2 should not be considered solidly as similarity metrics between the domains because other factors may also affect the results we notice. It is, although, a first step towards studying different music cultures using deep learning methods.

7. CONCLUSIONS

In this paper, the transferrability of music cultures by utilizing deep audio embedding models is studied. To that end, six datasets and three models were employed while experimentation with two fine-tuning methods took place. The automatic tagging of music pieces served as the supervised learning task where all cross-domain knowledge transfers were applied and evaluated.

The results show that state-of-the-art models can benefit from knowledge transfer not only from Western to non-Western cultures but also the opposite too. By aggregating the scores across all models and fine-tuning methods, the suitability of each source domain for a target task was calculated and, thus, which domain can be the best candidate to transfer knowledge from for each dataset was proposed. Based on the literature, we suggest that this result can be interpreted to a degree as a similarity metric between the music cultures.

We identify that the current study has limitations. In the future, the semantic similarities between the labels of the involved domains will be examined. More datasets and models, like those that process raw audio signals, will be considered as well as semi-supervised and unsupervised learning techniques. Other tasks may be employed such as mode estimation, assuming that key in Western cultures functions in a similar way with makam or raga in other cultures. All datasets can also be utilized to learn music embeddings in order to unveil cross-cultural links between acoustic features and tags.

8. ACKNOWLEDGEMENTS

The authors would like to thank Sertan Şentürk, Alastair Porter and the Universitat Pompeu Fabra for their willingness to provide us with the data without which this study would not have been possible. We would like to also thank Charalampos Saitis and the reviewers for their valuable and constructive comments that helped us improve our work.

ABSTRACT

Optical Music Recognition (OMR) has become a popular technology to retrieve information present in musical scores in conjunction with the increasing improvement of Deep Learning techniques, which represent the state-of-the-art in the field. However, its effectiveness is limited to cases where the target collection is similar in musical context and graphical appearance to the available training examples. To address this limitation, researchers have resorted to labeling examples for specific neural models, which is time-consuming and raises questions about usability. In this study, we propose a holistic and comprehensive study for dealing with new music collections in OMR, including extensive experiments to identify key aspects to have in mind that lead to better performance ratios. We resort to collections written in Mensural notation as a specific use case, comprising 5 different corpora of training domains and up to 15 test collections. Our experiments report many interesting insights that will be important to create a manual of best practices when dealing with new collections in OMR systems.

1. INTRODUCTION

Manual sheet music transcription is a tedious process, prone to errors, and generally requires professionals with precise knowledge of the type of notation and/or music at issue. The alternative to this manual digitization of content is to resort to cutting-edge technology based on artificial intelligence, which performs an automated reading of documents. This technology is known as Optical Music Recognition (OMR).

OMR has been an active research area for decades [1], although the field progressed slowly [2]. Recently, the use of modern machine learning techniques, namely Deep Learning, has led to a paradigm shift that has partially unlocked this situation [3, 4]. Indeed, it has been shown that

current OMR technologies, despite the fact that they are not yet fully mature, are usually a better alternative than performing the entire transcription by hand [5].

Concerning the machine learning methods, the related literature reports that the models provide sufficient precision when the collections to be transcribed are from the same graphic and content domain as the corpus used to train them. This, however, makes it difficult to transfer technology to new collections, since it is not always possible, desirable, or efficient to invest resources in annotating a small portion of the target collection. Although it is naive to assume the availability of training sets from the same domain as a given target collection, in the current data era we can assume to have at least a series of labeled collections, even with different graphic and musical characteristics. This, of course, can and should be used to improve the efficiency of fitting OMR models to new collections for which we do not have specific training sets.

In this paper, we report on a case study focused on Mensural notation to answer questions about the transferability of OMR models to new music collections. To our best knowledge, this work constitutes the first to analyze this issue in the field. We consider Mensural notation as the structuring experimental body because the OMR technology can be considered mature for this notation. Also, we have a significant number of labeled and unlabeled collections in this notation, which allows us to carry out an exhaustive study that is expected to lead to more generalizable conclusions. Specifically, we consider 5 labeled collections that will be used as training sets, along with their possible combinations, and up to 15 unlabeled collections as target.

The rest of the paper is structured as it follows: in Section 2, we provide some background to the topic; in Section 3, we present our methodology to analyze the question at issue; the experimental setup is described in Section 4, while the results and analysis are given in Section 5; finally, we conclude the paper in Section 6, while pointing out some interesting avenues for future work.

2. BACKGROUND

Recent advances in artificial intelligence, with extensive use of Deep Learning (DL) technologies, resulted in about successful approaches to OMR. Specifically, a holistic ap-

proach, also known as end-to-end formulation, which has been dominating the state of the art in other applications such as text or speech recognition [6, 7], is currently considered the reference model in OMR. The related literature includes many successful solutions of this type [8–10]. In this work, we resort to this approach as representative of the state of the art based on DL.

However, as introduced above, there is still no computational approach for creating a universal OMR system; *i.e.*, one that is capable of dealing with any kind of collection. The underlying issue is an overly unsolved challenge in artificial intelligence [11]: DL works well if the problem is statistically regular and there is abundant training data to adequately and representatively learn such regularity. This is, unfortunately, quite difficult to expect when dealing with ancient documents. Instead of trying to solve the underlying problem of machine learning, we take a more practical path to provide a series of best practices to tackle the situation of target collections in the absence of specific training data successfully.

It is important to highlight that, in the OMR literature, there are very few works dedicated to studying the practical aspects of the technology. Pugin and Crawford [12] estimated through a quantitative evaluation the suitability of using the Aruspix machine-learning-based OMR system on a real collection. Furthermore, Alfaro-Contreras et al. [5] analyzed the benefits of using OMR in cases where the accuracy of the system was not perfect. Our work further contributes to this barely explored line of practical aspects for the application of OMR to real-world scenarios from the perspective of the available training data.

3. METHODOLOGY

The focus of the work is essentially experimental. We want to be able to answer specific questions about how to approach the generation of generalizable OMR models. Our objective is to reduce the uncertainty when facing the recognition of collections for which there is no specific training set.

To answer these questions, we will consider as a starting point the availability of N training sets that, even depicting the same musical notation (Mensural notation), differ in graphic characteristics. This will allow drawing more interesting conclusions about the synergy of using a heterogeneous set of training collections. To cover all possibilities, we create models from all possible combinations of these sets ($2^N - 1$ possibilities). Each of these possibilities will be directly evaluated on M test sets (not seen in any training case), also showing heterogeneous characteristics.

As previously mentioned, we will consider a deep end-to-end model as representative of the state of the art in OMR. Below we explain in more detail how this model works.

3.1 Learning framework

For the task, a Convolutional Recurrent Neural Network (CRNN) scheme is proposed for the end-to-end optical music transcription pipeline. The CRNN architecture consists of a block of convolutional layers that learns the relevant features from the input image (single staff), followed by a group of recurrent stages that model the temporal dependencies of the feature-learning block. Finally, a fully-connected network with a softmax activation is used to retrieve the posterigram, which is decoded to obtain the predicted musical symbols.¹

The Connectionist Temporal Classification (CTC) [13] training procedure is used to train the CRNN model using unsegmented sequential data. The training set \mathcal{T} consists of pairs of single musical staff images x_i and their corresponding symbol sequence \mathbf{z}_i in a symbol vocabulary Σ , with 261 units corresponding to the number of different symbols among the training sets. To use CTC as an end-to-end sequence labeling framework, an additional "blank" symbol is included in the vocabulary Σ' .

Formally, let $\mathcal{T} \subset \mathcal{X} \times \Sigma^*$ be a set of data where an image $x_i \in \mathcal{X}$ of a single staff is related to symbol sequence $\mathbf{z}_i = (z_{i1}, z_{i2}, \dots, z_{i|\mathbf{z}_i|}) \in \Sigma^*$, where Σ represents the symbol vocabulary used for encoding the music score. Note that the use of CTC to model the transcription task as an end-to-end *sequence labeling* framework requires the inclusion of an additional "blank" symbol in the Σ vocabulary, *i.e.*, $\Sigma' = \Sigma \cup \{blank\}$.

At prediction, for a given musical staff image input $x_i \in \mathcal{X}$, the model outputs a posterigram $p_i \in \mathbb{R}^{|\Sigma'| \times K}$, where K represents the number of frames given by the recurrent stage. Finally, the predicted sequence $\hat{\mathbf{z}}_i$ is obtained resorting to a *greedy* policy that retrieves the most probable symbol per frame in p_i , later a subsequent mapping function merges consecutive repeated symbols and removes *blank* labels.

4. EXPERIMENTAL SETUP

In this section, we present our choices for the experimental design. First, we describe the considered evaluation metric. Then, we give more implementation details of the deep learning model. Finally, we present and describe the collections selected as train and target sets.

4.1 Evaluation

To evaluate the performance of the OMR model, we resort to the *Symbol Error Rate* (SER). This is computed as the average number of elementary editing operations (insertions, deletions, or substitutions) required to convert prediction $\hat{\mathbf{z}}_i$ into reference \mathbf{z}_i , normalized by the length of the latter.

In general, we are interested in computing the amount of effort it would take for a person to correct the remaining errors in the system. Since computing this human effort

¹ Understanding *musical symbol* as the conjunction of `glyph:position`, *i.e.*, `note_half:L2` (a `glyph note_half` present in the second staff line).

does not scale well in practice (it consumes huge amounts of resources), we believe that this metric is suitable to measure the transcription correctness. In addition, it is a metric that has been commonly applied in previous works on this subject (cf. Section 2).

4.2 Neural model configuration

The CRNN topology is based on the one used in the research [14], where the authors adopt a 4 convolutional layer block with batch normalization, Leaky ReLU activation, and max-pooling down-sampling. The feature maps extracted from the convolutional block are fed into two Bidirectional Long Short-Time Memory layers with 256 hidden units each and a dropout value of $d = 50\%$ followed by a fully-connected network with $|\Sigma'|$ units.

The models were trained with a batch size of 16 elements—note that in experiments where multiple training sets were used all the generated batches in the training process were balanced so the net didn't adjust to a certain corpus. The ADAM optimizer [15] was considered and a fixed learning rate of 10^{-3} . We iterate for 300 epochs, keeping the weights that minimize the SER metric in the validation partition with an early stopping policy of 30 epochs. Finally, all experiments were run using the Python language (v. 3.8.13) with the PyTorch framework (v. 1.13.0) on a single NVIDIA GeForce RTX 4090 card with 24GB of GPU memory.

4.3 Datasets

A set of 20 different white Mensural notation works has been collected for this work, consisting of pairs of staff images and their transcription into sequences of musical symbols. The pieces have been selected looking for diverse cases concerning printers or copyists, layouts, authors, the period in history, and extension.²

4.3.1 Training Datasets

For training, 4 different datasets were chosen from real collections, trying to cover as much variability as possible. When facing a new transcription project, it is usual that no training collection is similar or big enough for building a model to obtain reliable results from the automatic recognition process. In this scenario, the creation of synthetic training data from scratch is a valid alternative that will be evaluated in the work with the PRIMENS dataset. Therefore, we will add this synthetic collection to the set of training sets, resulting in 5 different collections. These training collections are described below.

- **CAPITAN.** The Capitan dataset contains 100 handwritten pages of ca. 17th-century manuscripts in late white Mensural notation extracted from the work with signature B59.850 in the Catedral del Pilar in Zaragoza [16].
- **SEILS.** The SEILS dataset contains 151 printed pages of the “Il Lauro Secco” collection corresponding to an

anthology of 16th-century Italian madrigals in white Mensural notation [17].

- **GUATEMALA.** The Guatemala dataset presents 383 handwritten pages from a polyphonic choir book, part of a larger collection held at the “Archivo Histórico Arquidiocesano de Guatemala” [18].
- **MOTTECTA.** This dataset corresponds to the work “Mottecta (Mottecta Francisci Guerreri, que partim quaternis partim quinis alia senis alia octonis concinuntur vocibus, liber secundus dataset)”, authored by Francisco Guerrero in the 16th-century and edited by Giacomo Vincenti in the 17th-century. This 297-printed mensural pages corpus has been obtained from the collection of mensural books of the Biblioteca Digital Hispánica.³
- **PRIMENS.** The Printed Images of Mensural Staves (PrIMenS) dataset is a synthetic corpus that tries to resemble low-quality real scans of printed mensural sources. It has been built from works composed by Agricola, Frye, and Ockeghem available in the Josquin Research Project⁴. Given polyphonic scores encoded in `**kern` [19] format, each voice is separated into a single file. In order to increase the variability, the original clefs are modified according to the instrument annotation in the voice. To obtain single staves, the whole work has been divided into a random number of measures from 3 to 18, and the resulting files have been converted into `**mens` [20] format. The corresponding agnostic encoding has been generated following the method described in [17]. The images have been obtained using the digital engraver Verovio [21] by applying random values to all the options in the allowed ranges. Finally, those images have been distorted to simulate real printed image scans by using a random sequence of graphical filters with the GraphicsMagick Image Processing. Additionally, this real-image simulation process has been complemented by composing randomly damaged old paper textures with distorted images.

To better understand the differences that might appear among these corpora, we provide a staff example from each corpus in Fig. 1.

4.3.2 Target Datasets

For the task of testing the suitability of each model, 15 datasets have been chosen. These corpora have been carefully and specifically labeled for this work, and are summarized in Table 1 and Fig. 2.

The printed sets have been extracted from the publicly available collection of Mensural books in the Biblioteca Digital Hispánica.⁵ The handwritten collections are obtained from archive of Catedral del Pilar in Zaragoza [16].

Figure 1: Samples of staves of the different training datasets employed.

Name (ID)	Number of staves	Printer
Amorosa (Amo)	224	H. of G. Scoto
Chansons (Cha)	173	A. Le Roy, R. Ballard
Dolci (Dol)	170	H. of G. Scoto
Lamentationes (Lam)	528	G. G. Carlino
Madrigali (Mad)	201	G. Scotto
Magnificat (Mag)	1361	Antonio Gardano
Missarum (Mis)	489	H. of G. Scoto
MusicaNova (Mus)	874	Antonio Gardano
Orlande (Orl)	259	A. Le Roy, R. Ballard
Responsoria (Res)	666	G. G. Carlino
Sacrarum (Sac)	460	Antonio Gardano
Villanelle (Vil)	59	G. G. Carlino
B3.28 (B3)	60	Handwritten
B50.747 (B50)	80	Handwritten
B53.781 (B53)	32	Handwritten

Table 1: Features of the different target collections considered in this work.

5. RESULTS

Given the number of training corpora (5), the test datasets (15), and the number of experiments (31), we are able to report up to 465 different SER results. This enables us to properly summarize the experimentation, extracting meaningful learnings that will be used to state the best practices to deal with training data on new projects. The analysis of the results follows. The extended raw results of each experiment are attached to this document in the supplementary material.

5.1 Importance of size and variability

In order to understand which is the best training set selection strategy when facing a new unseen collection, all the possible combinations of the datasets available for training have been evaluated against the different target sets.

Figure 2: Image examples from the selected corpora as test partition. The images follow a left-right-top-bottom order concerning the list order from Table 1.

The more training sets we include in the combination the greater the number of staves of that combined training set will be. To evaluate which factor is more important, either the variability, given by the number of different training sets included in each combination, or the size as the total number of staves to train, we have plotted in Fig. 3 the summary statistics of the SER obtained by each trained model over all the target collections.

In general, the best behavior has been obtained when merging all the available training corpora. This first outcome may seem obvious, but due to the variability of the training datasets and some of the test works, it was not illogical to expect otherwise. From this result, the fact to be explained is why it performs the best, either due to the size of the training set in terms of the number of staves or the generality the model encompasses due to the training corpora of different natures included.

The plot shows that, although adding more training corpus does not worsen the results, it is not a determining factor. In general, good results are generally obtained with combinations of at least 3 training sets. However, a combination of just two corpora (*i.e.* CS) yields a good performance both in mean and dispersion that denotes its robustness. These two corpora are complementary from the graphical point of view and seem to be representative of both printed sources (SEILS) and handwritten manuscripts (Capitan). When applying 3-corpora training set combinations, the results are equivalent: CGS experiment compared with the GMP, wherein the combination of the first two handwritten corpora and one printed appear compared to the collection of one handwritten and two printed training sets. From these evidences, it can be deduced that the variability of training sets is relevant for better overall performance.

If we focus on the size of the training collection, *i.e.*, the total number of staves used for training, the plot shows that it is not as important as the variability for the final performance. For example, experiment CMS, having less than 4 000 staves, brings better results than experiment GP with over 8 000 samples for training.

To confirm the size is not all that matters, Fig. 4 illustrates the results reported by calculating the number of experiments where the SER is minimized in any of the target datasets, taking into account the number of datasets used

Figure 3: The boxplot shows different statistical SER figures (min, Q1, mean, Q3, max) over the test corpora using a different combination of training corpora. The colors shown in the right bar represent the number of training corpora used in each experiment. The labels are the initials of the corpora included in each training set: C: Capitan, S: SEILS, M: Mottecta, G: Guatemala, P: PrIMenS.

Figure 4: Percentage of experiments that minimize the SER value for any of the available test corpora.

to train. It can be noticed that trained experiments with sizes 3, 4, and 5 report a value of 31.2%. Aside from the value itself, what this aspect exposes is that the size of your dataset at a given point is no longer a critical factor for the transcription quality.

5.2 The complexity of a corpus

The average SER values for all experiments on each target dataset are plotted in Fig. 5. The main noticeable aspect is the difference between Q1 and Q3 (the colored box ends) in the diverse corpora. This substantial contrast in dispersion is what we named “The complexity of a corpus”. The plot shows that, as expected, the performance depends on the precise selection of the combination of training corpora to use. The maximum SER values are obtained when the training data is built from just one dataset.

In general, the worst results in the graph are obtained for handwritten target works (those named with the prefix

“B”) because, intrinsically, they are more difficult to deal with and need a higher variability in the number of training corpora of handwritten works.

Figure 5: The boxplot shows different statistical SER figures over all experiments made in each one of the testing corpora.

5.3 The importance of leveraging the availability of training corpora

Figure 6 shows the results of the experiments that use each specific training corpus compared to the experiments that do not use it. The image presents the casuistry when having to choose either adding new samples from a different dataset or continue increasing the size of existing labeled samples. As the image reveals, every dataset available for the train, no matter the type—printed or handwritten, real or synthetic—should be included. It is worth mentioning, that the relevance of adding a new corpus is more noticeable than others. For example, referring to the Capitan corpus, if we compare the experiments CMP – MP, CPS – PS,

Figure 6: Comparison between all experiments containing (green) and not containing (blue) each training set.

and CMS – MS, we can observe this phenomenon: because of the variability that Capitan adds to the training set, the improvement is noticeable. Therefore, a new corpus seems to generally improve the model performance, as outlined in Fig. 5.

But not only adding a different corpus helps to improve, as the key is to be aware of what is missing in terms of graphical variability in the available training data to build a more robust model. An interesting piece of evidence in the plot that shows how to proceed when this happens is to notice that even a synthetic corpus helps in improving the overall results when it complements the available original training data. Note the reduction in SER when adding PrMenS, that synthetically simulates printed sources, to complement two other handwritten datasets (Capitan and Guatemala).

5.4 Lessons learned

In order to summarize and establish a set of best practices to improve the generalization performance of OMR systems in the absence of specific training data, we will introduce some questions and answers related to the knowledge acquired from the experimental outcomes.

- **Which is the best choice to transcribe a new collection?** In general, one must use all the available training corpora even if some of them are quite different from the target collection.
- **Is it better to have fewer collections with a high number of samples or more collections with fewer samples each?** It is preferable to have more variability even at the cost of a smaller sample set.
- **How important is it to be aware of the collection to transcribe for selecting the right corpora to train the model?** It is indeed relevant, and depending on the difficulty (for example, whether or not it is handwritten) the differences in performance can be very varied.

- **Does the introduction of a synthetic corpus improve the performance?** Yes, the introduction of a reliable synthetic collection adds size and variability to the training data, enabling better performance rates.

We consider that these answers can be used as general *rules of thumbs*, although of course in certain cases they may not hold.

6. CONCLUSIONS

OMR promises to make written music collections more accessible and browsable by automatically recognizing the symbolic content from their images. However, modern technologies are based on machine learning with deep neural networks, which typically causes unpredictable performance when processing a collection for which no specific training data is available. In this work, we have studied this issue using a large number of training and test collections depicting Mensural notation. This extensive study has been developed considering a state-of-the-art model as representative of the ability to transfer knowledge between collections with dissimilar characteristics.

Our experiments allowed us to analyze various phenomena related to the synergies created between different training collections, the importance of choosing a good recognition trained model to alleviate the uncertainty about performance in a new collection, as well as a series of general good practices on how to proceed for training general OMR models.

As future work, we want to keep on in this line of investigating practical aspects of OMR systems that have a direct impact on particular use cases. For example, we want to extend the case study to the scenario of transfer learning and fine-tuning, where a (limited) amount of training data from a new collection can be assumed. Also, it is interesting to analyze the nature of the errors made by the different OMR models, as well as to have a more precise estimate of the impact of the different errors on the amount of effort required during the post-editing correction process.

COMPOSER’S ASSISTANT: AN INTERACTIVE TRANSFORMER FOR MULTI-TRACK MIDI INFILLING

Martin E. Malandro
Sam Houston State University
malandro@shsu.edu

ABSTRACT

We introduce Composer’s Assistant, a system for interactive human-computer composition in the REAPER digital audio workstation. We consider the task of multi-track MIDI infilling when arbitrary track-measures have been deleted from a contiguous slice of measures from a MIDI file, and we train a T5-like model to accomplish this task. Composer’s Assistant consists of this model together with scripts that enable interaction with the model in REAPER. We conduct objective and subjective tests of our model. We release our complete system, consisting of source code, pretrained models, and REAPER scripts. Our models were trained only on permissively-licensed MIDI files.

1. INTRODUCTION

Many generative models for music exist. For instance, MuseNet [1] and SymphonyNet [2] can generate or continue a piece of music, and Music Transformer [3] can continue a piano performance or harmonize a piano melody. When we tried using these tools as compositional aides, however, we quickly ran into limitations. For instance, while Music Transformer is capable of harmonizing a given melody, it does not offer the ability to keep part of the harmonization and regenerate the other part. MuseNet and SymphonyNet can generate a continuation of a user’s prompt, but do not allow the user to regenerate individual instruments or measures within the continuation while keeping the rest of the continuation intact.

DeepBach [4] can perform infilling on Bach-like chorales in a window specified by the user. Motivated by the idea of extending the DeepBach user experience to more styles, arbitrary collections of instruments, and arbitrary infilling target locations, we train a transformer [5,6] model on the task of multi-track MIDI infilling. Our model allows composers to generate new notes for arbitrary subsets of track-measures in their compositions, conditioned on any contiguous slice of measures containing the subset. (By a *track-measure*, we simply mean a measure within a track—see Figure 1.) We also build a novel system for interacting with our model in the REAPER digital

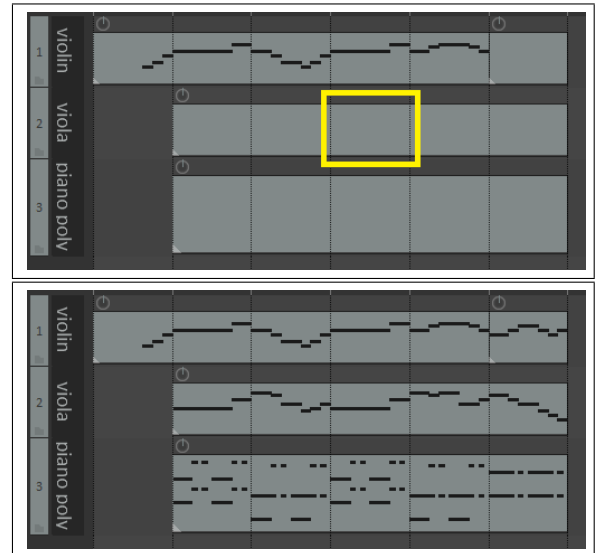

Figure 1. A prompt in REAPER, followed by a model output. Vertical lines separate measures. Users place empty MIDI items in REAPER to tell the model in which measures to write notes, and track names to tell the model what instrument is on each track. A track-measure in the prompt is boxed. Our model writes at least one note into every track-measure in every empty MIDI item in the prompt.

audio workstation (DAW).¹ Our system is cross-platform and easy to install. When a user runs one of our REAPER scripts, a model prompt is built directly from the slice of measures selected in the user’s REAPER project, our model evaluates the prompt, and the model output is written back into the user’s project—see Figure 1. All of this happens within a few seconds, allowing the user to listen to the output, modify it to create a new prompt, generate an output from that, etc. This allows our model to be used in an interactive manner, where model outputs are refined by the user over the course of several prompts.

We note that our infilling objective includes continuing a piece of music, simply by including empty measures at the end of the piece in the prompt. Additionally, our model has the ability to write variations: One can randomly mask $1/n$ of the track-measures in a measure selection and ask the model to fill in those parts, then feed the result back into the model with another $1/n$ masked, and so on, until

Malandro, “Composer’s Assistant: An Interactive Transformer for Multi-Track MIDI Infilling”, in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

¹ Our system and video demo are available at <https://github.com/m-malandro/composers-assistant-REAPER>.

all track-measures have been masked and filled.

Toward the end of this project we discovered MMM [7, 8], which consists of two separate GPT-2-like [9] models trained on the tasks of measure infilling and track infilling. The authors include code to use these models to infill arbitrary subsets of track-measures, as we do. MMM comes in 4-bar and 8-bar variants, which are limited to inputs with 12 and 6 tracks, respectively, and its web demo is limited to inputs having a 4/4 time signature.

The primary contributions of this work are as follows. First, in Section 3 we introduce a novel data filtering and preprocessing approach, applicable to any MIDI dataset used for training models. Our approach helps rectify certain issues we have encountered when using other models. Second, we train and release a new model, capable of infilling arbitrary track-measures in an arbitrary slice of measures in a MIDI file, with no effective restriction (aside from a soft input token limit of 1650) on tempos, number of measures, or number of instrument tracks. Tracks may be polyphonic or monophonic in any combination. The only time signature restriction is that all measures must be eight quarter notes or fewer. Our model is more flexible than MMM and compares favorably to MMM in both objective and subjective tests—see Sections 6–7. Additionally, our model was trained only on permissively-licensed MIDI files, so its outputs should be usable by composers with minimal risk—see Section 5. Finally, we release our complete system, including training code and scripts that enable rapid interaction with our model in REAPER. Our model is the first DAW-integrated model capable of infilling parts for all 128 pitched MIDI instruments (including repeated instruments) and drums, in any combination.

2. RELATED WORK

As mentioned in Section 1, MMM [7, 8] performs multi-track infilling for all MIDI instruments (subject to bar and track limits), and DeepBach [4] performs multi-track infilling for Bach-like chorales. Coconet [10] also performs multi-track infilling for Bach-like chorales. MusIAC [11] incorporates user controls and performs track-based and measure-based infilling, although its inputs and outputs are limited to a maximum of three tracks, 16 measures, and four common time signatures. MusicVAE [12] can interpolate between two given clips of music, which can be viewed as a type of infilling. To our knowledge, all other existing music infilling systems are limited to monophonic infilling [13–17] or single-instrument infilling [18, 19].

Generating or continuing a piece of music can be seen as a special case of infilling. Models which can generate or continue a piece of music include [1–3, 20, 21].

Previous DAW-integrated generative music systems include [4, 18, 22]. NONOTO [23] is a model-agnostic interface that can be linked with a model to perform interactive measure-based infilling. This interface could potentially be altered to allow for the expanded type of infilling our model is capable of. However, we opt to build an interface between our model and REAPER directly, essentially using REAPER as the GUI for our model.

3. DATA FILTERING AND PREPROCESSING

In this section we describe our filtering and preprocessing approach, any portion of which can be applied to any dataset of MIDI files. First, we remove from the dataset any file whose notes seem to have no relation to the underlying grid (Section 3.1). Next, we dedupe files from the dataset using note onset chromagrams (Section 3.2). Finally, we preprocess all remaining files to standardize properties like track order (Section 3.3). This final preprocessing step includes a method for detecting and removing shifted duplicate and near-duplicate tracks within files (Section 3.4).

3.1 Cosine Similarity for On-Grid Note Detection

Every MIDI file has a measure and grid structure defined by tempo and time signature events. However, MIDI file authors are free to ignore this structure, and frequently do when recording free-flowing performances. Other models we have used occasionally write a note in the wrong place—e.g., a 32nd note away from where it clearly should be—and a small experiment we ran suggests that training on MIDI files that don’t quantize well to the grid used by the model is a major cause of this. To address this, we remove from our dataset any MIDI file whose note onsets appear to have no relation to the underlying grid. This is not as simple as checking whether all (or most) note onsets occur on the grid, as many MIDI file authors who use the grid include “humanization” of note timings, where many note onsets that occur slightly off the grid nevertheless quantize correctly to the grid. For instance, in a MIDI file with a resolution of 960 ticks per quarter note, a humanized quarter-note performance might have notes occurring in a 40-tick window centered at every 960th tick.

To perform this filtering, given a MIDI file M , we quantize the note onsets in M to a resolution of 12 ticks per quarter note, and we form a length-12 vector v_M whose i th entry ($i \in \{0, \dots, 11\}$) is the number of note onsets in M occurring i ticks after a grid quarter note. The idea is that if the note onsets in M have nothing to do with the grid, then v_M will point in a similar direction to the uniform vector $v_1 = (1, \dots, 1) \in \mathbb{R}^{12}$. We therefore compute the cosine of the angle θ_M between v_M and v_1 :

$$\cos(\theta_M) = \frac{\langle v_M, v_1 \rangle}{\|v_M\| \cdot \|v_1\|},$$

and we declare a threshold T such that when $\cos(\theta_M) > T$ we remove the file M from our dataset. Hand exploration indicated that $T = 0.8$ was a reasonable threshold, which we chose for this project. We note that a straight fully-on-grid 8th-note pattern M has $\cos(\theta_M) \approx 0.41$ and a straight fully-on-grid 16th-note pattern M has $\cos(\theta_M) \approx 0.58$.

3.2 Deduping Using Note Onset Chromagrams

We dedupe our dataset to avoid data imbalance during training and to prevent overlap between our training and test sets. Given a MIDI file M , we compute a size-12 set of note onset chromagrams using the following procedure.

First, we remove all drum tracks from M . Then, using a 12-tick-per-quarter-note grid, we quantize the note onsets in M to the nearest 16th note or 8th note triplet. Then, we remove all empty measures at the beginning and end of M , and we replace each set of contiguous empty measures within M with one empty measure. Then, for each tick in M and for each pitch class, we record whether M has at least one note onset of that pitch class at that tick. This information comprises one note onset chromagram for M . The other 11 come from repeating this procedure for each possible transposition of M . We dedupe the dataset by keeping only one file with a given set of note onset chromagrams. Quantization helps us catch files that differ only trivially in grid resolution and/or note onset times, while transposition helps us catch files that differ only in key.

3.3 Preprocessing of Individual MIDI Files

After deduping, we preprocess each MIDI file in our dataset in the following way.

First, we arrange the information in the MIDI file so that each track holds notes for one instrument. We order tracks according to their MIDI instrument number (0–127), taking drums as instrument 128. We also consolidate all drum tracks to a single track, and we apply a drum simplification map (consolidating, e.g., three different bass drum pitches to a single pitch).

Next, we apply pedal information in the file (if present) to extend note lengths, and then delete all continuous controller (cc) data. We do not model cc data in this project.

With the exception of drums, we allow multiple tracks to use the same instrument. However, when this happens, if there is more than one track having a given instrument, we remove all but one of those tracks that are equal to, a shift of, or close to a shift of another track with the same instrument, using the procedure in Section 3.4.

We impose the restriction that all measures must be eight quarter notes or fewer. If any time signature in the file declares longer measures, we alter the time signatures to shorten the measures.

Finally, using a 24-tick-per-quarter-note grid, we quantize the events in the file to the nearest 32nd note or 16th note triplet. This is ultimately the level of quantization we use to train our model. (Earlier experiments involved quantizing to 16th notes or 16th notes + 8th note triplets, which we found insufficient for expressive generation.)

3.4 Removing Shifted Duplicate and Near-Duplicate Tracks

A MIDI file may contain duplicate tracks. Such tracks contain no useful information for modeling, so we remove them. Shifted duplicate tracks are frequently used by MIDI file authors to encode *delay* effects (as the MIDI spec offers no way to encode the use of a delay directly). Choosing to use a delay is a mixing decision, not a compositional decision, and we want our model to focus on making compositional decisions, so we remove shifted duplicate tracks as well. We have also seen tracks that are duplicates or

shifted duplicates of other tracks within a file, plus or minus a few notes and/or humanization. We remove such near-duplicate tracks as well.

Given a note n in a track T , let $\text{st}(n)$ and $\text{end}(n)$ indicate the start and end times of the note n , respectively, and let $\text{pitch}(n) \in \{0, \dots, 127\}$ indicate the MIDI pitch of n . We record, for $p \in \{0, \dots, 127\}$, the union of closed intervals

$$I_T(p) = \cup_{n \in T: \text{pitch}(n)=p} \{\text{st}(n), \text{end}(n)\} \subseteq \mathbb{R},$$

and we define $|I_T| = \sum_{p=0}^{127} |I_T(p)|$, where $|I_T(p)|$ is the sum of the lengths of the disjoint intervals in $I_T(p)$.

Given tracks T_1 and T_2 , we define the *overlap measure* $O(T_1, T_2) \in [0, 1] \subseteq \mathbb{R}$ to be

$$O(T_1, T_2) = \frac{\sum_{p=0}^{127} |I_{T_1}(p) \cap I_{T_2}(p)|}{\max(|I_{T_1}|, |I_{T_2}|)}.$$

The idea is that $O(T_1, T_2)$ measures the percentage of the note intervals in the larger of the two tracks accounted for by the note intervals in the smaller of the two.

We use a threshold of 0.9 for asserting near-overlap between two tracks. As we go through the tracks in a MIDI file in order, a later track T is thrown out if there exists an earlier track T_0 using the same instrument such that some shift T_s of T of no more than a half note has the property that $O(T_0, T_s) \geq 0.9$. In our experience with our trained model, we have found this preprocessing step sufficient to prevent the model from outputting duplicates or shifted duplicates of tracks in its inputs.

4. OUR LANGUAGE

After applying the procedure from Section 3 to a collection of MIDI files, we process the files into an event-based language for modeling. Our language is similar to the standard event-based MIDI language used for piano performance modeling in [3]. However, we use explicit measure tokens to denote the start of each measure. Also, we do not model velocity of individual notes directly. Instead, we assign a dynamics level to each measure based on the average velocity of the notes in the measure. We use eight dynamics levels, with thresholds learned from data.

The tokens used by our language are as follows:

- $M:x, x \in \{0, \dots, 7\}$. Declares a measure of dynamics level x .
- $B:x, x \in \{0, \dots, 7\}$. Declares the tempo (BPM) level at the start of a measure. We use eight tempo levels, with thresholds learned from data.
- $L:x, x \in \{1, \dots, 192\}$. Declares that a measure has length equal to x ticks.
- $I:x, x \in \{0, \dots, 128\}$. Changes the current instrument to MIDI instrument x ($128 = \text{drums}$).
- $R:x, x \in \{1, \dots, 63\}$. Declares that the current instrument is the same MIDI instrument as another instrument in the file/project, but on a different track. Higher x values indicate lower average pitch.

Figure 2. We tokenize this measure as M:5 B:6 L:96 I:0 w:48 d:24 N:67 I:0 R:1 d:48 N:36 N:43 N:48 I:73 w:12 d:12 N:84 w:12 N:81 w:12 N:79. Note that piano and flute are MIDI instruments 0 and 73.

- N: x , $x \in \{0, \dots, 127\}$. Note of pitch x . Used by instruments 0–127.
- D: x , $x \in \{0, \dots, 127\}$. Drum hit of drum pitch x . Used by instrument 128.
- d: x , $x \in \{0, \dots, 192\}$. Sets the duration of each note declared from this point forward to x ticks.
- w: x , $x \in \{1, \dots, 191\}$. Advances the current insertion point for new notes in the measure by x ticks.
- `<extra_id_x>`, $x \in \{0, \dots, 255\}$. Mask tokens.
- `<mono>`, `<poly>`. Instructs the model to write a monophonic or polyphonic part for a masked part. For our purposes a monophonic part is one where no two notes in the part have the same onset tick.

Tokens are assembled in a standardized manner to represent measures. Each measure begins with M: x , B: x , and L: x tokens. I: commands are included for a measure only when that instrument is present in the measure. We do not intermingle instrument note instructions as we write each measure from left to right (as MuseNet [1] did), as that would make it difficult to mask individual instrument parts within measures. Rather, we write the full part for one instrument within the measure before writing the full part for the next instrument within the measure. Figure 2 contains an example of a tokenized measure.

To form songs, we simply concatenate measures.

5. MODEL, DATA, AND TRAINING PROCEDURE

We use recent recommendations from the language modeling community to design and train our model. Based on the recommendations in [24–26], we choose a T5 (full, relative-attention) encoder-decoder architecture [6]. We opt for a full attention model because such models were found to outperform memory-efficient models in [24] when the full input sequence fits in memory, as we expect to be the case in most real-world applications of our model. Also, we adopt the *DeepNarrow* strategy of [27], opting for a model dimension of 384, 10 encoder layers, and 10 decoder layers. For training, we use the `pytorch` [28]

Hugging Face [29] implementation of T5. For inference, we use nucleus sampling [30] with a threshold of $p = 0.95$.

To train a model that is essentially free of copyright worry, we collect MIDI files from the internet marked as being in the public domain, freely available to use without attribution, or available under a CC BY license. We exclude files marked as having share-alike or non-commercial licenses, since we want composers to be able to use model outputs however they wish. We also collect private donations and files from the internet for which we secure direct permission from the MIDI file authors to use for training. This results in a dataset of approximately 40K MIDI files after filtering. Most of our training files are in Western classical, folk, and hymnal styles, although some modern styles are also present.

We follow the standard approach to the training of large language models of splitting our training procedure into pretraining and finetuning phases. A similar approach was also used in [31]. For pretraining, we use the T5 corrupted-span sequence-to-sequence objective [6]. We begin by pretraining on the 192K training files in the *CocoChorales* [32] dataset and their piano reductions for three epochs. The *CocoChorales* are only used for this initial pretraining to teach the model the basics of music theory and our language. We then move on to our dataset of 40K MIDI files. After tokenization and corruption, we greedily chunk each song into inputs of 512 or fewer (short) or 1650 or fewer (long) tokens. Additionally, each song in our dataset is transposed a random amount between -5 and +6 semitones (inclusive) for each epoch. Following the recommendations in [24], we train our model on short examples for 20 epochs and then long examples for 11 epochs. We release the resulting pretrained model, which others may find useful for finetuning on downstream tasks.

For finetuning, we continue to leverage the corrupted-span sequence-to-sequence objective to finetune our model on the task of multi-track MIDI infilling. We create training examples from songs in our training dataset by taking slices of measures from the songs and masking subsets of track-measures from these slices. During finetuning every N:, D:, d:, and w: token for a given track-measure is masked, and corresponds to a single mask token. With probability 0.75, we add a `<poly>` or `<mono>` token corresponding to the nature of the masked tokens for each mask. (We choose not to include these tokens in every training example since users will not always include these instructions in their prompts.) Finetuning examples are limited to inputs with a maximum of 1650 tokens and outputs with a maximum of 1650 tokens.

We generate our finetuning masks by selecting from mask patterns that we consider to be musically relevant and/or useful for training. To help train our model for use on small numbers of measures, we also occasionally (15% of the time) truncate examples to a random smaller number of measures than the number allowed by our token limits. As with pretraining, each example is transposed randomly. We finetune our model for 51 epochs, and we release the resulting finetuned model.

Table 1. Objective infilling summary statistics. All cells are of the form mean \pm (std dev)^s, where s is a letter. Different letters within a row indicate significant location differences ($p < 0.01$) in the samples for that row according to a Wilcoxon signed rank test with Holm-Bonferroni correction. Asterisks (*) indicate a significant performance difference ($p < 0.01$) between a 16-bar task and the 8-bar task in the previous row for our model according to a Wilcoxon rank sum test.

6. OBJECTIVE EVALUATION OF OUR MODEL

To form our test set, we select a set of 2500 MIDI files from the Lakh MIDI dataset [33, 34] that is disjoint (according to the procedure in Section 3.2) from our training set, all in 4/4 time and having at least 16 measures. Given a MIDI file in our test set, for each of the three mask patterns below, we select an 8- and a 16-measure slice of the file and mask the selected slice with that mask pattern. We thus generate six test examples from each test file, corresponding to the six different tasks on which we evaluate models. Given a slice of measures, our mask patterns for testing are:

1. Random mask: Each track-measure in the slice is masked with probability 0.5.
2. Track mask: Up to half of the tracks t are selected at random from the slice, and every measure of each such track t is masked.
3. Last-bar mask: Given the last measure m of the slice, measure m of every track is masked. This pattern is used to measure the ability of models to continue songs.

The ground truth for each example consists of the masked notes in the example. In our test data, 99% and 75% of our 8-measure and 16-measure prompts (respectively) encode to 1650 or fewer tokens. When input prompts are longer than 1650 tokens, we chunk the prompts prior to evaluating them with our model.

To compare our model to MMM [7, 8], we modify the MMM Colab worksheet to run our examples through the MMM models in batches. We recreate our test examples, quantizing them from their underlying MIDI files to MMM’s 12-tick-per-quarter-note resolution, and then modify them to accommodate the restrictions of the MMM models: Since the 4-bar and 8-bar MMM models are limited to inputs containing a maximum of 12 and 6 tracks, respectively, we chunk each test example into 4-bar and 8-bar chunks, and then we split each chunk into sub-chunks consisting of up to 12 and 6 tracks. The MMM models have a strict input + output token limit of 2048, so when sub-chunking, we only add enough tracks to a sub-chunk to ensure that the input + ground truth has no more than 2048 tokens. This biases the comparison in favor of the MMM models somewhat, as this requires us to look at the length of the ground truth as part of the input chunking procedure. Also, our test set is contained in MMM’s training set, but there is no reasonable way to avoid this as the MMM models were trained on the full Lakh MIDI dataset. (We wanted a diverse and well-randomized test set, and the Lakh MIDI dataset is the only publicly-available dataset we are aware of that fits this bill.)

We evaluate models with standard metrics: Note F_1 [35], average pitch class histogram entropy difference [19, 36], and average groove similarity [19, 36]. Note F_1 measures how closely the generated notes match, on a note-for-note basis, the notes in the ground truth. (For our purposes, a generated note matches a note n in the ground

	Real Music	Our Model	MMM
1st place	66	32	27
Avg rank	1.664	2.032	2.304
	<i>p</i> -values	Our Model	MMM
	MMM	0.0239	-
	Real Music	0.0034	$2.3 \cdot 10^{-5}$

Table 2. Subjective results from our listening test.

truth if and only if its onset tick, measure, pitch, and track match exactly those of n .) The other metrics measure how well certain higher-level statistics of the generated notes match those of real music. For pitch class histogram entropy calculations, drums are ignored. Each metric is computed on a per-example basis, and then for each model, task, and metric, the 2500 results are averaged to give the results in Table 1. For fairness of groove similarity comparison, we use a denominator of 48 for all models. (This is reasonable, as our models and the MMM models both effectively have 48 possible note onset positions per 4/4 measure.) For our model, “-MP” indicates that the examples were evaluated without `<mono>` or `<poly>` tokens present.

For each row of Table 1, we perform a Wilcoxon signed rank test [37] with Holm-Bonferroni correction [38]. We find significant differences between our model and the MMM models in all 18 rows, with our model outperforming the MMM models in 16 out of 18 rows. The MMM models outperform our model only for pitch class histogram entropy difference for full-track infilling.

Additionally, we find a significant difference in our model’s performance when `<mono>` and `<poly>` tokens are included in prompts in 11 out of 18 rows. All significant differences favor including these tokens, suggesting that the development of additional user controls (as in [11]) would be a useful line of future work.

Finally, a Wilcoxon rank sum test [37] reveals significant differences ($p < 0.01$) in 8-bar versus 16-bar results for our model in five out of nine comparisons. All significant differences favor the 16-bar results, emphasizing the importance of training on longer measure slices. However, we never observe a significant difference in 8-bar versus 16-bar results for track infilling, suggesting that larger context windows generally provide no additional useful information for completing this particular task.

Additional experiments not reported here indicate that scaling our training approach (training larger models on more data) is a feasible path for improving model performance on the metrics presented here.

7. SUBJECTIVE EVALUATION OF OUR MODEL

While the results in Section 6 are encouraging, the ground truth may not reflect the only reasonable way to fill in missing notes. To help address this, we conducted a small listening test with 25 participants. We prepared nine examples mostly involving melodic generation. Each example

consisted of three 8-measure clips, one of which was real multi-track music. The other two clips were created by removing some tracks from the real music and using our model and MMM to fill those tracks. Participants were shown five of the nine examples at random, and for each example were asked to rank the three clips in order of preference. Results are given in Table 2.

A Wilcoxon signed rank test with Holm-Bonferroni correction reveals significant differences in rankings between all three types of music, with p -values given in Table 2. In this test we see a clear preference for real music, and a significant ($p < 0.05$) preference for music generated by our model over music generated by MMM. One expert participant commented that melodies generated by the models were generally more directionless than those in real music, often failing to drive towards a cadence or “payoff.” We agree with this assessment, and this is a shortcoming of our model that we hope to address in future work.

8. LIMITATIONS AND RISKS

Our model writes music that is reflective of its training set. Most of our training files are in Western classical, folk, and hymnal styles. While we included in our training set only files marked as being permissively licensed, it is possible that some files were mismarked. It is also theoretically possible for our model to output copyrighted music, even if such music was not present in the training set.

The most common request we have heard from composers to whom we have shown our system is *personalization*. Generally speaking, they do not want systems that write full songs, and they do not want systems that write “generic” music. Rather, they want systems that can suggest ideas in their style. Some small experiments indicate that our finetuned model can be personalized by individuals (by continuing to finetune the model on their own MIDI files) to write in their styles. Low-rank adaptation [39] of our model may also be possible. Personalization is an avenue we would like to explore formally in future work. For now, our code supports training by users, and our model dimensions were chosen carefully to enable this on consumer hardware. A video card with 6 GB of RAM is sufficient to train our released model on examples with input and output lengths of 1024, and 12 GB of RAM is sufficient to train on examples with input and output lengths of 1650. While this can benefit composers who wish to use our system, there is also the risk that our models may be trained by users to impersonate the styles of others.

9. CONCLUSION

We have introduced Composer’s Assistant, a system for interactive human-computer composition in the REAPER digital audio workstation. Composer’s Assistant performs multi-track MIDI infilling and comes with an easy-to-use interface. We have released our source code, a pretrained model, a finetuned model, and scripts for interacting with our finetuned model in REAPER. Our models were trained only on permissively-licensed MIDI files.

10. ACKNOWLEDGMENT

We thank the many contributors to our MIDI training set for this project. Contributor acknowledgments can be viewed at our website.² We also thank the IT department at Sam Houston State University for building and maintaining the computational server on which we trained our model.

THE FAV CORPUS: AN AUDIO DATASET OF FAVORITE PIECES AND EXCERPTS, WITH FORMAL ANALYSES AND MUSIC THEORY DESCRIPTORS

Ethan Lustig

Ethan@EthanLustig.com Eastman School of Music, University of Rochester

David Temperley

ABSTRACT

We introduce a novel audio corpus, the FAV Corpus, of over 400 favorite musical excerpts and pieces, formal analyses, and free-response comments. In a survey, 140 American university students (mostly music majors) were asked to provide three of their favorite 15-second musical excerpts, from any genre or time period. For each selection, respondents were asked: “Why do you love the excerpt? Try to be as specific and detailed as possible (music theory terms are encouraged but not required).” Classical selections were dominated by a very small number of composers, while the pop and jazz artists were diverse. A thematic coding of the respondents’ comments found that the most common themes were melody (34.2% of comments), harmony (27.2%), and sonic factors: texture (27.6%), instrumentation (24.3%), and timbre (12.5%). (Rhythm (19.5%) and meter (4.6%) were less present in the comments.) The comments cite simplicity three times more than complexity, and energy gain 14 times more than energy decrease, suggesting that people’s favorite excerpts involve simple moments of energy gain or “build-up”. The complete FAV Corpus is publicly available online at EthanLustig.com/FavCorpus. We will discuss future possibilities for the corpus, including potential directions in the spaces of machine learning and music recommendation.

1. INTRODUCTION

Why do we like the music we like? Perusal of the range of options in a record store or streaming platform, or of live music offerings in a large city, shows the enormous diversity of musical taste among individuals. Research has probed some of the factors involved in this variability, such as gender, age, personality, social identity, cultural background, and musical training [1-6]. Still, there seems to be general agreement that particular pieces of music are especially “good.” Certain hymns, Christmas carols, folk songs, and classical pieces remain favorites across decades and centuries; certain popular songs cause world-wide and lasting explosions of enthusiasm. It seems, also, that specific sections or moments within these pieces are especially pleasurable, giving rise to what are sometimes called

peak experiences [7-8]. Our own personal reflections certainly confirm this, and anecdotally, there seems to be at least some agreement as to what the “best” moments of a piece are. But what makes a certain part of a piece especially enjoyable?

Music psychology has begun to address this issue, though in tentative and exploratory ways. Most of this research has focused on the physiological manifestations of peak experiences, such as chills, which have been shown to correlate with pleasure. A pioneering study by Sloboda [9] asked participants to identify passages causing strong physiological effects—what he called “thrills” (p. 110, after [10])—and to describe the nature of those responses. More recent studies follow Sloboda’s model in having participants identify pieces that cause physiological responses, especially chills, and then probing the possible causes and correlates of these responses: neurological correlates [11, 12], musical elicitors [13, 14], and self-reported perceptual correlates such as the perceived sadness or happiness of the music [15]. With regard to musical elicitors of chills, studies have found many factors including sequences, appoggiaturas, new or unexpected harmonies, crescendi, climaxes, sudden dynamic or textural changes, and entrances of instruments [9, 13-15]. Also deserving mention is a large project by Gabrielsson and Wik [16] focusing on the effects (physical, emotional, and cognitive) of “strong experiences” of music (p. 158). Musical elicitors are mentioned only briefly and in very general terms: “instruments, rhythm, melody, harmony, musical form, performance qualities etc.” (p. 198; see also [17], p. 568).

In this study we offer a novel approach to the study of peak experiences and the musical factors that elicit them. In contrast to the exploratory research cited above, our study takes a systematic, survey-based approach. Our conception of peak experience is close to Maslow’s [7]—a primarily internal albeit not physiological, intensely positive experience—and falls within the fairly broad range of ways that the term is used [8].

Our project differs from most research on peak experiences by focusing on passages of music directly reported to be strongly liked, rather than those causing chills and other physiological responses. While chills have generally been shown to coincide with pleasurable experiences [12, 13], they may not always do so; conversely, one can certainly get great enjoyment from a musical passage without experiencing chills.

In a survey, 140 respondents identified favorite musical excerpts. Respondents also provided free-response comments explaining their choices, and we provide a content

analysis of these comments. We also present a publicly available corpus, the FAV Corpus, which includes audio files of excerpts and complete pieces, formal analyses of a subset of the pieces, and the respondents' free-response comments.

2. METHOD

2.1 Participants

In 2017, 140 students at the University of Rochester (New York) were given a survey regarding their favorite musical excerpts. Approximately 85% of the respondents to the survey were students at the Eastman School of Music (a division of the university) and were therefore music majors. The remaining 15% were students in an introductory music psychology course; while students in this course were mostly not music majors, the course required basic knowledge of music theory as a prerequisite. While students with music-theory training may not be representative of the broader population, we deliberately chose them for their ability to articulate the musical reasons for their preferences, with regard to matters such as harmony, rhythm, and form. On average, the respondents had 11.1 years of music training on a musical instrument (including voice) ($SD = 4.2$). There were 73 females, 63 males, and four who preferred not to say. The average age of the respondents was 19.7 years old, with a range of 17 to 29 years old ($SD = 1.9$). Respondents received extra credit points in their courses for participation. The survey received ethical approval by the Institutional Review Board of the University of Rochester.

2.2 Data Collection

The survey asked each respondent to identify “three of your favorite excerpts of music... in any style and from any time period.” For each excerpt, they were instructed to provide a URL (web address) to a recording of the piece/song/movement on YouTube or Spotify. We used the phrase “piece/song/movement” to avoid stylistic bias, but hereafter we will refer only to “pieces.” Respondents were then asked to “identify the 15-second excerpt that’s your favorite” by providing start- and end-points for the excerpt in relation to the recording. The choice of 15 seconds was fairly arbitrary. We chose it, in part, because it roughly corresponds to the length of some of our favorite musical passages.

Following each selection, respondents were prompted to write a response to the following question: “Why do you love the excerpt? Try to be as specific and detailed as possible (music theory terms are encouraged but not required).” We take the term *love* to indicate a high degree of liking or preference, similar in meaning to *enjoy* or *greatly like*. Our mention of “music theory terms” was aimed at encouraging respondents to identify the musical features giving rise to their preferences. There is a possible downside to this wording; by drawing attention to our own

music-theoretical background, it may have steered respondents toward pieces or excerpts that they thought were theoretically “respectable” in some way. However, the huge stylistic variety of the chosen excerpts (described below), including many from very recent popular music, suggests to us that this was not a concern for many respondents. Additionally, respondents were asked to choose between either “I enjoy this excerpt much more than the other parts of the piece” or “I enjoy this excerpt about as much as the other parts of the piece.”

2.3 Creating the Corpus

Recordings of the complete pieces provided by the respondents were extracted from the YouTube/Spotify URLs and saved as WAV audio files; audio files were also made of each preferred 15-second excerpt. In some cases, the beginning of the internet recording did not correspond to the true beginning of the piece. To adjust for this, any time before the beginning of the piece was subtracted from the timepoints of the preferred excerpt, so that the adjusted timepoints indicated the excerpt’s location in relation to the piece. In about 8% of cases, the chosen excerpt was not exactly 15 seconds long, but usually just a few seconds shorter or longer. In such cases, the excerpt was converted to a 15-second excerpt with the same midpoint as the chosen excerpt. (For example, 0:00-0:25 would be converted to 0:05-0:20.) For more detail about this process, see [18].

The corpus, which we call the FAV Corpus, is publicly available at EthanLustig.com/FavCorpus. The corpus contains 420 items (three excerpts from each of the 140 respondents). A spreadsheet indicates, for each item, (a) the respondent’s number, which had been assigned arbitrarily, (b) the excerpt number for that respondent (1, 2, or 3), (c) the artist and title of the piece, (d) the style and historical era or year (explained below), (e) the duration of the piece, (f) the timepoints of the preferred excerpt, (g) whether the respondent indicated that they enjoyed the excerpt “much more than” [A] or “about as much as” [B] the rest of the piece, and (h) the respondent’s comment about why they liked the excerpt. In what follows, we indicate excerpts by respondent and excerpt number; for example, Respondent 1’s three excerpts are 1_1, 1_2, and 1_3. We also provide sound files for both the complete pieces and the preferred 15-second excerpts.¹

3. RESULTS

3.1 Stylistic Content of the Corpus

The distribution of styles and artists in the corpus was examined. While this is not the main focus of the current study, it provides a window into the musical tastes and passions of students at an American music school in 2017 (recall that roughly 85% of respondents were music students). Each excerpt was categorized as classical (49.5%), pop (41.8%), or jazz (8.7%). For most excerpts, classification was clear; there were a few borderline cases, such as jazz-rock fusion pieces. The most popular artists in the survey

¹ Due to reasons such as invalid web links, respondent errors, etc., the actual corpus contains 399 excerpt audio files and 402 piece audio files. (See EthanLustig.com/FavCorpus for details.)

are listed in Table 1, with the number of excerpts for each. Following convention, for classical works, we identify the composer as the artist; for jazz and pop, we identify the performer(s) as the artist. Table 1 alone might give the impression that respondents strongly favored classical music, but the style statistics just cited show otherwise; the preponderance of classical composers in Table 1 indicates, rather, that classical selections were dominated by a small handful of artists, while pop and jazz selections were much more widely dispersed.

Composer	# Excerpts
Bach	17
Brahms	14
Beethoven	12
Tchaikovsky	10
Rachmaninov	9
Mahler	6
Kendrick Lamar	6
Debussy	6
Sibelius	5
Handel	5

Table 1. Artists (composers/performers) most represented in survey.

Among the classical excerpts, 12.1% were from the Baroque period (1600-1749), 8.5% Classical (1750-1819), 31.7% Romantic (1820-1899), and 47.7% 20th/21st-century (1900-present). (Each composer was assigned to a single period, based on their years of greatest activity.) Again, the large number of 20th/21st-century selections is not reflected in Table 1 since they are distributed over a much larger number of composers. We also observed that many of these 20th/21st-century composers were toward the conservative end of the stylistic spectrum; the most popular was Rachmaninoff, with nine excerpts. For the pop and jazz selections, we identified the year of release of each recording. The pop selections strongly favored recent music: 69.0% were from 2010–2017 (more than half of these from 2016–2017 alone), and 17.9% from the 2000s. Jazz selections had a weaker bias toward recent music, with 31.4% of selections from 2010 through 2017.

3.2 Formal Analysis

One of us (David Temperley) did a formal analysis of a subset of pieces in the corpus. He did not know which excerpts were preferred when doing the analysis. The subset consisted of pieces in which respondents had said that they liked their preferred excerpt “much more than” the rest of the piece; this yielded a set of 127 pieces (about 30% of the survey responses).² The recordings of the pieces were divided into sections to the nearest second, and the sections were given formal labels, as the genre warranted (for instance, P = primary theme for a sonata-form piece; V (verse) and CH (chorus) for pop songs). It was assumed that each section continued until the beginning of the next

section, so that each piece was exhaustively partitioned into sections. As an arbitrary constraint to simplify the analysis, no section was allowed to be less than 15 seconds long. Two main criteria were used for determining the location of formal sections: change and repetition. A significant change in any musical parameter, such as harmony, melody, instrumentation, texture, meter, or rhythmic pattern, was considered to make a good candidate for a section break. Repetition could also define sections: for instance, the return of the opening theme in a sonata-form movement might define a new section beginning even in the absence of obvious local changes. Repetition of the same label signified exact or slightly modified repetition; for example, V would be used for two verses of a pop song, with different lyrics and perhaps some changes in instrumentation, but mostly similar melody and harmony. For more substantially modified repetitions, numbers were used (e.g., V1 and V2 for two verses that had significantly different melody or harmony). See [18] for more detail about the annotation system.

We analyzed the preferred excerpts in relation to their location within the piece. First, we wondered if people tend to choose excerpts that are near section boundaries. For each preferred excerpt, in the set of 127 excerpts for which formal analyses were available, we found the temporal distance between the midpoint of that excerpt and the closest formal section boundary; we then performed the same process for random 15-second excerpts from the same pieces, repeating the process 10 times to mitigate the effect of extreme values. (One piece had a 7-minute section that seemed to create outliers in the data; this piece was removed from the analysis.) Midpoints of preferred excerpts have an average (absolute) temporal distance from the nearest section boundary of 11.41 seconds, while for midpoints of random excerpts, the distance is 13.67 seconds—a modest but significant difference ($t(168.73) = -2.46, p < 0.01$). Thus, preferred excerpts show a slight tendency to be located near formal boundaries. A total of 49.2% of the preferred excerpts actually contain a section boundary; among the random excerpts, only 37.6% do. We then re-analyzed the same distances as signed values, to see whether preferred excerpts tend to be near the beginning or end of a formal section. For preferred excerpts, the mean signed difference between the midpoint and the nearest boundary is 2.90 (i.e., on average, the midpoint occurs 2.90 seconds after the boundary), significantly greater than zero (one-sample t -test, $t(125) = 2.22, p < 0.05$). This indicates a slight tendency to choose excerpts near the beginning of a section rather than near the end, or, perhaps, overlapping more with the beginning of a section than with the end of the previous one.

Finally, we examined the location of each excerpt in relation to the piece as a whole. For this analysis, we used all 399 excerpts in the corpus. Each excerpt received a value for its proportional position in the piece, where 0 would be at the very beginning, and 1 would be at the very end. The

² Altogether there were 137 eligible pieces, 10 proved impossible to analyze into formal sections, because there was no large-scale repetition and no clear moments of change demarcating reasonably-sized sections. Some of these were contemporary pieces; others were Baroque pieces,

for example imitative textures with a rapid or seamless alternation between subject entries and episodes.

mean value was 0.46; clearly there was not a strong bias toward choosing excerpts early or late in the piece.

3.3 Content Analysis of Comments

As mentioned earlier, respondents were asked to comment on their reasons for liking each excerpt in their own words. Responses varied from a few words to several sentences. While a few responses were flippant or minimal, a great many respondents showed enthusiasm for the task and took considerable effort in explaining their choices. We did a content analysis of the respondents' comments. One of us (David Temperley) coded all 420 comments, identifying 17 themes that seemed to appear repeatedly in the comments. We then provided a list of the 17 themes and their definitions (Table 2) to an independent coder (a music theory Ph.D. student at the Eastman School of Music) and asked him to assign themes to the comments using that list. Each comment could be tagged with any number of themes (including zero). In choosing themes, both coders aimed to represent the respondents' actual reasons for liking the excerpts, as opposed to aspects mentioned simply to aid reference, although this distinction was not always easy to make. For example, a comment like "I love the violin melody" was encoded as MEL (melody) rather than INS (instrumentation).

BIO Autobiographical connection: references to the respondent's past experience with the piece or excerpt, OR incidents in their life that it reminds them of for any reason.

COM (+/-) Complexity (or its opposite, simplicity).

DYN (+/-) Dynamics.

EN (+/-) Energy. Energy level in music is thought to be conveyed by such as dynamics, register, rhythmic activity, and textural thickness; an increase in any of these dimensions could create a rise in energy. However, when the change is described in these more specific terms (e.g. dynamics) it can be coded in that way; EN should be reserved for more general descriptions of energy change or level, e.g. "buildup" or "climax".

HAR Harmony: includes harmonic progression, function, or chord quality; also tonality (e.g. modulation), mode (major/minor), and dissonance/consonance.

INS Instrumentation: choices of instrument or instrument combinations; also includes general uses of an instrument (e.g. "I like the clarinet in a high register"), or special timbral effects prescribed by composer, e.g. extended techniques; also synthesized parts in popular music textures. (Compare to TIM).

INT Interpretation (e.g. expressive timing; also general statements about beauty/expressiveness of a performance or quality of performer).

LYR Lyrics.

MEL Melody: the main melody in this particular part of the piece. Also includes improvised solos, e.g. in jazz.

MET Meter (incl. tempo).

PHY Mentions of a physical or physiological response to the music.

RET Return of earlier thematic material.

RH Rhythm. Includes references to general rhythmic feel,

e.g. "groove".

SUR Explicit mentions of surprise or denial of expectation.

TEX Texture: a catch-all category including aspects of pitch-rhythmic patterns other than melody, such as details of accompaniment or bass lines, chord voicings, or polyphonic patterns.

TIM Timbre: when credited to performer (e.g. a singer's tone), or synthesized/electronic sounds that are not a consistent part of the texture. (Compare to INS).

VIR Virtuosity (or just proficiency, i.e. playing a very difficult bit accurately; also intonation).

Table 2. Themes and definitions used in content analysis.

Agreement between the two coders regarding the assignment of each theme was measured using Cohen's kappa, where 1.0 would indicate that the two coders assigned the theme to exactly the same comments. Agreement levels varied between 0.37 and 0.84, depending on the theme, and thus were mostly in the range of *moderate* or *substantial* according to Landis and Koch's [19] rubric. In what follows we discuss the results of this content analysis. We also analyzed word frequencies in the comments, grouping together similar words such as "simple," "simpler," and "simplicity". We include some results of that analysis in the following discussion.

Figure 1. The percentage of respondents' comments identified with themes in the content analysis. For explanation of abbreviations, see Table 2.

Figure 1 shows the percentage of occurrences of each theme in the comments. The counts of each theme were averaged between the two coders. The frequent mentions of melody (MEL, occurring in 34.2% of comments) and harmony (HAR, 27.2%) indicate the importance of the pitch domain in respondents' preferences. Rhythmic factors—rhythm (RH, 19.5%) and meter (MET, 4.6%)—were less important, though it should be remembered that melody has a rhythmic aspect as well. Notably, the word "groove" occurred 20 times—confirming the widely held view that this is a significant factor in musical enjoyment [20, 21]. What might be called sonic factors were also mentioned frequently: texture (TEX, 27.6%), instrumentation (INS, 24.3%), and timbre (TIM, 12.5%). There were comparatively few mentions of performance aspects: interpretation (INT, 6.0%) and virtuosity (VIR, 4.3%).

Given that a large majority of respondents were majoring in classical music performance, we had expected these factors to weigh more heavily. Lyrics (LYR) were mentioned in 12.5% of comments, and autobiographical factors (BIO, connections with the respondents' life experience) in just 3.6%. The PHY theme, physiological responses (such as chills), was mentioned in just 3.1% of comments. It is possible that the survey instructions—which encouraged the use of music-theory terms—steered respondents' attention towards musical features and away from autobiographical and physiological factors.

Three of the themes—complexity (COM), energy (EN), and dynamics (DYN)—were parametric: They could be subscripted as “+” (indicating an increase or relatively high level) or “-” (a decrease or relatively low level), though this was optional. While there were 6.5 instances of COM+ in the comments, there were 22 instances of COM- (again, theme counts reported here and below are averaged across the two coders' analyses). This result suggests that respondents favored moments of relatively low or decreasing complexity. Our analysis of word frequencies also supports this view: “simple” (and related words) occurs 32 times in the comments, while “complex” (and its variants) only occurs 11 times. Related to this, the words “tension/tense” and “resolution/resolve” were used about equally often (19 and 18 times, respectively). However, seven of the comments mentioning tension refer specifically to the resolution of the tension (sometimes using other words like “relax,” “release,” or “relief”); in the remaining cases, the tension seems to be valued in itself.

The energy (EN) theme shows an even stronger parametric tilt than complexity: 35.5 of its mentions are EN+, while only 2.5 are EN-. Energy is often treated as more or less synonymous with the arousal/activation dimension in Russell's [22] two-dimensional model of emotion, and this in turn has been associated with musical parameters such as loudness, pitch register, and rhythmic activity [23].³ Note from Table 2 that this theme reflects general references to energy, as opposed to mentions of energy-invoking musical dimensions such as dynamics, rhythm, or texture. The dynamics (DYN) theme also showed a parametric tilt, marked “+” eight times and “-” only three times. Analysis of word frequencies shows further evidence of a preference for increasing energy. For example, the word “build” and related words such as “build-up” occurs 47 times. It is not obvious what the opposite of “build” would be, indicating a general *decrease* in energy level; one thinks of such words such as “decrease,” “decline,” “fade,” “wane,” “subside,” and “dwindle.” None of these words occurred even once, except “fade,” which occurred just three times.⁴ Several other frequent word categories indicate an increase or peak in energy, such as “climax/climac-

tic” (used 28 times), “power(ful)” (27 times), and “crescendo” (9 times; “diminuendo” is never used and “decrescendo” just once).

In this connection, a result from our analyses of formal structures, described earlier, is relevant. In pop songs, which nearly always contain both choruses and verses, respondents' preferred excerpts were more often in choruses (13 times) than verses (7 times). (Recall that our analysis of formal structures included only about 30% of the survey responses.) Respondents' comments also mentioned choruses (44 times) much more often than verses (18 times).⁵ It has been observed that choruses tend to be higher than verses in the “energetic” dimensions mentioned above, such as pitch register and textural thickness [24, pp. 39-40]. Thus, several patterns in our data point to an increase in energy as an important elicitor of musical pleasure.

Perusal of the comments suggests other possible themes as well. For instance, many comments contain terms or phrases that could be described as emotional. In the first 20 comments, we see “aggressive” (1_2), “raw emotion” (2_3), “intensity” (2_3), “exciting” (4_2, 6_2), “[the singer] let[s] emotions loose,” (5_2) “dramatic” (6_1), and “triumphant” (6_2). In many cases, such terms are used to describe a specific aspect of the music that could also be encoded in some other way: for example, “a triumphant theme” (MEL); “the buildup is very exciting” (EN). Another issue is the distinction between induced and perceived emotion [25]. Sometimes the distinction is clear—“It is insanely happy” is perceived emotion, “[It] always makes me so happy” is induced emotion—but not always: if a passage is described as “exciting” or “relaxing,” is that induced or perceived emotion? If induced emotion is included in the “emotion” theme, one could potentially include a large number of comments implying a positive emotional reaction: for example, “I love the cellist's interpretation.” Indeed, one might say that such a reaction is implicit in all of the comments, given the nature of the task.

4. DISCUSSION

In our study, 140 college students, mostly music students, identified three of their favorite 15-second passages of music. One result emerging from our analysis of the survey comments was a preference for passages that increase in energy—often described by respondents as “builds” or “build-ups,” or as sections that “build.” As noted earlier, energy in music is generally associated with parameters such as loudness, pitch register, and rhythmic activity. It also seems intuitive to us, although this does not seem to have been widely studied, that textural thickness is also associated with energy, perhaps partly because a thickening of texture implies greater loudness, whether or not the loudness actually increases. Our finding that increases in

³ In experiments on music and emotion, manipulations in the temporal dimension usually involve changing the speed of a melody, and are therefore described (correctly) as variations in tempo (for a survey, see [23]). Within a piece, however, the tempo (i.e., the speed of the main beat) rarely changes, except for small fluctuations; temporal variation is more likely to involve changes in rhythmic values (e.g., from a quarter-note texture to a 16th-note texture). In both of these cases, though, the variations involve a change in the temporal density of events; if an increase in tempo conveys an increase in energy, it seems likely that an increase in rhythmic activity over a fixed tempo would also do so.

⁴ Some of these words, such as “build,” “decrease,” and “fade,” could be either nouns or verbs; we counted both, including all verb forms. The word “drop” is also of interest; it occurs 12 times, as noun or verb, but only five of those uses could be taken to refer to energy level. Sometimes the term is used to refer to the re-entrance of the kick drum in a pop or EDM song.

⁵ One might wonder if choruses are more frequent than verses in our corpus, and therefore take up more time. Actually they do not: choruses take up a total of 1769 seconds, in the portion of the corpus that was formally analyzed; verses take up a total of 1977 seconds.

energy are often pleasurable accords well with other work on peak musical experiences that has linked them to crescendi and increases in texture [13-15, 26]. It also appears that there is a strong preference for passages perceived as having relatively low or decreasing complexity and tension, compared to passages perceived to be high in complexity or tension. This is in line with Meyer's [27] observation that in music, "The greater the buildup of suspense, of tension, the greater the emotional release upon resolution" (p. 28) and Huron's [28] idea of "contrastive valence" (p. 39).

Earlier studies have found that a wide range of factors affect peak experiences [9, 13, 14], and this is apparent from the free-response comments in our survey. The single most common theme in the comments was melody. While it is hardly news that people like a good melody, this result draws our attention to the huge importance of this factor; the question of what makes a melody good is one that music theory and music psychology are still a long way from answering. Our corpus might provide a useful starting point for an exploration of this topic. Other frequent themes in respondents' comments—such as harmony, instrumentation, rhythm, and texture—also point to factors that greatly influence listeners' preferences; how they do so is, at present, largely mysterious.

4.1 Future Directions

In terms of future directions, the first avenue of exploration could be expanding the existing dataset. The survey could be re-run online, and globally, with many more participants, increasing sample size and statistical power, as well as diversifying the participant set. Instead of three songs and excerpts, many more songs and excerpts could be requested from each participant, allowing for better trend analysis *within* participants, to potentially identify different listener-types. The usefulness of this kind of data for the music-recommendation space, and associated industry applications, is clear [29].

As the corpus grows in size, the potential for using machine learning and related methods (which tend to excel with larger datasets) to analyze the data becomes more viable. An acoustical signal-analysis-based approach, using the many tools available in the field of music information retrieval, for instance, could be applied to the corpus, to determine which audio features (e.g. spectral flux, dissonance, loudness, etc.) are determinative of the favorite excerpts as compared to random controls from the same pieces. This acoustical approach could be effectively combined with a symbolic, music-theoretic approach.

In fact, even without venturing outside of the symbolic space, there is immense potential for further coding and analysis of corpus features such as scale-degree distributions, metric position, harmonic root patterns, and so forth, akin to the statistical work applied to the Rolling Stone Corpus [30, 31]. This computational approach to the corpus could be supplemented by a more humanistic, analytical approach in which more speculative and traditional analysis is conducted to attempt to understand why these particular excerpts are so powerful. For instance, given the overwhelming emphasis on pitch (melody and harmony)

in participants' comments, it would be interesting to determine the melodic, harmonic, rhythmic, and contrapuntal structures characteristic of the excerpts in the corpus; and what distinguishes a favorite excerpt from a non-favorite excerpt in the same piece.

Another possible direction for future research could be to measure the energy and complexity trajectories of the pieces in our corpus. While energy can be measured using low-level spectral features such as root-mean-square (RMS) acoustic energy, some efforts have been made to create more sophisticated predictors of perceived musical energy using combinations of features [32, 33]. Such algorithms could be applied to our corpus. Meanwhile, measuring complexity (especially in an automatic way) presents more of a challenge. Complexity—in its information-theoretic sense—is inherently subjective, since it depends on the listener's expectations, which in turn can vary widely depending on their musical experiences. Furthermore, complexity presumably depends heavily on patterns of pitch and rhythm, which cannot yet be reliably extracted from polyphonic audio [34]. For classical pieces, MIDI encodings could be used, but for popular songs, transcriptions would need to be created. Once these problems were solved, it might be possible to create measures of complexity using probabilistic models (such as Markov models); indeed, there have been interesting efforts in this direction, though they relate only to melody [35, 36].

Another intriguing area is the correlation of personality, personal values, and socio-economic data with music taste [1-6]. An expanded iteration of the survey could perhaps include a personality inventory and collect socio-economic data, building a more holistic and accurate model of music taste.

We hope that the current study has taken a small step toward advancing our understanding of peak musical experiences, and that our publicly available corpus will be useful to other researchers in this area, as we continue to answer the question: why do we like the music that we like?

ABSTRACT

We introduce LyricWhiz, a robust, multilingual, and zero-shot automatic lyrics transcription method achieving state-of-the-art performance on various lyrics transcription datasets, even in challenging genres such as rock and metal. Our novel, training-free approach utilizes Whisper, a weakly supervised robust speech recognition model, and GPT-4, today’s most performant chat-based large language model. In the proposed method, Whisper functions as the “ear” by transcribing the audio, while GPT-4 serves as the “brain,” acting as an annotator with a strong performance for contextualized output selection and correction. Our experiments show that LyricWhiz significantly reduces Word Error Rate compared to existing methods in English and can effectively transcribe lyrics across multiple languages. Furthermore, we use LyricWhiz to create the first publicly available, large-scale, multilingual lyrics transcription dataset with a CC-BY-NC-SA copyright license, based on MTG-Jamendo, and offer a human-annotated subset for noise level estimation and evaluation. We anticipate that our proposed method and dataset will advance the development of multilingual lyrics transcription, a challenging and emerging task.

1. INTRODUCTION

Automatic lyrics transcription (ALT) is a crucial task in music information retrieval (MIR) that involves converting an audio recording into a textual representation of the lyrics sung in the recording. The importance of this task stems from the fact that lyrics are a fundamental aspect of many music genres and are often the main way in which listeners engage with and interpret a song’s meaning. Additionally, ALT has numerous applications in the music industry, such as enabling better cataloging [1], music searching [2, 3], music recommendation [4], as well as

Figure 1. Concept illustration of the working LyricWhiz, where user prompts the two advanced models, Whisper and ChatGPT, to perform automatic lyrics transcription.

facilitating the creation of karaoke tracks and lyric videos. Moreover, ALT can assist in various music-related research tasks, including sentiment analysis [5], music genre classification [1], lyrics generation, which is further used for music generation [6], security review, and music copyright protection. Thus, accurate and efficient ALT is essential for advanced MIR and the development of new music-related applications.

However, to date, no sufficiently robust and accurate ALT system has been developed. Even major commercial music streaming platforms still rely heavily on manually-annotated lyrics, incurring high costs. One key reason is the challenging nature of lyrics transcription. The diversity of singing styles and skills leads to varied timbres of the same pronunciation. Moreover, the phonemes in singing may be pronounced in vastly different ways, such as longer duration, tone changes, or even vowel substitutions, to accommodate the melody. Lastly, the inclusion of various music accompaniments across different genres makes it challenging to distinguish the vocal signals from other sounds. To surmount these challenges, a more robust ALT system is necessary, capable of outperforming existing models in diverse scenarios, including the transcription of multilingual lyrics.

Another significant factor hindering the progress of

Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

ALT systems is the absence of large-scale singing datasets. Currently, only two relatively sizable datasets [7, 8] exist for ALT systems. However, all existing datasets are in English, with no multilingual datasets available. Besides, these datasets often have stringent copyright licensing restrictions, which significantly hampers their utilization by researchers. Consequently, developing a more comprehensive and representative dataset, encompassing multiple languages and without copyright issues, is essential for supporting the creation of a robust and accurate system.

In this paper, we present LyricWhiz, a novel method for automatic lyrics transcription. LyricWhiz surpasses existing methods on various ALT datasets, resulting in a significant reduction in WER for English lyrics and providing accurate transcription results across multiple languages. Our system is robust, multilingual, and training-free. To achieve these results, we combined two powerful models from their respective domains as shown in Figure 1: Whisper, a weakly supervised speech transcription model, and GPT-4, a large language model (LLM) from the ChatGPT family. Whisper acts as the “ear” while GPT-4 serves as the “brain” by providing contextualized output selection and correction with strong performance [9]. We further use LyricWhiz to build a multilingual lyrics dataset, named MulJam, which is the first large-scale, multilingual lyrics transcription dataset without copyright-related issues.

The contributions of our work are as follows:

- We propose a novel, robust, training-free ALT method, LyricWhiz, which significantly reduces WER on various ALT benchmark datasets, including Jamendo, Hansen, and MUSDB18, and is close to the in-domain state-of-the-art system on DSing.
- We introduce the first ALT system that can perform zero-shot, multilingual, long-form ALT by integrating a large speech transcription model and an LLM for contextualized post-processing.
- We create the first publicly-available, large-scale, multilingual lyrics transcription dataset with a clear copyright statement which eliminates further reviewing of the users and facilitates public usage. We provide a human-annotated subset to estimate noise levels and evaluate multilingual ALT performance.

2. RELATED WORK

2.1 Automatic Lyrics Transcription

Automatic lyrics transcription (ALT) is an essential task in music information retrieval and analysis, aiming to recognize lyrics from singing voices. It remains challenging due to facts such as the sparsity of training data and the unique acoustic characteristics of the singing voice that differ from normal speech. Traditional methods treat ALT in the automatic speech recognition (ASR) framework, which generally utilizes a hybrid of language model and acoustic model, e.g., HMM-GMM. Music-related characteristics have been used to further address these challenges [11–13].

Despite integrating domain-specific music priors into system designs, the data scarcity issue persists. Recently, some researchers have constructed datasets for end-to-end learning, which greatly advances ALT, but most datasets are either noisy (DALI [7, 14], Hansen [15], DAMP-MVP¹); not large (Vocadito [16]); or not diverse in terms of genre and language (MUSDB18 [17], DSing [8]).

Recent rapid progress in ASR has greatly benefited ALT. Some work focuses on applying the ASR model architectures [18–20], such as the Transformers, to ALT, and other work leverages the vast amount of public annotated ASR datasets [19–21] to bridge between the speech and music data. For the first time, a recent study [22] transferred a large-scale self-supervised pre-trained ASR model, mus2vec 2.0, to the singing domain, and exhibited superior performance on multiple benchmark datasets. Nevertheless, this approach consists of pre-training, fine-tuning, and transfer learning phases, thereby remaining relatively complicated and still requiring singing datasets.

2.2 Weakly Supervised Automatic Speech Recognition

The paradigm of large-scale unsupervised pretraining and non-large annotated dataset finetuning has dominated end-to-end ASR research [23]. Well-known pretrained ASR models include contrastive learning based Wav2vec [24], Wav2vec 2.0 [25], HuBert [26], WavLM [27], Whisper [28], and Vall-E [29], which have performed impressively in various downstream tasks, including ASR and speech synthesis. Among them, Whisper has been most recognized for its ASR robustness across different datasets and its multilingual and multitasking capabilities, making Whisper potentially applicable to music tasks. Besides, specifically for ALT, pre-trained musical audio models including JukeBox [6], MusicLM [30], MULE [31], SingSong [32], music2vec [33], and MERT [34], may also contribute to achieving strong performance.

2.3 Chat-based Large Language Models

ChatGPT², a chat-based large language model (LLM), has found broad application in optimizing workflows across a variety of domains, including multimodal intelligence [35, 36]. Recent breaking AutoGPT³ is even recognized as an embryonic form of artificial general intelligence. Inspired by these developments, LyricWhiz collaborates with both Whisper [28] and ChatGPT to optimize the workflow of ALT. Prompt engineering is known to be important to navigate LLMs to perform better [37]. LyricWhiz mainly adopts three primary strategies:

a) As shown in [38, 39], a well-formalized task description prompt can effectively improve ChatGPT’s performance on downstream tasks with strict format requirements. We follow this empirical observation to strictly formalize the expected format of ALT post-processing outputs. We also refer to the prompt pattern catalog in [39] for an intuitive understanding of prompt engineering.

² <https://openai.com/blog/chatgpt>

³ <https://github.com/Torantulino/Auto-GPT>

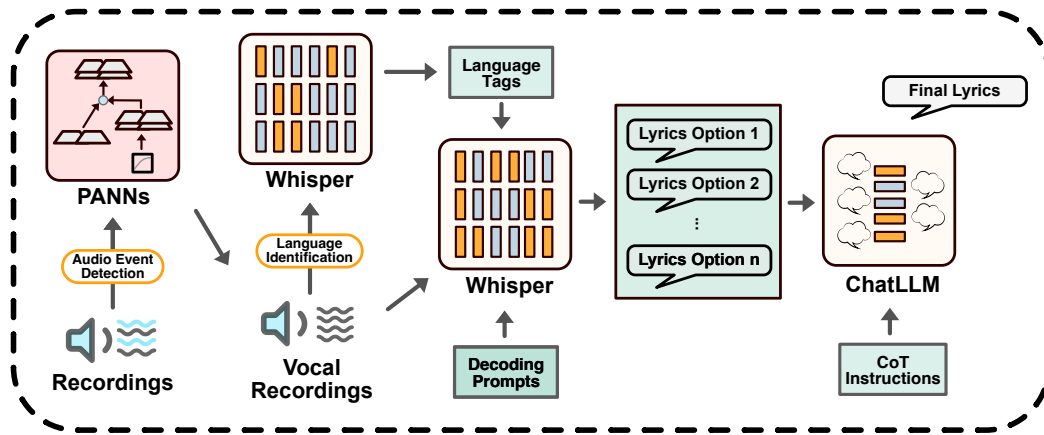

Figure 2. Framework of the proposed LyricWhiz. In the first stage, we employ PANNs [10], to detect audio events and filter out non-vocal recordings. In the second stage, we utilize the language identification module in Whisper to predict input audio language. We then construct language-specific prompts for Whisper and transcribe input audio multiple times. In the final stage, we request ChatGPT with CoT instructions to ensemble multiple predictions and generate the final lyrics.

b) Inspired by [40, 41], LyricWhiz utilizes prompt augmentation to ask ChatGPT to analyze the prompt and input lyrics, in order to select the most accurate prediction from multiple Whisper trials, which is done in the first phase as illustrated in Section 3.2. [41] designs a gradient-guided strategy to select prompts. By contrast, we simply feed ChatGPT with an instruction to select prompts for itself.

c) The importance of a well-designed CoT [42], which effectively divides a complicated task into several phases and designs specific prompts for each phase, is widely acknowledged for enhancing LLM performance. We also propose a concise CoT strategy, depicted in Section 3.2.

3. METHODOLOGY

The overall framework of our method is presented in Figure 2. This section will provide an in-depth analysis of the design of the Whisper and ChatGPT components, and our multilingual dataset.

3.1 Whisper as Zero-shot Lyrics Transcriber

In the Whisper [28] paper, the authors scaled the weakly supervised ASR to 680,000 hours of labeled audio data, which covers 96 languages and includes both multilingual and multitask training. This approach demonstrates high-quality results without the need for fine-tuning, self-supervision, or self-training techniques. By leveraging weak supervision and large-scale training, Whisper generalizes well to standard benchmarks and achieves robust speech recognition in various downstream tasks.

Motivated by this, we discovered that the weakly supervised Whisper model, trained on speech data, also excels in lyrics transcription within the music domain. We directly apply Whisper to transcribe lyrics of music from various genres, including pop, folk, rock, and rap, and find that the model consistently achieves accurate transcription results. The model excels at long-form transcription and is robust to different song styles, even for challenging genres such as rock and electronic music, where Whisper still provides

reasonable results. We further test Whisper on multiple benchmark datasets for lyric transcription. The results indicate that Whisper, without any training or fine-tuning, can achieve or surpass SOTA performance across multiple lyric transcription datasets.

Upon analyzing the transcription results from Whisper, we observed that the model occasionally outputs content unrelated to lyrics, such as music descriptions, emojis, website watermarks, and YouTube advertisements. We attribute this to the weakly supervised training of Whisper on large-scale noisy speech datasets. To address this issue, we utilize the input prompt designed in Whisper as a prefix prompt to guide it toward the lyric transcription task. Unlike prompt designing philosophy in other large language models, Whisper’s prefix prompt does not work well with explicit task instructions and has difficulty understanding lengthy explanations. In practice, we notice that using the simplest prompt, “lyrics:”, effectively prevents the model from outputting descriptions of the music in most cases, resulting in a significant improvement in transcription results. Therefore, in the following sections, this prompt is consistently used for Whisper’s transcription input.

Additionally, we apply post-processing tricks to Whisper’s output, utilizing the model’s predicted no-speech probability to handle situations where predictions are made despite the absence of vocals in the song. Specifically, we drop predicted lines of lyrics with a no speech probability greater than 0.9. This effectively filters out watermarks and advertisements, further enhancing the transcription results.

3.2 ChatGPT as Effective Lyrics Post-processor

Although we addressed some issues with Whisper’s predictions through prompt design and post-processing, we still cannot avoid transcription translation errors, as well as grammatical and syntactical errors. Furthermore, due to the inherently stochastic nature of temperature scheduling in Whisper, the transcription predictions vary with each run, leading to fluctuations in evaluation metrics. To reduce this variance and enhance overall accuracy, we gen-

GPT-4 Instruction Prompt
<p>Task: As a GPT-4 based lyrics transcription post-processor, your task is to analyze multiple ASR model-generated versions of a song's lyrics and determine the most accurate version closest to the true lyrics. Also filter out invalid lyrics when all predictions are nonsense.</p> <p>Input: The input is in JSON format: <pre>{ "prediction_1": "line1;line2;...", ... }</pre></p> <p>Output: Your output must be strictly in readable JSON format without any extra text: <pre>{ "reasons": "reason1;reason2;...", "closest_prediction": <key_of_prediction> "output": "line1;line2..." }</pre></p> <p>Requirements: For the "reasons" field, you have to provide a reason for the choice of the "closest_prediction" field. For the "closest_prediction" field, choose the prediction key that is closest to the true lyrics. Only when all predictions greatly differ from each other or are completely nonsense or meaningless, which means that none of the predictions is valid, fill in "None" in this field. For the "output" field, you need to output the final lyrics of closest_prediction. If the "closest_prediction" field is "None", you should also output "None" in this field. The language of the input lyrics is English.</p>

Table 1. Instruction prompt for GPT-4 contextualized post-processing. We decompose this task into three consecutive phases, inspired by Chain-of-Thought prompting. Note that lines in blue indicate additional prompts used exclusively for multilingual dataset construction.

erate 3 to 5 predictions for each input music under identical settings and employ ChatGPT as an expert in lyrics to ensemble these multiple predictions.

The crux of the problem lies in designing an effective prompt for ChatGPT to accomplish the ensemble task reasonably. As shown in Table 1, we first assign ChatGPT the role of a transcription post-processor, indicating that its task is to analyze multiple lyric transcription results and select the one it deems most accurate. We then stipulate that both input and output should be in JSON format to facilitate structured processing and provide detailed descriptions for each output field.

Drawing on the Chain-of-Thought in large language models for reasoning, we devised a concise thought chain for ChatGPT that decomposes lyrics post-processing into three consecutive phases. This involves first having ChatGPT analyze multiple lyric inputs and provide reasons for selection, then making a choice, and finally outputting the chosen lyric prediction. We test this approach using GPT-3.5 and the newly released GPT-4. The results demonstrate that using the analysis-selection-prediction prompt for ChatGPT's inference effectively enhances the final transcription results, with GPT-4 exhibiting a noticeably superior performance compared to GPT-3.5.

3.3 Multilingual Lyrics Transcription Dataset

Building upon the exceptional performance of the proposed framework in lyric transcription tasks, we further extend it to the challenging task of multilingual lyric transcription, introducing the first large-scale, weakly supervised, and copyright-free multilingual lyric transcription dataset. We utilize the publicly available MTG-Jamendo

Dataset	Languages	Songs	Lines	Duraion
DSing [8]	1 (en)	4,324	81,092	149.1h
MUSDB18 [17]	1 (en)	82	2,289	4.6h
DALI-train [14]	1 (en)	3,913	180,034	208.6h
DALI-full [14]	30*	5,358*	-	-
MulJam (Ours)	6	6,031	182,429	381.9h

Table 2. Comparison between different lyrics transcription datasets. Our model operates with a longer window (~30s), resulting in fewer lines compared to other datasets.

dataset for music classification, which comprises 55,000 full audio tracks, 195 tags, and music in various languages.

Since the MTG dataset contains a considerable proportion of non-vocal music, we first employ PANNs [10], a large-scale pre-trained audio pattern recognition model, to detect audio events and filter out non-vocal music with vocal-related tag probabilities below a predefined threshold. This filtering method eliminates approximately 60% of the music, thereby substantially reducing the time and resources required for dataset construction. We then utilize Whisper to transcribe lyrics from the music.

As the music in the MTG dataset encompasses multiple languages, we first utilize the Language Identification module within Whisper to predict the language of input music. Based on the predicted language, we translate the prefix prompt "lyrics:" into the corresponding language for input, e.g., "paroles" in French, and "liedtext" in German. After obtaining the transcription results, we discard lyrics that are too short or too long. When ensembling the prediction results with ChatGPT, we also incorporate the language of lyrics as an input condition in the prompt. Given the prevalence of nonsensical content in the transcription results, we additionally require ChatGPT to evaluate the validity of the transcribed lyrics in the prompt. If all input lyrics are deemed nonsensical, e.g., all special Unicode characters, or extremely divergent, the transcription result for that piece of music is considered invalid and discarded.

To prepare the dataset for training, it is essential to conduct line-level annotation. Timestamps can be obtained from the output of Whisper by aligning the lyrics both before and after ChatGPT processing. For the alignment of strings, the Levenshtein distance [43] is employed. To exclude aligned lines of lower confidence, the distance is normalized, setting a threshold at 0.2. The quality of annotation is further enhanced through two subsequent filtering stages. In the first stage, lines that exhibit unusually high character rates, exceeding 37.5 Hz, are eliminated. The second stage encompasses another Whisper iteration; segments yielding a transcription of "Thank you." are excluded. These segments, which typically represent instrumental sections, are believed to originate from Whisper's training on data similar to video transcripts.

Following the construction process outlined above, we ultimately obtained a multilingual lyric transcription dataset, MulJam, consisting of 6,031 songs with 182,429 lines and a total duration of 381.9 hours. The dataset's statistical information and comparisons with existing ALT datasets are presented in Table 2.

Method	Jamendo	Hansen	DSing
TDNN-F [8]	76.37	77.59	19.60
CTDNN-SA [44]	66.96	78.53	14.96
Genre-informed AM [12]	50.64	39.00	56.90
MSTRE-Net [13]	34.94	36.78	15.38
DE2-segmented [45]	44.52	49.92	-
W2V2-ALT [22]	33.13	18.71	12.99
LyricWhiz (Ours)	24.25	7.85	13.78
w/o ChatGPT Ens.	<u>28.18</u>	<u>8.07</u>	15.22
w/o Whis. Prompt	33.21	8.75	<u>13.40</u>

Table 3. The WERs (%) of various ALT systems, including ablation methods, on multiple datasets. Note that W2V2-ALT is an in-domain baseline that natively train on DSing. The results of our method on Jamendo, Hansen are obtained from full-length transcription results, and the results on DSing are obtained from utterance-level segments.

To our best knowledge, MulJam is the first publicly available large-scale dataset for multilingual lyrics transcription without copyright restrictions. While DALI [7] is another large-scale music dataset featuring multilingual lyrics, its restricted access and strict licensing requirements limit its applicability for downstream tasks. In contrast, MulJam is free from copyright-related constraints and can be utilized without approval, as the audio can be legally downloaded directly from public sources without the need for approval, making it easily accessible. This even includes audio that is permitted for use in the development of commercial software. Researchers are permitted to legally modify our dataset for derivative works and redistribution, provided they cite our work and adhere to the CC BY-NC-SA license. Furthermore, in contrast to the imbalanced language distribution in DALI, where English songs account for over 80% of the total songs, our dataset includes a greater proportion of songs in other languages, which is advantageous for multilingual lyrics transcription.

4. EXPERIMENTS

In this section, we first outline our experimental setup, including datasets and evaluation metrics. Next, we report lyrics transcription results on various benchmark datasets. We also conduct extensive ablation studies to verify the effectiveness of our methods. Finally, we demonstrate the reliability of our dataset through noise level estimation.

4.1 Experimental Setup

Datasets. Our proposed method does not require any training; thus, we directly test it on several accessible lyric transcription benchmark datasets, including Jamendo [46], Hansen [15], MUSDB18 [17], DSing [8]. Among these, Jamendo, Hansen, and DSing are widely used test datasets in music transcription. MUSDB18, originally a dataset for music source separation, contains 150 rock-pop songs. The authors in [17] provided line-level lyric annotations for MUSDB18, making it a challenging real-world dataset for lyric transcription. Additionally, we manually collected 40 multilingual songs with lyrics annotations from MTG-

Method	a)	b)	c)
CTDNN-SA-mixture [17]	76.06	78.44	89.24
Ours-mixture	50.90	47.04	50.70
CTDNN-SA-vocals [17]	37.83	30.85	58.45
Ours-vocals	26.29	25.27	33.30

Table 4. The WERs (%) of our method and baseline [17] on three subsets of annotated MUSDB18. The results of our method are obtained from utterance-level segments.

Jamendo as a test set for the proposed dataset, which can be used to validate the reliability of our proposed dataset via transcription accuracy.

Evaluation. We report the Word Error Rate (WER) as the evaluation metric, which is the ratio of the total number of insertions, substitutions, and deletions with respect to the total number of words. We calculate the average WER on the test sets. Since Whisper possesses the capability for long-form transcription, we directly evaluate entire songs using Jamendo, Hansen, and the multilingual test set. We perform utterance-level evaluations on MUSDB18 and DSing since they only have utterance-level annotations. We discovered that many songs in these evaluation datasets are problematic, such as incorrect lyric annotations and excessively short song segments. One notable problem is that sometimes there are prominent harmony parts in the background of a song. However, it is not provided in the lyric annotations (e.g., Adele’s “Rolling in the Deep”). LyricWhiz is powerful enough to transcript both the leading vocal and the background vocal with high accuracy. Therefore, we removed these problematic data from our evaluations. Finally, we normalize the transcription results to match the standardized ground truths. We remove all special Unicode characters, such as emojis. All text is converted to lowercase, and numeric characters are converted to their alphabetic correspondence.

Budget. To ensure fast and multi-round inference of the Whisper-large model on various datasets, including the large-scale MTG-Jamendo dataset, we conducted our experiments concurrently on a server with 8xA100 80G GPUs. It takes approximately 9 hours to complete one round of inference, and each process uses up to 12G VRAM. The vocal probability threshold is set to 0.07 for PANNs-based vocal event detection. To carry out contextualized post-processing using ChatGPT, we invested a total of US\$2,000 on GPT-4 API for the entire project.

4.2 Comparative Experiments

In order to verify the superiority of our approach, we compare it with several previous studies on benchmark datasets. W2V2-ALT [22], a transfer learning method based on ASR self-supervised models, represents the current state-of-the-art in lyric transcription tasks. In our experiments, we primarily compare our method with W2V2-ALT, as well as other previous methods. The experimental results, as shown in Table 3, indicate that our method achieves the best performance on Jamendo and Hansen and the second-best performance on DSing. In long-form

transcription datasets such as Jamendo and Hansen, our method significantly outperforms all previous approaches due to the strong contextual memory capabilities of both Whisper and ChatGPT. Furthermore, our method also leads by a considerable margin on MUSDB18, shown in Table 4, demonstrating the robust performance and resilience of our proposed method in more diverse and complex musical scenarios. It is worth noting that our method did not surpass previous results on the DSing dataset, which we attribute to two factors. First, previous models were trained on the DSing training set, making the DSing test set an in-distribution dataset for the models, while our approach does not require any training and directly employs large-scale ASR models for zero-shot lyric transcription. Second, the segmented evaluation on DSing results in the loss of contextual information, which consequently leads to inaccurate transcriptions.

4.3 Ablation Studies

To further substantiate the efficacy of each component within our proposed approach, we conducted comprehensive ablation experiments.

Whisper Prompt. In our experiments, we investigate the Whisper prompt mechanism and test various prompts. First, we construct a complex prompt following the format of ChatGPT prompts, including task descriptions, format specifications, and specific requirements. We then gradually reduce the constituent elements of the prompt and observe the results. We discover that, unlike general large language models, Whisper has weaker task understanding capabilities for complex prompts and can only comprehend shorter task prompts. In practice, using the simplest prompt “lyrics:” yielded the best results. For multilingual transcription, we translate “lyrics:” into the corresponding language. As shown in Table 3, the designed prompt performs better in long-form transcription scenarios, assisting the model in producing meaningful lyrics for difficult tasks. However, its performance is less effective at the utterance level, possibly because predicting a single line of lyrics does not require additional contextual information.

ChatGPT Ensemble. In order to confirm that ChatGPT can analyze and infer the most accurate version of lyrics, we first conduct a simple experiment. In this experiment, we add the ground truth lyrics to the predicted results and input them together into ChatGPT for ensembling. We then calculate the proportion of times ChatGPT ultimately chose the ground truth. If ChatGPT is able to choose the most accurate lyrics, *i.e.*, the ground truth, the final proportion should be close to 100%. The computed results on the Hansen dataset is 72.7% for ground truth data, which is sufficient to demonstrate that ChatGPT can make correct choices based on the constructed prompt and input lyrics. As further observed in Table 3, ChatGPT ensembling is particularly effective for long-form lyric transcription, suggesting that ChatGPT requires contextual information (the content of preceding and following lyrics, as well as the content of different versions of predicted lyrics) for inference. In contrast, utterance-level lyric inputs lack

Language	Songs _{train}	Songs _{test}	WER _{test}
English	3,791	20	21.86
French	1,030	7	26.64
Spanish	620	5	22.54
Italian	311	3	44.01
Russian	147	4	39.18
German	132	1	25.43
Overall	6,031	40	26.26

Table 5. The distribution of our dataset and WERs (%) on test set. We manually constructed a test set of 40 songs following the language distribution of the collected training set. Then, we applied our proposed method to the test set and computed the WER.

both context and diversity among different prediction results, leading to inferior performance.

4.4 Dataset Analysis

In order to demonstrate the reliability of the dataset constructed using Whisper and ChatGPT on MTG-Jamendo, we manually create a multilingual test set for noise level estimation. Specifically, we first select six languages from the intersection of the languages in MTG and those in which Whisper performs best. We then conduct a stratified sampling of 40 songs on Jamendo and manually annotate their lyrics. We use these 40 songs as a test set, assessing the WER to estimate the noise level of our collected dataset. Table 5 presents the number of songs in each language and the WER results for the test set, where our method achieves decent WER levels for the majority of languages. As our goal is to construct a large-scale, multilingual dataset for weak supervision, our method’s transcription results are acceptable. Furthermore, we have not implemented specific normalization for multilingual transcription results, such as removing diacritical marks, which could be employed to enhance performance.

5. CONCLUSION

This paper presents LyricWhiz, a novel zero-shot automatic lyrics transcription system excelling in various datasets and music genres. Combining Whisper and GPT-4, our approach significantly reduces WER in English and efficiently transcribes multiple languages. LyricWhiz further generates the first publicly accessible, large-scale, multilingual lyrics dataset with a human-annotated subset for noise level estimation and evaluation. The successful integration of the large speech model and large language model in LyricWhiz offers a novel avenue for traditional Music Information Retrieval (MIR) tasks, as previous task-specific solutions are being eclipsed by general-purpose models. Notably, large language models have demonstrated their superior language understanding abilities across various tasks. Hence, we anticipate further applications of large language models to a broader spectrum of music-related domains, such as text-to-music generation, to enhance the performance of various models.

ABSTRACT

In piano performance, some mistakes stand out to listeners, whereas others may go unnoticed. Former research concluded that the salience of mistakes depended on factors including their contextual appropriateness and a listener's degree of familiarity to what is being performed. A *conspicuous* error is considered to be an area where there is something *obviously* wrong with the performance, which a listener can detect regardless of their degree of knowledge of what is being performed. Analogously, this paper attempts to build a score-independent conspicuous error detector for standard piano repertoire of beginner to intermediate students. We gather three qualitatively different piano playing MIDI data: (1) 103 sight-reading sessions for beginning and intermediate adult pianists with formal music training, (2) 245 performances by presumably late-beginner to early-advanced pianists on a digital piano, and (3) 50 etude performances by an advanced pianist. The data was annotated at the regions considered to contain conspicuous mistakes. Then, we use a Temporal Convolutional Network to detect the sites of such mistakes from the piano roll. We investigate the use of two pre-training methods to overcome data scarcity: (1) synthetic data with procedurally-generated mistakes, and (2) training a part of the model as a piano roll auto-encoder. Experimental evaluation shows that the TCN performs at an F-measure of 0.78 without pretraining for sight-reading data, but the proposed pretraining steps improve the F-measure on performance and etude data, approaching the agreement between human raters on conspicuous error labels. Importantly, we report on the lessons learned from this pilot study, and what should be addressed to continue this research direction.

1. INTRODUCTION

A commonly held notion in automatic music performance analysis (MPA) research is that deviations of music performances from their underlying music score can be regarded as performance mistakes. But previous music pedagogy

research suggests that some of such deviations are more apparent to a listener than others [1, 2]. For example, a chord that is voiced differently from that written in the score might be overlooked, but missing a note in a characteristic motif or playing a note that clashes with the underlying harmony would stand out. Repp [1] referred to errors of the former category as *perceptually inconspicuous*. Accordingly, we consider a **conspicuous error** to be "a performance error that can be detected by the majority of listeners with a formal music training, regardless of their degree of knowledge about the underlying music score of a performed piece."

This paper explores the potential of building score-independent models that detect regions of *conspicuous errors* in MIDI piano performances of piano solo pieces based on Western music theory, as shown conceptually in Figure 1. Based on the intuition that a listener is capable of detecting obvious mistakes in piano performances by listening to the surrounding context, we use a non-causal variant of the Temporal Convolutional Network (TCN) [3]. We gather datasets for our task, since despite the plethora of work in automatic MPA that has spanned both the score-dependent (or reference-dependent) [4–7] and score-independent paradigms [8–13], there is no data available to support our desired goal.

More specifically we: (1) gather three datasets of conspicuous errors in various performance situations, reporting on the dataset creation process and annotation procedure, (2) study the properties of the annotated data through (i) observing the annotated data for sources of inconsistencies, (ii) analyzing the relationship between inconspicuous and conspicuous errors and (ii) analyzing the ambiguity of the task through listening experiments, (3) present a model based on TCN to identify conspicuous errors from piano MIDI performance and discuss its effectiveness through experimental evaluation, and (4) present and evaluate two pre-training strategies, depending on the nature of the unlabeled data that can be acquired. A subset of the gathered data and listening examples can be found on the companion page ¹

2. RELATED WORK

We distinguish between locally and globally-based automatic MPA. In local approaches (such as the majority

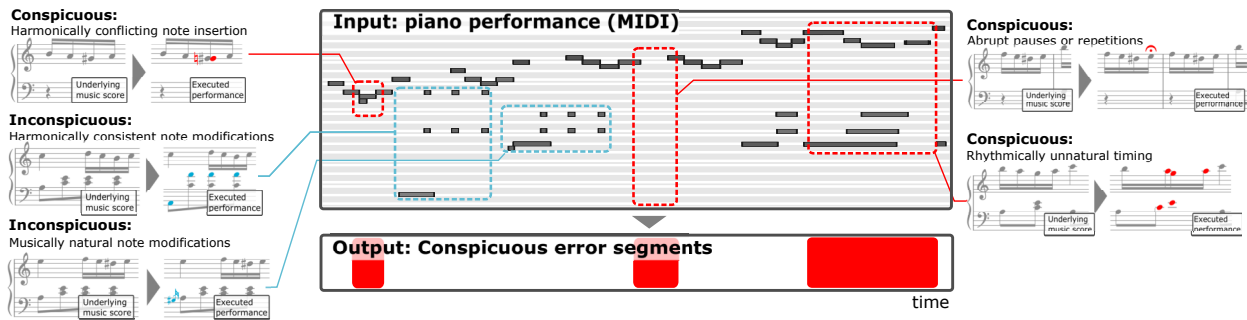

Figure 1: Illustration of our problem definition. Some errors stand out more than others in performance. Our goal is to identify segments containing conspicuous errors to the listeners, without the need for music score data.

of score-dependent performance assessment), the analysis is conducted at a note (or equivalent) level. Global approaches learn from data mapping large performance snippets (often entire performances) to overall evaluations.

Local approaches include score-based performance mistake identification, which tends to cover note-level (or equivalent) errors such as pitch [1, 2, 4, 7] and rhythm mistakes [2]. Pitch mistakes are essentially categorized as *pitch intrusions* (extra note) and *pitch omissions* (missing note), and occasionally *pitch substitutions* (wrong note in-place of a correct one), although the latter can be treated the joint occurrence of the former two [1]. Alignment/score comparison-based approaches for detecting deviations are locally-based by definition. Piano assessment examples of such include [4, 7, 14], which cover pitch mistakes. Not all local approaches are score-dependent, such as those which capture note-level aspects relating to the articulation or sound quality. Examples are [15] and [12], for piano (3-point scale for quality of legato or staccato) and trumpet (7-point scale) respectively.

Global approaches to performance assessment have usually been score-free, with the exception of [5] which utilizes the score as input. Usually, such approaches are based on regression models mapping features to performance-wide ratings [9, 11, 16, 17], or end-to-end approaches which learn correspondences between whole or parts of performances to performance wide ratings [5, 10, 13]. Such ratings can be discrete or continuous and can span several performance dimensions. Although the connection has not been explicitly made, we speculate that most likely they would excel in capturing conspicuous performance mistakes that manifest as consistent errors/error patterns across a performance.

Accordingly, we frame our approach as a score-independent locally based one since our goal is to return binary labels for each time point in a piano MIDI roll reflecting the presence or absence of an obvious performance mistake. Therefore, we need similarly annotated data for piano MIDI performances to train our models. Despite score deviations not necessarily indicating conspicuous errors, our desired output is closest to that of score-based performance mistake identification systems because their output can be interpreted as a binary sequence indicating the presence or absence of a score deviation albeit with-

out perceptual relevance. However, their methods are not applicable for our problem formulation.

3. DATA

We obtain 3 sources of non-commercial, piano MIDI performance data for different playing situations:

Sight-Reading Data (SR): 103 sight-reading performances comprising mostly of piano reductions of popular classical pieces, arranged for beginner to intermediate difficulty. They are played by seven beginning to intermediate adult pianists with formal music training.

Performance Data (PF): 245 performances of approximately 3 minutes each, collected from a digital piano recording app. Not all performed pieces are known, but most of them are pop and classical, that are either read from a score, or semi-improvised. While user attributes are unknown, the performance data suggests that the skill levels range between late-beginner and early-advanced.

Burgmüller Data (BM): 50 performances from Burgmüller’s 25 Etudes, Op. 100 recorded twice on a digital piano. They are played by an advanced pianist who had previously played the etudes. The pianist practiced each etude briefly before recording two takes.

The total time for the **SR**, **PF**, and **BM** are 379, 723, and 60 minutes respectively, of which 128, 176, and 3 minutes were annotated as conspicuous errors. Non-overlapping splits of **SR** and **PF** are used for training, validation, and testing, whereas **BM** is kept exclusively for testing. The annotation procedure is described in 3.1. **SR** and **PF** subsets cannot be shared, but short excerpts of them, and the full **BM** set can be found in the companion page.

3.1 Annotation Procedure

We had 2 annotators: *Annotator 1*, who has experience as a classical piano teacher, and *Annotator 2*, has training in music production and is also an intermediate-level pianist. We asked Annotator 1 to label the **SR** and **BM** data, and asked Annotator 2 to label the **PF** data, and to indicate (yes/no) whether they know the piece being performed. For the **SR** and **PF** subsets, annotators were given instructions to annotate *obvious* performance mistakes that can be recognized even without checking the score, and it was left open to them to decide what that entails. The an-

notation was done with Cubase², and they were asked to add an annotation at MIDI note 0 covering the span of the time window which they judge as pertaining to an error. Despite the potential label ambiguity due to the openness of the instructions, we wanted to observe the judgments of different people in this pilot study so that we can improve the data annotation protocol for future experiments.

The **BM** subset was treated differently because it has been played off of known music score data. First, the performances were automatically annotated with sites of score deviations using a score alignment system. Then, the annotator manually reviewed the labels by listening to the performance while looking at the corresponding sheet music, and added missing deviations from the score or removed those which do not reflect errors. The annotator simultaneously manually labeled each error as conspicuous or not.

3.2 Annotation Examples and Pitfalls

Some types of errors were labeled more consistently than others. The more common error modes, as shown in Figure 2, include insertions and deletions of notes that do not fit in musical context, abrupt pauses, and unstable rhythm coming from hesitations during playing. Annotators have shown reasonable consistency in terms of label location and span when mistakes are relatively short after which the player recovers into their playing flow, such as those of Figure 2. However, more compound deviations were labelled ambiguously. For example, sometimes after an error a player would 'sneak-in' some practice before resuming the flow of the piece. In such examples, if the short phrase being practiced sounds out of context, but in itself is coherent, an open question is where the label should be, and whether it should be one continuous label or an intermittent one.

Moreover, we also observe the presence of non-annotated conspicuous mistakes in the data, but there is an inherent ambiguity in how one would assess a "bad but acceptable" and "erroneous" performance". In a discussion with Annotator 1 after the annotations, they indicated that their mental model for deciding whether a segment should be labelled was dependent on every performance. If a region contrasts with their expectation of the music given how that performer is playing, then it was annotated. This opens the possibility that annotators have calibrated what should count as a mistake based on individual performance. Silence regions are one of the main sources of ambiguity, since silences between correct portions are non-annotated regardless of their length, but silences within or surrounding mistake portions often receive a mistake label.

3.3 Analysis of the dataset

3.3.1 Conspicuous to total label ratio in **BM**

Although the ratio of annotated regions to total performance time is very small in the **BM** data, its annotation approach of allows us to investigate the relationship between the set of errors obtained by comparing with a score

Figure 2: Examples of musical attributes that seemed to be consistently annotated as conspicuous errors (in red). (a) missed note that breaks a pattern, (b) harmonically unnatural note insertions, (c) repetition, (d) abrupt pauses.

(presumably all errors) to conspicuous errors. We found that 59% of all identified errors were perceived as conspicuous. Note that this is a very subset-specific result, because it depends on the ratio between subtle and obvious errors in the performances themselves as much as the qualities of the performer and the annotation.

3.3.2 Listening test of conspicuous errors

Through a listening test of some performance portions labeled as conspicuous errors and unlabeled areas for **PF**, we assess how different subjects agree with the annotations and among themselves. We chose **PF** because we expect it to contain a nice balance between famous and unknown pieces for each subject.

Conditions: We recruited 31 subjects, not necessarily trained musicians. 84% of the subjects had experience playing a musical instrument, and 97% of the subjects had experienced either reading or notating music scores. Each subject is asked to first listen with headphones to a snippet from the **PF** dataset, ranging from 4 to 12 seconds. The snippet is either (1) a randomly chosen conspicuous mistake segment, with 2 seconds of padding on either end, or (2) a segment that contains no error label, whose duration is the average duration of the conspicuous error segments within the piece, plus two seconds of padding. The subjects were allowed to skip questions and no constraints were given on the number of times the snippet may be listened to. The subject is then asked to choose if they hear an obvious mistake or not, along with the subject's knowledge of the piece. This procedure was repeated 15 times. Then, we scale the counts obtained when presenting non-conspicuous snippets, to provide a sensible assessment of the dataset itself. That is, the ratio of snippets containing the inconspicuous error to the conspicuous ones, ρ_0 , should match the ratio between the total duration of the inconspicuous error labels to that of the conspicuous labels in the dataset, ρ_1 . Thus, we scale the count of the responses obtained when presenting the inconspicuous error by ρ_1/ρ_0 .

Results and discussion: A total of 462 responses were obtained (30-31 responses per snippet). The precision, recall, and the F-measure of how correctly the subjects identified the mistakes were 0.37, 0.50, and 0.43, respectively. The result suggests that the notion of conspicuous error is not so clear-cut when only presenting a short snippet surrounding an error, without providing a longer musical context. We also found that famous pieces tend to get more consistent responses. To check this, we computed for each

² <https://www.steinberg.net/cubase/>

Figure 3: Our method reads a piano roll and outputs the probability of the center of a segment being a conspicuous error. It is comprised of a TCN backbone and a 1d convolution classifier head.

snippet (1) the probability that a song is unknown and (2) the entropy of the probability that a subject would identify that snippet to contain an error. The correlation between (1) and (2) was 0.63, indicating a moderate correlation between how well the piece is known among the subjects and how consistent are the labels.

4. METHODOLOGY

Given a sequence of piano note events, the goal is to infer a time sequence of binary labels that indicates the presence of conspicuous errors at a given time.

4.1 Model

Our model is a TCN-based network that receives a piano roll \mathbf{X} as input and emits a binary label of conspicuous error e at each time frame of the piano roll. As shown in Figure 3, it is comprised of a feature extraction backbone followed by a classification head. We choose to assign a label at *frame-level* instead of *note-level*, since not only the note itself but its absence can indicate errors.

4.1.1 Piano Roll Input

Two piano rolls are extracted for a given sequence of piano note events, one for the note onset and another for the sustained portion according to the key depression. Specifically, suppose a set of I MIDI note events (start time, end time, pitch, velocity) given as $\{(s_i, e_i, p_i, v_i)\}_i^I$, and a sampling rate of R are given. Then, a 256-dimensional piano roll $X \in \mathbb{R}^{256 \times T}$ is computed, such that $X(p_i, \text{round}(Rs_i)) = v_i$, and $X(128 + p_i, \text{round}(Rs)) = v_i$ for $s \in [s_i, e_i]$. Partitura [18] is used for the computation, and R is set to 16 Hz.

Notice that the sustain pedal information is ignored in the computation of the piano roll. This is necessary to prevent the piano roll of the sustained portion from smearing since a beginning pianist has a tendency to keep the pedal depressed which causes and excessive elongation of the computed note durations.

4.1.2 Conspicuous mistake detector

We model the mistake detector as a simple TCN comprising of a feature extraction backbone followed by a classification head, based on preliminary experiments exploring model architectures and inspired by the approach in [13].

Feature extraction backbone: Given the piano roll X , the feature extraction backbone computes a feature $\phi \in \mathbb{R}^{D \times T}$. We set $D = 256$ in this paper. This is realized as a 5-layer noncausal TCN with dilation of [1,2,4,8,16], and for all layers, has an output channel size of 256, kernel size of 3, uses ELU nonlinearity and has a residual connection, similar in spirit to [3].

Classification head: Given the feature ϕ , a network comprising of three layers of 1x1 convolution with output channel sizes [256,64,1] with residual connections and ELU nonlinearity followed by a sigmoid function is used to arrive at the conspicuous error posterior probability e .

4.2 Training strategies

The model is trained using RAdam with a learning rate of 10^{-3} , as to minimize the cross-entropy between the conspicuous error probability e and the posterior distribution computed from the ground-truth label. We augment the data by randomly transposing the entire MIDI file in the training data. Furthermore, when computing the cross-entropy loss, we smooth the ground-truth label to account for annotation inconsistencies in the start and end times of the conspicuous error segment. Furthermore, since it is difficult to obtain annotations of conspicuous errors, we pre-train the model as well, using the following two strategies.

4.2.1 Pretraining the feature extractor as an autoencoder

The feature extractor can be trained in an unsupervised manner, by training it as an autoencoder for a much larger collection of piano performances in the wild. Specifically, we train an auto-encoder using the feature extraction TCN introduced earlier as the encoder and a TCN with transposed 1d convolutions instead of a 1d convolution as the decoder. This way, the space of ϕ is pre-trained as to model the space of piano performances within a given receptive field of a TCN. This method could be useful if a large dataset of performances of unknown performance qualities are obtainable.

4.2.2 Pretraining the model with synthetic mistake labels

The model can also be pre-trained on performance data onto which mistakes are simulated and corresponding mistake labels are inserted to match the expected format of data in Section 3.1. Specifically, we apply systematic adjustments to a set of mistake-free performances and modify the note events, in a manner inspired by performance mistakes made by beginning adult pianists [19]. For each note event, with probability p_c we modify the note in one of the following ways:

1. With probability p_o omit a note with a probability p_o
2. With probability p_r replace a note, to the same note transposed n semitones, to simulate hitting the wrong key.
3. With probability p_i insert a note that is transposed by n semitones.

Method	Precision	Recall	F-measure
Baseline	0.79	0.80	0.78
SYNTH	0.65	0.76	0.69
SYNTH(FT)	0.61	0.69	0.62
AE	0.55	0.59	0.55
AE+SYNTH	0.44	0.65	0.51

(a) **SR** Data

Method	Precision	Recall	F-measure
Baseline	0.28	0.46	0.33
SYNTH	0.27	0.54	0.34
SYNTH(FT)	0.30	0.61	0.38
AE	0.28	0.52	0.34
AE+SYNTH	0.27	0.63	0.36

(b) **PF** Data

Method	Precision	Recall	F-measure
Baseline	0.26	0.36	0.26
SYNTH	0.26	0.69	0.35
SYNTH(FT)	0.26	0.49	0.32
AE	0.27	0.46	0.31
AE+SYNTH	0.28	0.52	0.35

(c) **BM** Data

Table 1: Results for different training strategies

4. With probability p_p pause the performance by a small amount distributed uniformly between 0.3 and 0.8 seconds. With probability p_{pr} , repeat the last played note.
5. With probability p_s pause the performance by a large amount distributed uniformly between 2 and 4 seconds. Repeat the last played note.

In this paper, we set $p_c = 5\%$, $p_o = 10\%$, $p_i = 39\%$, $p_r = 39\%$, $p_s = 2\%$, and $p_p = 10\%$. Furthermore, for note replacement and insertion, n is chosen so that $n = 1, 2$ are chosen with probabilities of 22% and $n = 4, 6$ by 2%. For a set of mistake-free performances, we obtained 260 hours of mostly jazz and classical MIDI piano performances. The quality and repertoire are comparable to those available from Yamaha PianoSoft³.

This method is useful if many performances that are known to be relatively error-free are obtainable. Furthermore, this idea may possibly be used for data augmentation, at the risk of increasing false positives, since not all synthetic errors sound conspicuous, as also hinted by [1,2].

4.3 Experiment: Model Evaluation

We evaluate our model using different training strategies.

4.3.1 Experimental conditions

Our model has been trained with the following strategies:

1. Baseline - The model is trained on **SR** and **PF** data.
2. SYNTH - Same as Baseline, in addition to the inclusion of a subset of the synthetic data introduced in Section 4.2.2 during training and validation.
3. SYNTH(FT) - The model is pretrained on the synthetic data, then fine-tuned using **SR** and **PF**. This

simulates a situation where a new annotated dataset becomes available after training a model solely trained on a synthetic data.

4. AE - Train TCN autoencoder introduced in Section 4.2.1 as a pretraining step for the backbone TCN, using approximately 100,000 MIDI performances played by various users. The set of performances does not contain **SR PF** or **BM**, although it is obtained from the same source as **PF**. The model is fine-tuned on **SR** and **PF**.
5. AE+SYNTH - Use the pretrained autoencoder backbone and fine-tune using **SR**, **PF** and the synthetic data.

The trained models have been validated on **SR** and **PF**, and tested on a test split of **SR**, **PF**, and the entire **BM**.

As the metric, we have evaluated the transcription precision/recall/F1-measure using `mir_eval` [20], treating the estimated and the ground-truth annotations as note events occurring at a predefined pitch. When computing the transcription metrics, the note onset and offset tolerances have been set to 2 seconds. Furthermore, based on the validation set, the ends of the estimated segments have been padded by 0.2 seconds and overlapping segments have been merged.

4.3.2 Results and discussion

The results are shown in Table 1. For **PF** and **BM** datasets, the augmentation strategies offer some improvements. The two strategies proposed, i.e., the use of synthetic data and autoencoder, also result in improvements. In general, both strategies tend to improve the recall rate, suggesting that they provide similar qualitative improvements, and either one can be used depending on the data available.

Despite the augmentation strategies, the F-measures for **PF** and **BM** data suggest future room for improvement, even taking into account the ambiguity of conspicuous errors. The **PF** and **BM** data are difficult to infer, as seen by the differences in the F-measure between the **SR** dataset and the two. As another example, the validation F-measure of the models on the synthetic dataset is about 0.60. This suggests that the model is moderately capable of pin-pointing the ground-truth labels if they are easy to classify, or generated stochastically but systematically. At the same time, however, the model has room for improvement, as the best-performing F-measure of 0.38 on the **PF** dataset falls somewhat short of the oracle F-measure of 0.43, as discussed in Section 3.3.

The method performs well for the **SR** data, perhaps because most of the mistakes are quite conspicuous in a sight-reading situation, especially compared to **PF** and **BM**, both of which contain mostly beginner-intermediate performances with occasional mistakes. The performance tends to drop as more pretraining steps are added, presumably because the pretraining data mostly contain data of the same type as the **PF** set, increasing the disparity between the training data and the test data. In sight-reading situations, the results suggest it is sufficient simply to train on a

³ <https://shop.usa.yamaha.com/>

(a) True positives. The black band indicates the detected conspicuous error with different training strategies. The model presumably responds to (a) repetition, (b) silences, (c) slight hesitations in playing, (d) note insertions, and (e) lack of synchrony voices.

(b) False positives. The model presumably confuses (a) the repeated motives as an error, (b) rhythm with rest as abrupt pauses, (c) an audible but weak note with a note deletion, and (d) a long chord after a fast passage with hesitations.

Figure 4: Examples of typical operation and failure modes.

dataset that solely contains data from the same set, instead of pretraining or augmenting the dataset with typical amateur performances containing some conspicuous errors.

4.3.3 Qualitative insights of the estimates

Figure 4 shows some examples of true positives that are consistent across different strategies and consistent false positives. The proposed method tends to capture repetition, pauses, hesitations, and note insertions that occur in narrow pitch intervals as mistakes. At the same time, however, the very same properties arising from musical expression or composition are detected as false positives, such as repeated motifs, ornaments, and grand pauses. Even though such musical aspects are superficially performed similarly to the aforementioned mistakes, humans are capable of differentiating between genuine performance mistakes and those within musical contexts. This suggests that the model has room to improve by modeling the underlying composition better. The readers are invited to check the companion page for examples.

5. LIMITATIONS AND IMPROVEMENTS

Our work opens door to many open problems that need to be solved, some more fundamental than others.

Problem definition and annotation protocol: More work is needed to define the concept of conspicuous errors, and how the task should be evaluated from a music technology perspective. Accordingly, a more comprehensive protocol for data collection should be developed. Although we had kept the annotation instructions open to also develop an understanding of annotator behavior, it became evident that our data collection approach does not guarantee that the labels we have are for solely conspicuous errors. In [1], conspicuous errors were identified in a music performance by finding the subset of agreed-upon mistake labels between multiple listening subjects.

To define manifestations of conspicuous errors, a midpoint should be found between a rule-based approach and one learned from empirical labels. The outcome should be a set of error descriptions, some of which happen at particular time instants and some over longer windows, whether continuous windows or a longer span of intermittent labels. However, since the conspicuousness of errors is in-

spired by a perceptual idea, we think these errors should be defined through an empirical process albeit better defined than the one in this study to avoid the same pitfalls.

Synthetic mistakes: Synthetic data is important for improving performance, but current synthesized mistakes sound unnatural. A simple example was a case of induced pitch insertions, where it seemed impossible that someone can perform with such confidence and tempo despite the extent of out-of-context pitch insertions. We observe that beginners make mistakes and employ recovery strategies in a manner that is more complex than the presented method, so a better understanding of beginning pianists' behavior is necessary to create more natural-sounding mistakes.

Listener, player, expression, and style: Conspicuous errors are dependent on the listener's knowledge of the piece and the proficiency of the performer. Furthermore, conspicuous error and expression are two sides of the same coin. For example, hitting an adjacent key can either come across as an expressive ornament or a conspicuous error. This suggests that conspicuous error detection should inherently be conditioned on the style, the level of the listener, and the player's proficiency.

Connecting with pedagogy and edu-tainment: The impact of music education software which provides analysis solely founded on rigid note-level rhythmic and pitch correctness has been challenged [21] on the basis that users might end up too focused on playing too correctly (almost robotically) to attain the highest scores. There are many pedagogical considerations for designing useful automatic assessments [22].

6. CONCLUSION

This paper presented a study on detecting conspicuous performance mistakes for a piano solo performance of beginning to intermediate players. We (1) clarified the idea of a *conspicuous* error in line with previous research, (2) gathered locally annotated piano MIDI performance data, and (3) discussed sources of inconsistencies in our data through analysis of the annotation procedure and subjective tests. Although some of our models show an acceptable performance on the test split of the **SR** data subset, we find that the our pre-training suggestions do not provide remarkable performance improvements.

ABSTRACT

We introduce VampNet, a masked acoustic token modeling approach to music synthesis, compression, inpainting, and variation. We use a variable masking schedule during training which allows us to sample coherent music from the model by applying a variety of masking approaches (called prompts) during inference. VampNet is non-autoregressive, leveraging a bidirectional transformer architecture that attends to all tokens in a forward pass. With just 36 sampling passes, VampNet can generate coherent high-fidelity musical waveforms. We show that by prompting VampNet in various ways, we can apply it to tasks like music compression, inpainting, outpainting, continuation, and looping with variation (vamping). Appropriately prompted, VampNet is capable of maintaining style, genre, instrumentation, and other high-level aspects of the music. This flexible prompting capability makes VampNet a powerful music co-creation tool. Code³ and audio samples⁴ are available online.

1. INTRODUCTION

In recent years, advances in discrete acoustic token modeling have resulted in significant leaps in autoregressive generation of speech [1, 2] and music [3]. Meanwhile, approaches that use non-autoregressive parallel iterative decoding have been developed for efficient image synthesis [4, 5]. Parallel iterative decoding promises to allow faster inference than autoregressive methods and is more suited to tasks like infill, which require conditioning on both past and future sequence elements.

In this work, we combine parallel iterative decoding with acoustic token modeling, and apply them to music audio synthesis. To the best of our knowledge, ours is the first¹ extension of parallel iterative decoding to neural audio music generation. Our model, called VampNet, can be

¹ While our work was under peer review, Google released SoundStorm [6], which leverages a similar parallel iterative decoding approach to ours.

Kumar, and B. Pardo, “VampNet: Music Generation via Masked Acoustic Token Modeling”, in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

Figure 1. VampNet overview. We first convert audio into a sequence of discrete tokens using an audio tokenizer. Tokens are masked, and then passed to a masked generative model, which predicts values for masked tokens via an efficient iterative parallel decoding sampling procedure at two levels. We then decode the result back to audio.

flexibly applied to a variety of applications via token-based prompting. We show that we can guide VampNet’s generation with selectively masked music token sequences, asking it to fill in the blanks. The outputs of this procedure can range from a high-quality audio compression technique to variations on the original input music that match the original input music in terms of style, genre, beat and instrumentation, while varying specifics of timbre and rhythm.

Unlike auto-regressive music models [2, 3], which can only perform music continuations – using some prefix audio as a prompt, and having the model generate music that could plausibly come after it – our approach allows the prompts to be placed anywhere. We explore a variety of prompt designs, including periodic, compression, and musically informed ones (e.g. masking on the beat). We find that our model responds well to prompts to make loops and variations, thus the name VampNet². We make our code open source³ and highly encourage readers to listen to our audio samples⁴.

² To vamp is to repeat a short passage of music with variation.

2. BACKGROUND

Two-stage approaches to generative modeling have gained traction in image [4, 5, 7, 8] and audio [2, 3, 6, 9] synthesis, largely in part due to their computational efficiency. In the first stage, a discrete vocabulary of “tokens” is learned for the domain of interest. The input is put through an encoder to obtain these tokens, which can be converted back into the input domain via a corresponding decoder. In the second stage, a model is trained to generate tokens, and is optionally given some conditioning (e.g. previous tokens, a text description, a class label) to guide generation.

2.1 Stage 1: Tokenization

In images, visual tokenization has been leveraged for state-of-the-art classification [10] and synthesis [4, 7, 8, 11]. The most popular approach is to use vector quantization on a latent space. Similar approaches have been explored for audio [12], but until recently such approaches have been restricted to low sampling rates (e.g. 16khz), or have been restricted to speech audio. The “sampling rate” of the latent space (the number of latent vectors required every second to represent audio) is a critical aspect of the tokenization scheme. The lower the sampling rate of the latent space, the easier the next stage (generation) will be to accomplish. Recently, methods based on residual vector quantization [13, 14] have been proposed for audio tokenization at high compression rates with good reconstruction quality of high-sample-rate audio.

The primary work we leverage for audio tokenization is the Descript Audio Codec (DAC) [15]. With DAC, audio is encoded into a sequence of tokens via a fully convolutional encoder. The output of this encoder is then quantized using a hierarchical sequence of vector-quantizers [11]. Each quantizer operates on the residual error of the quantizer before it. Because of this residual vector quantization, DAC is able to reconstruct audio with very high quality, at a high compression ratio. It, along with its predecessors [13, 14], are instrumental in enabling audio language models like AudioLM [2], MusicLM [3], and VALL-E [1]. While we later briefly describe our tokenizer, the key contributions of our work are applicable to the output of any audio tokenizer and our specific audio tokenizer is not the focus of this work.

2.2 Stage 2: Generation

Given audio encoded as tokens, the common approach is to use an autoregressive model [16] for generation. State-of-the-art (SOTA) audio generation approaches like AudioLM [2], MusicLM [3], and JukeBox [17] use this approach, generating each acoustic token in the sequence in a step-by-step fashion using transformer-based [18] decoder-only models. Autoregressive sampling is slow in nature due to the high number of steps required at inference time [4]. Further, autoregressive models inherently restrict downstream applications, as each generated token is only conditioned on the previous tokens. For an autoregressive model

to perform tasks like inpainting (“filling in the middle”), one must re-arrange the data during training [19].

In language, masked modeling has been used extensively as a pre-training procedure for high-quality semantic representations [20]. This procedure has also been extended for representation learning in images [21] and audio [22]. Masked modeling for representation learning generally has a constant mask probability. For example, in BERT [20], tokens are masked 15% of the time during training. It has been shown that this approach is equivalent to a single-step discrete diffusion model [23], that uses masking for its noising procedure. Therefore, we can extend masked modeling to masked generative modeling by varying the probability of masking a token during training. This was done for image generation in MaskGIT [4], and in language [23]. Similar to diffusion modeling [24, 25], which seeks to synthesize data starting from random noise through a series of denoising steps, masked generative modeling seeks to synthesize data starting from completely masked data through a series of “unmasking” steps.

Key to the efficiency of MaskGIT and related approaches is a *parallel iterative decoding procedure*. In parallel iterative decoding, the model predicts every token in the output sequence in a single forward pass. However, after just one forward pass of the model, the output often does not have high quality. The output of the first sampling step is re-masked, with a lower masking probability, and then put through the model again. In this way, masked generative models can efficiently refine their output, resulting in high quality generation.

In unconditional generation tasks, the model is asked to generate a realistic sample from the target data distribution from scratch, without any guidance. This is a difficult problem, as many target data distributions are highly multimodal. Unconditional generative models are susceptible to mode collapse [26], blurry samples, mode averaging, and other issues [27]. Therefore, some conditioning is helpful as it provides some signal for the model to resolve the multimodality. Conditioning is also a commonly used method to guide the output of the system towards desired content.

Conditioning can take the form of a class label, a genre tag or lyrics [17], or an associated text description [3, 8, 28]. Conditioning can also be applied at every timestep, like the semantic tokens of AudioLM [2], or aligned text or phonemes for text-to-speech generation [1].

In this work, we adopt a masked generative modeling approach with a parallel iterative decoding procedure, inspired by work in vision such as *MaskGIT* [4] and *Paella* [5], as illustrated in Figure 1. We do not apply any conditioning beyond that provided by the unmasked tokens in our encoded audio. As we show later, different approaches to masking, applied at inference time, can be used to steer generation in useful and artistic ways.

In training, tokens are masked randomly throughout the sequence. The model is then asked to predict the value of each of the masked tokens in a single forward pass, but it is conditioned on all of the unmasked tokens, both in the future as well as in the past. We vary the number of tokens

Figure 2. Training, sampling, and prompting VampNet. **Training:** we train VampNet using Masked Acoustic Token Modeling, where we randomly mask a portion of a set of input acoustic tokens and learn to predict the masked set of tokens, using a variable masking schedule. Coarse model training masks coarse tokens. Coarse-to-fine training only masks fine tokens. **Sampling:** we sample new sequences of acoustic tokens from VampNet using parallel iterative decoding, where we sample a subset of the most confident predicted tokens each iteration. **Prompting:** VampNet can be prompted in a number of ways to generate music. For example, it can be prompted periodically, where every P th timestep in an input sequence is unmasked, or in a beat-driven fashion, where the timesteps around beat markings in a song are unmasked.

that are masked during training, allowing us to generate audio at inference time through a sampling procedure. We now describe our method in more detail.

3. METHOD

We adapt the procedure of *Masked Visual Token Modeling*, proposed in MaskGIT [4] to audio, accounting for several key differences between the vision and audio domain. We call our approach *Masked Acoustic Token Modeling*.

3.1 Masked Acoustic Token Modeling

We first train an audio tokenizer based on the techniques described in DAC [15]. Unlike the visual tokens of MaskGIT, our acoustic tokens are hierarchical in nature due to residual vector quantization. As a first step, the audio signal x is encoded at each time step t as a D dimensional latent vector Z . We then quantize Z using N vector quantizers. Quantizer 1 produces \hat{Z}_1 , a quantized approximation of Z that has residual error $R_1 = Z - \hat{Z}_1$. Thereafter, the residual from each quantizer i is passed to the next quantizer $i + 1$, which produces a quantized approximation of the remaining residual error: $R_i \approx Z_{i+1}$. Vector Z is reconstructed by summing the output of the N quantizers: $Z = \sum_{i=1}^N \hat{Z}_i$.

Since the encoded signal is represented as a quantized vector of N discrete tokens at each timestep, we have N tokens that can be masked or unmasked at each timestep. Rather than attempt to generate all tokens at once, we instead split the N tokens into N_c “coarse” tokens, and N_f “fine” tokens, as in AudioLM. We then train two generative models: one that generates the fine tokens given the coarse tokens as conditioning, and one that generates the coarse tokens given a sequence of coarse tokens. To generate a

sample (Figure 1), we chain the two models together. First, we apply the coarse model to generate a sequence of coarse tokens. Then, we apply the coarse-to-fine model to generate the fine tokens. We decode the tokens to a 44.1kHz waveform using the decoder of our audio tokenizer.

3.2 Training procedure

Let $\mathbf{Y} \in \mathbb{R}^{T \times N}$ be a matrix representing the output of the encoder for some audio segment. Each element $y_{t,n}$ in \mathbf{Y} is a token from the n th level codebook at timestep t . Let \mathbf{Y}_M be the set of all masked tokens in \mathbf{Y} and \mathbf{Y}_U be the set of all unmasked tokens in \mathbf{Y} . The model generates a probability distribution over the set of possible codebook values for each token $y \in \mathbf{Y}_M$, given the unmasked tokens and the model parameters θ . The training objective is to maximize the probability of the true tokens. This corresponds to minimizing the negative log likelihood.

$$\mathcal{L} = - \sum_{\forall y \in \mathbf{Y}_M} \log p(y | \mathbf{Y}_U, \theta) \quad (1)$$

To predict the masked tokens, we use a multi-layer bidirectional transformer, which predicts the probabilities of each possible token at every timestep, for every quantizer. If each quantizer has a codebook size of C possible values, and there are N quantizers, then the last layer of the network will be a fully connected layer of shape (E, CN) , where E is the dimensionality of the output of the last layer. We then reshape this output into (EN, C) , and compute the cross-entropy loss between the ground-truth one-hot token and the predicted token. Because the transformer is bidirectional, it can attend to all tokens in the input sequence to optimize the loss for each token.

For the coarse-to-fine generative model, the input sequence always contains N_c coarse tokens, and the masking operation is restricted to the N_f fine tokens. The last layer of this network only predicts masked fine tokens. Otherwise, the training procedure for both models is identical.

3.3 Sampling

We follow the same iterative confidence-based sampling approach used in MaskGIT. More concretely, given Y_M as the set of masked tokens and Y_U as the set of unmasked tokens, do:

1. **Estimate.** For each masked token y in Y_M , estimate the conditional probability distribution over its vocabulary of codebook values V .
2. **Sample.** For each masked token, sample from the distribution to generate an associated token estimate $\hat{y} \in V$. We don't use any sampling tricks in this step, sampling from the categorical probability distribution for each token as-is.
3. **Rank by Confidence.** Compute a confidence measure for each of the sampled tokens by taking their prediction log-probabilities and adding temperature-annealed Gumbel noise to them:

$$\text{confidence}(\hat{y}_t) = \log(p(\hat{y}_t)) + \text{temp} \cdot g_t \quad (2)$$

where \hat{y}_t is a token estimate at timestep t , g_t is an i.i.d sample drawn from Gumbel(0,1) [29], and temp is a hyperparameter that is linearly annealed to 0 over the number of sampling iterations. Then, sort the set of sampled token estimates by the confidence computed above. We find that high temperature values (e.g. > 6.0) result in higher quality samples.

4. **Select.** Pick the number of tokens to mask at the next sampling iteration, k , according to the masking schedule⁵. Take the k lowest confidence estimates and toss them out, re-masking their tokens. Place the remaining high-confidence token estimates in Y_U , removing their tokens from Y_M .
5. **Repeat** Return to step 1 until the number of iterations has been reached.

3.4 Prompting

Interactive music editing can be enabled by incorporating human guidance in the sampling procedure through the conditioning prompt of unmasked tokens. Because our approach isn't conditioned on any signal other than the input audio itself, we find that various types of prompts are useful for obtaining coherent samples, as they lower the amount of multimodality when sampling from the model. Like AudioLM, we can prompt our model with prefix audio of some duration (usually between 1 and 4 seconds), and it will provide a continuation of that audio. Unlike AudioLM, and other auto-regressive approaches, we can also prompt our model with suffix audio, and it will generate

audio that leads up into that suffix. We can provide prefix and suffix audio, and the model will generate the remaining audio, such that it is appropriate, given the specified prefix and suffix.

We can also apply a "periodic" prompt, where all but every P th timestep are masked. The lower P is, the more the generated audio will sound like the original, as the model is highly conditioned. For example if $P = 2$, then the model is essentially behaving like a upsampler, imputing the tokens for every other timestep. As P increases, the model shifts from behaving in a *compression* mode to a *generative* mode, creating variations that match the style of the original.

Another useful style of prompt are "compression" prompts, where all codebooks other than the most coarse-grained are masked. This gives the model strong conditioning on every timestep, so the model is likely to produce audio that closely matches the original. We can combine this prompt with a periodic prompt with low P for even more extreme compression ratios. Given the bitrate of the codec B , which has number of codebooks N , a downsampling rate P for the periodic prompt, and a number of kept codebooks N_k , we can achieve a bitrate of $B/P(N - N_k)$.

Finally, we can design music-specific prompts, which exploit knowledge about the structure of the music. More concretely, we explore beat-driven prompting, where timesteps that fall on or around the beat are left unmasked. The model is left to create music between these beats, resulting in interesting variations on the original music. These prompts can all be combined to create a very useful music creation tool. In concert with a well designed user interface, VampNet shows promise as the basis for a next-generation music editing and creation suite.

4. EXPERIMENTS

Our experiments aim to evaluate VampNet's capability to both compress and generate music, given the various prompting strategies described in Section 3.4. For our objective audio quality measures, we use a multiscale mel reconstruction error and the Fréchet Audio Distance (FAD). Mel-reconstruction error is defined as the $L1$ distance between log-mel spectrograms at various time-scales,

$$D_{F,M} = \|\hat{S}_{F,M} - S_{F,M}\|_1 \quad (3)$$

where F is the FFT size of each spectrogram, and M is the number of mel-frequency bins. We use $F \in [2048, 512]$ and $M \in [150, 80]$, with a hop size of $\frac{1}{4}$ the FFT size. Mel-reconstruction is valuable as a metric for compression quality, but not for generation quality, since it is likely that models produce audio that does not match one to one with the original target audio. For generation quality, we use FAD, which measures the overlap between distributions of real and generated audio. Unlike mel-reconstruction, FAD is geared more towards evaluating if sample quality falls within the data distribution of the real audio, and can be used to evaluate generation quality.

⁵ $k = \gamma(\frac{t}{t_T})D$, where t is the current iteration, t_T is the total number of iterations, and D the total number of tokens in the sequence. The scheduling function γ is a cosine schedule.

Figure 3. Mel reconstruction error (top) and Fréchet Audio Distance (FAD, bottom) for VampNet samples taken with varying numbers of sampling steps, taken using a periodic prompt of $P = 16$. The samples were generated by de-compressing tokens at an extremely low bitrate (50 bps), effectively generating variations of the input signals.

4.1 Dataset

Similar to JukeBox [17], we collect a large dataset of popular music recordings. Our dataset consists of 797k tracks, with a sampling rate of 32 khz. These tracks are resampled to 44.1kHz to make compatible with our tokenizer. Our dataset contains music from thousands of artists across genres described in Echo Nest’s Every Noise at Once ⁶.

We use a subset of 2k tracks for validation, and another subset of 2k tracks for testing. We ensure that there is no artist overlap between train, validation, and test tracks. In addition, we collect a set of music and non-music data (speech, environmental sound), which we used to train our tokenizer, using the datasets described in DAC [15]. All audio is normalized to -24dbFS. We do not use any metadata about these files during training, as our model is trained unconditionally.

4.2 Network Architecture and Hyperparameters

The audio tokenizer model we use takes as input 44.1kHz audio, and compresses it to a bitrate of 8kbps using 14 codebooks, with a downsampling rate of 768x. The latent space therefore is at 57Hz, with 14 tokens to predict at every timestep. We designate 4 of these tokens as the coarse tokens, and the remaining 10 as the fine tokens. Refer to the Describe Audio Codec [15] for details on the tokenizer architecture. We train the tokenizer for 250k steps.

The VampNet architecture (for both coarse and coarse-to-fine models) consists of a bidirectional transformer [18] with relative attention [30] and an embedding dimension of 1280 and 20 attention heads. The coarse model has 20 attention layers, while the coarse-to-fine model has 16. We train the coarse and coarse-to-fine model for 1M and 500k steps, respectively. We train with the AdamW optimizer [31] with β_1 and β_2 set to 0.9 and 0.999, respectively. We

⁶<https://everynoise.com/engenremap.html>

Figure 4. Multiscale Mel-spectrogram error (top) and Fréchet Audio Distance (FAD, bottom) for VampNet 10s samples taken with a different types of prompts.

use the learning rate scheduler introduced by Vaswani et al [18] with a target learning rate of 0.001 and 10k warmup steps. We use a dropout of 0.1, and a batch size of 25, with a GPU memory budget of 72GB.

4.3 Efficiency of VampNet

We first validate that VampNet can generate realistic music audio in a low number of steps. To do this, we run VampNet using one of our prompts (the periodic prompt, with $P = 16$) on our test set, on 10-second excerpts. We vary the number of sampling steps in [1, 4, 8, 12, 36, 64, 72], and report metrics for each sampling step.

4.4 Effect of prompts

We seek to understand how VampNet responds to different prompts, as discussed in Section 3.4. The prompts range from “compression” prompts, which compress music to a low bitrate, to more creative “generative” prompts. We examine whether compression and generative prompts exist on a continuum, and whether decompression from low bitrates results in generative behavior.

We draw 2000 10-second examples from our evaluation dataset, encode them into token streams with our audio tokenizer, and manipulate the token streams in four ways:

1. Compression prompt: C codebooks are left unmasked, starting from the coarsest codebook. All other tokens are masked. We set $N_k = 1$.
2. Periodic prompt: every P th timestep is left unmasked. In an unmasked timestep, tokens from every codebook are unmasked. All other tokens (e.g. tokens in timesteps that do not correspond to the period P) are masked. We set $P \in [8, 16, 32]$.
3. Prefix and suffix (inpaint) prompts: a segment at the beginning and at the end of the sequence is left unmasked. All other tokens are masked. This prompt is parameterized by a context length in seconds. We set the context to be either 1 second or 2 seconds, which corresponds to 57 or 114 timesteps.

4. Beat-driven prompt: we first process the audio waveform with a beat tracker [32]. Then, around each detected beat, we unmask timesteps to the right of the beat. We examine a 75ms unmasked section around each beat, which is about 4 timesteps per beat.

After manipulating the input token streams with our prompts, we generate new musical signals from these masked token streams using VampNet, and compute FAD and mel-reconstruction error between the generated signals and the input signals from our music dataset. We include a noisy token stream baseline, where a portion (as dictated by mask ratio r) of the tokens in the input token stream are replaced with random tokens. We also include as baseline the codec by itself, as well as the coarse-to-fine model.

Finally, we examine how these prompts can be combined - specifically the compression and periodic prompts. By manipulating the hyperparameters of these prompts (C and P), we can shift the model behavior from compression to generation. As more timesteps are masked, the model must generate plausible musical excerpts that connect the unmasked timesteps, that may not match the input music.

5. RESULTS AND DISCUSSION

Results for our experiment varying the number of sampling steps used to generate samples with VampNet are shown on Figure 3. We find that VampNet achieves the lowest FAD with 36 sampling steps, although 12 sampling steps achieves comparable performance. In practice, we find that samples taken with 24 steps achieve a fair trade-off between generation quality and compute speed, with 10-second samples taking around 6 seconds to sample on an NVIDIA RTX3090. In contrast, to generate 10 seconds of audio with an autoregressive model would require 574 steps, which would take around 1 min to generate 10 seconds of audio, given an autoregressive model with the same number of parameters as ours, and the same tokenizer.

Results for our study on the effect of each prompt are shown in Figure 4. First, we note that while the noisy token baseline has comparable mel reconstruction to all prompts, it performs very poorly in terms of FAD. This indicates that while our prompting strategies may result in audio that is not a perfect match to the original input audio, it still falls inside the distribution of plausible music.

Of our proposed prompts, we find that beat-driven prompts perform best, achieving the lowest FAD of all prompts. A notable result here is that the periodic prompt with $P = 16$ (35 conditioning timesteps) performs on par with inpainting with 1 second of context (57 conditioning timesteps). Therefore, prompt techniques that spread out the conditioning tokens throughout the sequence (periodic prompts) are able to use fewer conditioning timesteps to generate samples of comparable quality to those generated by sampling techniques that place all of the conditioning tokens at the start and end of the sequences (inpainting).

Qualitatively, we also find that beat-driven prompts can keep a steadier tempo than other prompts, though their outputs tend to resemble the original music closer than peri-

Figure 5. Mel-spectrogram error (top) and Fréchet Audio Distance (FAD) (bottom) for VampNet samples at varying bitrates. A baseline is provided by replacing tokens in the input sequence with random tokens, per noise ratio r .

odic prompts. In practice, a mix of beat-driven, periodic, and inpainting prompts can be employed to steer of VampNet in creative ways. To illustrate, we highly encourage the reader to listen to the accompanying sound samples ⁷.

We then combined periodic and compression prompting to show how the model’s behavior shifts between reconstruction and generation tasks, as more tokens are masked away. Results for this experiment are shown in Figure 5. At higher bitrates, (600 bps and above), VampNet is able to accurately reconstruct the original music signal, achieving low mel-spectrogram error and FAD values with respect to the evaluation music audio. At bitrates of 200bps and below, VampNet has comparable reconstruction quality to the noisy token baselines, indicating that the sampled VampNet signals no longer resemble the input audio in terms of fine-grained spectral structure. However, the FAD for VampNet samples at low bitrates is much lower than the FAD for noisy baselines. This indicates that even though VampNet isn’t able to reconstruct the input music signal at low bitrates, it is still able to generate coherent audio signals with musical structure, that are closer to the distribution of “real music” than our noisy baseline.

6. CONCLUSION

We introduced VampNet, a masked acoustic token modeling approach to music generation. VampNet is bidirectional, and can be prompted a variety of ways using an input audio file. Through different prompting techniques, VampNet can operate in a continuum between music compression and generation, and is an excellent tool for generating variations on a piece of music. With VampNet, a musician could record a short loop, feed it into VampNet, and have VampNet create musical variations on the recorded idea every time the looped region repeats. In future work, we hope to investigate the interactive music co-creation potential of VampNet and its prompting techniques, as well as explore the representation learning capabilities of masked acoustic token modeling.

EXPERT AND NOVICE EVALUATIONS OF PIANO PERFORMANCES: CRITERIA FOR COMPUTER-AIDED FEEDBACK

Yucong Jiang

University of Richmond
yjjiang3@richmond.edu

ABSTRACT

Learning an instrument can be rewarding, but is unavoidably a huge undertaking. Receiving constructive feedback on one's playing is crucial for improvement. However, personal feedback from an expert instructor is seldom available on demand. The goal motivating this project is to build software that will provide comparably useful feedback to beginners, in order to supplement feedback from human instructors. To lay the groundwork for that, in this paper we investigate performance assessment criteria from both quantitative and qualitative perspectives. We gathered 83 piano performances from 21 players. Each recording was evaluated by both expert piano instructors and novice players. This dataset is unique in that the novice evaluators are also players, and that both quantitative and qualitative evaluations are collected. Our analysis of the evaluations indicates that the kind of specific, concrete piano techniques that are most elusive to novice evaluators are precisely the kind of characteristics that can be detected, measured, and visualized for learners by a well-designed software tool.

1. INTRODUCTION

Learning to play a musical instrument can be rewarding, but is also unavoidably a huge undertaking. Receiving feedback on one's playing is crucial for improvement. However, personal feedback from an expert instructor is seldom available on demand; it is typically available (if at all) only in weekly music lessons. Our long-term goal in this project is to build software that will provide comparably useful feedback to beginners, as needed, in order to supplement insights from human instructors. The modes of computer-generated feedback could involve textual or visual indicators, or a mix of both. However, determining what kinds of feedback are especially helpful for beginners (among those that are feasible for computers to generate) is not trivial and should not be based on assumptions. To lay the groundwork for meaningful computer-aided feedback, therefore, in this paper we gather information on how ex-

perts and novices assess piano performances and what criteria they tend to rely on in such assessments.

Recent years have seen rapid growth in commercial products for computer-assisted instrumental learning. Unfortunately, most applications cannot deal with performances involving expressive timing: they expect users to play at a fixed tempo throughout a piece, even though such performances in real life are often perceived as boring and far short of the full expressive potential of music. For example, Yousician [1] and Simply Piano [2] color correctly played notes as the user progresses through a song at a preset tempo. While platforms like this have their own purposes and values, such oversimplified music playing experiences can mislead some learners to think that making music is all about playing the correct notes (rather than better sounding notes). Moreover, real-time feedback could distract players from listening to themselves, and as Percival et al. [3] point out, "computer analysis and interaction should occur *after* a student has finished playing".

Therefore, for our purposes, it makes more sense to envision software that can analyze a complete performance recording before providing feedback. Given such a recording, we would like to investigate what additional evaluation criteria (beyond note accuracy) should be incorporated into the feedback. In fact, even beginner-level players can usually tell when they've hit wrong notes, as the music won't sound right, but they often lack the ability to make more sophisticated judgments about the quality of their playing: articulation, tempo control, dynamics, and interpretation or expressiveness. Therefore, in this paper we focus on analyzing performances that are relatively "correct" in terms of wrong notes, so that they are ready for more nuanced aspects to be evaluated.

We have gathered 83 such piano performances from 21 players, each of whom chose from among seven beginner pieces. Each recording was evaluated by four expert piano instructors, and also by 17 peers from among the players themselves, with both numerical ratings and written comments. In this paper we examine (1) whether instructors and players evaluate performances differently, (2) whether better players are also better evaluators, and (3) what objective indicators can be detected and measured by computers that would reflect comparable evaluation criteria. This dataset is unique in that the peer evaluators are also players, and both quantitative and qualitative evaluations are collected. Each performance has also been aligned to its score, making it possible in the future to derive addi-

tional objective measurements (e.g., tempo variations), and to support further analyses relating performances to their scores (e.g, inter-song performance analysis).

2. RELATED WORK

A recent review paper [4] offers a comprehensive discussion of computer-aided instrument learning. The authors emphasize the differences between systems that are designed to measure competence and those designed to enhance learning, as the former only need to provide a rating, but the latter need to provide descriptive evidence justifying the evaluation. Two other review papers [5] [6] discuss the potentials of utilizing MIR techniques in music education. Example work on piano music tutor systems include [7] [8] [9] [10] [11].

Music performance analysis (MPA) is a broader topic, encompassing other purposes and uses beyond assisting learners, but a recent review paper [12] does discuss its application potential and challenges in regard to music education. Another closely related topic is modeling expressive music performance [13] [14], which focuses on more abstract and higher-level aspects of a performance.

Related to examining performance evaluations, [15] discusses subjectivity in music performance assessment, [16] investigates how individual raters differ in their rating scale structure, and [17] provides insights on the benefit of peer assessment of music performance.

3. DATASET DESCRIPTION

Our dataset includes three components: 83 piano performance recordings in the WAV format, spanning seven different musical pieces; 803 evaluations of these performances, with players’ metadata; and 83 audio-to-score alignments (with seven MusicXML score files and 83 alignment text files) indicating the starting time in the audio of each musical note in each score. This dataset is publicly available at facultystaff.richmond.edu/~yjiang3/papers/ismir23/.

3.1 Performance Recordings

We recruited 21 participants from a local college, using flyers and campus-wide email announcements. These participants represent a range of piano experience, from a low of three months to a high of 16 years. Each participant completed a short questionnaire before recording a performance for the project. Except for one music major and one music minor, the participants play piano as a hobby. More than one participant recounted the story that they took piano lessons growing up, played on-and-off throughout the years, and recently came back to practicing it in college. When asked to self-identify their piano skill levels, nine of the 21 described their skills as “advanced”, eight as “intermediate”, and four as “beginner”. (None chose the “professional” category from our prompt.)

We selected seven pieces from a popular score book for adult group piano classes [18], and asked each player to play however many pieces they felt like from these. (This

flexibility helped recruit lower-level players who might otherwise be intimidated by this task.) The sheet music was shared with them weeks in advance to allow time for practice and preparation. Table 1 provides the names of these pieces and the number of performances of each. The players were advised to warm up before a recording session, and when recording, were offered the option either to be left alone in the piano room (to decrease nervousness) or to have the researcher present. They were allowed to re-record multiple times until satisfied with their own playing (e.g., with the preponderance of notes played correctly).

Piece Name	#Measures	#Recordings
Careless Love	16	11
Cielito Lindo	16	6
Lavender’s Blue	16	17
Over the Waves	32	11
She Wore a Yellow Ribbon	34	13
The Blues	16	17
The Entertainer	40	8

Table 1. Summary of performance recordings.

3.2 Performance Evaluations

To evaluate the quality of these recordings, we recruited four professional piano instructors and 17 out of the 21 players (the other four were unfortunately not available for this stage). The instructors all have doctoral degrees and at least two decades of teaching experience. Each performance was evaluated by all four instructors and at least five (sometimes six) randomly chosen peers, resulting in 803 evaluations in total. The evaluators were asked to provide a numerical rating from one (poor) to five (excellent) for each recording, and also to briefly explain the basis for their rating, describing what criteria they considered. We collected the evaluations through a web-based form where users can play the recordings (grouped by score), enter evaluations, and save their progress. The sheet music is also linked from the form. It took between two to three hours for each instructor to evaluate all 83 performances, and 50 minutes on average for each peer player to evaluate 27 or 28 performances.

3.3 Audio-to-Score Alignment and Web Interface

Based on the sheet music, we created seven digital scores in the MusicXML format, and aligned each performance to its score. The alignment was achieved by the hidden Markov model proposed in [19], with occasional manual corrections. Each of the 83 alignment files contains two columns of values: a musical time in the score, and its played time in the recording. The alignment can also support future analyses relating performance attributes to elements in scores. For example, one could easily investigate whether players tend to slow down at a particular measure.

To make it more convenient to explore this dataset, we have built a demonstration web-based interface where a user can select and play any of these performances, while looking at the sheet music with the currently

played notes highlighted. The evaluations of the selected performance are also shown on the same page. This interface can help anyone interested in this dataset to find connections among performances, scores, and evaluations. This website is publicly available at facultystaff.richmond.edu/~yjiang3/papers/ismir23/.

4. QUANTITATIVE ANALYSIS

4.1 Self-Identified Piano Levels

To verify the accuracy of the performers’ piano skill levels, we separate the performances into three groups according to their self-reported levels, and compare the evaluators’ ratings of those performances in each group. Figure 1 compares three box plots, one for each group of performance ratings, where each performance rating in a group represents the average among the four instructors. Although the median rating increases with the skill levels, the three distributions overlap with each other. To test whether the difference between the advanced group’s ratings and the intermediate group’s is statistically significant, we conduct a one-sided Welch’s t-test and get a p -value of 0.1826 ($\alpha = .05$)—so we cannot say the former played better than the latter. (The beginner group’s n is too small for statistical tests.) Although “beginner”, “intermediate”, and “advanced” categories are common labels applied to self-study courses and musical scores for amateur musicians, this result indicates that the ambiguity and subjectivity inherent in defining these categories make self-identified skill levels unreliable.

Figure 1. Comparing (averaged instructor) ratings among three self-identified groups.

4.2 Expert Evaluations

To examine how each instructor distributes their rating levels, we count the ratings at each level and compare their frequencies, as shown in Figure 2. It is clear that Instructors 1 and 2 tend to give high ratings more often than Instructors 3 and 4; the former also avoid giving the lowest rating almost completely. This indicates that the absolute rating values may be subjective and skewed.

Therefore, to measure how similarly these instructors rate, it makes more sense to compare ratings according to relative rather than absolute values. For this purpose we use Kendall’s τ coefficient, which focuses on the rank correlation and can handle ties (with the tau-b version). Table

Figure 2. Comparing instructor rating distributions.

2 shows how each pair of instructors’ ratings are associated with each other, with correlations sorted in descending order; all p -values are close to zero, statistically significant at the $\alpha = .01$ level. These instructors show strong correlations ($> .5$) with one another, especially Instructor 3 and Instructor 4.

I3 & I4	I1 & I2	I2 & I4	I1 & I4	I1 & I3	I2 & I3
.806	.595	.563	.521	.514	.508

Table 2. Kendall’s τ correlations (I=Instructor).

4.3 Peer Evaluations

As described in Section 3.2, 17 of the players also provided peer evaluations of the performances. To measure how the players’ ratings compared to the instructors’, we calculate the Kendall’s τ correlation between ratings provided by each player and the average rating for the same recording subset provided by the instructors. Let’s define k_p as the correlation for the p th player, where $p = 1, 2, \dots, 17$. All k_p end up ranging between .401 and .741 (p -values $< .01$), with a mean of .542.

If we use k_p to represent the degree of “accuracy” of the p th player’s ratings, we can investigate the question of *whether better players are also better evaluators*. Let’s define r_p as the average rating received by the p th player from all four instructors (for all pieces by this player). We use Spearman’s ρ to measure how r_p and k_p are monotonically related, and the result is:

$$\rho_{r,k} = 0.152$$

$$p\text{-value} = 0.56$$

Although the correlation is positive, the large p -value prevents us from rejecting the null hypothesis that no relationship exists between how well individuals play and how accurately they rate performances.

5. QUALITATIVE ANALYSIS

5.1 Content Analysis and Annotation

To understand the evaluation criteria used by the instructors and the (novice) peer evaluators, we conduct a content analysis of their written comments [20]. The process involves first building an annotation model representing various evaluation criteria that appear in the text, and then

using this model to annotate each evaluation comment. (These two steps are iterative, as described later, in keeping with best practices for textual analysis [21].) For example, one of the comments—“The player didn’t play the staccato notes in the left hand. No dynamic changes. A wrong note was played.”—is annotated with *staccato*, *dynamic contrast*, and *wrong note* (terms that are then categorized under Articulation, Dynamics, and Note Accuracy respectively).

We use specialized text analytics software (QDA Miner, from Provalis Research) to construct the annotation model and to annotate each comment. To define appropriate annotations, we find recurring words and phrases (frequency ≥ 3), and look at each original comment in context to understand the intended meaning. For example, one of the most frequent phrases is “left hand”, and one of its recurring contexts is that the left hand notes were played too loudly; therefore we create an annotation called *left hand loudness*. Other key words often associated with this aspect include “bass”, as in “... I would like the bass [to] sound softer”. By searching for related key words (e.g., “balance”), we have found similar contexts describing *right hand loudness* or just the *balance in general*. We group these conceptually related annotations under the same category called *Balance*. As we examine the contexts of these frequent words and phrases one-by-one, we create new annotations (and categories), and use them to annotate evaluator comments.

Building annotations and annotating comments is an iterative process: while examining the comments, we have discovered infrequent but useful key words like “8va” and “cresc” that we should search for. We sometimes carve out a new annotation from existing ones when observing enough cases to form a pattern (e.g., we have created a separate *tempo steadiness* annotation from *good tempo* and *inaccurate tempo*.) We have also spot-checked individual comments to make sure all evaluation criteria are sufficiently represented in our annotation model.

5.2 The Annotation Model

Figure 3 shows the annotation model developed from our dataset, containing 47 annotation terms arranged in 11 categories (and two subcategories). Many of these annotations can represent both positive and negative aspects of a performance: for example, *tempo steadiness* can be used to annotate both steady tempo and unsteady tempo. This is harmless, as our goal is to identify evaluation criteria, not the valence of the evaluations *per se*. A small handful of annotation terms exist only in the instructors’ comments or only in the peers’ comments, and these are mostly annotations in the Styles category: four styles are mentioned only by the instructors and five styles only by the peers. In addition, *dynamic shaping* (20 instances), *melodic shaping* (9 instances), and *rubato* (11 instances) only exist in the instructors’ comments.

The annotation model derived from this dataset represents a diverse set of criteria, and it serves as a pool from which computers can select and generate measurements.

Tempo and timing	Dynamics	Styles
- inaccurate tempo	- accurate dynamics	- smooth
- good tempo	- inaccurate dynamics	- heavy
- tempo steadiness	- dynamic contrast	- light
- tempo contrast	- dynamic shaping	- abrupt
- ritardando		- crisp
- rubato	Balance (between hands)	- character
- pause	- balance in general	- lively
	- left hand loudness	- flow
	- right hand loudness	- lyrical
Note accuracy		- mechanical
- correct note	Articulation	- style
- wrong note	- articulation in general	- bland
- missed note	- legato	- with emotion
- wrong octave	- staccato	
	- accent	Rhythm
Phrasings		- correct rhythm
- phrasing	Confidence	- incorrect rhythm
- melodic shaping	- confident or hesitant	- Notes too short
		- shortened note
Pedal	Note connection	- left hand too short
- inaccurate pedal	- choppy	- Notes too long
- good pedal	- connectedness	- note too long

Figure 3. The annotation model. Lower case: annotations; bold: categories; italic: subcategories.

Many of the criteria are objective in nature: e.g., tempo change, note accuracy, and rhythm. These have low ambiguity and thus computational methods can detect them in a fairly straightforward manner; in fact, many traditional MIR techniques can be used for measuring these criteria. For example, we can easily track tempo changes based on audio-to-score alignment results (although deriving *perceived* tempo involves a few more parameters [22]). At the other end of the spectrum, however, criteria like confidence and style are very abstract, and thus are extremely hard for computers to detect. The rest of the criteria fall in the middle. Dynamics, phrasing, and articulation, for example, are directly linked to measurable features of the audio signal, but they involve many other parameters and can be subjective. Some literature addresses this duality (e.g., [23] on articulation and [24] on dynamic shaping), but there is no consensus on how to model such features, and attempts are scarcer than the more traditional MIR work mentioned above. Such aspects are almost never considered in computer-aided instrument learning applications.

5.3 Frequency of Evaluation Criteria

In the end, we have a total of 885 annotation instances for the instructors’ comments, and 1015 for the peers’ comments, averaging 2.7 and 2.2 annotations per comment respectively. We count the number of annotation instances under each annotation category separately for the instructors and for the peers, and calculate the frequency with which each annotation category was used by the two groups respectively. These percentages are shown in Figure 4. For both the instructors and the peers, Tempo, Note Accuracy, and Rhythm are the top three categories, accounting for just over 60% of the total annotations (although the peers describe Tempo more frequently and Rhythm less frequently than the instructors). For the remaining categories, Balance, Styles, and Confidence show the most difference between the two groups.

Balance is the fourth most common evaluation criterion found among the instructors' comments, accounting for 8.4% of the annotations, versus only 2.4% of the peers'. Balance between hands is a well-known challenge for piano beginners, and it can be difficult to notice on one's own; the percentage discrepancy between experts and novices suggests a promising opportunity for computer assistance. Meanwhile, Styles is the fourth most common criterion for the peer evaluators (9.4%), but it is only the eighth for the instructors (4.4%). Confidence accounts for 7.3% of peer annotations, but only 2.7% of instructor annotations. Styles and Confidence are both abstract concepts. For the instructors, these two are both ranked after Balance, Dynamics, Articulation, and Pedal, which represent concrete piano techniques, and they occupy 28.2% in total. In contrast, all these four categories have lower percentages for the peers, and they occupy only 18.2% in total. This discrepancy implies that as compared to experts, novices might be more likely to judge a performance using abstract concepts, while experts tend to point out specific piano techniques.

Figure 4. Comparing annotation category percentages.

We further investigate the usage of the four “technique” criteria and the two “abstract” criteria just described by comparing three groups among the peer evaluators: the four peer players whose performances received the lowest average ratings, the four peer players whose performances received the highest average ratings, and the four ranked in the middle. For each group, we calculate the usage percentages as above, and focus on comparing the six criteria. Figure 5 shows the comparison among the three groups, as well as how they compare to the instructors. The left bars indicate a consistent positive association between piano skill levels and the usage of piano technique criteria. Although the (opposite) trend of the right bars is less consistent, as the middle group used abstract

criteria less frequently than the higher-skilled group, the lower-skilled group indeed used a significantly higher percentage of abstract criteria than the average of all 17 peer evaluators (16.7%). This suggests that lower-skilled piano players lack the ability to pin down specific piano techniques involved in a performance, and their evaluation criteria tend to be correspondingly more general and abstract, e.g., “There is some hesitancy in the chords. The bass clef chords are a bit abrupt”.

Figure 5. Comparing piano technique criteria (left) and abstract criteria (right) usage among three groups of peers and the instructors.

6. DISCUSSION

6.1 Do Instructors and Players Evaluate Performances Differently?

In terms of numerical ratings, the consistent high correlations between the peer evaluations and the average of the instructor evaluations (Section 4.3) suggest that even novices have a reliable sense of what good or poor performance is like. In terms of evaluation criteria, both the peers and the instructors use Tempo, Note Accuracy, and Rhythm the most, accounting for a little over 60% of the total comment annotations from both groups. However, beyond these top three criteria, the two groups exhibit different patterns: the peers tend to use more abstract and general criteria like Confidence while the instructors use more concrete and specific piano techniques like Balance (between hands). It is unsurprising that instructors would use more technical criteria, given their own training and teaching experience, and computer-generated feedback based on these criteria could be particularly illuminating to individuals seeking to improve their playing.

6.2 Are Better Players Also Better Evaluators?

For the sake of this discussion, we define good evaluations as evaluations similar to the ones done by the instructors. In terms of *ratings*, we do not find enough evidence confirming better player are also better evaluators—even players of poor performances can provide accurate ratings. However, in terms of evaluation *criteria*, we have found evidence that higher-skilled players tend to provide better

evaluations. Specifically, they are more capable of judging a performance based on piano techniques, which are in line with piano instructors’ evaluations.

6.3 Computer-Aided Feedback

These results suggest that there is a consistent standard of good and poor performances—at least for beginner pieces. However, numerical ratings have limited value for helping students learn. In fact, students take private music lessons not to be given a rating, but to seek specific formative feedback for improvement. Building a machine that can provide comparable feedback would offer much greater value to end users.

Much of the terminology in the annotation model is score-dependent, verifying whether or not the performer has followed elements in the sheet music. The basic elements are notes, rhythm, and tempo/timing, which also correspond with the top three evaluation criteria. Relevant MIR tasks for detecting such errors include music transcription [25], source separation [26], and audio-to-score alignment [27]. Other typical elements in the sheet music are dynamics, articulation, and pedaling, and some attempts (such as [23] [28] [29]) have been made at modeling and detecting them.

However, not every element or aspect worth evaluating is explicitly indicated in the score. For example, pedaling and balance between hands are often only implied in the score, and can also be up to personal interpretation by the performer. In such instances, text-based feedback can be of limited utility, and what a computer may be able to do more effectively is provide visualized feedback. The value of such feedback lies in making implicit aspects of a performance explicit to the player, rather than instructing the player what to do. For example, the computer could show a tempo curve indicating (intentional or unintentional) tempo changes. Such visualizations can be especially helpful to beginners, who might not be able to notice such aspects easily.

6.4 Peer Evaluation for Education

At the end of each peer evaluation session, we asked the evaluator two open-ended questions: “How do you feel after listening to so many recordings in a row?” and “How do you feel about this process compared to how you evaluate your own playing?” Most evaluators expressed that it was a positive experience, with words like “fun”, “very interesting”, and “enjoyed it”. A couple of them mentioned they were able to pay more attention to the elements in the sheet music when evaluating others. Four of them indicated that the process of comparing multiple recordings helped them judge their own playing better. This overall positive response suggests that there is educational potential for peer evaluation platforms where piano learners could anonymously give each other feedback.

6.5 Limitations

There are some inherent limitations in this project. First, the pieces we focus on are all at the beginner level, meaning they are relatively short and involve relatively few sophisticated piano techniques. It is possible that our findings might not apply to performances (or evaluations) of more advanced pieces. Second, the recording process might involve some bias against more advanced players who felt confident and could sight read, and thus did not prepare as much as the beginners. Third, the size of the dataset is relatively small. This facilitated our process of careful, manual content analysis, but imposes some limits on the statistical analysis.

7. CONCLUSIONS AND FUTURE WORK

In this paper, we contribute a unique dataset of amateur piano performance recordings and corresponding expert and peer evaluations. This dataset allows for interesting multifaceted analysis of nuances in the peer evaluations, because the peer evaluators are also players, and both quantitative and qualitative evaluations are recorded. Through the initial analyses presented in this paper, we find that even novices exhibit reliable judgement at distinguishing good performances from poor ones, but higher-skilled novices tend to base their judgement on piano techniques (as experts do), while lower-skilled novices rely on more subjective and/or abstract impressions. Most evaluation criteria used by experts are concrete, and are therefore precisely the kind that can be detected and measured by software evaluating an audio signal and its relationship to the score. Visualizing these aspects could provide valuable assistance to beginners seeking constructive insights on their playing. Despite some limitations to the generalizability of its findings, this paper lays the groundwork for building more advanced computer-aided instrument learning software. In future work, we plan to combine the audio-to-score alignments in this dataset with other MIR techniques to derive specific measurements reflecting experts’ evaluation criteria. Once that is achieved, we then plan to compare those computer-generated evaluations of these recordings (including measurements and/or visualizations) to the human annotations.

8. ACKNOWLEDGMENTS

We extend our sincere thanks to multiple individuals for their contributions to this project. First, we thank the piano players and the piano instructors for participating in our experiments. Second, we thank Joon Han and Liz Smith for helping record the piano performances. Third, we thank Caitlin Sales for creating the demo website. We would also like to thank the reviewers of this paper for their detailed and constructive feedback.

ABSTRACT

Music retrieval and recommendation applications often rely on content features encoded as embeddings, which provide vector representations of items in a music dataset. Numerous complementary embeddings can be derived from processing items originally represented in several modalities, e.g., audio signals, user interaction data, or editorial data. However, data of any given modality might not be available for all items in any music dataset. In this work, we propose a method based on contrastive learning to combine embeddings from multiple modalities and explore the impact of the presence or absence of embeddings from diverse modalities in an artist similarity task. Experiments on two datasets suggest that our contrastive method outperforms single-modality embeddings and baseline algorithms for combining modalities, both in terms of artist retrieval accuracy and coverage. Improvements with respect to other methods are particularly significant for less popular query artists. We demonstrate our method successfully combines complementary information from diverse modalities, and is more robust to missing modality data (i.e., it better handles the retrieval of artists with different modality embeddings than the query artist’s).

1. INTRODUCTION AND RELATED WORK

The MIR community has dedicated significant effort to defining and computing music similarity in the last 20 years. Music similarity can be used in multiple downstream tasks, from playlist continuation, music visualization/navigation, music categorization for organizing catalogs, or for personalized recommendations. The notion of similarity is subjective and there is no consensus on how to define and evaluate it [1]. To evaluate the performance of a music similarity algorithm, some previous works either focus on content-based aspects, such as melody or harmony. Other works measure similarity based on *cultural aspects*, such as based on the co-occurrence of items in playlists or on editorial data –this is the approach of our work.

Multiple methods have been proposed to compute music similarity based on a variety of data types related to the music, e.g., based on audio descriptors [2], document similarity [3], or graphs of musical connections [4, 5]. Some relatively recent works propose ways to produce embeddings –that can be used to compute music similarity– in a supervised or unsupervised way, by training models on large amounts of data (such as audio, text or image). Such pre-trained models, which are often released publicly, may produce feature representations –i.e. embeddings– that are effective for previously unseen tasks. Such embeddings can be computed from diverse types of modalities related to music such as audio [6–8], tags [9], album covers images [10], or biographies [4]. The multiple modalities of data that can describe a music item –such as audio, tags, or listening interactions– may contain *complementary* information. For example, the quality and scale of audio vs collaborative data has been shown to have significant influence in autotagging tasks [11]. It therefore appears beneficial to combine diverse complementary modalities to obtain a more informative representation of music items. In fact, recent research identifies the combination of diverse sources of data as specially promising for mitigating limitations and issues in music recommendation research [12].

Another aspect to take into account is that in any given music dataset, data of diverse modalities might be available for different subsets of items. Therefore, when querying with an item represented in a given modality, the maximum coverage for retrieval is limited to items for which that same modality is available, leaving out a potentially significant –and relevant– part of the dataset. For example, the availability of listening interactions or users’ explicit feedback is highly dependent on item popularity. Therefore, for artists with very little listening and user feedback, it may not be possible to obtain embeddings from that modality. Embeddings from other modalities may suffer from the same issue, either because there is no data available to produce an embedding or because the quality of the available information is very low. For instance in the case of a model trained on tag annotations to produce artist embeddings, where the output embedding may not be very informative for those artists that have a single or few tag annotations. Such issues are particularly common and problematic emerging or more underground artists, for which the available information is more limited.

In order to mitigate the issue of availability of some modalities, it is important to combine and take full ad-

vantage of all information available so that when querying with an artist that has only one modality available, we can also retrieve artists for which we have a different modality information. Therefore, the focus of this work is to combine diverse modalities into a common shared space that is beneficial for 1) leveraging each modality information from the artists, and 2) allowing to operate on a single space that covers the full population of artists, ensuring that whether or not an artist is retrieved for another does not depend on the number of modalities available.

The problem of combining embeddings from diverse modalities in a shared representation has received some attention in the last few years. In the music domain, there have been some works on combining embeddings by simple concatenation [13] or predicting one modality from another [14]. Contrastive learning techniques go beyond simple concatenation or prediction, trying to learn a shared representation between embeddings from different modalities. Some examples of research related to multimodal contrastive learning can be found in [10], where embeddings from a shared multimodal space are used as additional features for classification, or in [15, 16] where, e.g., music audio can be retrieved from natural language descriptions. In this work, we propose to apply a contrastive learning method that maps embeddings from diverse modalities to a shared embedding space, extending the advantages of multiple modalities to populations that would not be covered otherwise.

In summary, in this work we propose an approach to combine the multiple encoders of a contrastive learning method, showcasing several improvements over baselines and single-modality approaches in an artist similarity task. We show under two different contexts –using an open and an in-house dataset– that our proposed approach:

- achieves higher performance in terms of accuracy and coverage of retrieved artists (§ 3.1),
- successfully combines complementary information from diverse modalities (§ 3.2),
- is more robust to missing modality data (§ 3.3),
- particularly increases the performance for less popular query artists (§ 3.4).

2. METHODOLOGY

2.1 Single-Modality Embeddings and Contrastive Method

In this work, we use three modalities, namely: tags, user-listening interactions (i.e. collaborative filtering data, referred to as CF), and audio information. In all cases, we use pre-trained models to obtain embeddings for each of the modalities. We evaluate artist similarity performance using the embeddings from the pre-trained models directly, and compare to the performance when using the embeddings produced by our contrastive method which is trained with the same embeddings from pre-trained models.

In these experiments we apply a contrastive learning loss based on InfoNCE [17]. Specifically, we define the contrastive loss between two modalities, ψ_a and ψ_b , as:

$$\mathcal{L}_{\psi_a, \psi_b} = \sum_{i=1}^M -\log \frac{\Xi(\psi_a^i, \psi_b^i, \tau)}{\sum_{k=1}^{2M} \mathbb{1}_{[k \neq i]} \Xi(\psi_a^i, \zeta^k, \tau)}, \text{ where } M \text{ is the}$$

batch size and τ is the temperature parameter. We define $\Xi(\mathbf{a}, \mathbf{b}, \tau) = \exp(\cos(\mathbf{a}, \mathbf{b})\tau^{-1})$, based on the cosine similarity. ζ^k is defined as ψ_a^k , if $k \leq M$ and else ψ_b^{k-M} . This loss function attempts to minimize the distance between the modalities of the same artist while maximizing the distance with any modality from other artists.

We use three encoders –one for each modality– that will produce three representations in our shared space for each artist. During training¹ we minimize the sum of the pairwise losses between each of the modalities as in [18]: $\mathcal{L}_{\text{tot}} = \mathcal{L}_{\text{Audio-Tag}} + \mathcal{L}_{\text{Audio-CF}} + \mathcal{L}_{\text{Tag-CF}}$

Once the model is trained with the contrastive method and we want to use it for inference, for a given artist, we aggregate the output of each internal encoder by averaging all available information.

2.2 Training Data

In order to investigate the effectiveness of our contrastive method under different situations, we train our model using two independent datasets: We use a dataset based on public data to facilitate the reproducibility of some of the results. And we also use an in-house dataset that contains multimodal information for a larger set of artists.

Training our model requires *full coverage of the three modalities for all artists* –tag-based embeddings, CF embeddings, and audio embeddings. For the public dataset, we use the Million Song Dataset (MSD) [19] and its connections with other datasets to collect tags, audio and CF embeddings. We collected audio track embeddings using the public unsupervised model from [6] to extract embeddings from MSD audio previews, then we averaged all audio tracks embeddings for each artist. The tagging data was collected from the MSD500 dataset [11] and embeddings were computed using PMI factorization [13] of 500 tags. The CF embeddings were obtained using weighted matrix factorization [20] based on the Echonest Profile dataset,² with Gaussian process-based Bayesian hyperparameter tuning [21]. We gathered information from the three modalities for 17, 478 artists.

For the in-house dataset (hereafter, OWN) we collected tags, CF, and audio information for 38, 301 artists. This dataset is larger than MSD and includes what we believe is *higher-quality tags and CF data*, which allows us to compare the performance of our approach in a different setting. The CF information is computed from very large amounts of user-listening interactions on a streaming platform. The audio embeddings are computed using the supervised model³ described in [6]. The tag embeddings are

¹ For both datasets we use Adam optimization with a learning rate of 0.0001 and temperature of 0.1. We use a fully connected layer of 256 for the CF encoder, two layers with 512 and 256 for the Audio encoder and 4 attention heads of 256 for the tag encoder. The learned space has 200 dimensions. Batch size for C_{OWN} is 2048 and for C_{MSD} is 128.

² Specifically, we aggregated the per-song listening counts corresponding artists such that we obtain the ‘user-artist’ listening matrix.

³ i.e. a *different* model for audio embeddings than when training on MSD.

computed using PMI factorization from a total of 6,421 different tags, which are a combination of manual and automatic annotations. Since our pre-trained models for audio and CF are at the track level, we compute artist embeddings by averaging over artist track embeddings.

In the remainder of this work, we refer to the model trained with the contrastive method with in-house data as C_{OWN} and the model trained with public data as C_{MSD} .

2.3 Evaluation Dataset

The ground truth for artist similarity is defined herein by the OLGA public dataset [22], containing artist similarity information collected from AllMusic. Our evaluations are therefore based on a *cultural* ground-truth, following [5].

We collected data from the MSD dataset for the original 17,646 artists in OLGA. We obtained tag data from the MSD500 for 10,971 (62%) artists, user interaction data from the Echonest Profile dataset for 15,389 (87%) artists, and audio embeddings using MSD audio previews for 100% of the artists.⁴

We also create a subset of OLGA where *all* artists contain complete tags, user interaction, and audio information from MSD. We refer to this subset as OLGA Full Modality Coverage (FMC), which contains 9,474 artists and it is also mapped to our internal dataset. The OLGA FMC subset is used to compare the results of multiple methods pre-trained on different and independent datasets.

2.4 Evaluation Conditions

In order to provide insights on the performance of the contrastive method, we conduct analyses under 3 different situations, varying the degree of availability of the different modalities in the evaluation data:

Raw evaluation dataset: In one condition, we compare the methods using all the artists in the OLGA dataset. In this case, we are interested to understand performance in a scenario of a real –uncontrolled– evaluation dataset, accounting for some organic imbalance of the availability of data in different modalities.

Full Modality Coverage: In another condition, we use the OLGA FMC subset where all artists contain CF, tags, and audio embeddings in both MSD and OWN datasets. In this case, we want to understand performance while factoring out the potential influence of one or another modality being only partially available in evaluation.

Systematic variation of modality coverage: We also perform multiple comparisons by grouping artists from OLGA depending on how many modalities are available. Here, we want to look at how much the contrastive method and the baselines are capable of doing cross-modality retrieval when using different modalities as input. In particular, we want to see whether or not they are capable of retrieving artists that have different modality information

⁴ Note that we don’t control for artist separation between MSD, OWN and OLGA. But even if some artists may be present in both train and test sets, the artist similarity information from OLGA is *only* used for evaluation, and is never used during the training of the single-modality embeddings nor the contrastive models on either MSD or OWN.

available compared to the query artists. Therefore, in this part, we create 7 groups of artists –at random– of equal size with each group containing one, two, or three modalities (namely, CF, audio, tag, CF+audio, CF+tag, audio+tag, audio+CF+tag). We refer to these groups as ‘Modality Groups’. It is important to highlight the artificiality of this setting. We are considering an extreme case only to evaluate cross-modality retrieval capabilities of the methods. We are not considering here the accuracy of these results since it is already evaluated in the other analyses.

2.5 Baseline multimodal approaches

For multi-modal baselines, we employ two conventional models: PCA, and Gaussian random projection [23, 24] (which we refer to as Rand).⁵ For fitting these models, we consider artists who have access to all modalities. Their multimodal embeddings are concatenated and treated as a single feature vector. It yields a dimensionality of 2,063 for the MSD dataset, and 2,528 for the OWN dataset. We set the reduced dimensionality to 200, which is the same size as the embeddings of the contrastive model. If an artist has a missing modality in the prediction phase, we employ the global mean embedding of the missing modality.⁶

2.6 Metrics

Accuracy: We consider nDCG@200 to measure how accurate the retrieved artists are compared to the ground truth while taking into account the position in the ranking of the retrieved artists, a metric considered robust to missing relevance information [26].⁷

Distribution: We also compute the Gini@200 index, measuring the distribution of the top 200 retrieved artists in each experimental condition across the whole set of artists. A lower value of Gini indicates that the recommendations across artists are more uniformly distributed –covering more artists retrieved– while a higher value of Gini indicates that the recommendations are focused on only the few same artists.

We compute the confidence interval using the bootstrap method [27] on the evaluation artist population. We report them in Figure 1 at 95% confidence level.

Expected Contrastive Loss: We propose an additional metric that we named Expected Contrastive Loss (ECL). We use this measure to analyze to what extent an artist is coherent with respect to their multimodal representations. From how we defined the loss in Section 2.1, a high loss value implies that the artist is relatively difficult to be distinguished from other artists. Once the training is reasonably progressed, we employ ECL to quantify how ‘coherent’ the artist is with respect to their internal representations obtained from the different modalities, which is defined as: $ECL(i, u, v) = d_{ii}^{uv} - \mathbb{E}_{j \setminus i} [d_{ij}^{uv}]$,

⁵ For both algorithms, we employ the standard implementation provided from `scikit-learn` [25].

⁶ This does not happen in FMC

⁷ We focus on nDCG@200 in this work, as we experimentally observed high correlation with other retrieval metrics such as precision, recall, and R-Precision.

where i and j denote artist index, while u and v refer to the modality index. d_{ij}^{uv} means the cosine distance between artist i from modality u and artists j from modality v . Taking expectation over all the possible modality pairs leads to the final coherency measure for artist i : $ECL(i) = \mathbb{E}_{u,v \setminus u}[ECL(i, u, v)]$.

Clustering: We further analyze the multimodal embedding space of the contrastive model, by investigating how well the artist embeddings are clustered. The contrastive method essentially can be seen as a “supervised” clustering task, where we minimize the distance among “positive points” (i.e., multimodal embeddings from an artist) and maximize the distance between those to the “negative points” (i.e., embeddings belonging to the other artists). It implies that an artist will get a higher training loss when the embeddings are dispersed and overlapped with the embedding cluster of other artists, while the opposite cases will get lower values. The model will fit the multimodal embedding space such that the artist embeddings poorly clustered initially have more concentrated and distant clusters. While the contrastive learning implements this naturally by its loss function, there are other well-known measures for the validation of the clustering methods, such as *intra-cluster distance* (CD_{intra}) indicating how an artist embeddings are well clustered together, and *inter-cluster distance* (CD_{inter}) indicating how an artist-specific embedding cluster is far and distinct from others⁸.

3. RESULTS

3.1 Performance comparison of contrastive method

We now look at the performance of the contrastive method when some modality information is missing in the evaluation dataset (using the raw OLGA dataset) and when all modalities are available for each artist (FMC subset). We also compare the performance of the contrastive method to the baseline methods and to single-modality embeddings.

3.1.1 Performance with incomplete modality information

Focusing on the different combinations of input modalities to the contrastive method, we can see in Table 1 that the highest nDCG result is obtained when combining all modalities as input. We therefore focus only on this model for the remainder of the work.

Figure 1a shows the results for all artists in OLGA. We can see that when using features from MSD, the contrastive method outperforms the baselines and the original embeddings in all the metrics. The contrastive method always gives a better Gini compared to the other methods –which means that the distribution of retrieved artists is more uniform– while outperforming the other models in nDCG.⁹

⁸ we compute CD_{intra} as the mean cosine distance between multimodal embeddings of an artist to their centroid in the multimodal space of learned contrastive model. CD_{inter} is computed as the mean distance between the centroids of target artist and of all the other artists.

⁹ OWN-OLGA is omitted since we observe a similar behaviour.

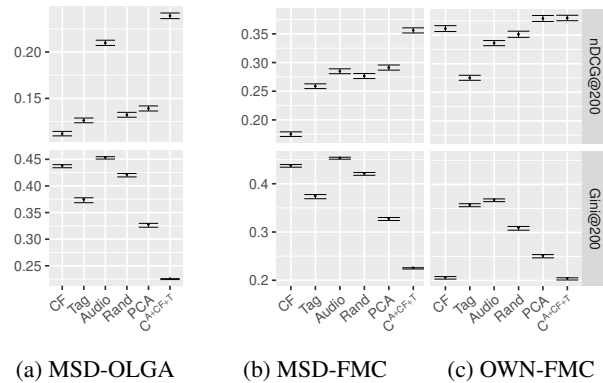

Figure 1: Performance comparison between contrastive and other methods. Training with MSD (a and b) or with OWN (c), Evaluation on OLGA (a) or on FMC (b and c).

	OLGA		FMC	
	nDCG@200	Gini	nDCG@200	Gini
C^{A+C^F+T}	0.2387	0.2264	0.3560	0.1666
C^{A+T}	0.2282	0.2035	0.3407	0.1559
C^{A+C^F}	0.1381	0.3425	0.2319	0.1873
C^{C^F+T}	0.1781	0.3467	0.3082	0.1917
C^A	0.2338	0.1857	0.3471	0.1353
C^T	0.1232	0.4939	0.2554	0.1745
C^{C^F}	0.1381	0.3425	0.2319	0.1873

Table 1: Evaluation of the contrastive method trained with MSD data using all combinations of modalities for OLGA dataset and FMC subset.

3.1.2 Performance with complete modality information

When we look at the results with Full Modality Coverage (Figures 1b and 1c), the contrastive method outperforms the baselines and the pre-trained models in all the metrics both when trained with MSD data or with OWN data.

When looking at baseline performance between OLGA and FMC (Figures 1a and 1b), we can see that in the latter, baselines are relatively close to the best single-modality embeddings, but in the former (i.e. with incomplete modality information) their performance drops significantly lower than the best single-modality embeddings. This is something we do not observe with the contrastive method, which suggests that the baseline models are more limited in the capabilities of retrieving artists that miss some of the modalities from the query artist, while our contrastive method may be more robust to missing modality information. We investigate this further in Section 3.3.

3.2 Combining complementary modality information

If we focus only on the single-modality approaches, and MSD pre-training, Audio gives the best single-modality performance in both OLGA and FMC (Figure 1a and 1b). On the other hand, when pre-trained with OWN, CF is slightly better than Audio and Tag (Figure 1c). These results suggest that performance is highly dependent on the quality of the data used to pre-train the single-modality embeddings. Results from Figure 1b and 1c also sug-

	Audio	CF	Tag	Rand	PCA	C_{MSD}	C_{OWN}
Entropy	0.76	0.79	0.79	0.73	0.96	1.86	1.59

Table 2: Entropy of each model for Modality Groups. Higher values indicate better distributed retrieved artists.

(a) Contrastive - MSD training (b) Contrastive - OWN training

(c) PCA - MSD training (d) PCA - OWN training

Figure 2: Analysis of modality-group dependency ratio when restricting the information available for each group to one, two, or three modalities. Rows indicate the groups used to make the queries and the columns are the groups of retrieved artists. Darker green indicates a higher concentration of the retrieved artists in that cell. The color scale is normalized across all figures. Groups of artists are randomized, so an ideal situation is a homogeneous color in the full matrix.

gest that, whichever single-modality embedding is best, our contrastive method is able to successfully build on top of it and still gain in performance by combining complementary information from other embeddings.

3.3 Robustness to missing modality data

In this subsection, we further analyze how the contrastive method would be able to retrieve artists depending on the available information for the query artists and the candidates for retrieval. In Figure 2, we can see how artists are retrieved from each of the Modality Groups when only considering the top 5 results for each query artist. Typically we see that with the contrastive method, the same group used for query comprises between 15-38% of the retrieved artists. We see however an exception for the CF group which obtains a larger portion of the retrieved artists (59%) when using OWN data to train the models.

When we do a similar comparison for the PCA baseline method, we see in Figure 2 that there are higher percent-

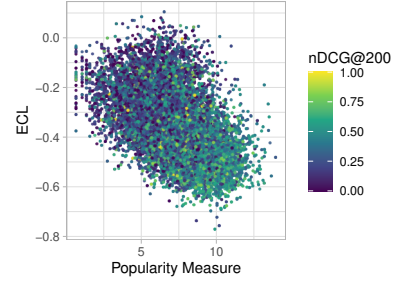

Figure 3: Scatter plot of artists based on the popularity proxy measure and the ECL. Each point represents an artist, where the color brightness represents the per-artist retrieval performance ($nDCG@200$). It is computed on the FMC subset with MSD data.

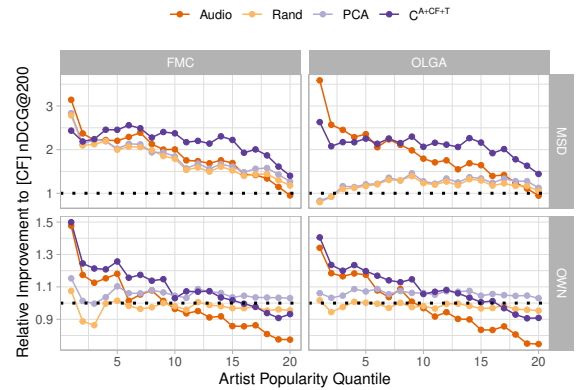

Figure 4: Relative retrieval improvement against CF modality. The x axis represents the grouped popularity quantile in 20 levels, meaning the first group includes artists whose popularity is under 5% percentile, while the top 5% popular artists belongs to the last group. The y axis is proportional improvement of $nDCG@200$ compared to the CF embedding model. The dotted horizontal line indicates the retrieval performance of CF modality. FMC and OLGA are evaluation datasets. MSD and OWN are training conditions.

ages in the diagonal of the matrix. This indicates that most of the retrieved artists are concentrated in the same modality group used to make the query. Therefore, these results highlight the difficulty for the PCA baseline method to retrieve artists beyond the query artist’s modality.

In Table 2 we compare the entropy of each model for the Modality Groups. A higher entropy indicates that retrieved artists are better distributed across the different modality groups, i.e. that retrieval is less biased by the query modality –or more robust to partial modality data in the query. We can see that the contrastive model is more robust to missing modality data than the single-modality embeddings and the baseline approaches to combining modalities. This is true when trained with MSD or with OWN.

3.4 Effect of Popularity

Artist popularity may be a deterministic factor in artist retrieval, both for training and evaluation. Intuitively, we likely have more data about popular artists, which implies more multimodal data is available for training. At the same time, the scale of evaluation metric themselves can be inflated as more popular artists would have more ground truths (annotated as ‘similar artists’). To confirm this, we compute a proxy measure for the artist popularity (POP) as $POP(\text{artist}) = \log(\#\text{listen} + 1)$,¹⁰ and then further compare it to other training and evaluation measures.

Firstly, we compare POP with ECL and the retrieval performance. Figure 3 shows that there is correlation among POP, ECL, and nDCG. In particular, ECL has a negative correlation with nDCG. This is a desirable outcome as a model that minimizes the contrastive loss recommends “similar” artists even though such a model is not being explicitly shown artist-relatedness ground truth during training. Meanwhile, POP also correlates with nDCG, which demonstrates the confounding effect of popularity to the task itself.

Further, we investigate how multimodal models interact with artists with different popularities. One of the benefits of employing multiple modalities is the potential mitigation of the information void for “cold-start” artists from their music audio data. For MIR applications, audio is likely accessible even when some of the other modalities are not readily available. For instance, the CF modality is not available before artists’ songs are consumed by the listeners. To confirm whether the audio and further multimodal embedding models would benefit less popular artists via multimodality, we divided the artists in 20 groups by popularity quantiles. For each group, we further compute the relative improvement of retrieval performance (nDCG) compared to the CF single modality model.

Figure 4 suggests that the original audio embedding achieves better performance for the less popular artists in all training and evaluation conditions. The contrastive model shows improvements for the majority of the groups compared to the audio, while it may have smaller or no improvement over audio in the least popular group for the MSD dataset. In the OWN dataset, a similar trend is observed where the contrastive model shows a small decline for the most popular groups compared to the original CF embeddings. The two baseline models indicate relatively flat results except in the case of the MSD-FMC subset, which implies that their prediction may be more reliant on the CF modality. For the MSD-FMC subset, both baselines follow similar trends to the audio and contrastive model.

3.5 Multimodal Embedding Space Analysis

We conduct a correlation study of multiple measures where, for each artist, we compute clustering measures and other key indicators such as contrastive loss ECL, retrieval performance (nDCG@200), and finally the popular-

¹⁰ #listen denotes the total listening count of the artist, computed from the MSD-Echonest Profile dataset.

Figure 5: Correlation (Kendall’s τ) among variables of interest. Each cell indicates value of τ between two associated variables. POP denotes the popularity measure.

ity measure. In this way, we expect to obtain a better understanding of what contrastive learning achieves in terms of clustering of embeddings, and how they are connected to retrieval performance and popularity.

The result of the correlation study can be found in Figure 5. We see that the ECL is highly correlated to CD_{intra} , while almost independent to CD_{inter} . Notably, in terms of magnitude, all other measures (ECL, CD_{intra} , and POP) are relatively more correlated to nDCG compared to CD_{inter} , and also correlated to each other.¹¹

These relations suggest that our contrastive learning method aims at producing an artist embedding space where the diverse modalities of an artist occupy a coherent region, but not necessarily a region that is unique to the artist. CD_{inter} shows lower correlation with most of the other measures, which confirms its relatively small connection to the contrastive learning and the artist retrieval downstream task. We hypothesize that this is because the maximization of CD_{inter} is constrained by the artist similarity inherent in the multimodal information and ultimately preserved. This is desirable if the ultimate goal is a representation that can measure artist similarity.

4. CONCLUSION AND FUTURE WORK

In this work, we propose a method based on contrastive learning to combine multiple artist modalities into a single representation. In an artist similarity task, we show our method yields clear improvements over other methods in terms of retrieval accuracy and coverage, and successfully combines complementary information from diverse modalities. In particular, we investigate retrieval bias towards the query’s modality. Although our method exhibits a slight bias towards retrieving artists with similar modality to the query, we show it handles cross-modal retrieval better than other methods. Future work may be dedicated to further mitigate this bias. Additionally, we show that our method is particularly beneficial for less popular artists.

Our method appears to generate an artist representation space with high local coherence for intra-artist modalities, but at the cost of inter-artist separation. Depending on the final application, this is a property that could perhaps be managed by iterating on the contrastive learning method, for instance, by adapting the loss function or by adapting the size of the training sample batch as suggested in [28].

¹¹ We focus on the magnitude, as the goal of this study is to investigate the degree to which some of the key indicators are associated with clustering quality measures in absolute manner

5. ACKNOWLEDGEMENT

We would like to express special thanks to Matt McCallum for the help collecting audio features and Sam Sandberg for his valuable comments.

ABSTRACT

The concept of form in music encompasses a wide range of musical aspects, such as phrases and (hierarchical) segmentation, formal functions, cadences and voice-leading schemata, form templates, and repetition structure. In an effort towards a unified model of form, this paper proposes an integration of repetition structure (i.e., which segments of a piece occur several times) and formal templates (such as AABA). While repetition structure can be modeled using context-free grammars, most prior approaches allow for arbitrary grammar rules. Constraining the structure of the inferred rules to conform to a small set of templates (meta-rules) not only reduces the space of possible rules that need to be considered but also ensures that the resulting repetition grammar remains interpretable in the context of musical form. The resulting formalism can be extended to cases of varied repetition and thus constitutes a building block for a larger model of form.

1. INTRODUCTION

Repetition is one of the most central aspects of music [1] and constitutes a constant across almost all cultures, styles and genres. The repetition of material is one of the major compositional devices for the arrangement of parts in overarching musical form [2, 3, 4], be it a folksong, a minuet, a sonata, a jazz standard, or a pop song. In general, musical form could be characterized in terms of exhaustive segmentation, hierarchical grouping structure, rhythmic-hypermetrical structuring, the form functionality of segments [3], and repetition structure. For the purpose of this paper, three aspects of form are considered: a hierarchical organization [5], which is also reflected in hierarchical harmonic structure [6]; repetition of formal constituents, which is one of the most prominent and salient features of form perception in human music cognition [1]; and prototypes of formal organization (such as AABA) which can characterize classical forms [3] but are also common structures in pop, jazz, and folk songs.

Figure 1: A German 19th-century folksong melody on the lyrics “Stille, stille, kein Geräusch gemacht” or “Bier her, Bier her, oder ich fall um.”

The GTTM [5] defines *grouping structure* in terms of a tree of hierarchical containment relations that provides an exhaustive segmentation of the piece. GTTM’s preference rules for grouping structure include Gestalt principles [7] as well as repetition. In addition to grouping structure, repetition structure is defined as a hierarchical grouping tree that captures (optimal) reuse of material (exact or in variation) in terms of groups of musical units and recursive groups of groups. Repetition structure provides a full grouping of a piece, however, it may potentially result in a different tree than what is obtained by a general formal analysis of a piece (see Figure 6). For human judgement of form in general, repetition is not the only factor, as features of (hyper-)metrical structure, form functions, or harmony may play a role as well (see also below in section 4.2). Accordingly, the objective of a computational model of repetition structure as an aspect of musical form may ultimately require to take such aspects into account as well.

Repetition structure plays a role within a single piece as well as over a corpus of pieces since abstract repetition patterns generalize over a whole dataset or style. The melody shown in Figure 1, for example, exhibits repetition of parts on several levels: On the highest level, the melody follows an ABA form, as the first four measures are literally repeated at the end (mm. 9-12). The B part (mm. 5-8) itself consists of a repetition of a two-measure phrase (yellow). Similarly, the first measure of the A part is repeated in the second measure (blue). Even on the level of individual notes, the direct repetition of a note is a prominent feature of mm. 5 and 7.

In the context of form, repetition structure refers to the re-occurrence of formal constituents (such as phrases and sections) that form a hierarchical segmentation structure,

Figure 2: A possible repetition tree of the melody in Figure 1. The leaves of the tree encode pitch and duration of the melody notes. The second occurrence of part A is identical to the first (not shown here).

as opposed to motivic or thematic material, for example. An example of such a segmentation structure for the example piece (Figure 1) is shown in Figure 2. Every formal segment of the piece corresponds to a subtree in the repetition tree. Note that all occurrences of the same segment share the same label and have exactly the same subtree structure. For this reason, the repetition structure shown in the tree can be more compactly described as a restricted context-free grammar (CFG) which has one non-terminal symbol for each segment (with terminal symbols for the notes of the piece) and exactly one rule for each symbol, encoding the decomposition of the corresponding segment. This relationship between the repetition structure of a piece and a compact representation of the piece as a CFG has been utilized for compression-based pattern discovery algorithms such as SEQUITUR [8].

Another aspect of the repetition tree shown in Figure 2 is that its rules use a limited set of formal prototypes, such as $\alpha\beta\alpha$ (e.g., $\text{Piece} \rightarrow \text{ABA}$), $\alpha\alpha\beta$ ($\text{A} \rightarrow \text{CCD}$), or $\alpha\alpha$ ($\text{B} \rightarrow \text{GG}$). In order to avoid confusion with the letters for specific form parts, we denote these form templates with greek letters, e.g., $\alpha\beta\alpha$, $\alpha\alpha\beta$, or $\alpha\alpha$. A concrete instance of a form template is denoted by applying the template to specific segments: $\text{CCD} = \alpha\alpha\beta(\text{C}, \text{D})$. While the rules in a piece’s repetition grammar are specific to a particular segment in that particular piece, the form templates establish a relation between different rules with the same shape, within the same piece or across different pieces. We therefore call them *meta rules*.

This paper is a contribution towards an integrated computational model of musical form, combining two important aspects of form: repetition and formal prototypes. The model characterizes the relationship between meta rules and hierarchical repetition structure and provides a *proof of concept* algorithm and evaluation for repetition structure inference based on *minimal description length* [9].

2. RELATED WORK

Identification of repetition structure is closely related to compression, as identification of redundant information is important to achieve shorter encodings. An early example of grammar-based compression is SEQUITUR, an algorithm that infers a (not globally optimal) grammar for

a given sequence in linear time [8, 10]. For an overview of approximate grammar-based compression, see [11, 12]. Besides inference of segmentation structure, grammar-based compression algorithms have been used for tasks such as error detection and tune classification [12, 13]. The principle of minimum description length has also been used outside of grammar-based approaches, e.g., in combination with hidden Markov models [14]. The approach presented in this paper differs from previous smallest-grammar approaches in two ways: the shape of the grammar rules is not arbitrary but constrained to a set of formal prototypes, and this constrained model is evaluated by inferring the global optimum instead of an approximation, which is generally NP-hard and thus only feasible for short sequences.

The segmentation structure of a piece can also be inferred based on criteria other than repetition. The GTTM [5] defines grouping structure based on a set of well-formedness and preference rules for recursively combining events into larger segments. In the MIR community, the analysis of musical form is known as *music structure analysis* (MSA) [15, 16, 17, 18, 19, 20, 21, 22]. MSA comes in a variety of tasks, involving boundary detection, (hierarchical) segmentation, the identification of segment labels and relations, and combinations of these tasks. While MSA uses a wide spectrum of supervised and unsupervised methods, from matrix factorization to deep learning, the definition of musical form in this context is usually given implicitly in the form of a dataset (e.g., [21, 22]) on which the model may be trained, and on which it is evaluated. The present paper, in contrast, presents a theoretical contribution towards an explicit definition of musical form, and the resulting model is not intended as a solution to a computational problem, such as performing a general segmentation and labeling task. As a consequence, our evaluation focuses on exploring the characteristic properties of the model.

3. METHODS AND DATA

3.1 Problem Description

A specific repetition structure for a given piece can be characterized through a piece-specific context-free gram-

$m_1 : \alpha\alpha$	$m_2 : \alpha\beta$
$m_3 : \alpha\alpha\alpha$	$m_4 : \alpha\beta\alpha$
$m_5 : \alpha\alpha\beta$	$m_6 : \alpha\beta\beta$
$m_7 : \alpha\alpha\beta\alpha$	$m_8 : \alpha\beta\beta\alpha$

Table 1: The set of meta rules used in this paper.

mar that generates exactly one string — the piece. We call such a grammar a *local grammar* for the piece. It consists of:

- a set of terminal symbols T , corresponding to the unique atomic segments of the piece;¹
- a set of non-terminal symbols N , corresponding to the unique composite segments of the piece;
- a starting symbol P that stands for the full piece;
- a set of production rules R .

Since each non-terminal symbol stands for a specific segment, R contains exactly one rule for each non-terminal symbol, signifying the decomposition of the segment and enforcing that all occurrences of the segment are decomposed identically. As a consequence, the rules are not allowed to be (mutually) recursive since a segment cannot contain itself as a proper subsegment.²

In order to establish a relation between local repetition grammars and general formal prototypes, the right-hand side (RHS) of each rule must be an instance of a *meta rule*. Meta rules are generally of the shape $\{\alpha, \beta, \gamma, \dots\}^+$ and are instantiated by creating a bijective mapping between letters and specific non-terminal symbols. For example, the meta rule $\alpha\alpha\beta\alpha$ encodes the formal prototype AABA and can be instantiated as

$$\alpha\alpha\beta\alpha(S, T) = \alpha\alpha\beta\alpha\{\alpha \mapsto S, \beta \mapsto T\} = SST S \quad (1)$$

where $S \neq T$. Thus, a local grammar can express that a piece has an overarching AABA structure by using a rule

$$P \longrightarrow \alpha\alpha\beta\alpha(S, T) \quad (2)$$

that takes the starting symbol P to an instance of $\alpha\alpha\beta\alpha$ with $\alpha = S$ and $\beta = T$. The set of meta rules can be chosen freely to encode a set of typical formal prototypes. The meta rules used in the following experiments are shown in Table 1.

The goal of repetition structure inference is to find a local grammar for a given piece according to some optimality criterion, such as musical plausibility, probability, or description length (DL). In accordance with prior approaches that use repetition grammars, our proof-of-concept implementation searches for local grammars with

¹ In the case of melodies, these atomic segments correspond to notes and rests, but they could also correspond to polyphonic events (slices), or previously annotated elementary phrases.

² A unary identity rule (e.g. $X \longrightarrow X$) is not permitted. Other unary rules are not possible because of the one-to-one correspondence between segments and grammar symbols.

minimum description length, defined in analogy to [13] by counting the symbols needed to encode the grammar:

$$DL(R) = \sum_{r \in R} 2 + |\text{params}(r)| \quad (3)$$

where $\text{params}(r)$ denotes the parameters of the meta rule on the RHS of rule r . That is, for each rule we count one symbol for the meta rule, one symbol for each parameter of the meta rule, and one separator symbol³ marking the end of the rule. For example, the rule in Equation 2 has a description length of 4: one meta-rule symbol ($\alpha\alpha\beta\alpha$ or m_7)⁴, two parameters (S and T) and the separator. It is not necessary to encode the left-hand side (LHS) of a rule since there exists a canonical order of rules, starting with the rule for P and then listing the rules in the order in which their LHS symbols are introduced on the RHS of other rules.

3.2 Algorithm

The minimal grammar for a given piece is found in a two-stage process. First, a set of possible rules for each unique segment of the piece is computed. Second, a set of rules is selected from these candidates, ensuring that the resulting grammar is consistent and minimizing the cost of the selected rules.

Algorithm 1 Enumerating all rule candidates.

```

1: function PARSE(input)
2:   subs  $\leftarrow$  uniqueSubsequences(input)
3:   chart  $\leftarrow$  {}
4:   for seq  $\in$  sortByLength(subs) do
5:     for s from 1 to |seq| - 1 do
6:       cs  $\leftarrow$  COMPLETE(seq[s], seq[s + 1 :])
7:       chart[seq]  $\leftarrow$  cs
8:   return chart

9: function COMPLETE(left, right)
10:  il  $\leftarrow$  chart[left]incomplete
11:  ir  $\leftarrow$  chart[right]incomplete
12:  bs  $\leftarrow$  binaryRules(left, right)
13:  is  $\leftarrow$  incompleteConstituents(left, right, il, ir)
14:  ns  $\leftarrow$  nAryRules(left, right, il, ir)
15:  return (complete = bs  $\cup$  ns, incomplete = is)
    
```

The first stage (Algorithm 1) begins with collecting all unique subsegments of the piece. For each of these subsegments, all possible decompositions according to the meta rules are computed using dynamic programming, analogous to the CYK algorithm: The segment is split at every possible split point (l. 5), generating two subsegments left and right of the split point. For binary meta rules ($\alpha\alpha$ and $\alpha\beta$), an instance of the rule can be identified directly by comparing the subsegments (l. 12). Meta rules

³ The separator is not strictly necessary since the length of the rule is known from the meta rule, but it is included here to stay as close as possible to [13].

⁴ $\alpha\alpha\beta\alpha$ is counted as one symbol since the set of meta rules is assumed to be fixed and cannot be freely extended.

of higher arity are decomposed into binary parts. For example, the meta rule $\alpha\beta\alpha$ can be decomposed into an incomplete constituent $\alpha\beta^*$ and another α . When a segment $S = S_1S_2$ has a decomposition into $\alpha\beta(S_1, S_2)$, it additionally stores an $\alpha\beta^*(S_1, S_2)$ item (l. 13). At a later point, a larger segment $T = SS_3 = S_1S_2S_3$ retrieves the item $S \rightarrow \alpha\beta^*(S_1, S_2)$, checks whether $S_3 = S_1$, and accordingly stores a rule $T \rightarrow \alpha\beta\alpha(S_1, S_2)$. Similarly, all larger meta rules are constructed from incomplete constituents such as $\alpha\beta^*$ and $\alpha\alpha^*$ (l. 14).

Once the possible decompositions of each subsequence are known, the second stage of the algorithm converts the set of possible rules into an integer linear program (ILP) which then extracts a set of rules with minimal cost. Each subsequence of the input of length ≥ 2 corresponds to a potential non-terminal symbol, so one binary indicator variable s_{symbol} for each symbol symbol encodes the inclusion of the symbol in the grammar. Similarly, the inclusion of each candidate rule is indicated by a binary variable r_{rule} . The optimization problem is then given by

$$\begin{aligned}
 & \min_{\substack{r \in \{0,1\}^{|rules|} \\ s \in \{0,1\}^{|symbols|}}} \sum_{rule \in rules} r_{rule} \cdot DL(rule) \\
 & \text{s.t. } s_{\text{symbol}} = \sum_{\substack{rule \in rules \\ \text{LHS}(rule) = \text{symbol}}} r_{rule} \\
 & r_{rule} \leq \sum_{\text{symbol} \in \text{RHS}(rule)} \frac{s_{\text{symbol}}}{|\text{RHS}(rule)|} \\
 & s_{\text{start}} = 1.
 \end{aligned} \tag{4}$$

Two constraints define the relationship between symbols and rules: each included symbol requires exactly one corresponding rule; and each included rule requires the symbols on its right-hand side.⁵ A third constraint requires the presence of the starting symbol which corresponds to the full input sequence. The rules and symbols are then selected by minimizing the total cost of the included rules as defined in Equation 3.

4. RESULTS AND DISCUSSION

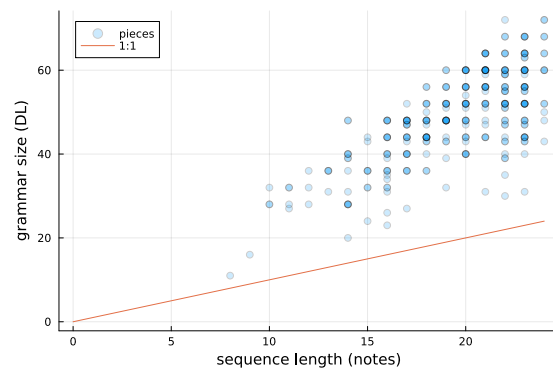

4.1 Quantitative Evaluation on a Dataset

For evaluating the above approach, we infer the minimal grammars (under the meta rules from Table 1) for the 298 shortest melodies from the Essen folksong collection [23], with a length of 8 to 24 notes. The melodies are represented as sequences of notes (including rests), consisting of pitch (or a rest symbol) and duration. Other aspects, such as the position of a note in a measure, are not taken into account. The minimization algorithm is implemented in Julia and is available online.⁶ For ILP optimization we use the JuMP framework [24] together with the Gurobi solver backend.⁷

⁵ The logical conjunction of the RHS symbols is expressed as a normalized sum instead of a product in order to maintain linear relationships between the variables in the program.

⁶ <https://github.com/DCMLab/form-repetition-ismir23>

⁷ Gurobi requires a license, which is provided freely for academic purposes. Alternatively, the JuMP framework supports using different solver

(a) Grammar size vs. input length.

(b) Optimal grammar size vs. Monte-Carlo minimum.

Figure 3: Comparison of the description length of the minimal local grammars to (a) the input sequence length and (b) local grammars obtained through Monte-Carlo minimization.

Since the local repetition grammar formalism is not designed to obtain optimal compression of the input sequence (but uses description length as a rather arbitrary proxy for the plausibility of a specific segmentation), we cannot expect very good compression rates. Indeed, when comparing the length of the input sequences to the total description length of the corresponding minimal grammar, the grammars are usually larger than the original piece (Figure 3a) with a average ratio of 2.47 (geometric mean). This indicates that restricting the grammars to a small set of meta rules is not sufficient to achieve an actual compression of the dataset, at least when only considering exact repetition.

Since finding the global minimum is expensive (see below), most grammar-based compression algorithms only attempt to approximate the global optimum [8, 12, 13]. We estimate the payoff of inferring the global optimum by comparing the optimal description lengths to approximate solutions obtained by a Monte-Carlo minimization process: Beginning with the start symbol, the rule for each required symbol is chosen randomly from the set of possible rules, and the corresponding RHS symbols are added to the list of required symbols. This process is repeated until all required symbols are covered. Out of 10,000 randomly sampled grammars for each piece, the smallest grammar is selected. The results are shown in Figure 3b. For the backends.

(a) Runtime relative to input length.

(b) Runtime relative to possible rules.

Figure 4: The measured runtime of the optimization step relative to (a) the length of the input sequence and (b) the number of possible rules for the sequence. Note that in both cases, the time axis is scaled logarithmically, so the fitted exponential curves appear as straight lines.

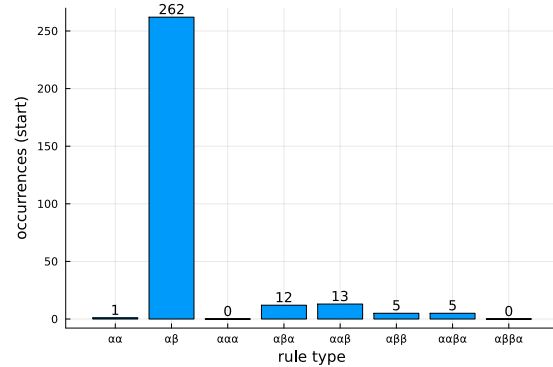

given dataset, the Monte-Carlo minimum is on average 1.08 times longer than the true grammar. In many cases, the Monte-Carlo process finds a true optimum, since the sample size of 10,000 is large enough to find an optimal solution by chance. However, with growing input size, the range of possible grammars grows exponentially, in the worst case.⁸ So, while a Monte-Carlo estimate can be a useful approximation on short sequences, it cannot keep up with the size of the search space for longer sequences, unless the sample size is increased exponentially as well.

The runtime behavior of the optimization problem is shown in Figure 4. The problem of finding an unrestricted minimal CFG is known to be NP-hard [13]. The runtime for the restricted case relative to the input length is shown in Figure 4a with logarithmic scaling. Since the actual size of the optimization problem depends not only on the input length but also on the amount of redundancy within the sequence, Figure 4b shows the runtime relative to the number of possible rules obtained in the first stage of the algorithm. In both cases, the runtime grows approximately exponentially with the number of rules. This is supported by an exponential regression in both figures, fit as a linear function in logarithmic space which minimizes the squared

⁸ The number of subsequences grows quadratically, and the number of possible grammars is a product over all substrings.

(a) Overall meta rule usage.

(b) Meta rules used at the top of the form tree.

Figure 5: The meta rules used in the inferred minimal grammars for the melodies in the dataset.

ratio between measured and predicted runtime instead of the squared difference.

The distribution of meta rules in the inferred grammars is shown in Figure 5a. By far the most common rule type is $\alpha\beta$, which is not surprising since it is the only rule type that does not require any form of repetition. The rule type $\alpha\alpha$ is used very infrequently, which may seem surprising due to its simplicity. However, all other rules (except for $\alpha\beta\beta\alpha$ and $\alpha\alpha\alpha$ which are similarly rare) have one part that does not need to be repeated and are thus applicable to a wider range of situations. The distribution of starting-rule types is shown in Figure 5b. These rule types correspond to the overarching form of the melody in terms of exact repetition. The even stronger prevalence of $\alpha\beta$ in this case indicates that there is very little exact repetition on the highest form level in the given dataset of melodies, which might be biased due to the focus on short melodies. On the other hand, this lack of repetition indicates that a model of formal segmentation cannot be exclusively based on repetition but needs to take into account at least the possibility of varied repetition, as well as other markers of form such as cadences and meter.

4.2 Qualitative Evaluation on an Example Melody

Table 2 displays the minimal grammar for the example piece in Figure 1. Compared to the overall distribution of meta rules, the grammar uses many repeating rules, which reveals that the piece features an unusual amount of inter-

Figure 6: The minimal tree for the example piece in Figure 1.

rule	meta rule	cost

r_7	$S_{173} \rightarrow g2 e2$	$\alpha\beta(g2, e2)$	4
r_8	$S_{18} \rightarrow f4 e4$	$\alpha\beta\alpha(f4, e4)$	4
r_9	$S_{136} \rightarrow f4 e4$	$\alpha\alpha\beta\alpha(f4, e4)$	4

Table 2: The minimal grammar for the example piece in Figure 1.

nal repetition. As the derivation tree in Figure 6 shows, the optimal solution found by the algorithm captures many aspects of the human intuition. Similar to the hand-annotated segmentation in Figure 2, the minimal tree captures the overarching repetition of mm. 1-4 and mm. 9-12 as well as mm. 5-6 and mm. 7-8. However, whereas the human intuition groups the single note repetitions together and splits non-repeating segments according to bar units (mm. 5, 7), the algorithm finds that other groupings provide an even more economic description length in terms of rule usage, which leads to a somewhat counter-intuitive dangling half note g at the end of the phrase. This illustrates that human decisions in terms of repetition structure do not purely optimize repetition, but that they take rhythmic-metric boundaries into account. Therefore, the objective of a model of repetition structure that captures or comes close to the human intuition needs to be further developed to also incorporate such features. A candidate model may be the hierarchical model of rhythmic structure as a formal grammar [25].

5. CONCLUSION

In this paper we have presented a computational model of musical repetition structure as an aspect of musical form. Since repetition structure is an aspect of human music cognition, the overarching objective of our approach is to approach human listening. The model captures repetition structure with a special form of context-free grammar, in which the rewrite of each category is only defined once

such that it captures a unique repeating fragment of a given piece. A set of meta-rules defines the generic types of repetition patterns that could occur within a piece. The model is very generic and can also be applied to more complex textures as well as music of all styles and cultures, as long as a representation as a sequence of symbols is meaningful.

Inferring the optimal grammar with respect to a suitable objective criterion (such as description length) is able to effectively capture the repetition structure in a piece. Other objective criteria (e.g., prior probabilities of meta rules) can be used in a similar way since the algorithm does not depend on a fixed cost function. On the other hand, maximizing the redundancy that is captured by a segmentation does not ensure that the segmentation is a good analysis of the form of a piece. For one, not all repetition and reuse of material is exact, which is evident from the low proportion of repeating meta rules used in the example dataset. Simple forms of varied repetition could be integrated in our model relatively easily: given a suitable measure of similarity, not only identical segments are grouped together but also sufficiently similar segments. More sophisticated versions of this model could capture how variations are produced through the generative process of the grammar (e.g., by making different decisions in different subtrees), or how only certain aspects of a segment are repeated while others change (e.g., using the same rhythm with a different melodic contour). Furthermore, even when all repetitions are exact (as in the example piece), capturing repetition is not the only criterion for grouping tokens into formal segments, as other criteria such as cadences, rhythm and meter, formal function, or harmonic and contrapuntal schemata interact with grouping as well.

The runtime complexity of finding the smallest grammar for a given piece is generally exponential. For sufficiently short pieces, exact inference can be approximated probabilistically, but there is no guarantee that the resulting suboptimal grammars resemble the true optimum. For larger inputs, the search space grows exponentially, so naive Monte-Carlo approximation can become arbitrarily bad. This indicates that further research is required to find plausible estimates of formal structure, integrating the technical aspect of optimization with the musical problem of defining what constitutes a plausible analysis.

ABSTRACT

Most melodies from the Western common practice period have a harmonic background, i.e., a succession of chords that fit the melody. In this paper we provide a novel approach to infer this harmonic background from the score notation of a melody. We first construct a pitch context vector for each note in the melody. This vector summarises the pitches that are in the preceding and following contexts of the note. Next, we use these pitch context vectors to generate a list of candidate chords for each note. The candidate chords fit the pitch context of a given note each with a computed strength. Finally, we find an optimal path through the chord candidates, employing a score function for the fitness of a given candidate chord. The algorithm chooses one chord for each note, optimizing the total score. A set of heuristics is incorporated in the score function. The system is heavily parameterised, extremely flexible, and does not need training. This creates a framework to experiment with harmonization of melodies. The output is evaluated by an expert survey, which yields convincing and positive results.

1. INTRODUCTION

One of the essential aspects of Western folk music is that it is in oral circulation among practitioners regardless of formal music training. As such, the transmitted music is expected to conform to melodic patterns which belong to Western music traditions. This is most tangible in the perception of rules of tonality, including the perception of stable scale tones, modes, and key centres [1]. These factors dictate the implied harmonic movement within the melody. Detecting this implied harmony is an integral part of the accompaniment of folk music. With this knowledge, it is possible to create musically meaningful harmonic progressions, using symbolic chord representations to accompany a melody.

In this paper, our aim is to explicitly design a model of how to generate a sequence of accompanying chords for a given melody, such that e.g., a guitarist could play

along. Most of the recent work on this task involves machine learning in which a model is trained on a set of examples. In contrast, an essential aspect of our approach is to explicitly incorporate musical expert knowledge into the model. Our model is heavily parameterized. This has the advantage of allowing the user to have full control over the process. A disadvantage could be that the resulting model lacks the flexibility to handle various situations, which often is a reason to train a neural network instead of handcrafting a model. Our results show, however, that our current model is capable of generating convincing chord sequences for a given melody.

The model can be employed in a wide range of applications. It allows a musician to quickly obtain a suitable accompaniment for a given melody. This can be accomplished by using the default parameter settings that are established in this paper, but the model also allows to tune the parameters to get a certain desired effect. In Section 5 of this paper we provide an example in which the number of generated chords greatly varies, while each generated chord sequence is acceptable to accompany the melody. Thus, the generated harmony can be adjusted to various levels of mastering an instrument.

From a music theory perspective, our model can be considered an experimental framework to explore general principles of harmonization. In this approach, the model is used to better understand these principles. It is extremely instructive to add a heuristic to the model, or to adjust a parameter, and to examine the cases in which this leads to strong chord sequences, but even more so to examine the cases that are not acceptable. These are conditions under which the general rule apparently fails. In the current paper, we do not elaborate on this use of our model, but it is an important affordance that we do not want to be left unmentioned.

We also can imagine the system being used in an artistic way, rather than to just generate an accompaniment for practical use. In the current implementation, we incorporate well-established principles of harmonization, but it is very well possible to include other heuristics that generate chord sequences that, although not adhering to the general principles of Western tonality, could be considered an artistic contribution, or an inspiration for a new composition.

Finally, we mention the possible educational use of the model. By exploring the generated chord sequences, students can get ideas to improve or enrich their own compositions or improvisation.

2. RELATED WORK

Multiple approaches have been taken for the task of automatic harmonization [2]. Early applications of formal grammars and rule-based algorithms for automatic harmonization [3, 4] mainly sought to compose chorales in the style of Bach. This was achieved by harmonizing the soprano melody line using a set of rules to ascertain harmonic choices. These rules and heuristics are informed by observation of chorales, and enhanced by rules found in treatises. The resulting systems output successful harmonizations of existing melodies, as well as new compositions.

Context free grammars have found use for this task. Koops [5] adopts this approach in his HarmTrace and FHarm models to derive the harmonic function of a chord in its tonal context according to a set of predefined rules.

Temperley [6] proposed a rule-based algorithm to harmonize a melody by dividing the piece temporally into segments (chord spans). All possible roots are then assigned a score according to a set of four rules. The model prefers root relations which best conform to the circle of fifths. The model also predominantly chooses chord spans which begin on the metrical downbeat, and identifies and prefers ornamental dissonances which can be resolved in the subsequent chord span. While approach is related to Temperley’s algorithm, it is more flexible as it does not hard-code one musical model, but instead allows basically any kind of musical preference by redefining the chord transition scoring function. Our approach is also more practical since it not only generates a sequence of root notes, but also the chord qualities.

Most of the more recent approaches are based on some form of machine learning, sometimes explicitly stating the aim to include a “minimal use of music knowledge” [7]. These approaches include Statistical Grammar learning [7], Hidden Markov Models [8–10], and neural networks [11, 12]. [13] presents a hybrid approach based on Markov chains, combining a music theoretic framework with learning from data. Our approach is distinct in that it does not require learning at all, and thus allows for full control over the process of generating the sequences.

3. DATA

The algorithm is evaluated using MTC-FS-INST-2.0, which forms part of the Meertens Tune Collections [14]. The data set consists of c. eighteen thousand melodies, both vocal and instrumental, collected from Dutch sources. The melodies have a variety of time signatures and modes. We use the pre-computed features as distributed in MTCFeatures.¹ Since our model relies on notated meter, we only use the melodies with a meter.

3.1 Music Representation

We represent the melodies as sequences of feature values, one value per note. In this paper, we use three features as provided by MTCFeatures, namely `pitch40`,

Figure 1. Example melody with the values for `pitch40`, `beatstrength`, and `beatinsong` per note.

and `beatinsong`, which gives onset times in units of the beat. The base-40 representation of pitch preserves the pitch spelling [15]. It includes 40 values per octave representing 40 possible pitches starting with $C\flat$ and ending with $B\times$. We map all pitch values into one octave. We use the encoding as designed by Hewlett with one adaptation: we give the first pitch ($C\flat$) index 0 instead of index 1, which has a practical advantage when doing the implementation in Python.

We use the `beatstrength` as computed by the music21 meter model [16, 17]. Music21 is a Python library for processing symbolic musical scores. We heavily use this library. In the meter model of music21, a `beatstrength` is computed for each note, which indicates the metric weight at the moment of onset of the note. The main accent in the measure gets value 1.0, secondary accents get value 0.5, lower metric positions get 0.25, 0.125, etc. Figure 1 shows an example.

4. METHOD

Our approach to generate a sequence of chords for a given melody consists of three stages: First, we construct for each note a vector summarising the pitch context of that note. Second, we generate for each note a list of potential chords from the pitch context vector. Each chord gets a score indicating the extent to which it fits the pitch context. Finally, for each note, we choose one of the candidate chords, based on its score, and on a chord transition score, such that the sum of all transition scores across the sequence of chords is maximized.

The evaluation also consists of several steps. First, we tune the various parameters on a randomly chosen set of melodies. Next, we use the best parameter setting to generate chord sequences for an independent, disjoint set of melodies. We then provide six music experts with the results and to provide us with a rating of each harmonization on a five-level rating scale. Finally, we use statistics to explore and summarise the responses.

¹<https://zenodo.org/record/3551003>

In the following of this section, we will explain each of these steps in detail.

4.1 Weighted Pitch Context Vectors

For a given note, which we indicate as the *focus note*, we consider both a preceding and a following context. These consist of the sequences of notes that are preceding, and respectively following the focus note. For both the preceding and the following context we construct a *weighted pitch context vector*. Each of these vectors has 40 elements corresponding to the 40 pitches in base-40 representation. The value of each of the elements represents the “amount” of the corresponding pitch that is present in the context of the focus note. The full context vector is a 80-dimensional vector which is the concatenation of the preceding and following context vectors.

4.1.1 Length of Contexts

Choosing the length of the contexts is not straightforward. It is, in fact, an important parameter in our model. The music21 meter model provides metric information for each note, notably concerning the *beat* and the *beatstrength* of a note (as explained in Section 3.1). This allows us to express the length of the context as a number of beats. This seems a good approach since the beat is a perceptually meaningful unit. Alternatives would be a fixed number of notes or a certain amount of score time. We did not explore these for the current study.

We experimented with different values for the context length, as well as with a variable context length based on the beatstrengths of the surrounding notes. We found that the latter approach, with variable length, yielded the best results in terms of acceptable chord sequences. In our resulting implementation the context length is computed as follows. We start with the focus note. For the preceding context, we consider the notes before the focus note in reversed order, starting with the note directly before the focus note, and we keep adding the notes to the context until (and including) we reach a note with beatstrength 1.0. For the following context, the same procedure is followed, except that the first encountered note with beatstrength of 1.0 is not included in the context. In our implementation, there is also a parameter whether to include the focus note itself into the context or not. Since the current aim is to generate a chord for the focus note, we always add the focus note to the contexts.

The consequence of this procedure is that for a note on the main accent of the measure (i.e., the first note), the preceding context is the entire previous measure, and the following context is the remainder of the measure of the focus note. In contrast, for notes that are not on the main accent, the preceding context includes all the previous notes in the same measure, while the following context includes the remaining notes in the measure. To a certain extent, this accounts for harmonic progression at different metric levels.

4.1.2 Weighting of Context Notes

The contribution of each context note to the value of the corresponding pitch in the pitch context vector is determined by two components: the metric weight (beatstrength) of the context note, and the distance to the focus note.

Intuitively, the duration of a context note has an impact on its importance in the context of the corresponding focus note. Therefore, we do not simply take the beatstrength of the moment of onset of the context note as weighting factor. Instead, we compute a metric grid, which is a succession of evenly spaced moments in score time. The basic unit of the grid, i.e., the distance between two subsequent positions in the grid, is the greatest common divisor of all note durations. Therefore, each note of the melody starts at a position in the grid, and the “span” of the note mostly includes several grid positions. The metric weighting factor of a context note is the sum of metric weights (beatstrengths) of all positions of the metric grid that are in the “span” of the note. Thus, the duration of the note, as well as the metric importance of the note are incorporated in the weighting. This approach also accounts for syncopation. During the span of a syncopated note, a grid-position with higher metric weight than the metric weight at the start of the note occurs. This is included in the sum.

Also intuitively, the further a note is away from the focus note, the lower the importance in the context of the focus note. In our model, we use a linearly decreasing windowing function. The metric weighting factor of a given context note is multiplied by the value of this window function at the position of the onset of the context note. The value of the window function during the span of the focus note is 1.0, and is linearly decreasing towards the end of the context. The value at the end of the context is a parameter in our model. We set this to a value slightly higher than 0.0 in order to have some influence from the notes that are at the outer boundaries of the contexts.

4.2 Generating Candidate Chords

Once we have computed a pitch context vector consisting of a preceding and following pitch context for each of the notes in a melody, we use these vectors to generate a set of candidate chords for each of the notes in a melody.

In our current implementation, we consider four types of chords: diminished triad, minor triad, major triad, and dominant seventh chord, and we consider three types of context: preceding context, following context, and full context. The full context just is a superposition, i.e., an element-wise sum, of the preceding and following contexts. Discerning these three types of contexts is a crucial element in our model. It allows the method to determine the position of a chord change. If the set of chords that is implied by the preceding context is sufficiently different from the set of chords that is implied by the following context, a chord change is likely, while the presence of a chord that sufficiently fits the full context likely results in a continuation.

Figure 2. Example of a Pitch Context Vector. The vector consists of two parts, wpc_{pre} and wpc_{post} , which represent respectively the preceding and the following context. The full Pitch Context Vector is a concatenation of the two parts. Each element in the vector gets a value representing the ‘amount’ of the corresponding pitch that is present in the context.

Thus, considering 40 possible root notes, we have 160 (40*4) possible chords for each of the preceding, following, and full contexts.

4.2.1 Candidate Chord Score and Strength

For each focus note, we construct a 120*4 matrix, containing a score for each possible chord in each possible context.

The score of a chord with respect to a context vector is determined by two factors: first, the extent to which the chord pitches match the pitches in the context vector, and, second, whether the root note of the chord is present in the local scale. We will explain these two factors in the following.

For each chord quality (diminished, minor, major, and dominant), a chord mask is defined. This is a 40-dimensional binary vector with ones at the positions of the corresponding chord tones. E.g., for a major chord on C \flat the positions 0, 12, and 23, corresponding with C \flat , E \flat and G \flat are assigned value 1, while other positions get value 0. To compute the score of this chord for a given context, we multiply the mask element-wise with the pitch context vector, and we sum the resulting values. The resulting value represents the overlap between the context and the chord.

To compute the scores for all possible root notes, we subsequently rotate the mask over all possible 40 shifts, and compute for each shift the sum of products. We do this for the preceding context vector, the following context vector, and the full context vector. For the repertoire we have, we do not perform all 40 shifts, we only take into account natural root notes, root notes with one flat, and root notes with one sharp.

Next to these scores, we also compute a *strength* value for each of the possible chords. The strength takes a value between 0 and 1, and is computed as the ratio of the sum of the pitch context values for the chord tones (as determined by the mask) and the sum of all pitch context values. E.g, if a pitch context vector has some weight for C, E, G, and A, a C major chord would get a high score, but a strength lower than 1.0, because there is also weight for the A, which is not a chord tone.

To obtain a single score for each chord candidate, we

simply multiply the score with the corresponding strength. This implies a penalty for non-chord tones within the pitch context.

We normalize the score matrix for a given focus note by dividing all scores by the highest score. Thus, the best fitting candidate always has a score of 1.0.

4.2.2 Local Scale

A second factor that determines the possible candidate chords is the local scale. As with the chord mask, we define a scale as a 40-dimensional binary vector. The elements with value 1 are the scale tones. For each note in the melody we derive a local scale vector. This records the alterations of the stemtones that are ‘in use’ at that position in the melody. For each stemtone $\in \{A, B, C, D, E, F, G\}$, we look for the occurrence closest to the focus note, accepting all possible alterations, and we record the alteration in the scale vector. This accounts for modulations. E.g., if in a melody in D major a G \sharp occurs, which is eventually cancelled back to a G, the notes that are closer to the G \sharp have a 1 at position 26 in the local scale vector (the base40 representation of G \sharp) while the notes closer to the G have a 1 at position 25.

One problem is posed if a stemtone is missing altogether in a melody. For example, the melody in Figure 1 lacks the note F. The key signature suggests a F \sharp , but that is not available to our algorithm. In these cases, we add the tone with the most likely alteration to the scale vector. For sharps, we find this by following the circle of fifths upwards from the missing tone and check the alteration of the next tone. For example, if a C \sharp is present in the local scale, we infer that the scale should have a F \sharp , and not a F natural. For flats, we do the same, but we inspect the circle of fifths in reversed order. For edge cases, we include both the natural and altered tone in the scale. E.g., if stemtone G is missing throughout the melody, and the scale does have a C \sharp and a D natural, we include both the G natural and the G \sharp as possible scale tones in the local scale vector.

We use the local scale for a given focus note to eliminate those chord candidates that have a root which is not in the scale, by setting its score to 0.0. E.g., a C \sharp diminished chord fits a context vector with weight for pitches E and

G, but we eliminate this candidate for a melody in C major because $C\sharp$ is not in the scale (except when sometime during the melody the C is temporarily raised).

4.3 The Chord Transition Score

The result of the procedure as described in the previous section is a sequence of matrices, one for each melody note, containing a score for each possible chord for that melody note. The next challenge is to choose one chord for each melody note out of these 120×4 possibilities. For that, we employ a chord transition scoring function (TRS), which computes a score for a given succession of chords, c_1 and c_2 for two subsequent melody notes, n_1 and n_2 .

This transition scoring function can be considered a model of what would be a good chord transition. We implement this function as a series of heuristics, each penalizing the score if an aspect of the transition is undesired. We discern two kinds of penalty which could be described as a “total ban” and a “discouragement” respectively. For a total ban, we assign a very low score (-10 in our implementation), which forbids the transition in almost all cases. For a discouragement, we multiply the score by multiplier $\in [0, 1]$. The lower the multiplier, the higher the penalty for the undesired aspect of the chord transition. In our model we include the following heuristics.

- The initial transition score is the candidate score of c_2 for note n_2 , as computed in the previous step.
- If the root note of c_2 differs from the root of c_1 , multiply with 0.8. This stimulates continuation of a chord.
- If the root notes of both chords are the same, but the chord qualities differ, multiply with 0.1. Except for a change from major to dominant.
- For a root movement other than a prime, a fourth, or a fifth, multiply by 0.75. Root movements of fourths and fifths generally account for good harmonic progression.
- If c_1 is a dominant chord and the root of c_2 is not a fourth higher, multiply by 0.1. We strongly want a V-I relation after a dominant chord.
- If the root of c_2 is a fourth up, and c_1 is not major or dominant, multiply by 0.8.
- If c_1 is diminished, and the root of c_2 is not a semitone up, multiply by 0.1. We strongly want a VII-I relation after a diminished chord.
- If the beatstrength of n_2 is below a threshold, do not allow a chord change (score -10), except for a transition from major to dominant with the same root. The threshold is determined by the meter. For 2/4, 2/8, and 2/2 meter we take 0.25, for all other meters 0.5.
- Do not allow a chord change (score -10) if n_2 is not a chord tone in c_2 , and if the beatstrength of n_2 is 0.5 or higher. The seventh of a dominant chord is not considered a chord tone. On strong metric positions, we want chord tones in the melody.
- As an exception to the previous rule, do always allow a chord change to c_2 if the next note after n_2 is a chord tone of c_2 , and has a lower beatstrength than n_2 . This allows for appoggiaturas.
- Do not allow (score -10) a chord that starts at a low

beatstrength (<1.0) to continue past a note with higher beatstrength. Except for a chord that starts on an up-beat. This prevents chord syncopation.

- If the final root change is not a fourth up, or a fifth down, multiply with 0.1.
- If the final root change is a fifth up (a plagal cadence), multiply with 0.8.
- Only allow the root or the third of c_2 as melody note if n_2 is the final note of the melody. If this is not the case assign score -10. If the final note is the third, multiply with 0.75.

4.4 Finding the Optimal Sequence

We designed an algorithm that optimizes the score for a sequence of chord transitions. It takes the sequence of chord score matrices as input and uses the chord transition scoring function. Algorithm 1 shows the pseudo code of our algorithm. We fill a matrix, Score, which contains for each note, and for each possible chord, the total score of the chord sequence up until that note and that chord. In parallel, we fill a traceback matrix, Trace, which for each note, and for each chord, points to the chord of the previous note which is the previous chord in the sequence (i.e., maximises the total score of the chord sequence). After both the Score and Trace matrices are filled, we find the chord sequence by finding the chord with the maximal score for the final note, and following the trace back according to the pointers in the Trace matrix.

Algorithm 1 Algorithm to find the optimal sequence of chord transitions, in which l is the length of the melody in number of notes, Cand is the sequence of matrices with scores for the chord candidates, and TRS is the Chord Transition Scoring Function as defined in Section 4.3.

Require: Cand : ARRAY[l][120][4] of float

4.5 Evaluation

To evaluate our algorithm, we first tuned the various parameters ourselves by inspecting the parameter space and chose settings which seemed to yield good results. The values as reported in Section 4.3 are the result of this process.

Next, we randomly chose another unrelated set of 50 melodies and computed chord sequences for these using the parameter values from the previous step. We then asked six music experts to evaluate each harmonization. All evaluators are practicing musicians on a professional level, and have extensive experience in musical analysis. They were given a five level scale and a set of directions in order to rate the harmonizations:

1. Bad. Numerous basic mistakes.
2. Somethings are good but contains a number of incorrect chord choices.
3. Largely okay, small number of incorrect chord choices.
4. Acceptable harmonization.
5. Excellent harmonization. No improvements to be made.

Evaluators were also given a set of directions on how to rate the harmonizations. They were asked to judge to what extent the chords fit the melody, with an emphasis on the correctness of chords with regards to the local context, as opposed to creativity. They were not to take voice leading into consideration for the chord correctness, as the bass line is not modelled in this version of the algorithm.

We then use these ratings to compute inter-rater agreement and explore the extremes.

5. RESULTS

5.1 Parameter Exploration

Exploring the parameter space of our model is an interesting endeavor which appears meaningful in itself. It allows a better understanding of general textbook rules for harmonizing melodies. By implementing and manipulating these principles in our scoring function we can observe the impact of the rigorous application of these principles.

As an example, there are various ways to influence the change rate of chords. Figure 3 shows three sequences of chords at different levels of abstraction. For the middle sequence we used the default parameters as established in

Figure 4. Distribution of ratings.

the previous sections. The other sequences have been obtained by changing the following parameters with respect to the defaults. The top sequence is generated by tolerating chord changes at every metric level, and by not penalizing root changes. For the bottom sequence we set the context lengths to the length of the entire melody, i.e., all preceding notes are in the preceding context and all following notes are in the following context of a given note. These three sequences show which harmonies are implied by the same melody at different time scales. This could be employed in a hierarchic strategy of harmonization, by e.g. first generating a sequence on a high level to find modulations and extended harmonic sections, and subsequently using that high level sequence as a background for the selection of more fine-grained chord sequences.

5.2 Expert Ratings

Figure 4 shows the distribution of the ratings of the experts. The average over all ratings is 3.52 and the standard deviation is 1.05. It can be observed that only a minority of the harmonizations got a rating lower than 3. Only one harmonization (no. 48) has a highest rating of 2 across the raters, and only six have a highest rating of 3. All 45 others got a 4 or 5 as highest rating. 22 sequences got a 1 or 2 as lowest rating, and 28 sequences 3 or higher. It appears that our algorithm produces an acceptable output, but there are still some issues to address. Some problems we observed are related to tonality, e.g., starting and ending in a different key (mostly the parallel), or including a leading tone at inappropriate places. Also, a low harmonic movement might be unsatisfactory.

6. CONCLUDING REMARKS

We presented a successful approach to generate a sequence of chords to accompany a folk-like melody by leveraging musical expert knowledge and a dynamic programming algorithm to find an optimal trace through the chord space.²

There are many directions to further build on the current model. We plan to address the observed shortcomings in a next version. Our framework can be used to explore theory on harmonization or to model implied harmony. It also can serve as tool in educational settings, and of course to generate a accompaniment for a performance.

² The full code of our implementation as well as the test set, the expert ratings, and a demo are available at: <https://github.com/pvankranenburg/ismir2023>.

TEXT-TO-LYRICS GENERATION WITH IMAGE-BASED SEMANTICS AND REDUCED RISK OF PLAGIARISM

ABSTRACT

This paper proposes a text-to-lyrics generation method, aiming to provide lyric writing support by suggesting the generated lyrics to users who struggle to find the right words to convey their message. Previous studies on lyrics generation have focused on generating lyrics based on semantic constraints such as specific keywords, lyric style, and topics. However, these methods had limitations because users could not freely input their intentions as text. Even if such intentions can be given as input text, the lyrics generated from the input tend to contain similar wording, making it difficult to inspire the user. Our method is therefore developed to generate lyrics that (1) convey a message similar to the input text and (2) contain wording different from the input text. A straightforward approach of training a text-to-lyrics encoder-decoder is not feasible since there is no text-lyric paired data for this purpose. To overcome this issue, we divide the text-to-lyrics generation process into a two-step pipeline, eliminating the need for text-lyric paired data. (a) First, we use an existing text-to-image generation technique as a text analyzer to obtain an image that captures the meaning of the input text, ignoring the wording. (b) Next, we use our proposed image-to-lyrics encoder-decoder (I2L) to generate lyrics from the obtained image while preserving its meaning. The training of this I2L model only requires pairs of “lyrics” and “images generated from lyrics”, which are readily prepared. In addition, we propose for the first time a lyrics generation method that reduces the risk of plagiarism by prohibiting the generation of uncommon phrases in the training data. Experimental results show that the proposed method can generate lyrics with different phrasing while conveying a message similar to the input text.

1. INTRODUCTION

Automatic lyrics generation methods have been proposed as an important research topic in lyrics information processing [1]. With the aim of supporting users who already know what they want to convey in their lyrics but struggle to find the appropriate words, the methods are used in writing

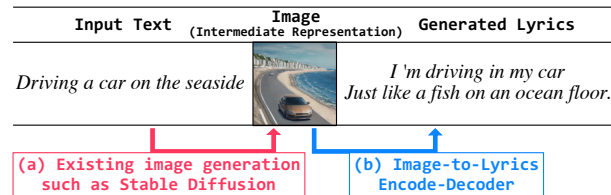

Figure 1. Overview of the proposed text-to-lyrics generation method.

support systems providing them with generated lyrics as a source of new inspiration [2–8]. Most previous studies have focused on lyrics generation that is conditioned by semantic constraints, including specific keywords, lyric style, and topics. For example, Watanabe et al.’s system generates lyrics based on pre-defined topics selected by the user, but the limited range of topics results in similar styles of generated lyrics [2]. Oliveira et al.’s system generates poems based on keywords entered by the user, but it cannot generate poems based on sentences or paragraphs representing the user’s intention [3, 4].

To provide more flexible lyric writing support, we propose generating lyrics based on freely formatted text entered by the user. We believe this approach surpasses the use of semantic constraints such as topics and keywords in terms of flexibility. While existing paraphrase systems [9] can be considered useful for this approach, the paraphrased lyrics may not provide sufficient inspiration because they tend to be similar in wording to the input text. For example, even if a similar phrase “Driving a car along the coastline” is generated from the input text “Driving a car on the seaside”, the user is unlikely to get new inspiration.

Therefore, the aim of this study is to develop a method for generating lyrics that not only have meanings similar to the input text but also use wording different from the input text. For example, if a user freely enters text that represents the content of the lyrics, such as “Driving a car on the seaside”, our method generates lyrics with different wording, such as “I’m driving in my car. Just like a fish on an ocean floor.”. As a simple way to achieve this aim, Transformer-based encoder-decoders [10] could be used for generating lyrics from text, but they require large text-lyric paired data for training, which is currently unavailable. To address this issue, we could use text summarization and machine translation to generate text from lyrics and obtain paired data automatically. However, since the generated text

and lyric pairs have similar wording, an encoder-decoder trained using those paired data may generate lyrics with wording similar to the input text.

To achieve text-to-lyrics generation without using any paired text data for training, we propose a two-step pipeline framework: (a) using an existing text analyzer to obtain only the semantic representation from the input text, and (b) generating lyrics from the obtained representation. The core idea of this framework is to leverage a text-to-image generation technique such as Stable Diffusion [11] as the text analyzer. An image generated from the input text can serve as a reasonable intermediate representation that captures the meaning of the text while ignoring the details of its wording (Figure 1 (a)). Using the generated image, our image-to-lyrics encoder-decoder generates semantically related lyrics (Figure 1 (b)). It needs many image-lyric pairs as training data, but we can readily prepare those pairs by generating images from lyrics of many songs. This is an advantage of using text-to-image generation. Another advantage is that it can generate images without regard to the input text's format, i.e., whether it is a word, phrase, sentence, or paragraph. We can thus provide flexible lyric writing support that is not constrained by the format of the input text.

Machine learning-based generation methods may inadvertently output portions of the training data directly without modification. This output can be considered plagiarism in some cases [12, 13]. Therefore, this paper also proposes an anti-plagiarism method to reduce this risk. We assume that generating common phrases (word sequences having high commonness [14]) used in many songs is not plagiarism, and reduce the risk of plagiarism by prohibiting the generation of uncommon phrases used in only a few songs. To the best of our knowledge, this is the first study to include such an anti-plagiarism method in lyrics generation.

Experimental results show that our text-to-lyrics generation method can generate lyrics with meaning similar to the input text but expressed differently. Another experiment shows that lyrics generated without using our anti-plagiarism method would result in plagiarizing uncommon phrases in the training data, but those undesirable phrases can successfully be removed by our method.

2. RELATED WORK

While natural language generation methods such as machine translations and chat systems have been actively studied and their performance greatly improved by deep neural networks (DNNs), automatic lyrics generation has also attracted attention as a research topic [1]. Most studies of lyrics generation have focused on lyric-specific musical constraints such as melody [15–20], rhyme [6, 8, 21–25], and audio signal [26–28]. While these lyric-specific musical constraints are an important aspect of lyrics generation, the main focus of this study is on the controllability of the semantic content of the generated lyrics.

Other studies have focused on lyrics generation that is conditioned by semantic constraints such as input keywords, styles, and topics [2–5, 29–32]. However, although these

constraints allow some control over the semantic content of the generated lyrics, there may be differences between the user's intentions and the semantic content of the generated lyrics. To improve the usability of the lyrics generation method as a creative tool, we believe that users should be able to enter freely formatted text (words, phrases, sentences, paragraphs, etc.). Our proposed method therefore allows any text format, giving users greater control over the semantic content of the generated lyrics.

Some studies have proposed methods for generating lyrics that are semantically related to the input text [6, 7]. Ram et al. proposed a fine-tuned T5 model [9] that generates single-line lyrics that follow several lines of input lyrics [6]. This method allows the user not only to enter sentences but also to control the rhyme and syllable count of the generated lyrics by adding special tokens at the end of the input sentence. In contrast to that method, in which the generated lyrics are a continuation of the input lyrics, ours generates lyrics that capture the semantic content of the input text. Zhang et al.'s research motivation is similar to ours, as they have also proposed a method for generating lyrics that capture the semantic content of the input text (which they refer to as passage-level text) [7]. To overcome the problem of the lack of text-lyric paired data for training the text-to-lyrics encoder-decoder, they collected lyrics data and passage-level text data (such as short novels and essays) separately and utilized an unsupervised machine translation framework. Specifically, they prepared two encoder-decoders, one for lyric text and one for passage-level text. They then aligned the latent representation space of these two encoder-decoders to build a text-to-lyrics encoder-decoder. In this paper, we propose a novel approach to develop a text-to-lyrics generation method that requires only lyrics data. While Zhang et al.'s method requires the collection of both lyrics and input texts, ours does not require additional text data, thus simplifying the development of the lyrics generation method.

3. TEXT-TO-LYRICS GENERATION WITH IMAGE-BASED SEMANTICS

As described in Section 1, the proposed text-to-lyrics generation method first generates an image from the input text by leveraging an existing text-to-image generation method. It then generates lyrics from the generated image by using our own image-to-lyrics encoder-decoder that we call *I2L*. Since the image serves as an intermediate representation to extract the meaning of the input text, the generated lyrics can have similar meaning but different wording.

The network structure of the *I2L* is illustrated in Figure 2. By assuming that one paragraph of lyrics can be represented in a single image, we set the unit of the generated lyrics to a paragraph.

We first use the animation-style image generation method *Anything V3.0*.¹ to obtain an image having a uniform style. The reasons for using *Anything V3.0* here are

¹ A fine-tuned Stable Diffusion model. <https://huggingface.co/Linaqruf/anything-v3.0>

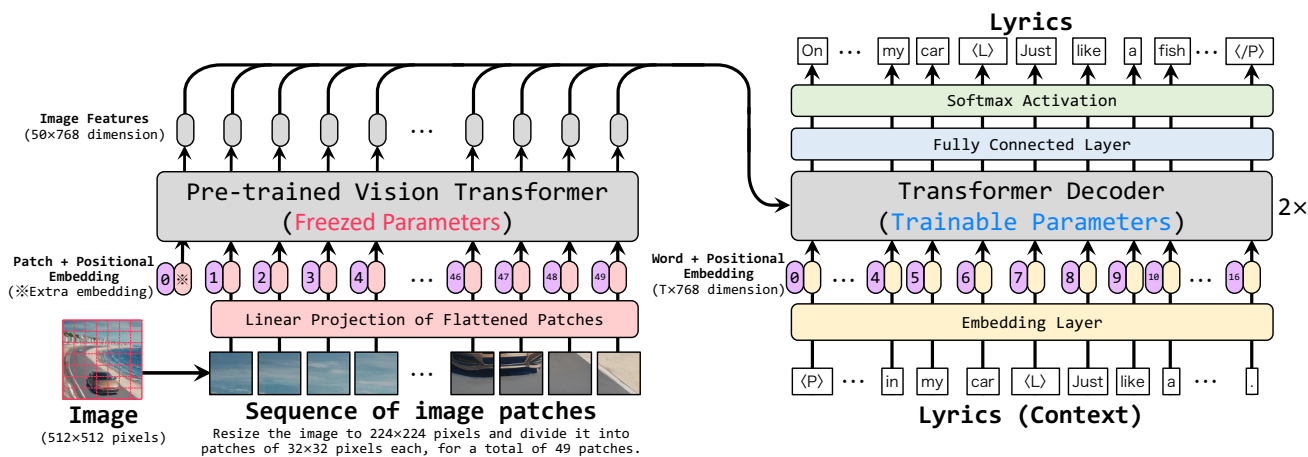

Figure 2. Image-to-lyrics encoder-decoder (I2L) for generating lyrics from an image that is generated from the input text.

(1) it can generate images that represent the input text without prompt engineering, and (2) the use of images with a uniform style facilitates I2L training. The image has a resolution of 512×512 and corresponds to a paragraph of the English lyrics.

As shown in Figure 2, we then segment the generated image into 49 patches and compute the features of the image patches by using a pre-trained Vision Transformer² [33] to obtain 50 features (each with 768 dimensions) per image. These 50 image features are fed into the multi-head attention layer of the Transformer decoder [10]. We feed each word in a paragraph into the word embedding and positional embedding layers to compute the word vectors, and feed each word vector into the masked multi-head attention layer of the Transformer decoder. The output of the Transformer decoder is fed into the fully connected layer FC to obtain a vector of vocabulary size dimensions. Finally, we apply the softmax activation function to this vector to calculate the word probability distribution.

3.1 Parameters

We use 768 as the number of embedding dimensions, 6 as the number of multi-heads, 2 as the number of decoder layers, 1024 as the number of feedforward layer dimensions, and GELU as the activation function. For optimization we use AdamW [34] with a mini-batch size of 8, a learning rate of 0.001, and a warm-up step of one epoch. Training was run for 40 epochs, and the I2L used for testing was the one that achieved the best loss on the development set.

We dare to train our Transformer decoder from scratch using only the lyrics data we have, without reusing available pre-trained large-scale language models (LLMs) such as BERT [35] or GPT-2 [36]. This is because when the training data of LLMs contain copyrighted literary works such as novels, poems, or essays, reusing pre-trained LLMs can result in plagiarizing those works. Since we would like to reduce the risk of plagiarism as described in Section 3.4, we cannot leverage pre-trained LLMs.

3.2 Training data

We sample 129,747 English songs from the Music Lyrics Database V.1.2.7³ so that each song contains at least three paragraphs. The resulting dataset contains 927,535 paragraphs. This means that we can obtain 927,535 images by using Anything V3.0. We then split these songs into training (90%) and development (10%) sets. We use the top 52,832 words with the highest document-frequency as the vocabulary for training, and convert the other words to a special symbol $\langle \text{unknown} \rangle$. This vocabulary includes $\langle L \rangle$ tags for line breaks, $\langle P \rangle$ tags for the beginning of paragraphs, and $\langle /P \rangle$ tags for the end of paragraphs.

We applied the same procedure not only to the lyrics of English songs but also to the lyrics of 142,772 Japanese songs. This Japanese dataset contains 1,078,500 paragraphs, and the vocabulary size is 50,989 words. To extract word boundaries for Japanese lyrics, we apply the CaboCha parser [37]. Japanese lyrics are pre-translated into English by a Japanese-English translator⁴ for use with Anything V3.0. We use these English and Japanese lyrics datasets to train two I2Ls (one for each language).

3.3 Decoding algorithm

We expect that generating and suggesting different variations of lyrics can give users new ideas for writing lyrics. To generate such different variations, we use a sampling method rather than a beam search method. In the sampling method, we sample each word according to the probability distribution calculated by the Transformer decoder. Sampling words according to a probability distribution allows a wide variety of words to be included in the generated lyrics, although some words that make the generated lyrics meaningless may be included. To avoid generating such meaningless lyrics, we use a Top- p sampling method that prohibits sampling words with low generation probabilities [38]. We can generate several lyrics simultaneously by

² <https://huggingface.co/google/vit-base-patch32-224-in21k>

³ <https://www.odditysoftware.com/page-datasales1.htm>

⁴ <https://huggingface.co/staka/fugumt-en-ja>

running Top- p sampling in parallel. The probability distribution for word sampling in Top- p sampling is calculated using the formula $\text{softmax}(\mathbf{z}/\tau)$: where \mathbf{z} is the output of the fully connected layer FC and τ is the temperature parameter. If τ is less than 1, common words with high probability values are more likely to be sampled. In model training we set τ to 1, while in lyrics generation the user can set τ freely.

3.4 Anti-plagiarism method for lyrics generation

One of concerns with lyrics generation based on machine learning is the risk of plagiarism since the generated lyrics may contain phrases that are identical to existing lyrics phrases in training data, potentially leading to copyright infringement issues. To address this issue, we propose a method to reduce the risk of plagiarism in machine learning-based lyrics generation. This method not only allows the generation of new phrases that are not present in the training data, but also permits the use of commonly used phrases such as “*I love you*” in the generated lyrics. In contrast, it prohibits the use of uncommon phrases that we consider to be a form of plagiarism. To achieve this, we create a list of uncommon phrases, *UncommonPhrase*, and prohibit the generation of phrases that are included in this list.

First, we define the uncommon phrases included in *UncommonPhrase*, as well as the new phrases and common phrases that are allowed to be generated. A phrase is defined by a word n -gram, denoted by $\{w_1, \dots, w_n\}$, where w is a word. We categorize a phrase as “new”, “common”, or “uncommon” according to $SN(\{w_1, \dots, w_n\})$ defined as the number of songs in which the n -gram occurs in the training data:

- If $SN(\{w_1, \dots, w_n\}) = 0$, this n -gram is a new phrase (i.e., it does not appear in the training data).
- If $3 < SN(\{w_1, \dots, w_n\})$, this n -gram is a common phrase (i.e., it appears frequently in the training data).
- If $1 \leq SN(\{w_1, \dots, w_n\}) \leq 3$, this n -gram is an uncommon phrase (i.e., it appears infrequently in the training data).⁵

Note that there is a possibility of mistaking uncommon phrases for common phrases when duplicate lyrics are contained in the training data, which results in larger SN values than they should be. It could happen when different artists sing the same lyrics, the same lyrics is repeatedly registered, and so on. We therefore identify duplicate lyrics according to the following two criteria: (1) we assume that pairs of lyrics with the same 20-grams are duplicates, and (2) we assume that pairs of lyrics with a normalized edit distance [39] of less than 0.5 are duplicates. To calculate SN accurately, we then concatenate the identified duplicate lyrics and replace those lyrics with the single concatenated lyrics. When lyrics that do not duplicate are mistaken for

duplicate lyrics, a common phrase can be mistaken for an uncommon phrase, but it is better than vice versa from the anti-plagiarism viewpoint. This reduced the number of English songs in our lyrics data from 129,747 to 108,497.⁶

Based on this SN criteria, we collect uncommon phrases from our training data. However, it is important to note that even if a word 3-gram is a common phrase, it may become an uncommon phrase when it becomes a word 4-gram. For instance, “*I love you*” is a common 3-gram with a large SN , while “*I love you darling*” is an uncommon 4-gram with a small SN . Therefore we do not use a single value of n but instead consider all values of n within a range from 1 to sufficiently large values. However, it is difficult to store all uncommon phrases in memory because the number of n -grams that have to be listed increases with n . To overcome the memory limitation problem, we propose to use the following procedure to minimize the number of uncommon phrases we need to store in memory: (1) we start by examining 1-grams, then move on to 2-grams, 3-grams, and so on until we have looked at all possible n -grams in the training data. (2) For each target n -gram, we generate all possible sub- n -grams of length 1, 2, ..., $n - 1$. If any of these sub- n -grams are already in *UncommonPhrase*, we can skip adding the target n -gram to *UncommonPhrase* because we know it is uncommon. Otherwise, we add the target n -gram to *UncommonPhrase*. Following this procedure, we collected approximately 22.3M uncommon n -grams with n ranging from 1 to 21 for English lyrics.⁷

After creating *UncommonPhrase* using the above procedure, we prohibit their generation during Top- p sampling by the following two steps: (1) During word generation, we check whether any sub- n -grams derived from the word sequence $\{w_1, \dots, w_t\}$ are included in *UncommonPhrase*. (2) If any of these sub- n -grams are found in *UncommonPhrase*, we prohibit the generation of word w_t by setting its generation probability $P(w_t|\{w_1, \dots, w_{t-1}\})$ to zero.

4. QUANTITATIVE EVALUATION

The proposed text-to-lyrics generation method was quantitatively evaluated using two metrics:

Test-set perplexity (PPL): This is a standard evaluation measure for encoder-decoders. The PPL metric measures the degree of predictability of the phrasing in the original text in the test set [40]. A smaller PPL value is better since it indicates that the encoder-decoder has a higher ability to generate lyrics that capture the meaning of the input text.

Normalized edit distance (NED): The normalized edit distance [39] between the generated lyrics and the input text is calculated to evaluate whether the proposed method generates lyrics that differ in wording from the input text. A larger NED is better since it indicates that the generated lyrics have wording more different from the input text.

⁵ In this study, we tentatively set the threshold for SN at 3. Since there is no established legal rule, we believe that this threshold will be determined by social consensus in the future. Providing the technical basis for such discussions is also a contribution of this study.

⁶ For Japanese lyrics, the number of songs was reduced from 142,772 to 119,595.

⁷ For Japanese lyrics, we collected approximately 18.2M uncommon n -grams with n ranging from 1 to 19.

Method	English		Japanese	
	PPL	NED	PPL	NED
I2L (proposed)	84.86	0.78	231.49	0.92
S2L	346.73	0.69	306.19	0.86
B2L	544.21	0.71	1051.58	0.66
H2H	163.98	0.68	583.13	0.90

Table 1. Results of quantitative evaluation.

4.1 Experimental dataset

To evaluate the proposed lyrics generation method, we constructed a small test dataset consisting of pairs of lyrics and input text representing the semantic content of the lyrics. Since such a dataset is not available, for English songs, we prepared a test dataset that included plot texts from 20 Disney animated films, taken from Wikipedia, along with their corresponding theme song lyrics. We here assume that the lyrics of each theme song are written based on the content of that film. For Japanese songs, we prepared 51 Japanese animation plot texts and their theme song lyrics.

4.2 Methods Compared

To compare the proposed method with possible different methods, we prepared the following encoder-decoders trained on paired data created in different suitable ways.

Image-to-Lyrics encoder-decoder (I2L) This is the proposed encoder-decoder trained on image-lyric paired data.

Summary-to-Lyrics encoder-decoder (S2L) We converted each lyric paragraph in the training data into a summary using a text summarization method⁸ to create summary-lyric paired data. The data is then used to train a Transformer-based summary-to-lyric encoder-decoder.

Back-translated-lyrics-to-Lyrics encoder-decoder (B2L) We translated each lyric paragraph in the training data from English to Japanese to English by using English-Japanese and Japanese-English translation methods⁹ to create paired data of the back-translated lyrics and the original lyrics. The data is then used to train a Transformer-based back-translated-lyrics-to-lyrics encoder-decoder.

Half-to-Half encoder-decoder (H2H) Inspired by an existing text-to-lyrics encoder-decoder training method [6], we first split each lyrics paragraph in the training data into first and second halves. We then used this split lyrics data to train a Transformer-based encoder-decoder that generates the second half lyrics from the first half lyrics.

Since the above S2L, B2L, and H2H are also Transformer-based encoder-decoders, their parameter settings are the same as for the proposed I2L. Given one input text, five lyrics were generated by each method. The parameter p for Top- p sampling was set to 0.9 and τ was set to 0.4. The generation process stops when the symbol $\langle P \rangle$

⁸ <https://huggingface.co/google/pegasus-xsum> for the English summarization. https://huggingface.co/tsmatz/mt5_summarize_japanese for the Japanese summarization.

⁹ <https://huggingface.co/staka/fugumt-en-ja> for the English to Japanese translation. <https://huggingface.co/sstaka/fugumt-ja-en> for the Japanese to English translation.

Figure 3. The percentage of generated lyric n -grams that are included in *UncommonPhrase*, a list of phrases that should not be generated (plagiarized). For example, 18.4% at English 4-grams means that among all 4-gram phrases in the generated lyrics, 18.4% are uncommon phrases, though 81.6% are new or common phrases.

(end of paragraph) is generated. For this comparison, we did not use the proposed anti-plagiarism method.

4.3 Experimental results

Table 1 indicates that the proposed I2L method had the best PPL in both the English and Japanese experiments and that the NED between the lyrics generated by this method and the input text was the largest ($p_t < 0.05$ based on the paired t-test). As expected, the NEDs were smaller for the S2L and B2L methods, which were trained on paired data where the wording of the input text and lyric pairs was similar. In contrast, although the H2H method can generate lyrics with wording different from the input text, it cannot generate lyrics that are semantically related to the input text like the proposed method can. These findings confirm that image-lyric pairs are more effective than other paired data sets as training data for encoder-decoders generating lyrics that are semantically related to the input text but differ from it in wording.

5. EFFECTIVENESS OF THE PROPOSED ANTI-PLAGIARISM METHOD

We examined whether the absence of the anti-plagiarism method proposed in Section 3.4 results in plagiarizing uncommon phrases found in existing lyrics. In the lyrics generated by the I2L method in Section 4, we calculated the percentage of n -grams included in *UncommonPhrase*.

The results with n ranging from 1 to 12 are shown in Figure 3. The percentage of uncommon 1-grams and 2-grams in the generated lyrics is almost 0%. This indicates that almost all of the generated 1-grams and 2-grams are common phrases used in many existing lyrics, even without the use of the anti-plagiarism method. On the other hand, the percentage of uncommon 3-grams to 8-grams ranged between 3% and 18%. This suggests that many phrases in the generated lyrics may plagiarize if the proposed anti-plagiarism method is not applied. Furthermore, as n increases beyond 9, the n -gram combinations become

Input text	Image (intermediate representation)	Generated lyrics
A group of explorers are walking through the grass neutral.		Out in the country, out of sight We've got to get this together right now I'm going out with you today And some day we'll make a lot better way
We meet again I guess our love is forever.		This is the last time We've been together for long years I'm here with you To be forever yours

Table 2. Examples of lyrics generated by our text-to-lyrics generation method with the anti-plagiarism method.

so vast that the generated n -grams are rarely included in *UncommonPhrase*. These results confirm that our machine learning-based lyrics generation method tends to sample common words, but the generated 3- to 8-gram phrases, even though they are composed of common words, may be uncommon enough to raise suspicion of plagiarism. Using the proposed anti-plagiarism method, in contrast, ensures that uncommon phrases contained in *UncommonPhrase* are never generated, thereby reducing the risk of plagiarism.

While the proposed anti-plagiarism method is effective, it is important to note that it is not intended to be a fool-proof solution that ensures legal compliance. Rather, it is designed to provide a helpful guideline for those who wish to generate original lyrics while reducing the risk of plagiarism. We hope that our approach can contribute to further discussions on a reasonable balance between encouraging creativity and respecting intellectual property rights.

6. QUALITATIVE EVALUATION

Table 2 shows two examples of lyrics generated using the proposed method. Given the input text, our method can generate any number of lines of lyrics, but here four lines are generated by stopping the generation process when four $\langle L \rangle$ (line break) symbols and the $\langle P \rangle$ (end of paragraph) symbol are generated. In the first example, the input text is taken from the SICK dataset [41], while in the second example the input text is taken from lyrics in the RWC Music Database [42]. In both examples, our method can generate lyrics that reflect the content of the input text. In the first example, it generates an image that represents the scene described in the input text and generates corresponding lyrics that reflect the image. In contrast, in the second example, our method generates an image of a person with emotional expression corresponding to the input text and generates lyrics that express the emotion depicted in the image. Other examples can be found in the supplementary material A.¹⁰

In addition to the quantitative evaluation and the generated examples, we evaluated the similarity between the input text and the generated lyrics through a human evaluator. To prepare the input text in an objective way, we collected the titles of the “Hot 100 Songs” in 2022 on the Billboard year-end charts¹¹, extracted the first verse from

their lyrics, and summarized each verse into a short sentence using ChatGPT.¹² Since 9 songs contained explicit content in either the input text or the generated lyrics, they were excluded for ethical reasons.¹³ We then showed the evaluator the input text and the lyrics generated from it, and asked to classify whether the impressions of the two were similar or not. As a result, the impressions of the input text and the generated lyrics were judged to be similar for 52 of the 91 songs, confirming that the proposed method can generate lyrics that express the content of the input text to some extent. In cases where the impressions were classified as dissimilar, most of the input texts contain complex situations or abstract content that is difficult to generate as images. Thus, the limitation of this approach is that it cannot generate lyrics for input texts that are difficult to represent as images. Nevertheless, our method is useful as a writing support tool for many situations where users have intentions that can be represented as images, and is also valuable because it pioneered a novel lyric generation approach. Detailed results of the generated lyrics and the judgments are included in the supplementary material B.¹⁴

7. CONCLUSION

This paper has described a method for generating lyrics that are similar in meaning to the input text but expressed differently. The contributions of this study are as follows: (1) We proposed a novel two-step pipeline framework. First, we apply text-to-image generation as a text analyzer to extract only the semantic content from the input text. Next, we use our proposed image-to-lyrics encoder-decoder to generate lyrics that capture the semantics of the generated image. (2) We proposed a method to reduce the risk of plagiarism by prohibiting the generation of uncommon phrases in the training data and verified its effectiveness. (3) We quantitatively showed that our proposed method outperforms other methods in generating lyrics for our purpose.

Future work will develop the flexible lyric writing support system incorporating the proposed lyrics generation method.

ABSTRACT

Automatic music captioning, which generates natural language descriptions for given music tracks, holds significant potential for enhancing the understanding and organization of large volumes of musical data. Despite its importance, researchers face challenges due to the costly and time-consuming collection process of existing music-language datasets, which are limited in size. To address this data scarcity issue, we propose the use of large language models (LLMs) to artificially generate the description sentences from large-scale tag datasets. This results in approximately 2.2M captions paired with 0.5M audio clips. We term it Large Language Model based Pseudo music caption dataset, shortly, **LP-MusicCaps**. We conduct a systemic evaluation of the large-scale music captioning dataset with various quantitative evaluation metrics used in the field of natural language processing as well as human evaluation. In addition, we trained a transformer-based music captioning model with the dataset and evaluated it under zero-shot and transfer-learning settings. The results demonstrate that our proposed approach outperforms the supervised baseline model.¹

1. INTRODUCTION

Music captioning is a music information retrieval (MIR) task of generating natural language descriptions of given music tracks. The text descriptions are usually sentences, distinguishing the task from other music semantic understanding tasks such as music tagging. Recently, there have been some progress in music captioning including track-level captioning [1, 2] and playlist-level captioning [3–6]. These approaches usually utilize a deep encoder-decoder framework which is originally developed for neural machine translation [7]. Choi *et al.* [3] used a pre-trained music tagging model as a music encoder and an RNN

¹ Our dataset and codes are available at <https://github.com/seungheondoh/lp-music-caps>

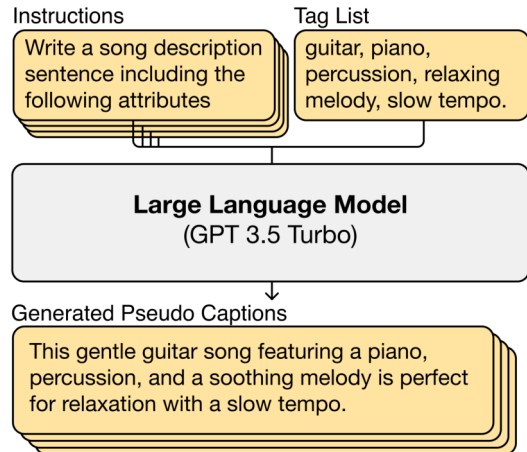

Figure 1. The generation process of pseudo captions by feeding a large language model with instructions and manually-annotated labels.

layer initialized with pre-trained word embeddings for text generation. Manco *et al.* [1] introduced a temporal attention mechanism for alignment between audio and text by pairing a pre-trained harmonic CNN encoder [8] with an LSTM layer. Gabbolini *et al.* [5] generated playlist titles and descriptions using pre-trained GPT-2 [9].

Currently, the primary challenge of track-level music captioning is the scarcity of large-scale public datasets. Manco *et al.* [1] used private production music datasets. Huang *et al.* [10] also used a private dataset with 44M music-text pairs on YouTube, but this approach is hardly reproducible or affordable for other researchers. To address this data issue, a community-driven data collection initiative has been proposed [11]. As of now, the only publicly available dataset for track-level music captioning is MusicCaps [12], which includes high-quality music descriptions from ten musicians. However, it is limited to 5521 music-caption pairs as it was originally created as an evaluation set for a text-prompt music generator.

With the scale of the aforementioned datasets, it remains difficult to train a music captioning model successfully. A workaround for this situation is to use music tagging datasets and generate sentences with tag concatenation [2, 13] or prompt template [14]. As relying on tagging datasets, however, the tag-to-sentence approaches would have the same limitation tagging datasets have. For example, high false-negative rates of tagging datasets [15]. Tag-

ging datasets also has some typical issues text data have, for example, synonyms, punctuation, and singular/plural inconsistencies. Without proper treatment, these can limit the performance of the corresponding music captioning models.

A potential solution is to use strong language models, i.e., large language models (LLMs). LLMs refer to the recent large-scale models with over a billion parameters that exhibit strong few-shot and zero-shot performance [9, 16]. Large language models are usually trained with text data from various domains such as Wikipedia, GitHub, chat logs, medical articles, law articles, books, and crawled web pages [17]. When successfully trained, they demonstrate an understanding of words in various domains [9]. There have been similar and successful use cases of LLMs for general audio understanding [18] and music generation [19].

Motivated by the recent success of LLMs, we propose creating a music captioning dataset by applying LLMs carefully to tagging datasets. Our goal is to obtain captions that are i) semantically consistent with the provided tags, ii) grammatically correct, and iii) with clean and enriched vocabulary. This dataset-level approach is rather pragmatic than sophisticated; it alleviates the difficulty of music captioning tasks not by theory or model, but by data. The aforementioned ambiguous aspects of the music captioning task are addressed by the powerful LLMs that cost reasonably [20], considering the training cost music researchers would spend otherwise. Once the creation is complete, it is straightforward to train some music captioning models by supervised learning.

There are some existing works in the pseudo-labeling using language models. Huang *et al.* [19] introduced the MuLaMCap dataset, which consists of 400k music-caption pairs generated using the large language model and the music-language joint embedding model. They utilized a large language model (LaMDA [21]) to generate 4M sentences using 150k song metadata as input in the format of {title} by {artist}. Then the text and music-audio joint embedding model, MuLan, calculates the similarity between music and generated captions, annotating pairs with high similarity [10]. However, it is not possible to reproduce or evaluate this work as the adopted language model as well as the final music-audio embedding model are not publicly available. Moreover, using metadata has some issues – a popularity-biased, limited coverage and a low reliability – as we discuss later in Section 2.1. Wu *et al.* [22] introduce keyword-to-caption augmentation (K2C Aug) to generate captions based on the ground truth tags of audio clips in AudioSet. They used a pre-trained T5 model without any instruction. Finally, Mel *et al.* [18] introduce WavCaps, a 400k audio captioning dataset using ChatGPT [23]. However, previous approaches only reported task performance and did not directly evaluate the quality of generated captions.

We propose a solution in this paper with three-fold key contribution. First, we propose an LLM-based approach to generate a music captioning dataset, **LP-MusicCaps**. Sec-

ond, we propose a systemic evaluation scheme for music captions generated by LLMs. Third, we demonstrate that models trained on LP-MusicCaps perform well in both zero-shot and transfer learning scenarios, justifying the use of LLM-based pseudo-music captions.

2. PSEUDO CAPTION GENERATION USING LARGE LANGUAGE MODELS

In this section, we introduce how music-specific pseudo captions are created using a large language model in the proposed method.

2.1 Large Language Model for Data Generation

We first take multi-label tags from existing music tagging datasets. The list of tags are appended with a carefully written task instruction as an input (prompt) to a large language model. The model then generates and returns sentences that (may) describe the music in a way the task instruction conditions. Table 1 shows examples of generated captions according to multi-label tags and task instructions. For the language model, we choose GPT-3.5 Turbo [23] for its strong performance in various tasks. During its training, it was first trained with a large corpus and immense computing power, then fine-tuned by reinforcement learning with human feedback (RLHF) [24] for better interaction with given instruction. As a result, GPT-3.5 Turbo demonstrates state-of-the-art zero-shot abilities in understanding, reasoning, and generating human-like responses to natural language inputs.

Since LLMs contain a wide range of information, music captions may be generated based on some famous musical entities such as the artist name or album name. However, LLMs may generate inaccurate text in a confident tone which is hard to detect without ground truth. This issue, known as hallucination, can be a fun aspect when using LLMs for creative purposes [25]. However, hallucination should be avoided in an application like ours as the resulting captions should be factual. Therefore, we do not use any metadata unlike a previous work [19]. We also added a question to measure hallucination in the proposed evaluation scheme.

2.2 Task Instruction Design

Our proposed caption generation follows the formulation: $\tilde{y}_{cap} = f_{LLM}(y_{tag}, i)$, where y_{tag} and \tilde{y}_{cap} refer to the multi-label tag and the generated caption, respectively, and i is the task instruction provided. Given that the output can vary based on the task instruction, even with the same model and input, task instructions become a crucial aspect of data generation. Therefore, we define four different tasks and generate captions accordingly.

Writing: *Write a song description sentence including the following attributes. {input tags}*

Summary: *Write a single sentence that summarizes a song with the following attributes. Don't write the artist name or album name. {input tags}*

Input tags
video game theme, no singer, instrumental, analog sounding, small keyboard, beatboxing, playful, cheerful, groovy
Result of "Writing" Instruction
This instrumental track has a joyful and playful vibe, perfect for a video game theme. With no singer, the analog-sounding music features a small keyboard and beatboxing, creating a groovy and cheerful atmosphere.
Result of "Summary" Instruction
A cheerful and groovy instrumental track with playful beatboxing and an analog sound, featuring a small keyboard and video game-inspired theme.
Result of "Paraphrase" Instruction
This upbeat instrumental tune captures the essence of a fun-filled video game theme, incorporating analog-sounding beats, playful beatboxing rhythms, and a groovy small keyboard melody, all without the need for a singer.
Result of "Attribute Prediction" Instruction
{ "new_attribute": ["8-bit sound", "chiptune style", "retro vibe"], "description": "This instrumental tune is straight out of a video game with its analog sounding melodies and small keyboard tinkles. Beatboxing adds a playful element to the groovy, cheerful vibe. Reminiscent of classic 8-bit sound and chiptune style, this retro vibe is sure to put a smile on your face." }
Ground Truth
This is a video game theme cover. The theme belongs to the Super Mario franchise. The main theme is being played on an analog sounding small keyboard. There is an added rhythmic background of beatboxing in this version. The atmosphere is playful. This piece could be used in the background of arcade gaming social media content.

Table 1. An example of generated captions from MusicCaps dataset.

Paraphrase: Write a song description sentence including the following attributes. Creative paraphrasing is acceptable. {input tags}

Attribute Prediction: Write the answer as a Python dictionary with new_attribute and description as keys. For new_attribute, write new attributes that show high co-occurrence with the following attributes. For description, write a song description sentence including the following attributes and new attributes. {input tags}

In every instruction, we add ‘include / with the following attributes’ to prevent hallucination. The “Writing” task instruction is a simple prompt that uses tags to generate a sentence. The “Summary” task instruction aims to compress information into a short length. The “Paraphrase” task instruction expands the vocabulary. Finally, the “Attribute Prediction” task instruction predicts new tags based on tag co-occurrence in large corpora (i.e. the training data of GPT-3.5 Turbo), which is expected to address the issue of high false-negative rates in existing tagging datasets while mitigating the risk of hallucination. In this instruction, ‘new attributes’ exists to bridge the description and the input, and we only use the ‘description’ as caption.

3. EVALUATION OF PSEUDO CAPTIONS

It is crucial to ensure the quality of generated captions, especially since they are supposed to be used as ground truth. In this section, we introduce a holistic evaluation scheme that includes objective and subjective assessment – and its result on the captions from the proposed method.

3.1 Objective Evaluation

We conduct evaluation on the generated captions using MusicCaps dataset [12]. It has audio (x), tag list (y_{tag}), and ground truth caption (y_{cap}). The pseudo captions (\hat{y}_{cap}) are generated with four pre-defined instructions as explained

in Section 2.2 for all items in the evaluation split. During the evaluation, the generated captions are compared to the ground truth captions with respect to n -gram, neural metrics. We also report diversity metrics.

Following the previous work [5], we measure four n -gram metrics [26–28]: BLEU1 to 4 (B1, B2, B3, B4), METEOR (M), and ROUGE-L (R-L). They are all based on n -gram precision and recall between the ground truth and generated captions. These metrics capture different aspects of the caption quality. BLEU and METEOR focus on n -gram overlap between the generated and ground truth captions, while ROUGE-L measures the longest common subsequence between the two.

In addition, we use BERT-Score (BERT-S) based on pre-trained BERT embeddings to represent and match the tokens in the ground truth with respect to the generated caption [29]. By computing the similarity between the BERT embeddings of each token, BERT-Score can better capture the semantic similarity between the generated and ground truth captions than n -gram metrics; as it is more robust to synonyms, paraphrasing, and word order variations.

Finally, we evaluate the diversity of the generated captions by measuring how many different words are used. $novel_v$ indicates the percentage of new vocabulary in generated captions that are not among the training vocabulary. $Vocab$ is the number of unique words used in all the generated captions. It is worth noting that diversity metrics are generally considered as subsidiaries and do not capture the overall quality of the generated captions.

3.2 Subjective Evaluation

Following the previous work [12], we set up an A-vs-B human rating task, in which a participant is presented with a 10-second single music clip and two text descriptions. We randomly selected 240 music samples from the MusicCaps evaluation dataset. Since the research goal is to generate

Table 2. Performance of existing pseudo caption generation methods and the proposed method. LM stand for the language model. Avg.Token stand for the average number of token per caption.

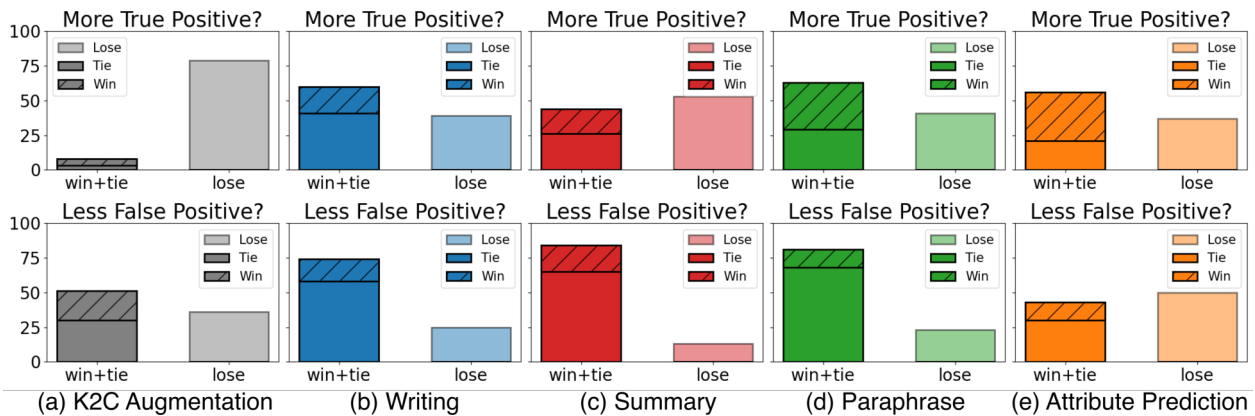

Figure 2. A-vs-B test results. Each method is compared to ground truth in terms of having more true positives and fewer false positives. The proposed methods (b, c, d, e) show comparable **win+tie** performance to ground truth.

music captions that can be used as pseudo-ground truth, one description is always fixed to the ground truth and the other is chosen from 5 types of generated captions including the K2C Augmentation [22] and the four proposed instruction methods. This yields up to 1200 (= 240 x 5) questions. We hired 24 participants who are music researchers or professionals in the music industry. Each of them rated 20 randomly selected questions. As a result, we collected a total of 480 ratings. The rater was asked to evaluate caption quality on two different aspects: (Q1) *More True Positive*: which caption describes the music with more accurate attributes? (Q2) *Less False Positive*: which caption describes the music less wrong? For example, if a method produces long and diverse sentences with many music attributes, it may be advantageous for Q1 but disadvantageous for Q2. Conversely, if a method conservatively produces short sentences with few music attributes, it may be advantageous for Q2 but disadvantageous for Q1. We determine the ranking of conditions by counting the number of wins, ties, and losses in the pairwise tests.

3.3 Results

We compare our LLM-based caption generation with two template-based methods (tag concatenation, prompt template²) and K2C augmentation [22]. In Table 2, we present the captioning result for MusicCaps [12] evaluation set. When comparing our proposed method with existing meth-

ods, we observe significant differences in *n*-gram metrics. This is because the tag concatenation fails to complete the sentence structure. In the case of K2C Augmentation, due to the absence of instruction, the input tag is excluded from the generated caption, or a sentence unrelated to the song description sentence is created. In contrast, the template-based model shows improved performance as the musical context exists in the template. We next consider diversity metric with BERT-Score. Our proposed method shows higher values in BERT-Score while generating diverse vocabularies. This indicates that the newly created vocabulary does not harm the music semantics.

Comparing within the proposed different task instructions, we can observe that each instruction performs a different role. “Writing” shows a high *n*-gram performance as it faithfully uses input tags to generate captions. “Summary” has the smallest average number of tokens due to its compression of information, but it shows competitive performance in ROUGE-L which is specialized to summarizing, as well as the highest BERT-Score. “Paraphrase” generates many synonyms, resulting in a large vocabulary size and the use of novel vocabulary. “Attribute Prediction” predicts new tags based on the co-occurrence of tags. This instruction shows lower performance in BLEU but competitive results in METEOR, which utilizes a thesaurus, such as WordNet, to consider the accuracy scores of words with similar meanings, indicating that newly predicted tags have similar semantic with ground truth.

Figure 2 shows the subjective A-vs-B test results. Each

² Template example: the music is characterized by {input tags}

Dataset	# item	Duration (h)	C/A	Avg. Token
General Audio Domain				
AudioCaps [30]	51k	144.9	1	9.0±N/A
LAION-Audio [22]	630k	4325.4	1-2	N/A
WavCaps [18]	403k	7568.9	1	7.8±N/A
Music Domain				
MusicCaps [12]	6k	15.3	1	48.9±17.3
MuLaMCap* [19]	393k	1091.0	12	N/A
LP-MusicCaps-MC	6k	15.3	4	44.9±21.3
LP-MusicCaps-MTT	22k	180.3	4	24.8±13.6
LP-MusicCaps-MSD	514k	4283.1	4	37.3±26.8

Table 3. Comparison of audio-caption pair datasets. C/A stands for the number of caption per audio. *Although we include MuLaMCap in the table for comparison, it is not publicly accessible.

method is compared to the ground truth in terms of having more true positives (Q1) and fewer false positives (Q2). For the first question, compared to the baseline K2C augmentation, the proposed methods using the instructions show an overwhelmingly higher *win+tie* score. This indicates the importance of music-specific instructions when utilizing LLM. In particular, ‘‘Paraphrase’’ and ‘‘Attribute Prediction’’ achieve high *win* scores by incorporating new information that is different from the existing vocabulary. In the second question, all caption generation methods except ‘‘Attribute Prediction’’ show higher *win+tie* scores than *lose* scores. This advocates the trustworthiness of LLM-based caption generation as it shows a similar or less false-positive rate to the ground truth. With its longest average length, ‘‘Attribute Prediction’’ turns out to be ‘too creative’ and shows a slightly higher false-positive rate than the ground truth.

4. DATASET: LP-MusicCaps

Based on the proposed pseudo caption generation method, we introduce LP-MusicCaps, an LLM-based Pseudo music caption dataset. We construct the music-to-caption pairs using three existing multi-label tag datasets and four task instructions. The data sources are MusicCaps [12], MagnatagTune [31], and Million Song Dataset [32] ECALS subset [13]. We respectively refer to them as MC, MTT, and MSD. MC contains 5,521 music examples,³ each of which is labeled with 13,219 unique aspects written by music experts. MTT [31] consists of 26k music clips from 5,223 unique songs including genre, instrument, vocal, mood, perceptual tempo, origin, and sonority features. We used the full 188 tag vocabulary and did not generate captions for tracks that do not have associated tags (decreased to 22k). MSD consists of 0.52 million 30-second clips and 1054 tag vocabulary [13]. The tag vocabulary covers various categories including genre, style, instrument, vocal, mood, theme, and culture. Each dataset uses an average of 10.7 / 3.3 / 10.2 labels per music clip for generating pseudo captions, respectively.

Table 3 provides a comparison of statistics between the LP-MusicCaps family and other audio-caption pair

³ We only use 5495 out of the total due to the loss of 26 data samples.

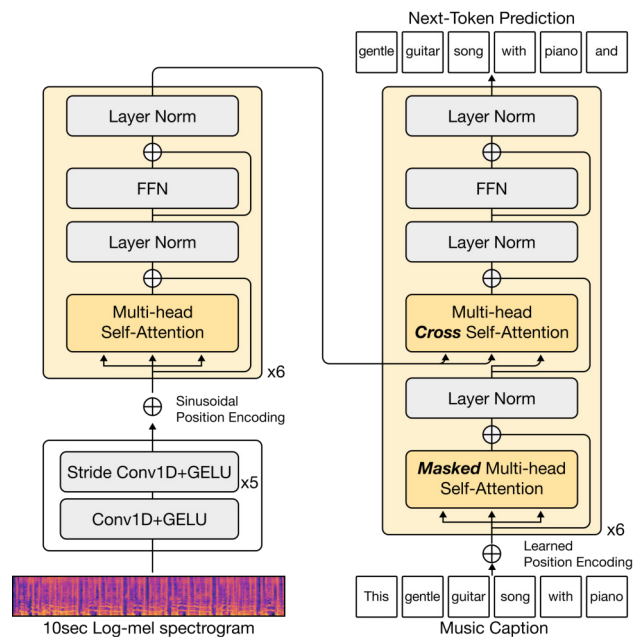

Figure 3. A cross-modal encoder-decoder architecture.

datasets. When comparing the two domains, AudioCaps [30] and MusicCaps have high-quality human annotated captions, but they have fewer captions with shorter audio duration. When comparing large-scale datasets, the music domain lacks available datasets compared to the general audio domain (such as LAION-Audio [22] and WavCaps [18]). Although MuLaMCap has an overwhelming amount of annotated captions, it is not publicly available. In contrast, LM-MusicCaps is publicly accessible and provided with various scales. LP-MusicCaps-MC has a similar caption length to manually written captions while having four times more captions per audio. LP-MusicCaps-MTT is a medium-sized dataset with audio download link, and LP-MusicCaps-MSD has the largest audio duration among various captions in the music domain caption dataset.

5. AUTOMATIC MUSIC CAPTIONING

We trained a music captioning model and evaluated it under zero-shot and transfer-learning settings. This section reports the experimental results.

5.1 Encoder-Decoder Model

We used a cross-modal encoder-decoder transformer architecture that has achieved outstanding results on various natural language processing tasks [33], lyrics interpretation [34], and speech recognition [35], as shown in Figure 3. Similar to Whisper [35], the encoder takes a log-mel spectrogram with six convolution layers with a filter width of 3 and the GELU [36] activation function. With the exception of the first layer, each convolution layer has a stride of two. The output of the convolution layers is combined with the sinusoidal position encoding and then processed by the encoder transformer blocks. Following the BART_{base} architecture, our encoder and decoder both have 768 widths and 6 transformer blocks. The decoder

Table 4. Music captioning results on the MusicCaps eval-set. Avg.Token stands for the average number of token per caption.

processes tokenized text captions using transformer blocks with a multi-head attention module that includes a mask to hide future tokens for causality. The music and caption representations are fed into the cross-modal attention layer, and the head of the language model in the decoder predicts the next token autoregressively using the cross-entropy loss, formulated as: $\mathcal{L} = -\sum_{t=1}^T \log p_{\theta}(y_t | y_{1:t-1}, x)$ where x is the paired audio clip and y_t is the ground truth token at time t in a caption with length T .

5.2 Experimental Setup

To evaluate the impact of the proposed dataset on the music captioning task, we compare a supervised model trained on the MusicCaps [12] training split and a pre-trained model trained on an LP-MusicCaps-MSD dataset. For the pre-trained model, we perform both a zero-shot captioning task that does not use any MusicCaps [12] dataset and a fine-tuning task that updates the model using MusicCaps [12] training split. For comparison with other pseudo caption generation methods, we report results on baseline models trained with the same architecture and amount of audio, but different pseudo captions. In addition to all the metrics we used in Section 3.1, we compute $Novel_c$, the percentage of generated captions that were not present in the training set [37]. It measures whether the captioning model is simply copying the training data or not.

For all the experiments, the input of the encoder is a 10-second audio signal at 16 kHz sampling rate. It is converted to a log-scaled mel spectrogram with 128 mel bins, 1024-point FFT with a hann window, and a hop size of 10 ms. All models are optimized using AdamW with a learning rate of 1e-4. We use a cosine learning rate decay to zero after a warmup over the first 1000 updates. For the pre-training dataset, we use 256 batch-size and the models are trained for 32,768 updates. We adopt a balanced sampling [38], which uniformly samples an anchor tag first and then selects an annotated item. For supervised and transfer learning, we use a 64 batch size, 100 epochs. We use beam search with 5 beams for the inference of all models.

5.3 Results

When comparing within zero-shot captioning models, the model trained on the proposed LP-MusicCaps dataset

shows a strong performance in general. The model using tag concatenation shows the lowest performance as it fails to generate musical sentences. In case of the model using a prompt template, it demonstrates a slightly higher BERT-Score, while still exhibiting poor performance in terms of n -gram metrics due to its limited vocabulary. The model using K2C augmentation outperforms the other two methods but still falls short due to its lack of a musical context. In general, zero-shot models does not perform as well as the supervised baseline in most of the metrics with few exceptions.

Among the transfer captioning models, the model with LP-MusicCaps pre-training achieves strong performance overall by winning in the BERT-Score and most of the n -gram metrics. It is noteworthy that our proposed model shows a meaningful increase in BERT-Score compared to the supervised model. This improvement is likely a result of successful semantic understanding rather than word-to-word matching. Moreover, by the improvement of $Novel_c$, the LP-MusicCaps model demonstrates that it can generate new captions instead of repeating the phrases in the training dataset. This advantage is observed in both the zero-shot and supervised tasks in transfer learning models.

6. CONCLUSION

We proposed a tag-to-pseudo caption generation approach with large language models to address the data scarcity issue in automatic music captioning. We conducted a systemic evaluation of the LLM-based augmentation, resulting in the creation of the LP-MusicCaps dataset, a large-scale pseudo-music caption dataset. We also trained a music captioning model with LP-MusicCaps and showed improved generalization. Our proposed approach has the potential to significantly reduce the cost and time required for music-language dataset collection and facilitate further research in the field of connecting music and language, including representation learning, captioning, and generation. However, further collaboration with the community and human evaluation is essential to enhance the quality and accuracy of the generated captions. Additionally, we believe that exploring the use of LLMs for other topics under music information retrieval and music recommendation could lead to novel and exciting applications.

ABSTRACT

Contrastive learning has recently appeared as a well-suited method to find representations of music audio signals that are suitable for structural segmentation. However, most existing unsupervised training strategies omit the notion of repetition and therefore fail at encompassing this essential aspect of music structure. This work introduces a triplet mining method which explicitly considers repeating sequences occurring inside a music track by leveraging common audio descriptors. We study its impact on the learned representations through downstream music segmentation. Because musical repetitions can be of different natures, we give further insight on the role of the audio descriptors employed at the triplet mining stage as well as the trade-off existing between the quality of the triplets mined and the quantity of unlabelled data used for training. We observe that our method requires less non-annotated data while remaining competitive against other unsupervised methods trained on a larger corpus.

1. INTRODUCTION

The task of music structure analysis consists in locating the boundaries between consecutive segments and grouping them into relevant categories, called musical sections. This problem has gained attention in the field of music information retrieval and has numerous applications, such as music generation [1, 2], music recommendation [3] or music similarity estimation [4]. Structure is also strongly linked to other musical elements such as harmony, melody and rhythm [5] and has been leveraged to address other tasks such as beat and downbeat tracking [6] or chord transcription [7].

Most methods that have been proposed for the task of music structure analysis can be categorized according to the structure trait they rely on, namely: *homogeneity*, *nov-*

elty and *repetition* [8]. The homogeneity rule states that musical attributes should be relatively homogeneous inside musical segments or sections. Consequently, transitions from one segment to the next should result in points of important changes in musical features (*i.e.* novelty). The idea of repetition in structure assumes that sections of the same type are rather similar sequences. In other words, musical sections are generally characterized by the degree at which they repeat throughout the entire music piece, which has been the starting point of many algorithms to infer song structures [9–11]. However, both the extent to which two sequences can be considered as repetitions, or how homogeneous a given musical segment is, imply a certain definition of similarity between time instants. Such similarity criteria are usually derived from frame representations based on common audio descriptors such as harmonic and timbral features, or their combinations [8].

A line of work has focused on finding better-suited audio representations so as to make sure that frames from the same musical sections yield similar features and therefore, sharpen transitions between consecutive musical segments. Methods based on contrastive learning have recently been proposed to find such representations [12–15], as they can leverage commonalities from large quantities of music data to learn a distance metric that complies with the aforementioned requirements. Training such models either involves the use of structural annotations [13] or some pre-defined proxies to select frames that should be brought close to one another in the latent space [12, 15]. In the latter case, these heuristics mainly rely on the homogeneity principle and discard the notion of repetition occurring inside a track, preventing them from fully exploiting unlabelled data.

The method introduced in this work aims at bridging the gap between current unsupervised deep metric learning methods for music segmentation and both ideas of homogeneity and repetition that are inherent to musical structure. As in previous work [12, 15], a contrastive learning pipeline using a triplet loss is adopted. However, triplets are mined by seeking repeating sequences inside the input track with respect to various hand-crafted audio features. In a preliminary analysis, a qualitative evaluation of the triplets generated is performed by direct comparison with structural annotations of a manually annotated test dataset. We then measure how these representations impact down-

stream segmentation on two datasets for music structure analysis. Finally, we demonstrate that our approach requires less non-annotated data than previous similar methods. We also give further insight on how the choice of the input features used to mine triplets affects training and its relationship with the music genre that the resulting representations are tested on.

2. RELATED WORK

Numerous methods for music structure analysis rely on measuring similarity between every point of a music recording to retrieve homogeneous segments and transitions between them. Since music is naturally multi-dimensional, many factors such as harmony, timbre or instrumentation can be associated with boundaries between musical sections [16]. Therefore, several strategies have been adopted to capture short-term similar regions, and it has been shown that sharp timbre changes can be a good cue for section transitions [17–19].

However, not all boundaries can be explained solely by such changes in musical features, as the perception of structure is also greatly affected by additional characteristics of a music recording such as parallelism, pauses or musical rules proper to the music genre considered [16]. Therefore, other approaches tend to rely on the repetition principle to characterise the structure of a music piece. For example, early work on music segmentation has attempted to find audio representations to identify repeating elements inside music recordings, such as pitch estimation or polyphonic transcription [10]. Generally, repetition-based methods rely on harmony-related information from the audio, as the instrumentation or other factors are subject to variations between different occurrences of a given musical section [18, 20].

Several algorithms have also been proposed to unify these two types of approaches by recognizing similar regions and repetitions of varying lengths. For example, integrating structural information at different scales into frame representations has led to considerable improvements in the recognition of musical segments [21, 22].

Even though these methods are theoretically well grounded and have proven to be efficient on commonly used datasets, the traditional hand-crafted descriptors they use can fail at accommodating different structure types and music genres. On the other hand, deep learning-based methods are able to extract efficient features from large quantities of data, thus, surpassing traditional audio descriptors [12]. Approaches based on contrastive learning also have the advantage to be easily incorporated into the classical music structure analysis pipeline, by simply replacing the original input features by the deep embeddings they learn from training data. To this end, Wang *et al.* [13] use structural annotations from a labelled training dataset to find positive and negative pairs of frames and a multi-similarity loss function [23]. They additionally employ a mining mechanism to further improve convergence of their model. Using structural annotations allows for explicitly enforcing frames of identical sections to yield similar fea-

tures regardless of their appearance throughout the track. Despite not relying on annotations, the method in this work is similar to theirs, in the sense that it explicitly considers section repetitions inside a music recording.

A similar method proposed by McCallum [12] proceeds in an unsupervised manner with a triplet loss. This time, positive and negative frames are sampled using time proximity as a proxy: frames occurring within a small time interval are more likely to belong to the same musical sections than those separated by a larger amount of time. While this assumption generally holds true, it completely discards the notion of repetition, which can limit the efficacy of the approach. In the present work, this limitation is addressed by using pairwise frame similarity measures as prior information to guide the triplet sampling mechanism. This temporal-based mining method [12] is used as a baseline in this work and referred to as *temporal sampling*.

3. METHOD

The core of the triplet mining method proposed in this work resides in the estimation of a self-similarity matrix, which should reflect as much as possible section label assignment corresponding to structural annotations. This approximation of ideal pairwise frame similarities should yield high values for frames belonging to the same musical section, and low values otherwise. This self-similarity matrix is used as a probability mass function according to which are sampled, for each given frame, positive and negative examples across the whole input track.

3.1 Triplet loss

The method proposed in this work consists in finding triplets of audio feature patches (x_a, x_p, x_n) where x_a is the anchor, x_p is a positive example from the same musical section and x_n the negative example sampled from a different one without using structural annotations. The models are trained using the triplet loss, which for a given triplet $\mathcal{T} = (x_a, x_p, x_n)$ is expressed as:

$$\mathcal{L}(\mathcal{T}) = [d(f(x_a), f(x_p)) - d(f(x_a), f(x_n)) + \delta]_+, \quad (1)$$

where $d(x, y)$ is a pre-defined distance metric, $[\cdot]_+$ denotes the Hinge loss, $\delta > 0$ is the margin parameter, and $f(x)$ is the projection of x into the embedding space by a deep neural network.

3.2 Finding repetitions

The choice of the input features from which frame-wise similarities are extracted greatly influences the final triplet sampling mechanism. As the goal is to jointly detect homogeneous regions and overall repetitions throughout the input track, we employ a combination of timbral and harmonic features as done in previous work [24, 25]. These features are beat-synchronized beforehand, using the algorithm from Korzeniowski *et al.* [26] implemented in the *madmom* package [27]. One way to emphasize repetition is to encode features into time-delay embeddings, so

that pairwise comparisons are performed over short time-windows: given a sequence $X = \{\mathbf{X}_i\}_{i \in \{1, \dots, N\}}$ of feature vectors, the i th time embedding vector $\tilde{\mathbf{X}}_i$ is obtained by stacking the m feature vectors ranging from $i - (m - 1)$ to i :

$$\tilde{\mathbf{X}}_i = \left[\mathbf{X}_i^T \mathbf{X}_{i-1}^T \dots \mathbf{X}_{i-(m-1)}^T \right]^T, \quad (2)$$

where m denotes the embedding dimension, ruling how much of past information is considered. Such transformations have successfully been used for music structure analysis [22], structure-based music similarity [4] and more generally in the field of non-linear time series analysis [28]. The final representation's temporal dimension remains N , as X is first zero-padded before transformation. Then, a self-similarity matrix is built from the obtained sequence of time-lag features such that:

$$M(i, j) = \begin{cases} \exp\left(-\frac{d(\tilde{\mathbf{X}}_i, \tilde{\mathbf{X}}_j)}{b}\right), & \tilde{\mathbf{X}}_j \in \text{NN}_k(\tilde{\mathbf{X}}_i) \\ 0, & \tilde{\mathbf{X}}_j \notin \text{NN}_k(\tilde{\mathbf{X}}_i) \end{cases} \quad (3)$$

where $d(x, y)$ is the euclidean distance, b the bandwidth parameter, $\text{NN}_k(x)$ denotes the k -nearest neighbors of x and $i, j = 1, \dots, N$. The self-similarity matrix M is then filtered with a sigmoid activation, such that:

$$\hat{M}(i, j) = \sigma\left(\frac{M(i, j)}{\max_k M(i, k)}\right), \quad (4)$$

where $i, j = 1, \dots, N$ and the σ function defined as:

$$\sigma(x) = \frac{1}{1 + e^{-\alpha(x-\beta)}}, \quad (5)$$

where $\alpha > 0$ is a parameter ruling the steepness of the curve and $\beta \in [0, 1]$ a threshold above which the components of S are set to values close to 1. This process is applied both using MFCC and chroma features, from which we obtain their respective filtered self-similarity matrices S_M and S_C using Equation (4) (first row of Figure 1). The matrix S is then obtained by linear combination, such that:

$$S = \gamma S_M + (1 - \gamma) S_C, \quad (6)$$

where $\gamma \in [0, 1]$ weights the contributions of each feature type. The matrix S (second row, left column of Figure 1) is row-wise min-max normalized and filtered with the sigmoid function defined in Equation (5), diagonal stripes indicating repeating sequences are enhanced by median filtering similar to the one used by McFee *et al.* [18].

3.3 Imposing segment homogeneity

The obtained pairwise similarity S provides information about the repetitions present inside the input track. However, using it as it is to mine positive (large $S(a, p)$) and negative examples (small $S(a, n)$) would result in many trivial triplets, as positives would be located at exact points of repetitions. Therefore, a dilation operation is applied to the matrix S to enlarge these detected regions of repetition. Similar to the method by Serra *et al.* [22], a two-dimensional Gaussian kernel G of size K is convolved with S :

$$S_p = S * G, \quad (7)$$

Figure 1. Example of the self-similarity approximation process for *The Beatles — Baby's In Black*. Top to bottom, left to right: self-similarity lag-matrices obtained using MFCC (S_M), chroma features (S_C), median filtered combination (S), reference self-similarity matrix (supervised scenario), positive matrix (S_p), negative matrix (S_n), positive (T_p) and negative (T_n) sampling matrices using *temporal sampling* [12]. White dotted lines denote boundary instants.

This has the effect of blurring the regions of S around its diagonal stripes, which approximates the width of the corresponding musical segments in a more uniform manner than directly using the unfiltered matrix S . The size of the kernel K logically impacts the extent to which this dilation is performed. It was found that setting $K = 8$ (beats) provided a good balance between the amount of dilation and its alignment with segment boundaries (third row, left column of Figure 1), as it blurs repetitions over 2 bars when songs follow a 4/4 time signature¹.

¹ Such value might induce a bias towards specific western music genres. This parameter should ideally be adapted to each training track.

3.4 Negative mining

While the matrix S_p guides the selection of positive examples for any frame of the input track, the triplet loss requires to find a third point with a different label, called negative example. In our case, such example should belong to a different musical section, which could be easily solved by searching for the least similar frames from the anchor (*i.e.* using the matrix $S_n = 1 - S_p$ for sampling). However, doing so is likely to result in trivial triplets where the relative difference between $d(f(x_a), f(x_p))$ and $d(f(x_a), f(x_n))$ from Equation (1) might already be larger than the margin δ , thus, yielding small gradients that prevent the network from learning features that are discriminative enough [29]. Instead, we enforce negative examples to be chosen close to the anchor’s location while still avoiding homogeneous regions indicated by the positive matrix S_p . To this end, the negative sampling matrix S_n is obtained by applying an exponential decay to $1 - S_p$ such that:

$$S_n(i, j) = (1 - S_p(i, j))e^{-\lambda \max(\frac{|i-j|}{N}, S_p(i, j))}, \quad (8)$$

where $\lambda > 0$ is a parameter that defines the strength of the smoothing. As a consequence, components near the main diagonal of S_n (third row, right column of Figure 1) receive greater values than those close the opposite edges, thus favoring frames located within consecutive segments of that of the anchor.

The final sampling process works as follows: given an anchor point i_a chosen among the N frames of the input track, the weight attributed to a certain index i_k when sampling the positive example follows the discrete probability distribution defined by the a -th row of S_p , such that $Pr(I = i_k) = S_p(a, k)$. The negative example is chosen in a similar fashion with the matrix S_n , such that $Pr(I = i_k) = S_n(a, k)$.

4. EXPERIMENTAL SETTING

This section details the experiments performed to assess the efficacy of the proposed triplet mining method. First, a preliminary evaluation of the triplets generated is done against structural annotations from a commonly used dataset for music structure analysis. Secondly, we train two separate convolutional neural networks using triplets obtained by *temporal sampling* and those from our method. The obtained embeddings are fed as input to a downstream music segmentation algorithm and performance on both boundary detection and structural grouping is measured. Finally, to gain more insight on the quality of the triplets generated, training is performed on different fractions of the unlabelled training dataset.

4.1 Datasets

Since this work falls under the scope of unsupervised learning, a non annotated external audio collection is used for training. It is composed of 20,000 tracks, spanning various musical genres such as rock, popular, rap, jazz, electronic or classical. These were retrieved from publicly

available playlists and the audio obtained from YOUTUBE. Care has been taken to discard any track from this external collection also present in one of the following testing datasets. Training is separately done on 10%, 50% and 100% of this dataset.

SALAMI: the Structural Annotations for Large Amounts of Music Information (SALAMI) [30] contains 1,359 tracks ranging from classical, jazz, popular to world and live music. For evaluation, we use the *upper* annotations of a subset of 884 songs labelled by two different annotators.

JSD: the Jazz Structure Dataset [31] gathers 340 jazz recordings provided with two-level annotations: the chorus level (a full cycle of the harmonic schema, which is the annotation level used for evaluation) and a solo level, consisting of one more choruses. These annotations follow the common jazz structure schema that includes the introduction of the main melody (theme), followed by alternating solos from the different musicians and a final return towards the main theme at the end of the track.

4.2 Evaluation metrics

Common evaluation metrics for automatic structure analysis are employed throughout our experiments. For boundary detection, we report the F-measure² of the trimmed³ boundary detection hit-rate with a 0.5 and 3-second tolerance windows (HR.5F, HR3F respectively). For structural grouping, we report the F-measure of frame pairwise clustering [21] (PFC), which gives another view on flat segmentation performance in terms of frame-wise section assignment. Additionally, the normalized conditional entropy score (NCE) [33] is also calculated, in order to indicate from a probabilistic perspective the amount of information shared between predicted label distributions and their corresponding reference annotations. In the case where the test dataset has more than one annotator, the best score across annotators is kept, as the goal of the evaluation process is to measure how close to human ground-truth the predicted segmentations are. The average score obtained per metric is reported and the statistical significance is assessed using a paired-sample T-test with $p < 0.05$.

4.3 Implementation details

Input features: All tracks are resampled at 22.05 kHz. We use log-scaled Mel-spectrograms as input to the deep network, with a window and hop size of 2048 and 256 respectively. We compute 60 Mel-band coefficients per frame. Feature patches are composed of 512 frames ($\simeq 5.94s$) and centered at each detected beat location.

Mining parameters: Chroma features are extracted using a minimum frequency of 27.5 Hz over 8 octaves. 20 MFCC coefficients are calculated per frame and the very first one is discarded. Both are calculated with the *librosa*

² All evaluations are done using the *mir_eval* package [32].

³ The first and last boundaries are discarded during evaluation, as they correspond to the beginning and the end of the track and therefore, do not provide any information regarding the system’s performance.

library [34]. The features are encoded into time-delay representations using context values of $m = 16$ and $m = 8$ beats respectively. The parameters α and β of the sigmoid filtering step are set to 60 and 0.85. We give equal weight to each feature by setting the $\gamma = 0.5$ in Equation (6). Finally, the negative matrix S_n is calculated with a smoothing parameter $\lambda = 5$. These parameters were found using simple grid searches and visual inspections of the obtained self-similarity matrices.

Network architecture: The encoder consists of a convolutional neural network composed of 3 convolutional layers, each followed by a max-pooling layer and Elu activation, and two fully-connected layers comprising 128 units with Elu and linear activations respectively. All convolutional layers use a kernel size of size (3, 3) with 32 filters each. The output embeddings are ℓ_2 -normalized before calculating the triplet loss. The models are implemented⁴ with Pytorch 1.7.1 [35]. The SGD optimizer with 10^{-4} weight decay and 0.9 momentum is used, the models are trained for a maximum of 200 epochs, where each batch is composed of 256 triplets obtained from one single track. Similar to previous work [12], the margin parameter δ is set to 0.1 and the embedding dimension to $d = 128$.

Downstream segmentation: For all experiments, the embeddings returned by each model are fed as input to spectral clustering [24], as this algorithm jointly performs both boundary detection and structural grouping in an unsupervised manner and has proven to be efficient in previous studies [13, 14]. This also allows one to compare the influence of each of the tested representations into a single unified framework. The original algorithm takes two distinct beat-synchronized audio features as input (MFCC and CQT). We consider this method as a second baseline which we denote as LSD (Laplacian Structural Decomposition). However in our case, it is directly applied to the self-similarity S_p of each track. When this algorithm is combined with deep representations, we simply replace both input features by the embedding matrix. Finally, because spectral clustering outputs multiple levels of segmentation, only the one maximizing the considered metric is reported (HR.5F and HR3F for boundary detection, PFC and NCE for structural grouping).

5. RESULTS

5.1 Preliminary evaluation

We generate 256 triplets per track contained in the SALAMI dataset and report the proportions of true positives, true negatives and correct triplets in Table 1. For comparison purposes, we also provide a random baseline, where each anchor, positive and negative example is uniformly sampled over the whole track. The sampling method proposed significantly improves the selection of negative examples compared to the *temporal sampling* approach. However, random negative sampling performs better than our approach. This was to be expected, since
