the latter samples negatives over the whole track while our method greatly narrows down the number of probable candidates (see Equation (8)). Conversely, the *temporal sampling* returns a higher proportion of true positives than ours, since these are sampled in a relatively short time window around their respective anchor, thus omitting any section repetition occurring inside the input track. All in all, our approach returns a much higher proportion of correct triplets than either of the comparison strategies while guaranteeing that positive examples are located within the right musical sections and the negative within a relatively short time window around their anchor’s.

Sampling	TP	TN	CT
Random	.401 ± .22	.595 ± .21	.194 ± .06
<i>Temporal</i> [12]	.886 ± .32	.398 ± .49	.325 ± .47
Ours	.800 ± .40	.583 ± .49	.432 ± .50

Table 1. Triplet mining results on *upper* annotation level of SALAMI dataset. TP, TN, CT: proportions of true positives, true negatives and correct triplets respectively. Results highlighted in bold denote statistically significant improvements over *temporal sampling* according to a paired-sample T-test with $p < 0.05$.

5.2 Segmentation and structural grouping

Table 2 shows the performance of our approach against *temporal sampling* on the *upper* annotations of the SALAMI dataset. Regardless of the amount of training data, our method constantly improves both boundary detection and structural grouping in a significant manner. It is also interesting to see that such improvement is already achieved when the proposed method uses only 10% of the training dataset. This corroborates the results from Section 5.1, showing that improving the triplets quality provides a cleaner training signal and makes learning more efficient.

Method (Split)	HR.5F	HR3F	PFC	NCE
LSD	.195	.486	.707	.682
<i>Temp.</i> (10%) [12]	.280	.665	.770	.677
Ours (10%)	.291	.676	.777	.691
<i>Temp.</i> (50%) [12]	.288	.671	.773	.678
Ours (50%)	.296	.682	.778	.690
<i>Temp.</i> (100%) [12]	.284	.670	.773	.678
Ours (100%)	.297	.683	.781	.694

Table 2. Flat segmentation results on SALAMI (*upper* annotations). Results in bold denote statistically significant improvement over *temporal sampling* on same split (denoted as *Temp.*).

From a more qualitative perspective, Figure 2 shows examples of self-similarity matrices derived from the embeddings trained with *temporal sampling* and our method. In the latter case, consecutive musical sections are better discriminated (clearer block structures on the main diagonal). Section repetitions (visible as diagonal stripes and off-diagonal blocks) are more straightforward to recog-

⁴Code: github.com/morgan76/Triplet_Mining

nize, especially those with relatively small durations (sections A, B or D).

Method (Split)	HR.5F	HR3F	PFC	NCE
LSD	.195	.486	.707	.682
Temp. (10%) [12]	.221	.568	.739	.745
Ours (10%)	.219	.586	.744	.749
Temp. (50%) [12]	.243	.586	.763	.766
Ours (50%)	.222	.583	.755	.758
Temp. (100%) [12]	.229	.590	.766	.767
Ours (100%)	.225	.592	.754	.760

Table 3. Flat segmentation results on JSD (*chorus* annotation level). Results in bold denote statistically significant improvement over *temporal sampling* (denoted as *Temp.*) on same split.

Results on the JSD dataset are given in Table 3. Here, the improvements made are not as consistent. However, when using only 10% of the training dataset, the performance of our approach remains within the same range than that of the baseline when trained on larger splits. Compared to the results obtained on SALAMI, the small improvements made here can be associated with the way structure is defined in terms of feature similarity in jazz.

Figure 2. Example of self-similarity matrices for the track SALAMI 1380. Left: encoder trained with *temporal sampling*. Right: encoder trained using the proposed triplet mining method. White dotted lines denote boundary instants.

5.3 Discussion on mining parameters

Impact on triplet selection: The sampling parameters could further be tuned to improve performance. More specifically, the audio descriptors employed at the first stage and their combination could be adapted to the training data in order to better emphasize more specific aspects of the audio. For example, some music genres such as pop music or rock generally rely on the repetition of certain chord progressions [1]. However, introducing a degree of timbral homogeneity allows for differentiating two sections that are semantically similar, such as in the example from Figure 1, ‘refrain’ and ‘refrain-Solo’. Putting more emphasis on timbral features might be better adapted to music genres such as jazz, where structure is highly influenced by changes in soloists. As an example, Figure 3 displays the positive sampling matrices obtained when vary-

ing the γ parameter from Equation (6). It is clear to see that favoring timbral similarity helps better approximating segment transitions and mutual dissimilarities between the successive solos of saxophone, piano and guitar.

Figure 3. Example of positive sampling matrices for *Michael Brecker — Song for Bilbao*. Left: emphasis on timbral content ($\gamma = 0.9$). Right: emphasis on harmonic content ($\gamma = 0.1$). White dotted lines denote boundary instants.

Impact on segmentation: To illustrate how the balance between harmonic and timbral features impacts the final segmentation, the encoder is trained on the 10% and 50% splits of the dataset with $\gamma = 0.9$, thus putting a stronger emphasis on the MFCC-based similarity at the triplet mining stage. All other parameters are kept to their initial values described in Section 4.3. The segmentation results summarized in Table 4 show that the choice of the parameter γ does impact the training process. In this case, putting more weight on timbral information seems to make the representations more sensitive to timbral changes and improves boundary detection (HR3F) in a significant manner compared to *temporal sampling*.

Method (Split)	HR.5F	HR3F	PFC	NCE
Temp. (10%) [12]	.221	.568	.739	.745
Ours (10%, $\gamma = 0.9$)	.223	.585	.743	.750
Temp. (50%) [12]	.243	.586	.763	.766
Ours (50%, $\gamma = 0.9$)	.234	.607	.769	.772

Table 4. Flat segmentation results on JSD (*chorus* annotation level) with emphasis on timbral features ($\gamma = 0.9$). Results in bold denote statistically significant improvement over *temporal sampling* (denoted as *Temp.*) on same split.

6. CONCLUSION

This work introduced a repetition-based triplet mining mechanism to learn efficient audio representations prior to music segmentation, which can significantly improve both boundary detection and structural grouping, while needing less data than previous similar methods. Complementary experiments demonstrate that this sampling process can be further adapted to the final type of segmentation desired by either emphasizing harmonic or timbral information from the input track.

PREDICTING MUSIC HIERARCHIES WITH A GRAPH-BASED NEURAL DECODER

ABSTRACT

This paper describes a data-driven framework to parse musical sequences into dependency trees, which are hierarchical structures used in music cognition research and music analysis. The parsing involves two steps. First, the input sequence is passed through a transformer encoder to enrich it with contextual information. Then, a classifier filters the graph of all possible dependency arcs to produce the dependency tree. One major benefit of this system is that it can be easily integrated into modern deep-learning pipelines. Moreover, since it does not rely on any particular symbolic grammar, it can consider multiple musical features simultaneously, make use of sequential context information, and produce partial results for noisy inputs. We test our approach on two datasets of musical trees – time-span trees of monophonic note sequences and harmonic trees of jazz chord sequences – and show that our approach outperforms previous methods.¹

1. INTRODUCTION

Tree-like representations are a powerful tool in many approaches to music analysis, such as Schenkerian Theory and the Generative Theory of Tonal Music (GTTM). In the Music Information Retrieval (MIR) literature, we find tree models of melodies [1–4], chord progressions [5–8], and rhythm [9–13]. Parallels between aspects of music and language are often drawn, as these have similar hierarchical properties and their underlying cognitive mechanisms could be closely related [14]. However, with a few exceptions, such as instrument grouping and metrical information in scores, music is generally encoded sequentially without explicit information about its hierarchical organisation. The task of creating such hierarchies from a sequential representation is called *parsing* and it is an active object of study in the MIR community [3, 7, 11, 15].

Current parsing approaches are based on *generative grammars*, typically context-free-grammars (CFG) or similar related mechanisms, which can be fundamentally seen as a set of expansion rules generating a tree from the top (the root) to the elements that compose the sequence (the leaves). Grammar rules can be enriched with a probability model that permits the ranking of different parses by plausibility. When a grammar is available, parsing can be achieved with grammar-based parsing algorithms, typically variants of the Cocke–Younger–Kasami (CYK) algorithm [16]. While the grammar rules are most often built by hand, by relying on musicologists’ knowledge, the probabilities can be learnt from data if sufficient amounts of musical sequences with ground-truth tree annotations are available. The grammar approach has the strong advantage of leveraging an interpretable and cognitively plausible mechanism. Still, it has the following limitations: it is hard to achieve robustness against noisy data, which can cause a complete failure with no output in case the sequence cannot be produced by the grammar rules; it requires a high degree of domain knowledge; it is challenging to account for multiple musical dimensions in a single grammar rule; and parsing is usually so slow for long sequences that heavy pruning is necessary (CYK-parsing complexity is cubic in the length of the sequence, parallelisation does not help much, and there is no active research in developing dedicated hardware).

Inspired by recent research in the field of natural language processing (NLP), we propose a novel, *grammar-less* approach that requires little domain knowledge (only for the feature extraction phase), can easily consider multiple musical features and sequential information, produces partial results for noisy input, and is potentially scalable to longer sequences and larger datasets (since its components are proven to succeed in such scenarios). Our system works by predicting *dependency trees* which consist of dependency arcs between the input sequence elements. Such a structure can be used as-is or later be converted into *constituent trees* which are typically used to model music hierarchies (see Figure 1). The probability of each dependency arc is predicted in parallel (i.e., without considering other dependencies during prediction) by leveraging the rich contextual information produced by a transformer encoding of the input sequence. This set of probabilities is then run through a post-processing algorithm to ensure a valid tree structure (i.e., no cycles of dependency arcs).

We pair our Music Dependency Parser MuDeP with a

Figure 1. The tree harmonic analysis of the A Section of “Take the A Train” in three different representations. Top: dependency tree, Left: GTTM-style constituent tree. Right: CFG-style constituent tree.

procedure that enables its usage from constituent trees, and test it on two tree datasets: the time-span treebank from the GTTM database [17], which expresses subordinate relations between notes in monophonic melodies; and the Jazz Harmony Treebank (JHT), a set of harmonic analyses for chord sequences [18]. We compare the results of our system with the best-performing available approaches and obtain new state-of-the-art results.

2. RELATED WORK

Music Trees and Music Parsing. Trees of musical sequences have traditionally been notated as constituent trees [1–3, 5–13, 19], with few exceptions, such as the usage of a dependency-based evaluation metric [20], and the computation of pairwise voice dependencies [4, 21].

A system for parsing jazz chord sequences into harmonic analyses has been proposed by Harasim et al. [7] and later evaluated on a larger dataset [20]. We compare our results to this approach below. Automatic grammar-based parsing of time-span GTTM trees has been attempted by Hamanaka et al. [22, 23] and Nakamura et al. [2]. The latter obtained comparable results with an approach that doesn’t require manual parameter tuning, and we compare our system with it. More recently, deep-learning-based approaches were also proposed [3, 24, 25] but the first two focus only on GTTM metrical and grouping information, and the latter focus mainly on evaluating the usage of time-span trees for melodic morphing and we could not reproduce their results. **Natural Language Parsing.** Our model architecture is inspired by the graph-based dependency parser of Dozat and Manning [26, 27]. This model, extended with second-order dependency predictions [28] and pretrained language models [29], is still the state of the art for NLP sentence parsing [30]. Still, we make some substantial changes: the embedding layer is adapted to work from musical input, the encoder is a transformer instead of an LSTM, and, instead of the bilinear layer for arc prediction, we use a linear layer. All these choices are motivated by ablation studies.

3. TREE FORMATS FOR MUSIC ANALYSES

In this section, we detail the types of tree used in this paper, highlight their differences, and propose algorithms to translate between them.

Figure 2. A dependency tree with double-sided dependencies (left). It corresponds to two possible constituent trees (middle and right).

3.1 Constituent vs Dependency Trees

A tree can be defined recursively as a node with an arbitrary number (including 0) of children that are also trees. The node that is not a child of another node in the tree is called *root*, the nodes that do not have children are called *leaves*, and the remaining nodes are called *internal nodes*. When a tree is used to model some relations of the elements of a sequence there are two possible configurations: *dependency trees*, where each node (leaf, internal, and root) represents one and only one element of the sequence; and *constituent trees* where all elements of the sequence are represented in the leaves, and root and internal nodes represent nested groupings of such elements.

Among the constituent trees there exist different representations. The bottom part of Figure 1 shows the two kinds we consider in this paper: the one introduced by Lerdahl and Jackendoff [31] in their Generative Theory of Tonal Music (GTTM), and the one built from the Context-Free Grammar (CFG) of jazz harmony by Harasim et al. [7]. The two representations convey almost the same information: they are both binary trees (i.e., every node has either 0 or 2 children), the internal nodes are denoted by line intersections on the first, and by explicit labels on the second; they both specify an order of importance among the children (i.e., the choice of a *primary* and *secondary* child) by the straight line continuation, or by labelling the node with the label of the primary child. However, this latter mechanism cannot differentiate between primary and secondary when both children have the same label; therefore, the GTTM representation is slightly more informative.

Our approach does not directly treat constituent trees but considers dependency trees. Each child in such a tree is called *dependent*, and the node of which it is a child is called the *head*. Dependency trees can represent the same information as the binary constituent trees described above. Indeed, a dependent-head arc is equivalent to a head-labelled constituent node with two children: the primary is again the head, and the secondary is the dependent. There is only one ambiguity: the dependency tree does not encode a splitting order in the case of *double-sided dependencies*, a configuration in which one head has dependents on both sides. This makes the dependency-to-constituent transformation not unique (see Figure 2). This configuration is never present in our datasets (i.e., the root is always the left-most or right-most element in the sequence) thus we don’t handle it. For more general datasets, one could add a binary classifier that predicts the splitting order.

The dependency trees built from the constituent trees

are *projective*, i.e., for all their arcs $x_{\text{dep}} \rightarrow x_{\text{head}}$, there is a path from the head to every element x that lies between the head and the dependent in the sentence [32]. This means that there are no “crossing arcs”, e.g., $x_1 \rightarrow x_3, x_2 \rightarrow x_4$.

Before proceeding with the paper, we introduce some notation we will use in the next sections. We denote the sequence that constitutes the input of our system as $x = [x_1, \dots, x_\lambda]$, where λ is the sequence’s length. We represent the dependency tree over x as the set of dependent-head² indices that corresponds to each arc $x_{\text{dep}} \rightarrow x_{\text{head}}$:

$$y = \{(\text{dep}, \text{head}) \mid \text{dep}, \text{head} \in [1, \dots, \lambda]\} \quad (1)$$

3.2 Tree Conversion Algorithms

Since the ground-truth annotations in our datasets are constituent trees, we translate them into dependency trees for training. We also translate tree predictions back to constituent trees to run constituent-based evaluation metrics, and when we are interested in using such a representation as input for further applications. We assume our constituent trees to be binary trees and not contain double-sided dependencies. For simplicity, we consider CFG-style constituent trees with labels in their internal nodes.

3.2.1 Dependency to Constituent Tree

Existing NLP implementations of this transformation are unnecessarily complicated for our scenario because they consider compound node labels and double-sided dependencies [33]. Instead, we present a recursive top-down algorithm which yields a unique constituent solution for every single-sided dependency tree.

The algorithm takes a fully formed dependency tree and starts with the root of the (to-be-built) constituent tree. At each step, it removes one dependency and adds two new constituent nodes. The recursive function takes as input a dependency tree node and a constituent tree node, both labelled with the same sequence element. The constituent node gets assigned two children: the primary is labelled with the element of the input nodes, and the secondary is labelled with the dependent that is further away in the sequence. The choice of which is the left and the right child respects their label position in the sequence. The considered dependency is removed from the tree and the recursive function is called two times, once for each constituent child (with the corresponding dependency node). The process stops when the dependency tree node has no dependents.

3.2.2 Constituent to Dependency Tree

This algorithm was used in the literature (e.g., [18]). It starts from a fully formed constituent tree and a dependency tree without any dependency arcs, consisting only of the nodes labelled with sequence elements. The algorithm groups all internal tree nodes with their primary child (which all have the same label) and uses all secondary child relations originating from each group to create dependency arcs between the group label and the secondary child label.

² We indicate dependency arcs as arrows pointing in the direction of the head. Note that in other (NLP) papers, the opposite convention is used.

4. PARSING TECHNIQUE

Our goal is to predict a dependency tree y for a given musical sequence x . Our pipeline consists of three steps: feature extraction from x ; prediction of dependency relations; and postprocessing to ensure that the output is a valid tree structure. In the training phase, the output (before postprocessing) is compared with the ground truth dependency tree and a loss is computed to update the model parameters via backpropagation.

4.1 Feature Extraction

For each input element, $x_i \in x$, we produce three groups of features. The first is a “static” description of the element (i.e., without any temporal information), the second encodes the element’s duration, and the third encodes the element’s metrical position, i.e., its position in the measure relative to the hierarchy induced by the time signature. The static description is built differently for chords and notes, while the other two are independent of the input type. Note that, due to our model architecture (see next section), we need categorical features and it is not primarily important to keep their number small or to have them ordered.

For note sequences, the *static description* of each element is a single integer corresponding to either the MIDI pitch of the element in $[0, \dots, 127]$ if it is a note or with the value 128 if the element is a rest. For chord sequences, we use three integers. The first in $[0, \dots, 11]$ encodes the pitch-class of the chord root. The second in $[0, \dots, 5]$ specifies the basic form of the chord among major, minor, augmented, half-diminished, diminished, and suspended (sus). The last in $[0, 1, 2]$ denotes a chord extension among 6, minor 7, or major 7. The chord labels were simplified by the author of the dataset to only include these extensions, but in a more general scenario, a larger set of integers could be used. The chord sequences do not contain rests.

We represent the *durations of the elements* with discrete values normalised by the duration of the measure. We pre-collect the list of all durations occurring in the dataset and encode each element’s duration as an index on that list. For the GTTM dataset, this would be an integer in $[0, \dots, 44]$, while for the JHB dataset, it is an integer in $[0, \dots, 5]$. The number of possibilities is very different, since the temporal position of chords follows much simpler rules, mostly occurring only at the beginning or in the middle of a bar for simple time signatures and at three bar positions for compound time signatures. For tied notes, we consider a single note with the total duration, and notes can last more than one measure. This is different from the annotations in the JHT in which each measure opens a new chord symbol, even if the same chord is repeated in consecutive measures.

To represent the *metrical position*, we use an inverse measure of metrical strength, encoded with a single integer in $[0, \dots, 5]$. This integer is computed as a function of the normalised temporal position in the measure $t \in [0, 1[$, and the time signature numerator. Each time-signature numerator is associated with a template of metrical divisions m , as proposed by Foscarin [10] and here extended to more time signatures. For example, a time signature with a nu-

Figure 3. Left: metrical divisions m for different time signature numerators. Right: visualisation of metrical divisions for a measure with time signature 12/8.

merator 12 (e.g., 12/8 or 12/4) will have metrical divisions $m = [1, 2, 2, 3, 2]$, i.e., the whole measure at level 0 is divided into two parts at level 1, each resulting part is divided in 2 at level 2, then 3 at level 3, and 2 at level 4. Table 3 reports metrical divisions for all numerators we consider.

Each level l in the metrical division defines a temporal grid with step $\delta_l = 1 / \prod_{i=0}^l m_i$, and the *inverse metrical strength* is defined as the lowest level for which the note position falls on the temporal grid, $\min_l(l \mid t/\delta_l \in \mathbb{N})$. For example, a time signature 6/8 defines grids with steps $[1, \frac{1}{2}, \frac{1}{6}, \frac{1}{12}, \frac{1}{24}]$, and the notes of the measure $|\text{♩} \text{♩} \text{♩}|$ will have normalised temporal position $[0, \frac{2}{6}, \frac{1}{2}]$ and inverse metrical strength $[0, 2, 1]$. If the note doesn't align with any temporal grid, then its inverse metrical strength is the maximum, 5 in our settings. Using metrical strength as input to our system may seem overly complicated. However, given the small size of our datasets and the high variety of time signatures, we need a mechanism to encode metrical information generalisable across different time signatures. It is to be expected that with a larger dataset size, this feature could be discarded, as the model could learn similar information from the list of notes with duration.

The feature extraction process lets us build the input matrix $\mathcal{X} \in \mathbb{N}^{\lambda \times \phi}$ where λ is the sequence length, and ϕ is the number of features for each element: 3 for the GTTM dataset, and 5 for the JHT dataset. Before moving on, it has to be noted that there exist other more general ways of transforming symbolic music into convenient inputs for deep learning models, notably the tokenisation techniques, e.g., [34, 35] inspired by NLP research. However, given the small dimension of our dataset and the fact that our melodies are strictly monophonic, we prefer to use a more compact, ad-hoc input representation. Our parsing framework remains general and usable with other techniques.

4.2 Model

Our model consists of two parts: an encoder and an arc predictor (see Figure 4). The goal of the encoder is to enrich the input features \mathcal{X} with contextual information. The arc predictor uses the enriched sequence features to predict whether each possible pair of elements in the input sequence should be connected by a dependency arc.

The first part of the encoder is an embedding layer, a learnable look-up table which maps our collection of categorical features (each integer) to points in a continuous multidimensional space. Specifically, we use ϕ embedding

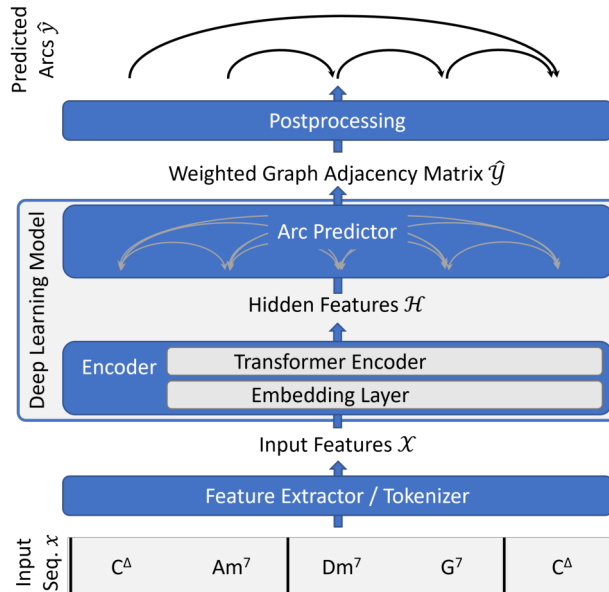

Figure 4. Architecture of our model. The input displayed is an example of a chord sequence, but the same architecture is used for note sequences.

layers (one for each input feature), which work independently, and map all values that the feature can have to a vector of a fixed embedding dimension. All vectors are then summed together to obtain a unique representation while keeping the input size small (see [36] for an explanation of why summing is better than concatenating). After the embedding layer, we have the encoder part of a transformer [37] with relative position representations [38]. It outputs a matrix with the same number of rows as the input matrix \mathcal{X} (one for each sequence element) but with a (possibly) different number of hidden-feature columns h . Onto this, we concatenate a new learnable single row that acts as the head of the root node. The result is a new matrix $\mathcal{H} \in \mathbb{Q}^{(\lambda+1) \times h}$.

The arc predictor part of our model is a multilayer perceptron (MLP) that performs the binary classification task of deciding whether each pair $(x_{\text{head}}, x_{\text{dep}})$ in the Cartesian product of the input elements, i.e., $\{(\text{head}, \text{dep}) \mid \forall \text{head}, \text{dep} \in [1, \dots, \lambda]\}$, should be connected by a dependency arc. Depending on the input representation and the specific task we are targeting, there may be some pairs that are not connectable by a dependency arc, for example, pairs where head = dep. For the GTTM input, pairs for which at least one element is a rest are also not connectable. Therefore, the binary classification is performed only on a subset of all pairs Λ that we call *potential arcs*. For every potential arc $(x_{\text{dep}}, x_{\text{head}})$, we predict the probability $\hat{y}_{\text{dep}, \text{head}}$ of a dependency arc by concatenating the two rows of \mathcal{H} that correspond to the head's and the dependent's index into a single vector of length $2h$ and giving it as input to the MLP. We concatenate the two inputs instead of summing or multiplying them because our arcs are directed, so we need to preserve the order when aggregating the two embeddings. Moreover, despite the bilinear layer being a major selling

point of Dozat’s paper [26], we find that the concatenation approach yields better results. We can collect the output for all potential arcs into a *weighted graph-adjacency matrix* \hat{Y} , which is a $\lambda \times \lambda$ matrix with entries $\hat{y}_{\text{head,dep}}$ at the corresponding indices. We assign a probability 0 to the matrix entries that correspond to arcs $\notin \Lambda$.

4.3 Training Loss

In the training phase, we use the sum of the binary-cross-entropy (BCE) loss and the (multiclass) cross-entropy (CE) loss. The BCE loss is computed independently for each potential arc and measures the difference between the ground-truth label (0 or 1) and the predicted probability. We also use the CE loss because our problem can be framed as a multiclass classification problem where for each element we predict his head among $\lambda + 1$ possibilities (each sequence element plus a dummy element for the root and rests elements). The CE loss is therefore applied column-wise to the adjacency matrix \hat{Y} predicted by our model.

In NLP, the BCE loss was used by [27] while the CE loss is used more generally, for example, by [26, 39]. We experimentally found that the sum of the two losses yields the best results.

4.4 Postprocessing

Since the prediction of our model is made independently for each potential arc, simply taking the row-wise maximum of the weighted adjacency matrix to select which head to assign to each element of the sequence could produce dependency cycles and, therefore, not yield a tree structure. We use a maximum-spanning-tree algorithm to find the tree over \hat{Y} with the highest weight. Since our dependency trees are projective, we use the Eisner algorithm [40] which solves this problem using bottom-up dynamic programming with a time complexity of $O(\lambda^3)$. For applications involving non-projective trees other post-processing approaches such as Chu-Liu/Edmonds [41, 42] ($O(\lambda^2)$) are implemented in our framework.

5. EXPERIMENTS

Below, we describe the datasets, evaluation metrics, and experimental settings for the two kinds of trees we consider.

5.1 Datasets and preprocessing

We obtain the melodic time-span trees from the GTTM database [17], which contains MusicXML encodings of monophonic scores and a dedicated XML-based encoding of the constituent time-span trees (among other trees that we don’t consider in this paper). We extract the note features with the Python library Partitura [43]. Some pieces have two different trees, and we keep only the first. We also discard 4 pieces that we could not import due to inconsistencies in the XML file encoding. In total, we have 296 melodies of lengths between 10 and 127 (notes + rests). For training, we augment the dataset by considering all transpositions between one octave higher and one octave lower.

We obtain the chord analyses from the Jazz Harmony Treebank (JHT) [9], which encodes both chord labels and harmonic analyses as constituent trees, in JSON format. As discussed in Section 3 this format does not distinguish between the primary and the secondary child when both have the same chord label. In this case, we assume by default that the right is the primary. The dataset contains two kinds of trees: open and complete constituents. We use the former for comparison reasons since the results are reported only for those [20]. In total, we have 150 sequences of lengths between 11 and 38 chords. For training, we augment the dataset by considering all 12 possible transpositions of the chord roots.

5.2 Evaluation metrics

The papers we compare use different metrics, and we implement all of them. The work of Harasim [20] uses two metrics, one more relevant for dependency trees and the other for constituent trees. The first is the *arc accuracy*, i.e., the normalised cardinality of the intersection between the set of predicted arcs and the ground truth arcs. The second is the *span accuracy*, computed as the normalised cardinality of the intersection between all the spans of the predicted constituent tree (i.e., the pair of the leftmost and rightmost leaf that is part of the subtree rooted at any non-leaf node) and the spans of the ground truth tree (see [20] for a more detailed explanation). Nakamura et al. [2] use the *node accuracy* metric, i.e., the normalised cardinality of the intersection between nodes in the predicted and ground truth trees, where two nodes are considered equal if the labels of the parent and children (or a dummy label if the node have no parent or children) are equal.

We also report another metric, the *head accuracy*, computed as the multiclass classification accuracy on the indices of the predicted heads, ordered by their dependent. For example for the dependency tree of Figure 1, this would correspond to the accuracy computed on the sequence [4, 2, 3, 4, -1], where -1 indicates the root (which has no head). This is similar to the arc accuracy but enforces the presence of a dependency head for each sequence element (which may not be the case for a generic system), and gives more weight to the correct root prediction. It is also faster to compute and commonly used in NLP, so we include it to set a metric for future research. Note that all metrics presented above don’t consider the nodes corresponding to rests, since they are only part of the input sequence, but not part of the tree.

5.3 Results

For our experiments, we set the hyperparameters of our encoder to an embedding size of 96, and 2 transformer layers of hidden size 64. The arc predictor (MLP) has 2 linear layers with the same hidden size. We use the GeLU activation [44] and the AdamW optimiser [45], with a learning rate of 0.0004 and weight decay of 0.05. We train with learning rate warm-up [46] of 50 steps and cosine annealing to limit the problem of high variance in the initial and final stages of training. The latter was particularly important

Figure 5. Boxplots of three accuracy metrics (higher is better) computed with leave-one-out cross-validation and their average. For Nakamura et al. [2], we report the average from their paper, so there is no deviation information.

since we did not use a validation set to perform early stopping due to the small size of our datasets. We train for 60 and 20 epochs for the JHT and GTTM datasets, respectively, since the latter is bigger and the data augmentation yields twice as many pieces in total). The training time is roughly the same, around 1 hour on a GPU RTX 1080.

We compare the results of our MuDeP on the JHT with Harasim [20] and on the GTTM with Nakamura et al. [2]. We use leave-one-out cross-validation, i.e., for a dataset with N pieces, we run our system N times, by training on $N - 1$ pieces and evaluating with the remaining one. As shown in Figure 5, MuDeP outperforms previous methods.

By comparing the head accuracy between JHT and GTTM (79.2% vs 57.9%), it is clear that time-span prediction is a much harder problem than the chord analysis problem, despite the dataset being bigger. Another interesting result is that the span accuracy is lower than head accuracy for the JHT dataset (63.1%), but higher for the GTTM (64.8%). Apparently, the main problem for JHT is to select which two chords to connect, but the arc direction (i.e., which is the head and which is the dependent) is almost always correctly inferred; conversely, for the GTTM dataset, the system often connects the correct notes, but in the wrong direction. And this type of misprediction is punished in the head accuracy, but not in the span accuracy.

The full piece-wise statistics on all metrics, a graphical rendering of all our predicted trees, and the qualitative evaluation of some examples are available in our repository.

5.4 Ablation study

We report the difference in head accuracy averaged over 10 runs with 90/10 random train/test split for the JHT dataset. Regarding the loss, sole usage of the (multiclass) CE loss reduced the accuracy by 0.3%, and only using the binary CE loss reduced the accuracy by 4.1%. The use of a bilinear layer in the decoder reduced the accuracy by 1.2%. The absence of post-processing did not reduce the accuracy (when the network is fully trained, otherwise the reduction is very evident). This is promising but it does not automatically

implies that the network is producing correctly formed trees since dependency loops could still be present in the output. There are also cases when the postprocessing is reducing the accuracy, by incorrectly deciding which arc to remove in a dependency loop.

6. CONCLUSION AND FUTURE WORK

We presented MuDeP, a system for the dependency parsing of music sequences, and a procedure to make it applicable to constituent trees. MuDeP improves upon previous methods, by incorporating the ability to consider multiple musical features simultaneously, taking advantage of sequential context, and handling noisy inputs robustly. Moreover, since it is based on widely researched deep learning components, it has the potential to scale to large datasets and longer sequences. The bottleneck for such scalability is the post-processing algorithm with cubic complexity. Two solutions exist to this problem: if one is interested in non-projective trees, algorithms with a square complexity are available. Apart from that, our system is already having good accuracy without the postprocessing phase, as highlighted in the ablation study. Therefore, a faster heuristic may suffice to correct the few problematic dependencies without decreasing the performance.

Since our deep learning model is a black box, it is notably complicated to find a human-understandable explanation of its functioning. Although work in this direction exists [47, 48], it is still very limited [49]. Therefore, our model is mainly intended for scenarios in which one is only interested in obtaining the parsing trees, for example, to use them as input for another MIR task. Conversely, this paper might have limited utility if one’s goal is to model music understanding and interpretation by humans. Grammar-based models are much more suitable for this goal, although there is a (somewhat speculative) possibility that the dependency-arc probabilities in our approach relate to first-guess heuristics.

As research on the deep learning components we use is rapidly evolving, any new discovery is likely to benefit our system. Self-supervised pretraining on larger datasets of monophonic music or chord sequences, for example by predicting next or masked tokens, could also improve the performance, as already proved for language parsing. While the goal of this paper was to present a general framework, we can also think about several domain-specific improvements, for example, training the GTTM time-span parser with a multi-target approach to predict at the same time the metrical, time-span, and prolongation structure. We hope that this work will motivate the development of more datasets of hierarchical music analyses, including datasets of dependency trees, which may be a valid alternative to constituent structures, and even open up more possibilities due to the missing projectivity constraints. Finally, we intend to explore in future research how the knowledge encoded in our model could be reused to guide other tasks, for example, automatic chord recognition from audio files.

STABILIZING TRAINING WITH SOFT DYNAMIC TIME WARPING: A CASE STUDY FOR PITCH CLASS ESTIMATION WITH WEAKLY ALIGNED TARGETS

Johannes Zeitler Simon Deniffel Michael Krause Meinard Müller
International Audio Laboratories Erlangen, Germany

{johannes.zeitler, michael.krause, meinard.mueller}@audiolabs-erlangen.de

ABSTRACT

Soft dynamic time warping (SDTW) is a differentiable loss function that allows for training neural networks from weakly aligned data. Typically, SDTW is used to iteratively compute and refine soft alignments that compensate for temporal deviations between the training data and its weakly annotated targets. One major problem is that a mismatch between the estimated soft alignments and the reference alignments in the early training stage leads to incorrect parameter updates, making the overall training procedure unstable. In this paper, we investigate such stability issues by considering the task of pitch class estimation from music recordings as an illustrative case study. In particular, we introduce and discuss three conceptually different strategies (a hyperparameter scheduling, a diagonal prior, and a sequence unfolding strategy) with the objective of stabilizing intermediate soft alignment results. Finally, we report on experiments that demonstrate the effectiveness of the strategies and discuss efficiency and implementation issues.

1. INTRODUCTION AND RELATED WORK

Deep neural networks (DNNs) have been commonly used in many music information retrieval (MIR) tasks, such as music transcription [1], or pitch class estimation (PCE) [2, 3]. The latter provides a widely-used feature representation for various subsequent processing pipelines, e.g., audio thumbnailing [4], or chord recognition [3]. Deep learning-based feature extractors yield the highest prediction accuracy when trained on data from the same distribution, which is, however, often not readily available. Thus, one major challenge is the acquisition of a sufficient amount of correctly labeled training data. In classical music, it is often difficult to automatically annotate strongly aligned targets (short: *strong* targets), i.e., with frame-wise target labels, due to changes of tempo. On the other hand, weakly aligned targets (short: *weak* targets) only globally

Figure 1: Deviation of strong reference alignments (dashed green) and soft alignments (red) and stabilizing strategies. (a) Alignment mismatch of standard SDTW. Stabilizing alignments with (b) hyperparameter scheduling and (c) diagonal prior.

correspond to the input without containing frame-wise local alignments [5,6]. These weak targets are relatively easy to obtain, e.g., by only annotating start and end of an audio segment and deriving targets from the musical score. In our definition of weak targets, the order of the target vectors is correct, but their duration is unknown. Using weak targets in DNN training requires a loss function that aligns network predictions with the corresponding weak targets.

In classification tasks, one widely used technique for training DNNs with weakly aligned targets is the connectionist temporal classification (CTC) loss [7], which aligns network predictions with a sequence of discrete labels. Despite being extendable to multi-label problems such as multi-pitch estimation (MPE) [8], CTC remains limited to discrete targets and is algorithmically complex.

In contrast to CTC, dynamic time warping (DTW) can be used to measure similarity between two real-valued sequences and has been successfully applied in, e.g., music

synchronization and structure analysis [9]. Recently, differentiable approximations of the minimum function [10–12] have been included in DTW, enabling the usage of the DTW principle in gradient-based optimization algorithms. The algorithm proposed in [10], soft dynamic time warping (SDTW), uses so-called *soft alignments* to compute a differentiable cost measure between sequences of different length. In [13], SDTW is used in the context of performance-score synchronization and [6] employed SDTW as a loss function to train DNNs for MPE with weakly aligned pitch annotations. Experiments in [6] indicated training instabilities with SDTW when the sequence lengths of inputs and targets are significantly different. This poses a severe problem in many MIR tasks, where sequences of input audio are typically very long, while weakly labeled targets, i.e., without note durations, are significantly shorter.

In this paper, we investigate the cause of training instabilities under the SDTW loss and show that it is due to a mismatch between the estimated soft alignment and the reference alignment (see Figure 1a) in the early stages of training. This mismatch causes incorrect parameter updates and the training may diverge. Therefore, we introduce and investigate strategies to decrease this alignment error to stabilize training. In particular, we analyze a hyperparameter scheduling strategy to yield smooth alignments in the early training phase (see Figure 1b) as well as the strategy of adding a diagonal prior to the SDTW cost matrix to initially favour diagonal alignments (see Figure 1c). Furthermore, we investigate a sequence unfolding approach, where we uniformly stretch the weak target sequence to the length of the input sequence as proposed in [6]. We choose DNN-based PCE as an exemplary task to study the training process of standard SDTW and the impact of our stabilizing strategies. We demonstrate that the hyperparameter scheduling and the diagonal prior strategies reliably reduce label mismatch in the early training stage and therefore lead to successful trainings. In addition, these two strategies are computationally efficient and require only small modifications to the standard SDTW algorithm.

The remainder of this article is structured as follows. First, in Section 2, we discuss the SDTW loss function and define the concept of soft alignments. Next, in Section 3, we introduce three conceptually different strategies for stabilizing DNN training under SDTW loss. After describing the experimental setup in Section 4, we evaluate cause and effect of training problems with SDTW in Section 5, along with the impact of our stabilizing strategies. Finally, we conclude with Section 6 and give an outlook to potential areas of future research regarding SDTW-based training in MIR.

2. INTRODUCTION TO SDTW

In this section, we introduce SDTW as a loss function in a DNN training framework and define the concept of soft alignments, closely following [10, 14].

2.1 Definition

Let $X = \{\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_{N-1}\}$ denote a sequence of DNN predictions, $Y = \{\mathbf{y}_0, \mathbf{y}_1, \dots, \mathbf{y}_{M-1}\}$ denote a sequence of weak targets and $Y^S = \{\mathbf{y}_0^S, \mathbf{y}_1^S, \dots, \mathbf{y}_{N-1}^S\}$ denote a sequence of strong targets, where $\mathbf{x}_n, \mathbf{y}_m, \mathbf{y}_n^S \in \mathbb{R}^D$ for $n \in \{0, 1, \dots, N-1\}$ and $m \in \{0, 1, \dots, M-1\}$. Without loss of generality, we assume $N \geq M$.

Using the mean squared error (MSE) as a local cost function, the elements of the cost matrix $\mathbf{C} := \mathbf{C}_{X,Y} \in \mathbb{R}^{N \times M}$ are computed as

$$\mathbf{C}_{X,Y}(n, m) = \|\mathbf{x}_n - \mathbf{y}_m\|_2^2. \quad (1)$$

We next define binary alignment matrices $\mathbf{A} \in \{0, 1\}^{N \times M}$ which align two sequences of length N and M . Each matrix \mathbf{A} encodes an alignment via a path of ones from cell $(0, 0)$ to $(N-1, M-1)$ using only vertical, horizontal, and diagonal unit steps [10]. All cells not corresponding to the alignment are set to zero. The set of all binary alignment matrices for sequences of length N and M is denoted $\mathcal{A}_{N,M}$. Using a differentiable approximation of the minimum function

$$\text{softmin}^\gamma(\mathcal{S}) = -\gamma \log \sum_{s \in \mathcal{S}} \exp(-s/\gamma) \quad (2)$$

for a given finite set $\mathcal{S} \subset \mathbb{R}$ and a hyperparameter $\gamma \in \mathbb{R}$, the SDTW cost is given by

$$\text{SDTW}_C^\gamma = \text{softmin}^\gamma(\{\langle \mathbf{A}, \mathbf{C} \rangle, \mathbf{A} \in \mathcal{A}_{N,M}\}) \quad (3)$$

and can be computed efficiently via dynamic programming [10]. The inner product $\langle \mathbf{A}, \mathbf{C} \rangle$ is the sum of all elements of \mathbf{C} along the alignment given by \mathbf{A} .

2.2 Soft Alignments

The expectation over all alignments \mathbf{A} for a cost matrix \mathbf{C} is captured by the soft alignment matrix [14]

$$\mathbf{E}_C^\gamma = \sum_{\mathbf{A} \in \mathcal{A}_{N,M}} p_{\mathbf{A},\mathbf{C}}^\gamma \mathbf{A} \in \mathbb{R}^{N \times M}, \quad (4)$$

where the probability of an alignment is defined as

$$p_{\mathbf{A},\mathbf{C}}^\gamma = \frac{\exp(-\langle \mathbf{A}, \mathbf{C} \rangle / \gamma)}{\sum_{\mathbf{A}' \in \mathcal{A}_{N,M}} \exp(-\langle \mathbf{A}', \mathbf{C} \rangle / \gamma)}. \quad (5)$$

The soft alignment matrix is of particular interest as it is the the gradient of the SDTW cost w.r.t. the local cost matrix

$$\nabla_{\mathbf{C}} \text{SDTW}_C^\gamma = \mathbf{E}_C^\gamma \quad (6)$$

and is computed during the backward pass of an SDTW training step with a dynamic programming algorithm [10, 14]. In contrast to the *binary* alignments \mathbf{A} , the entries of the soft alignment matrix $\mathbf{E}_C^\gamma(n, m)$ can be interpreted as the *probability* of an alignment path going through cell (n, m) . Only if this soft alignment assigns probability mass to the correct alignments (n, m) , the local cost terms (1) between the correct pairs of predictions \mathbf{x}_n and

targets \mathbf{y}_m constitute the overall SDTW cost and the DNN parameters can be successfully trained.

The hyperparameter γ , also termed temperature, controls the smoothness of the softmin function (2). Larger values of γ lead to smooth minima in (3), i.e., with contributions of multiple alignments \mathbf{A} , and therefore a “blurry” soft alignment matrix \mathbf{E}_C^γ (see Figure 1b). On the other hand, small values of γ promote “sharp” soft alignments \mathbf{E}_C^γ with fewer non-zero entries (see Figure 1a), as (2) converges to the hard minimum function in the limit $\gamma \rightarrow 0$ and a single binary alignment \mathbf{A} becomes dominant in (3) and (4).

3. STABILIZING TRAINING WITH SDTW

In this section, we introduce three strategies for stabilizing SDTW-based training: hyperparameter scheduling, diagonal prior, and sequence unfolding.

3.1 Hyperparameter Scheduling

As described in Section 2, the softmin temperature parameter γ controls the smoothness of the SDTW soft alignments. While a low value of γ is desirable to ensure exact correspondences between predictions and targets due to sharp alignments, the latter are problematic in the initial training phase as inaccurate predictions from randomly initialized network parameters lead to erroneous alignments, thus hampering convergence. Therefore, as a first strategy to stabilize SDTW training, we discuss an epoch-dependent scheduling of γ . Starting a training with a large softmin temperature $\gamma^{\text{start}} = 10$ makes the soft alignment fuzzier, which leads to coarse, yet mostly meaningful target assignments (see Figure 1b). After ten epochs with $\gamma = 10$, when the trained network predicts meaningful features, we linearly reduce γ during the following ten epochs to a final value of $\gamma^{\text{final}} = 0.1$, which stays constant for the remaining training.

3.2 Diagonal Prior

On average, the correct alignment of two sequences with arbitrary symbol durations has a higher probability to be close to the diagonal than to deviate from it. Therefore, as a second approach to stabilize the initial training phase, we investigate an additive prior $\mathbf{P} \in \mathbb{R}^{N \times M}$ which penalizes elements of the cost matrix \mathbf{C} that are far from the diagonal (see Figure 2 for an illustration of a prior matrix). A similar strategy was employed in [15] for restricting speech-text alignments to the diagonal. Assuming equal symbol durations, the diagonal alignment of a target \mathbf{y}_m starts at input frame $q_m = \lfloor \frac{Nm}{M} \rfloor$ and ends at $q_{m+1} - 1$. To yield no penalty along the diagonal and a smoothly increasing penalty for distant alignments, we define the elements of the prior matrix as

$$\mathbf{P}(n, m) = 1 - \begin{cases} 1, & q_m \leq n < q_{m+1} \\ \exp\left(\frac{(n-q_m)^2}{-2\nu}\right), & n < q_m \\ \exp\left(\frac{(n-q_{m+1})^2}{-2\nu}\right), & n \geq q_{m+1}, \end{cases} \quad (7)$$

Figure 2: Diagonal prior matrix \mathbf{P} for $N = 500$, $M = 50$ and $\nu = 1000$.

where the parameter ν controls the sharpness of the prior. In our experiments, we use $\nu = 1000$. Finally, the prior matrix is added to the cost matrix with a weight ω to obtain the penalized cost matrix

$$\mathbf{C}_P := \mathbf{C} + \omega\mathbf{P}, \quad (8)$$

which replaces \mathbf{C} in (3) to (6). Similarly to the hyperparameter scheduling strategy, we choose a constant prior weight $\omega = 3$ during the first five epochs and then linearly reduce it to $\omega = 0$ during the following five epochs.

Note that the numerical parameters for the strategies presented in Sections 3.1 and 3.2 were determined empirically by the authors and small changes did not affect the training performance. However, when training on sequences of different length, with a different learning rate, or other DNN types, parameters should be adjusted on a validation set. As presented in Section 5, analysis of the soft alignment matrix \mathbf{E}_C^γ provides a good indication of the current alignment stability.

3.3 Sequence Unfolding

Based on the observation that equal sequence lengths stabilize SDTW training, a third strategy is to uniformly unfold the target sequence (see also [6]). The unfolded target sequence $Y^U = \{\mathbf{y}_0^U, \mathbf{y}_1^U, \dots, \mathbf{y}_{N-1}^U\}$ is constructed by uniformly repeating elements from the weakly aligned target sequence, i.e., setting

$$\mathbf{y}_n^U \leftarrow \mathbf{y}_{\lfloor \frac{Mn}{N} \rfloor} \quad (9)$$

to yield equal sequence lengths of the predictions X and the targets Y^U . Note that the repetition of target vectors introduces ambiguities, leading to multiple optimum alignments.

4. EXPERIMENTAL SETUP

In this section, we describe the task for our case study, the employed dataset, as well as the used DNN architecture and the training procedure.

4.1 PCE Task

We choose PCE from music recordings as an illustrative case study to investigate the problems of the SDTW loss function and the effect of the stabilizing strategies. In our experimental setting, a DNN takes N frames of input audio (including context) and, for all frames, predicts twelve-dimensional pitch class activation vectors X (see Figure 3

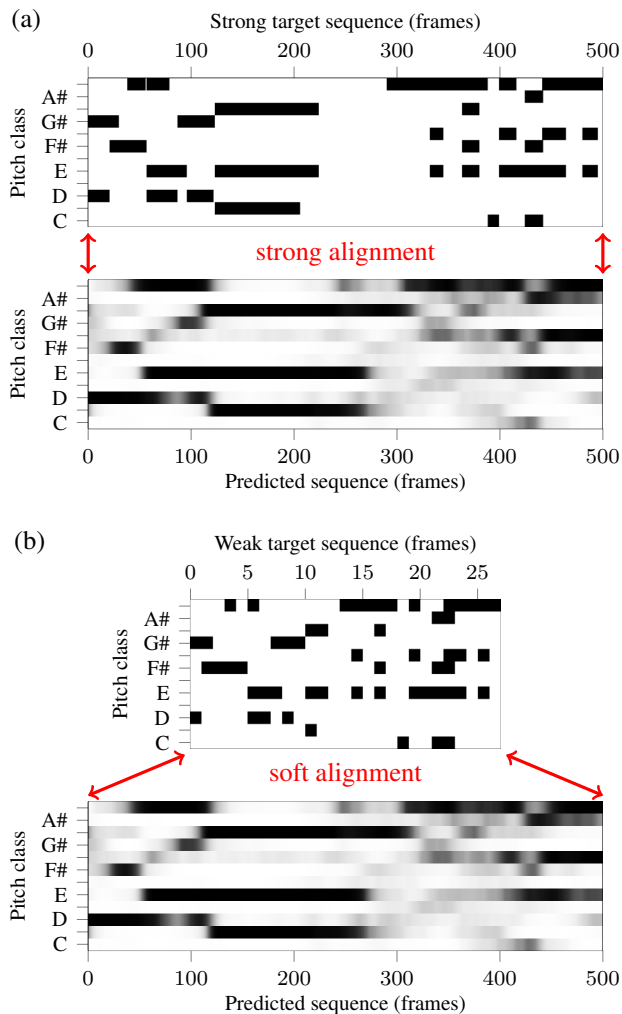

Figure 3: Alignment between training targets and predicted pitch class features X for the running example from *Frühlingstraum*. (a) Strong reference alignment for MSE loss with strong targets Y^S . (b) Soft alignment for SDTW loss with weak targets Y .

for an illustration of predicted pitch class features). We want to train the DNN such that the predictions X match the training targets as close as possible. In the case of strong targets Y^S , each predicted frame \mathbf{x}_n is assigned to exactly one target frame \mathbf{y}_n^S using a strong alignment (see Figure 3a). When using weak targets Y , SDTW internally computes a soft alignment based on the cost matrix $C_{X,Y}$ to assign predictions and targets (see Figure 3b).

4.2 Dataset

Throughout all experiments, we use the Schubert Winterreise dataset (SWD) [16] which contains audio recordings and strongly aligned pitch class annotations. Winterreise is a song cycle for piano and singer, consisting of 24 songs. For each song, SWD comprises nine different performances, resulting in $9 \cdot 24$ recorded songs with a total duration of 10 h 50 min. We split the dataset for training, validation, and testing using a performance split [16]. The publicly available performances by Huesch (HU33, recorded in 1933) and Scarlata (SC06, recorded in 2006)

Layer	Kernel Size	Stride	Output Shape
Prefiltering

Table 1: Musically motivated CNN architecture [3, 5].

were annotated manually [16] and constitute the test set. For training and evaluation we choose sequences of length $N = 500$, corresponding to approximately 8.7 s of audio at a sampling rate of 22 050 Hz and a hop length of 384 samples. In order to generate weak training targets Y from SWD (which provides strongly aligned pitch class annotations Y^S , see Figure 3a), we remove all adjacent repetitions of a pitch class vector (see Figure 3b) [5]. We choose an excerpt from the song *Frühlingstraum*, performed by Randall Scarlata (SC06), as a running example (see Figure 3) to visualize the soft alignment matrices (see Figure 4).

4.3 DNN Architecture and Training

We adapt a conceptually simple and musically motivated five-layer convolutional neural network (CNN) from [3, 5] with 43383 trainable parameters to predict twelve-dimensional pitch class activation vectors from an input sequence. Table 1 provides an overview of the architecture. We choose the harmonic constant-Q transform (HCQT) [17] with five harmonics as an audio feature representation, spanning six octaves at a resolution of three bins per semitone (resulting in 216 frequency bins starting from C1), a hop length of 384 samples and a frame rate of 57.4 Hz. From an input sequence of length $N + 74$, the CNN sequentially predicts N vectors of pitch class activations. For the prediction of one frame, the CNN’s receptive field covers 37 adjacent context frames on each side. Leaky ReLU with a negative slope of 0.3 is used as a non-linearity after all hidden convolutional layers and sigmoid activation is used after the final layer. The dropout rate is set to 0.2. All models are trained using the Adam optimizer [18] with a batch size of 32 and an initial learning rate of 0.001. We reduce the learning rate by a factor of two if the validation loss did not decrease during the last four epochs, and terminate the training if the validation loss did not decrease during the last twelve epochs. At the end of training, the model from the epoch with the lowest validation loss is restored. The source code for reproducing our experiments, as well as the trained models are available on github.com/groupmm/stabilizing_sdtw.

Loss	Targets	γ	Strategy	F-measure	
				mean	std
MSE	strong	-	-	0.82	0.07
SDTW	weak	0.1	-	0.56	0.37
SDTW	weak	0.3	-	0.63	0.32
SDTW	weak	1.0	-	0.24	0.36
SDTW	weak	3.0	-	0.31	0.38
SDTW	weak	10.0	-	0.57	0.37
SDTW	weak	10 \rightarrow 0.1	hyp. sched.	0.80	0.04

SDTW	weak	0.1	seq. unfold.	0.53	0.04

Table 2: Averaged test results for DNNs trained on strongly aligned reference targets as well as DNNs trained with SDTW on weakly aligned targets using either the standard configuration or the discussed stabilization strategies. We report the mean (higher is better) and standard deviation (lower is better) of the F-measure.

5. EVALUATION

In this section, we investigate the training process as well as the prediction accuracy under the standard SDTW loss, and compare it to the discussed stabilizing strategies. For quantitative evaluation, we repeat all DNN trainings ten times from random initializations. For the test set predictions of each trained model, we compute the F-measure w.r.t. time-pitch class bins using a threshold of 0.5. The mean and standard deviation of the F-measures from all trained models are displayed in Table 2.

5.1 Baseline: Strongly Aligned Targets

As a first baseline and an upper bound for all following experiments, we consider DNN training with strongly aligned targets Y^S . For the sequence lengths $M = N = 500$ and an MSE loss function, the networks achieve the overall highest mean F-measure of 0.82 with a standard deviation of 0.07 on the test set.

5.2 Standard SDTW

We next analyze DNN training with weak targets Y and the unmodified SDTW formulation from [10, 19] as a loss function. We investigate five different values of $\gamma \in \{0.1, \dots, 10\}$ which we keep constant during training. Analyzing the mean F-measure on the test set in Table 2, the five variants with standard SDTW yield comparably low results between 0.24 and 0.57, and high standard deviations between 0.32 and 0.38. Between 20% ($\gamma = 0.3$) and 70% ($\gamma = 1.0$) of all training runs converged to the all-zero output, indicating a highly unstable training process of standard SDTW. In order to determine the cause of these instabilities, we analyze the quality of automatically generated soft alignments in the SDTW algorithm by visualizing the soft alignment matrix for the running example after training epochs one and 25, respectively. To highlight the effects of small and large values of γ , we focus on the edge cases $\gamma \in \{0.1, 10.0\}$. For $\gamma = 0.1$, the estimated soft alignment exhibits a sharp structure (see Figure 4a), which, after a collapse to a single target frame

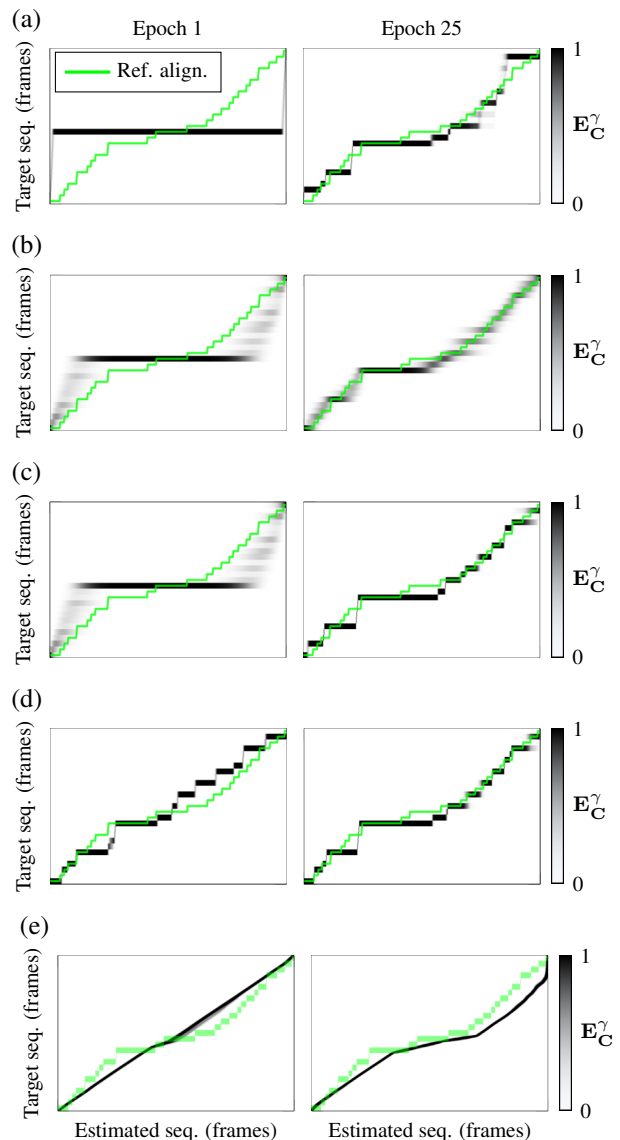

Figure 4: Reference alignment (green) and soft alignment matrix E_C^γ (gray/black) for the running example after training epoch 1 (left) and epoch 25 (right) for different training strategies. (a) $\gamma = 0.1$, (b) $\gamma = 10$, (c) hyperparameter scheduling, (d) diagonal prior, (e) sequence unfolding.

at epoch one, still only marginally overlaps with the reference alignment after 25 epochs. This sharp and erroneous soft alignment causes unstable gradient updates and leads to the collapse of many training runs. When choosing a large softmin temperature $\gamma = 10$, SDTW yields “blurry” soft alignments (see Figure 4b) which at least partially capture the actual target frames in early epochs and coincide well with the reference alignments as training progresses. However, a blurry soft alignment also leads to blurry network predictions as multiple target frames are aligned to each predicted frame, thus resulting in a low F-measure when compared to strongly aligned targets..

5.3 Stabilizing Strategies

After evaluating the unsatisfactory training behavior of standard SDTW, we investigate the effect of the previously

introduced training strategies in the following section. We empirically choose $\gamma = 0.1$ as the final softmin temperature in all following experiments, as sharp alignments are necessary for training an estimator with frame-wise precision.

5.3.1 Hyperparameter Scheduling

First, we combine the advantages of high and low values of γ in a hyperparameter scheduling strategy. Starting a training with $\gamma = 10$, the soft alignment matrix for our running example after one epoch is blurry and at least partially overlapping with the reference alignment (see Figure 4c). The successive reduction to $\gamma = 0.1$ until epoch 20 permits sharp alignments at a later training stage. Indeed, Figure 4c shows a soft alignment after epoch 25 which is sharp and coincides well with the reference. The mean F-measure (0.80) in Table 2, as well as the standard deviation (0.04), are the second best of all SDTW-based trainings. However, as the softmin function in (2) is a lower bound for the minimum function [12] which becomes tight for $\gamma \rightarrow 0$, the SDTW loss is increasing when decreasing γ , despite unchanged network parameters. Therefore, this strategy does not allow for loss-based learning rate scheduling and early stopping before γ is set to its final value.

5.3.2 Diagonal Prior

The second strategy stabilizes SDTW trainings with low values of γ by adding a penalty cost to off-diagonal elements of the cost matrix. For our running example in Figure 4d, the soft alignment is indeed close to the diagonal after the first training epoch. As, on average, the alignments are diagonal, this often leads to correct assignments of predictions and targets even for randomly initialized DNNs. When the prior weight ω is reduced to zero after the initial training phase, the network is still able to adapt to off-diagonal alignments, as seen in our running example in Figure 4d. Analyzing the performance metrics in Table 2, using a diagonal prior yields the highest mean F-measure (0.81) and the lowest standard deviation (0.02) of all SDTW variants, almost reaching the mean F-measure of the baseline experiments with strong targets and element-wise MSE loss. Moreover, when the prior weight ω is reduced during training, the loss also decreases and therefore learning rate scheduling and early stopping are possible from the beginning.

5.3.3 Sequence Unfolding

Last, we investigate the strategy of unfolding the weak target sequence to the length of the input, which was employed in [6]. For this strategy, we observe fully diagonal soft alignments in the initial training phase, as visualized for our running example in Figure 4e. This is caused by the equal length of the predicted and the target sequence, which can be aligned using only diagonal steps. In the SDTW formulation from [10], the cost of a diagonal step is equal to the cost of a vertical or horizontal step. Thus, for a uniform cost matrix (which is probable at the initial

training phase due to random network initialization), taking a diagonal step only accumulates half the cost compared to going “around the corner”, i.e., one step in the vertical and one in the horizontal direction, or vice versa. This diagonalizing behavior leads, on average, to decent soft alignments in the early training phase (as discussed in Section 5.3.2). However, in contrast to the additive diagonal prior strategy, the implicit diagonalization of alignments is not reduced during the training, as can be seen in Figure 4e, which still exhibits strong diagonal components after 25 training epochs. Thus, the softly aligned SDTW targets seldom match the reference targets and performance remains low, resulting in a mean F-measure of 0.53 in Table 2.

Note that the sequence unfolding strategy adds a significant computational overhead compared to the previous two strategies, as unfolding always corresponds to using a target sequence length of $M = N$. The forward and backward pass of the SDTW loss function both have linear complexity w.r.t. the sequence lengths $\mathcal{O}(MN)$ [10]. Thus, in our setting with $N = 500$ and a mean length of the weak target sequences in the test set of $M = 24$, the unfolding strategy leads to an increase in the computational cost of the SDTW loss by a factor of more than 20.

6. CONCLUSION AND OUTLOOK

In this paper, we analyzed DNN training instabilities with SDTW as a loss function by the example of PCE. By analysis of the soft alignment matrix, we argued that alignment mismatch in the early training phase often causes a collapse of the training procedure. Motivated by these findings, we investigated three strategies for stabilizing the early training phase. We found that the previously applied strategy of unfolding the weakly aligned target sequence leads to almost exclusively diagonal alignments due to a naïve weighting of horizontal, vertical, and diagonal alignment steps. Furthermore, this strategy is computationally inefficient, as it increases the target sequence length. In contrast, the two introduced strategies of hyperparameter scheduling and diagonal prior can be implemented with negligible additional computational cost and stabilize SDTW-based training by two different mechanisms. The hyperparameter scheduling strategy promotes smooth alignments in the early training phase, which increases the probability of the predicted frame being at least partially aligned to the correct target. Penalizing off-diagonal alignments in the SDTW cost matrix by an additive diagonal prior is a strategy that initially restricts the soft alignment to a region of high probability. Experimental evaluation showed that these strategies reliably stabilize the SDTW training process. Implementing them as a default in the SDTW loss highly increases convergence rates.

Future research on SDTW-based loss functions in MIR applications might incorporate musically informed prior information, e.g., based on note durations or tempo annotations extracted from the musical score. Furthermore, the preference of diagonal alignment steps could be addressed by choosing different step weights.

ABSTRACT

In this paper, we introduce a computational analysis of the field recording dataset of approximately 700 hours of Korean folk songs, which were recorded around 1980-90s. Because most of the songs were sung by non-expert musicians without accompaniment, the dataset provides several challenges. To address this challenge, we utilized self-supervised learning with convolutional neural network based on pitch contour, then analyzed how the musical concept of *tori*, a classification system defined by a specific scale, ornamental notes, and an idiomatic melodic contour, is captured by the model. The experimental result shows that our approach can better capture the characteristics of *tori* compared to traditional pitch histograms. Using our approaches, we have examined how musical discussions proposed in existing academia manifest in the actual field recordings of Korean folk songs.

1. INTRODUCTION

Folk songs are considered as a musical language. Not only that, but they are also regarded as the root of all traditional music. Folk songs are potent embodiments of a region's cultural and linguistic characteristics, serving as a foundation for all artistic and musical developments since their inception. It is believed that research for folk music can provide new inspiration for existing art music research, and facilitate an interdisciplinary approach that encompasses both music and other fields.

In Korean musicology, there have been ongoing discussions aimed at identifying regional characteristics in folk music. Through numerous debates, *tori* is used as the most representative theory in many studies. Even though the use of *tori* as a term to describe the musical characteristics of Korean folk music is widespread and its utility is well acknowledged, the existing *tori* classification methods were unable to fully explain the features of the actual music. Various scholars have defined the different *tori* according to musical characteristics such as scales (intervals between notes), primary notes, ornamentation, ending note and id-

iomatic melodic patterns in folk songs, leading to a refinement process for the classification of *tori*. So far, there are still ongoing opinions, controversies, and discussions concerning the existing *tori* [1, 2].

In order to conduct valuable discussions on analyzing folk songs, the relationships within the audio must be examined and systematically shared. However, checking numerous audio files individually is extremely time-consuming and difficult, so previous research has focused on analyzing small amounts of audio. The most common method used by musicologists has been transcription, which involves listening to the music and notating it in a specific music notation system. However, the task of transcribing orally transmitted music into a music notation system has inherent limitations [3], such as quantizing the pitch and rhythmic features of folk songs.

For these reasons, there have been several research on analyzing folk music empowered with methods derived from music information retrieval (MIR) on audio recording. For example, Indian *raga* music has been analyzed based on first-order pitch distributions [4], and for traditional three-part Georgian singing, F0-based tonal analysis [5] or development of tuning systems [6] has been introduced. [7] also presented analysis using audio-signal processing on Flamenco and Arab-Andalusian vocal music.

In this paper, we take a computational approach to analyze a vast corpus of Korean folk songs, utilizing deep-learning-based methodologies. Our primary aim is to investigate the connection between conventional musicological classifications of Korean folk songs, *tori*, and the actual field recordings. Through a comparison of our analytical results with established musicological frameworks, our objective is to offer insights on identifying meaningful clustering or distinguishable features among Korean folk songs. We also share our code and metadata that contains links to original audio with our manual *tori* labels for 218 songs¹.

2. KOREAN FOLK SONGS AND TORI

2.1 Dataset

The “Anthology of Korean Traditional Folksongs” is an audio collection consisting solely of traditional Korean folk songs [8]. As part of a cultural project conducted by Munhwa Broadcasting Corporation (MBC) from 1989

© D. Han, R. Caro Repetto, and D. Jeong. Licensed under a Creative Commons Attribution 4.0 International License (CC BY 4.0).

Attribution: D. Han, R. Caro Repetto, and D. Jeong, “Finding Tori: Self-supervised Learning for Analyzing Korean Folk Song”, in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

¹ <https://github.com/danbinaerinHan/finding-tori>

to 1995, the folk song collection was compiled under the direction of Sang-il Choi. The available audio contains 15,861 songs, with approximately 700 hours in total length.

The audio was field-recorded across 153 city/county and 1,010 villages in South Korea. The metadata accompanying the recordings includes title, machine-readable lyrics, regions, recording dates, and the singer’s name and age. The region represents the administrative districts of South Korea at the time of recording, which consists of nine categories in total. Due to its extensive audio corpus and detailed accompanying metadata, this dataset has become a crucial resource for research on Korean folk music within the domestic academic community [9–11]. We obtained the audio material through crawling the original website,² which has been hosted by MBC since April 2022, where every audio and metadata is openly published. We received official approval for using these data for research purposes from MBC.

2.2 Tori

Tori was proposed by a Korean musicologist named Bo-hyeong Lee in the early 1980s to explain the musical characteristics of regional folk songs [12, 13]. Prior to the development of tori theory, Korean music academia used the terms *jo* and *cheong* to explain the musical features of folk songs, based on the tonal center and intervals between notes [14]. However, Bo-hyeong Lee argued that *jo* and *cheong* are insufficient in capturing the unique musical characteristics of Korean folk music. Therefore, he proposed the tori classification system as an alternative approach, which covers primary notes, ornamentation, ending note and idiomatic melodic patterns.

The most widely-used tori classification method divides songs into four categories. We encourage readers to refer Figure 3, which presents scale of three tori with staff notation. The pitch name in this section is used as a conventional representation, not absolute pitches. **Gyung-tori** utilizes five notes and is mainly sung in the capital region. It often uses a gentle vibrato overall and finessed ornamental melody. **Menari-tori** is widely distributed throughout the eastern regions and the entire Korean Peninsula. When the melody ascends, it leaps through notes, while during the descending melody, it comes down through passing notes. **Yukjabaegi-tori** is commonly found in the southern regions of the Korean Peninsula. It is characterized by a thick and vibrant vibrato in G note and passing briefly through E \flat in a descending melody from E \flat to D. **Sushimga-tori** commonly appears in the northwestern region of the Korean Peninsula, characterized by its unique vibrato inflecting upward.

2.3 Tori annotation

As the dataset did not include any tori labels, one of the authors, who has over 10 years of experience in Korean traditional music, selected a subset of 218 high-quality record-

Figure 1. Example of pitch contour from the dataset extracted by CREPE. F0 value under confidence of 0.8 was masked out

ings and manually annotated them in terms of tori classification.

To create this tori-subset, we focused on identifying clear musical characteristics present in the tori classification method, such as pitch scale, ornamentation, and idiomatic melodies, rather than considering the audio’s recorded region. We found that there are not many instances of sushimga-tori in the audio dataset, as the dataset predominantly consists of folk songs from the central and southern regions of the Korean Peninsula. Also, we observed that songs belonging to menari-tori appeared not only in the eastern region but also nationwide. In conclusion, we mainly focused on the remaining three types of tori, *gyung-tori*, *yukjabaegi-tori*, and *menari-tori*. Finally, audio recordings that were closer to speech or chanting (non-musical) and did not exclusively belong to any other subdivided tori types were labeled as ‘others’. We have labeled totally 218 songs: 65 gyung, 73 menari, 49 yukja, and 31 others.

3. METHODOLOGY

In this study, we take an approach of representing the musical characteristics of a given folk song using a high-dimensional single vector, which can also be called an embedding of the song. If this embedding accurately represents the musical characteristics of tori, it can be utilized for various purposes including tori classification, song similarity searches and clustering songs in the corpus based on tori similarity.

Even though the dataset is provided with audio recordings, we focus on the contour of fundamental frequency (F0) rather than using audio directly. By doing so, our embedding could better capture the melodic features of the songs rather than timbral characteristics such as the dialect of the singer. To extract the F0 contour from each audio recording, we utilized CREPE [15], a widely-used CNN-based model. It extracts F0 value for every 10 ms as well as confidence score ranging from 0 to 1. Figure 1 illustrates an example of an extracted pitch contour.

3.1 Pitch Histogram

Since the characteristics of a musical system can be largely studied from the pitch distribution of its melodies, there

² <http://urisori.co.kr/urisorien/en/doku.php/>

has been numerous research using pitch histograms to analyze traditional musics from different culture, such as for Indian Carnatic music [16], Turkish Makam [17], Arab-Andalusian music [18], or Iranian *dastgāhi* music [19]. Therefore, we applied a similar approach to Korean folk music.

One of the important features one has to know to exploit pitch histogram is the tonic of the song so that one can normalize the pitch histograms of each song into relative pitch, rather than directly using absolute pitch value. During our preliminary experiment, we found that the tonic of each recording in the dataset is usually the most frequently appearing pitch in the song. Therefore, we determined the tonic by counting the number of appearances of each pitch in terms of time frames, utilizing a 100 cents range to count pitch (i.e. MIDI pitch 60.49 and 59.51 are counted as the same pitch). As the center pitch may differ from the typical 440 Hz tuning, we identified the best matching pitch by adjusting the pitch center by increments of 10 cents and selecting the pitch that showed the maximum pitch count.

3.2 CNN contour encoder

While the pitch histogram can offer a comprehensible representation of each song, it cannot fully capture the concept of tori as it does not consider the relationship between each note in the scale. Additionally, because most of the recordings were sung by non-professional singers without instrumental accompaniment, the intervals of singing and tonic frequency has significant amount of noise. Therefore, we employ a convolutional neural network (CNN) to learn the representation of a given pitch contour. This approach allows us to better capture the underlying musical characteristics of each song in relation to tori classification.

The problem is setting the training objective of the CNN model. One option is to train the model in a supervised manner, as typically done in other MIR tasks, such as classification tasks with an annotated dataset. In our dataset, region labels, which represents the administrative region where the recording took place, can be used for training labels. It can be regarded as a reasonable approach considering that tori has strong correlation with the regional characteristics of each folk song. However, we discovered several different types of tori in a single recorded region, which would make it difficult to learn distinguishable musical characteristics only using the region label.

To address this issue, we propose to adopt a self-supervised representation learning, so that we can obtain a representation of given pitch contour that is consistent within a song without extra annotated labels as shown in Fig. 2. This approach of exploiting intra-song similarity has been widely used for music audio representation learning [20,21]. We use triplet loss with hinge margin as Equation 1,

$$L = \max(0, m - \text{Sim}(v_a, v_p) + \text{Sim}(v_a, v_n)) \quad (1)$$

where m denotes hinge margin, $\text{Sim}(v_a, v_{p,n})$ represents cosine similarity between anchor vector v_a and positive vector v_p or negative vector v_n .

Figure 2. Self-supervised learning with triplet loss using cosine similarity, with four layers of convolutional neural network

As presented in Fig. 2, the model consists of 4 layers of 1D convolution layer, each with a kernel size of three and channel size of 64, 128, 256, and 256, respectively, each followed by batch normalization layer. We used a max pooling layer between each convolutional layer with size 5 for the first layer and 4 for the second and third layers. On top of the convolutional stack, we used context attention to summarize the arbitrary length of vectors, which was initially proposed in hierarchical document classification [22], with a slight modification of multi-head attention weight [23] instead of single-head. Context attention is a type of attention mechanism that uses an independent learnable parameter named context vector as a query while using the input vectors as key and value. The final embedding size of the model was 256.

The input is a pitch contour in the shape of $T \times 2$, where T denotes the number of time step of pitch contour. Throughout the experiment, we used the frame rate of 20 Hz, which means that 30 seconds of pitch contour is converted to 600 time steps. During the training, we randomly slice the contour to have 30 seconds length, while using the entire contour in the test or visualization. Two channels are tonic-normalized MIDI pitch and confidence of the F0 estimation at that time frame. Since the automatic F0 estimation includes noise, especially in the unsung silent part, we masked the estimated pitch value to zero if the confidence is lower than 0.8.

4. EXPERIMENTS

4.1 Evaluation Design

In the experiments, we explored the quantitative relation between tori and different embedding schemes to see which type of embedding can explain the concept of tori

better. To evaluate the correlation between tori and the given embedding scheme, we exploit our tori-labeled subset with two metrics.

The first metric is the ranking of cosine similarity. If the embedding shares important characteristics with the concept of tori, we can expect that songs with high cosine similarity in the given embedding space share the same tori with the query song. Therefore, we calculated the cosine similarity between each song in the tori-subset, and obtained normalized discounted cumulative gain (nDCG), which is a frequently used metric to evaluate the quality of search results. If all the other n songs with the same tori are ranked within n -th order in the similarity, nDCG becomes one.

The second metric is the tori classification accuracy using a random forest classifier. If the embedding includes essential characteristics that define tori, one can expect that it can be exploited to classify the tori for a given song. Among many options, we used a simple random forest classifier. The random forest classifier with 100 trees was trained with 75% of the tori-set and tested with the remaining 25%. For each embedding scheme, we repeated the procedure 30 times with different train/test split and reported mean and deviation of accuracy to ensure that the results were not dependent on the specific dataset split.

4.2 Training

While a pitch histogram can be obtained from a given song without additional training data, CNN models require training procedures. We employ F0 contour extracted from the ‘‘Anthology of Korean Traditional Folksongs’’ to train our model.

Some of the songs in the dataset were recorded with multiple singers or percussion accompaniment. Because these can degrade the performance of F0 estimation, we excluded them while training the CNN model. Instead of manually filtering the dataset, we used a CNN-based sound event detection model [24] to calculate the activation of ‘choir’ and ‘percussion,’ which are included among the model’s event vocabulary. We filtered the song by the maximum activation value exceeding a certain threshold, which was manually decided by observing the activation distribution across the dataset.

The CNN model was trained for 25,000 updates. For the self-supervised learning using triplet loss, we used eight negative samples with one positive sample, and hinge loss using a margin of 0.4. For the region-supervised training, we use cross-entropy loss with class weight to address the class imbalance issue. The architecture of the CNN remained the same, but we added a fully connected layer to project the embedding to logits for nine different region categories. We used the Adam optimizer with an initial learning rate of 0.001 and batch size of 128. The entire training process was conducted on a single RTX A5000, which took approximately 10 minutes to complete 25,000 updates. We validated the model’s training procedure and hyperparameters using a specific split of the tori-subset and chose the simplest setting to avoid overfitting the hyperpa-

Embedding	Similarity Ranking	Random Forest Classifier
	nDCG	Accuracy
Hist. (25 bin)	0.783	0.744 \pm 0.058
Hist. (124 bin)	0.777	0.722 \pm 0.054
CNN (region)	0.792	0.634 \pm 0.055
CNN (SSL)	0.853	0.848 \pm 0.039

Table 1. Experiment results on the tori subset. Hist. denotes normalized pitch histogram, specified with the number of bins to cover two-octave range. region and SSL denotes the region-supervised and self-supervised learning.

rameters to the small subset.

4.3 Results

The evaluation result of each embedding scheme is presented in Table 1. As tori is closely related to the use of pitch, the pitch histogram showed about 74 % accuracy when combined with a random forest classifier, and 0.783 or 0.777 nDCG in the similar song search. The result shows that increasing the resolution of the histogram does not achieve better performance. The performance of CNN embeddings trained with region classification was worse than the pitch histogram in classification accuracy. However, the CNN embedding trained with self-supervised learning showed the best nDCG and classification accuracy, even though both CNN shares the same architecture except the final projection layer.

The performance gain compared to the pitch histogram can be caused by the fact the concept of tori includes not only the pitch scale the song uses but also ornamentation and idiomatic phrases it, which can be easily captured by contour CNN.

The result also shows that the region label did not help to learn tori-related characteristics. Even though the concept of tori is strongly related to each region, folk songs were widely spread nationwide at the time of the recording, which made it difficult to learn coherent musical characteristics from the region label.

It is also worth noting that self-supervised learning did not use any other musical knowledge that is related to tori, except that it was trained to extract constant embedding throughout a given song regardless of the segment position. From a machine learning point of view, the model has to extract an embedding that can explain the entire song or distinguish it from other songs from a given fragment. The high correlation between the trained embedding and tori labels shown in the evaluation implies that the concept of tori is clearly related to the distinguishable characteristics of each Korean folk song.

5. ANALYSIS AND DISCUSSION

In this section, we introduce interesting musicological findings that we have found from the pitch histogram and embedding learned from self-supervised training.

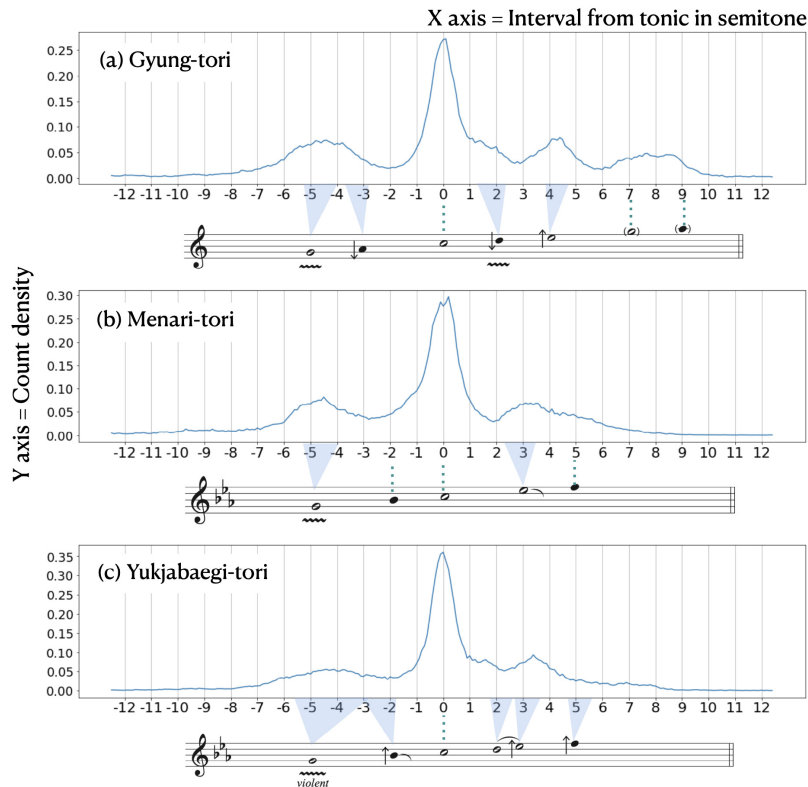

Figure 3. Average pitch histogram of each tori obtained from the tori-subset and corresponding scale description.

5.1 Pitch Histogram Analysis

To explain the scale and characteristics alongside with pitch histogram of each tori, we present the staff notation of each tori in Figure 3 based on various studies describing tori [2, 25, 26]. In the score, the *cheong* (a main note that generally appears most frequently) was fixed as the C5. The unfilled notes are primary tones, and the filled notes are passing tones. In cases where there is a vibrato mark below the note, it is called *yoseong*, meaning the pitch generally oscillates up and down. In addition, the arrow on the left side of the note indicates that the pitch is slightly raised or lowered compared to the equal-tempered pitch. The slur mark flowing down to the right of the note represents *twoe-seong*, which means the pitch slides down.

While menari-tori and yukjabaegi-tori remain within a perfect fifth range from the center, in gyung-tori, there is a larger proportion of high notes (G5-A5) or more from the center. This indicates that the distribution of notes from low to high in gyung-tori is evenly spread. This could be due to the fact that folk songs of gyung-tori are more commonly found in popular folk songs than in those that appear nationwide. Perfect 4th below the center tone is common in all Korean music. However for example in gyung-tori, there is vibrato in the G4 note, and the A4 note has a low pitch, resulting in a distinct distribution in that part. In menari-tori, it can be observed that the B \flat 4 note is used as a passing tone between C5 and G4. Yukjabaegi-tori is characterized by a vibrant vibrato in the G4, resulting in a gentle distribution in the nearby pitch than other tori.

Whether a major third or a minor third is used in the

scale is an important factor in distinguishing the regional musical characteristics of the eastern and western parts of the Korean Peninsula in the traditional method. Subtle pitch differences can be observed in all three tori. In gyung-tori, the D5 note is clearly distributed lower and the E5 note is definitely higher than the line appearing the equal-tempered tune. In yukjabaegi-tori, it is also confirmed that the E \flat note is slightly higher than the minor third note's

Through the above analysis, we found that pitch histograms can be utilized to roughly identify musical characteristics, such as the range, interval from tones and subtle pitches, etc. However, we also acknowledged that this approach solely exhibits the constituent pitches and their frequencies, without accounting for other aspects like uses of melody and ornamentation and more.

5.2 UMAP visualization

We visualized the embeddings learned through self-supervised learning in 2D using UMAP, a dimension reduction technique that is frequently used for visualization of high-dimensional vectors in Figure 4. In the first figure, we demonstrated the distribution of four different tori labels. In addition, by examining the metadata information of the embeddings, we figured out several interesting topics from this visualization. We also implemented a web demo using this visualization where one can directly access the corresponding audio recording³.

Menari-tori has a much wider distribution area and en-

³ <https://danbinaerinhan.github.io/korean-folksong-visualization/>

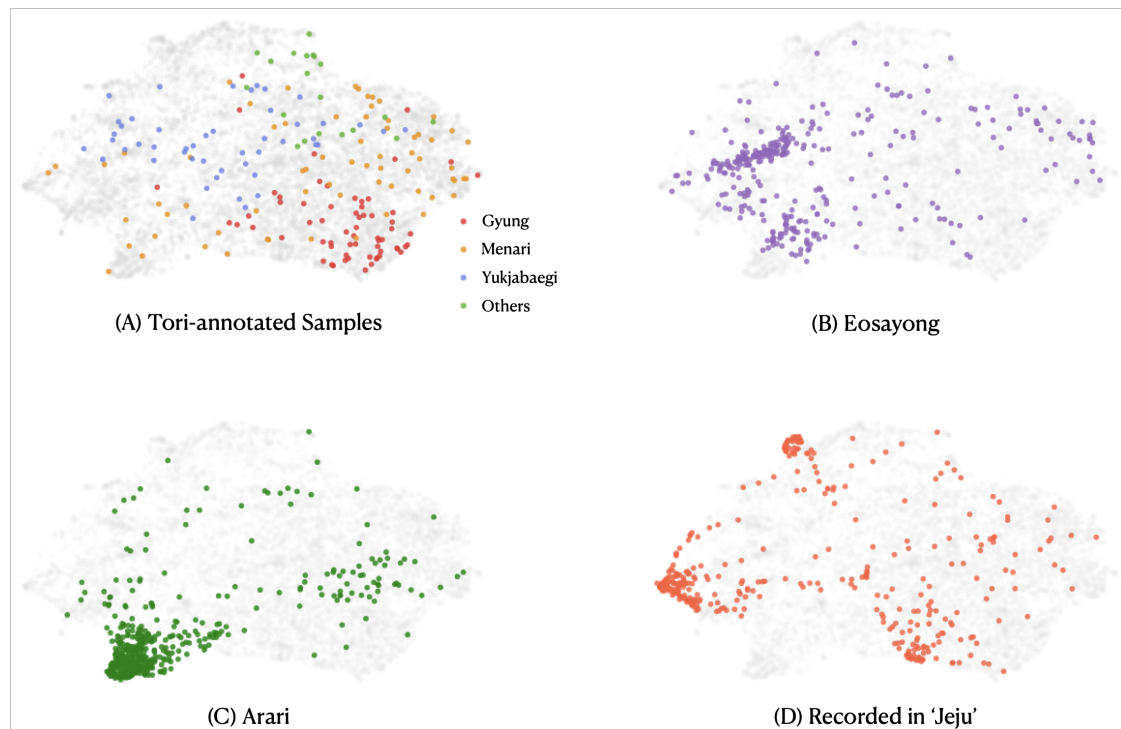

Figure 4. UMAP visualization of folk song embeddings obtained from our self-supervised-trained CNN model. Note that no tori label was used to train the model.

compasses a broader musical range. In Figure 4 (A), the menari-tori distribution can be seen to be wider compared to the other tori. We mentioned that several subdivided tori of it have been identified by scholars. Among them, eosayong-tori is a representative example of refining the musical characteristics of eastern folk songs [11]. Eosayong-tori, a lamenting song sung by lumberjacks, was suggested to have distinct musical characteristics compared to menari-tori. For instance, in eosayong-tori, the lowest pitch is a semitone higher, and it concludes on the lowest pitch of the scale instead of the final pitch and the middle pitch found in menari-tori. We examined embeddings corresponding to eosayong-tori in the metadata’s title information, and they were clearly gathered in a different space than the area annotated as menari-tori, as presented in Figure 4 (B).

Similar results can be observed in the following cases with *arari*. *Arirang*, having repetitive refrain lyrics such as “arirang” or “arari”, is the most representative Korean folk song, with countless versions appearing in various regions. Among them, *arari*, another name for *Jeongseon arirang*, was sung primarily in Gangwon province before spreading nationwide in the 1930s [27,28]. *Arari* is also regarded as a separated tori from menari-tori for some researchers [29], with its own slower tempo, monotonous skeleton tones, and the use of decorative tones. In Figure 4 (C), we can see the clustering of entities with the title *arari* extracted from the metadata.

Another interesting example is songs from Jeju. Folk songs sung from Jeju island, which is the largest island in Korea, have fewer research results compared to other regions. In Jeju folk songs, the interval between the pitches

is narrower compared to other provinces’. Due to these reasons, the traditional method of transcribing into staff notation was unsuitable for capturing the characteristics of Jeju music [30–32]. However, using our embeddings, we can identify three clusters as in Figure 4 (D). It implies the potential usefulness of our approach to uncover the unique characteristics of folk songs in Jeju Island.

We also checked the UMAP of the pitch histograms but could not find clear clustering as in the presented examples.

6. CONCLUSIONS

In this paper, we have presented our computational approach to obtaining a high-dimensional embedding vector for a given pitch contour, which allows us to analyze a vast amount of Korean folk songs. Using these embeddings and a manually labeled subset, we have examined how musical discussions proposed in existing academia are manifested in our dataset. As our results cover various music characteristics, the learned embeddings can be utilized as a monitoring aid when dealing with numerous undefined data to review and find the tori. Also, we have discussed the methods and possibilities for utilizing and interpreting experimental results in the future research. Through this material, we can review and refine our understanding of the concept of the tori, and provide easily accessible resources and utilize them as appropriate evidence. Furthermore, there is potential to clarify the musical characteristics of regions that are distinct from other regions, like Jeju, about which existing research has not been as active. Ultimately, we expect this research to be valuable in illuminating the relationships and transformations of folk songs over time.

7. ACKNOWLEDGEMENT

We wish to express our deepest gratitude to Sang-il Choi and his team for their invaluable work on the “Anthology of Korean Traditional Folksongs”. Their effort to collect more than ten thousand unique recordings from across Korea has not only significantly contributed to the preservation of the rich tapestry of Korean folk music but has also created a monumental resource for academic research. Without their extraordinary efforts, our work would not have been possible. We sincerely thank them for laying such a robust foundation and for enabling future researchers and us to build upon it. We also appreciate MBC for kindly allowing us to utilize the dataset for this research.

The web demo was implemented with the kind help of Dongmin Kim.

ABSTRACT

Significant strides have been made in creating voice identity representations using speech data. However, the same level of progress has not been achieved for singing voices. To bridge this gap, we suggest a framework for training singer identity encoders to extract representations suitable for various singing-related tasks, such as singing voice similarity and synthesis. We explore different self-supervised learning techniques on a large collection of isolated vocal tracks and apply data augmentations during training to ensure that the representations are invariant to pitch and content variations. We evaluate the quality of the resulting representations on singer similarity and identification tasks across multiple datasets, with a particular emphasis on out-of-domain generalization. Our proposed framework produces high-quality embeddings that outperform both speaker verification and wav2vec 2.0 pre-trained baselines on singing voice while operating at 44.1 kHz. We release our code and trained models to facilitate further research on singing voice and related areas.

1. INTRODUCTION

Singer representation learning is a complex task in Music Information Retrieval (MIR) that involves extracting a representation of a singer’s voice, capturing their unique identity or vocal timbre. This task is closely related to singer recognition, which comprises two major tasks: singer identification and singer verification. The first aims to determine the singer of a given song from a fixed set of singers in the dataset, while the latter aims to determine if two audio excerpts come from the same singer or not. Singer representation learning has many potential applications, including retrieval tasks (such as retrieving songs with a similar singing voice), and providing singer embeddings for conditioning Singing Voice Synthesis (SVS) [1] and Singing Voice Conversion (SVC) systems [2].

*Work mostly conducted during an internship at Sony CSL Paris

Singer recognition is related to speaker recognition, a well-established domain with vast literature. Historically, it has received a much greater interest in particular due to the need for authentication by voice in many telecommunications applications. Singing voice, however, is different from speech in several ways, typically containing a wider variance of phoneme duration, utterances, and a wider pitch range, which makes singer recognition more challenging. Moreover, the lack of large labeled datasets further restricts the development of data-driven approaches.

In this study, we investigate if speaker recognition models trained on labeled speech data can be applied to singing voice, and whether self-supervised learning (SSL) models trained on singing voice data can achieve comparable performance. We compare different self-supervised techniques, including SimCLR [3], Uniformity-Alignment [4], VICReg [5] and BYOL [6], trained on a large collection of isolated vocal tracks. We also explore high-frequency regions that are traditionally ignored in speech [7, 8] but might be present in singing voice by working in 44.1 kHz sampling rate. Finally, we evaluate the generalization capabilities of our models on out-of-domain data.

Our main contributions are as follows: 1. We perform singer representation learning experiments using self-supervised techniques, an area that few works have explored. 2. We train encoders that operate at 44.1 kHz on a large dataset of singing voice recordings. 3. We conduct an extensive evaluation of the obtained embeddings for singer identification and singer similarity tasks, comparing them with publicly available pre-trained speech baselines. 4. We measure the out-of-domain generalization capabilities of our models on four public datasets.

2. RELATED WORK

Singer recognition has traditionally relied on acoustic features such as Mel-frequency cepstral coefficients (MFCCs) or Line Spectral Frequencies (LSFs) to capture timbre [9–11]. Some approaches focus on singer identification on polyphonic music [12, 13], while others separate vocals from background [14, 15]. In speaker verification literature, time-invariant embeddings such as i-vector [16] or x-vector [17] have been extensively used, and the domain has shifted towards data-driven approaches using deep neural networks to encode acoustic features into a lower-dimensional representation that captures speaker charac-

teristics. Temporal aggregation is used to remove the time dimension, and these systems are usually optimized using speaker label information for classification or metric learning losses. Recent works have also explored SSL for speaker verification [18–21].

SSL has been successful in many domains, particularly with approaches such as SimCLR [3], MoCo [22], CPC [23], and BYOL [6]. In the audio domain, following the success in Computer Vision and Natural Language Processing (NLP), successful SSL models for speech include Wav2Vec 2.0 [24], HuBERT [25], and WavLM [26]. SSL has also been successful in learning general-purpose audio representations, with examples like COLA [27], CLAR [28], and CLMR [29].

While the idea of finding singer embeddings using contrastive approaches is not new [30], to the best of our knowledge, only one work has employed SSL for singer representations [31]. In their work, contrastive learning is used to acquire feature embeddings of singing voices using data augmentations that disturb a singer’s identity to make the embeddings more attentive to timbre or technique. In contrast, our work explores different SSL techniques, focuses on out-of-domain testing, and evaluates on singer similarity as well as singer identification.

3. METHOD

3.1 Goal

Our objective is to obtain, from isolated vocal tracks, unique singer representations that capture the timbre of the singer’s voice. These representations must satisfy three criteria: (I) clips from the same singer should have a higher average similarity than clips from different singers; (II) the representation should not be dependent on fundamental frequency or linguistic content variations; and (III) the representations should generalize well to out-of-domain data.

3.2 Overview

The ideal embedding space for singer representations should cluster elements of the same singer while also ensuring semantic consistency by placing similar voice timbres close to each other within the space [4]. In line with the criteria outlined in Section 3.1, we conducted experiments with various self-supervised techniques which force embeddings of similar input data to be close in the embedding space. We experimented with four frameworks: SimCLR [3], Uniformity-alignment [4], VICReg [5], and BYOL [6]. Although these frameworks share a common goal, they differ in their approach (see Section 3.3). We took great care in selecting appropriate data augmentations and used a diverse set of singing voice training data. In the current section, we describe the general training framework common to all our self-supervised experiments.

Data sampling: In our methodology, we use a COLA [27] approach to train our models by sampling audio segments on the fly, from a randomly drawn audio clip coming from a large database. We first extract two segments $(x, x') \in \mathbb{R}^N$ cropped randomly from the audio clip,

called the anchor and positive segment. We obtain augmented views of both audio segments of the positive pair via a data augmentation module $\text{Aug}(\cdot)$ that operates in the waveform domain, resulting in an augmented positive pair $(x^{(1)}, x'^{(2)})$. We repeat this process B times for a batch size of B , obtaining a positive pair batch $(\mathbf{x}^{(1)}, \mathbf{x}^{(2)})$, with no repetition of audio clips during a training epoch. The superscript l is further omitted for simplicity.

Model: Our proposed model takes raw audio waveforms sampled at 44.1 kHz as input. Firstly, we compute log-compressed mel-spectrogram features $m \in \mathbb{R}^{F \times L}$ on the fly using the *nnAudio* library¹. Next, the encoder module $g(\cdot)$ maps the extracted mel-spectrograms to a latent representation $h' = g(m) \in \mathbb{R}^{H \times L}$. At this stage, adaptive average pooling is used to aggregate embedding vectors h' into time-invariant feature embeddings $h \in \mathbb{R}^H$. A projection layer $p(\cdot)$ maps h into a lower dimensional latent space $z = p(h) \in \mathbb{R}^D$ using a shallow neural network.

We denote the full model $f(\cdot)$ by stacking the acoustic feature extraction, encoder, and projection modules. During training, we encode the training batch and obtain projections $\mathbf{z} = f(\mathbf{x})$. After training is completed, we discard the projection layer and use only the feature embeddings h . The similarity between a pair of embeddings is computed using the cosine similarity.

Although there are many specialized speaker verification architectures in the speech domain [32, 33], we use the EfficientNet-B0 [34] architecture as the backbone for the encoder module and a single SiLU non-linearity followed by a fully-connected layer for the projection layer. The projections are ℓ_2 normalized.

3.3 Self-supervised frameworks

The core concept of all used approaches is to leverage big amounts of unlabeled data to build a good representation space by aligning similar elements (and possibly separating dissimilar ones). At training time, model $f(\cdot)$ acts in a Siamese setup by encoding both elements of the augmented pair $\mathbf{z}^{(1)} = f(\mathbf{x}^{(1)})$ and $\mathbf{z}^{(2)} = f(\mathbf{x}^{(2)})$. For BYOL, we have a separate encoder f' with the same architecture as f and we compute $\mathbf{z}^{(1)} = f(\mathbf{x}^{(1)})$ and $\mathbf{z}^{(2)} = f'(\mathbf{x}^{(2)})$. For all setups, we compute a loss function on the batch projections $\mathcal{L}(\mathbf{z}^{(1)}, \mathbf{z}^{(2)})$.

Contrastive Learning: We employ the contrastive loss called *NT-Xent* from SimCLR [3]. The loss maximizes the agreement between positive samples and pushes all other embeddings of the batch (the negative parts) away in the representation space. It does so by maximizing the cosine similarity (sim) between positive samples and minimizing the sum of similarities for all other pairs formed in the batch:

$$\mathcal{L}_{\text{cont}}(\mathbf{z}) = - \sum_i \log \frac{\exp(\text{sim}(\mathbf{z}_i^{(1)}, \mathbf{z}_i^{(2)})/\tau)}{\sum_{j \neq i} \exp(\text{sim}(\mathbf{z}_i^{(1)}, \mathbf{z}_j^{(2)})/\tau)}. \quad (1)$$

We decouple the term $\exp(\text{sim}(\mathbf{z}_i^{(1)}, \mathbf{z}_i^{(2)})/\tau)$ from the

¹ <https://github.com/KinWaiCheuk/nnAudio>

denominator of the original *NT-Xent* [3], which has been shown to make the SSL task easier for smaller batch sizes and less sensitive to the hyperparameter τ [35].

Uniformity-Alignment: Proposed in [4], Uniformity-Alignment aims to align similar examples and distribute elements uniformly in an ℓ_2 normalized embedding space. Instead of using a contrastive loss, the authors propose optimizing directly for these two properties, resulting in two loss functions: alignment ($\mathcal{L}_{\text{align}}$) and uniformity ($\mathcal{L}_{\text{unif}}$).

$$\mathcal{L}_{\text{align}}(\mathbf{z}^{(1)}, \mathbf{z}^{(2)}) = \frac{1}{N} \sum_i \left\| \mathbf{z}_i^{(1)} - \mathbf{z}_i^{(2)} \right\|^2, \quad (2)$$

$$\mathcal{L}_{\text{unif}}^k(\mathbf{z}^{(k)}) = \log \frac{1}{N} \sum_{i,j} \left(\exp(-t \|\mathbf{z}_i^{(k)} - \mathbf{z}_j^{(k)}\|^2) \right), \quad (3)$$

where $t = 2$ and $\mathcal{L}_{\text{unif}} = \sum_{k=1,2} \mathcal{L}_{\text{unif}}^k / 2$.

VICReg: VICReg [5] is an approach that attempts to maximize the information content of the learned embeddings. Three losses are proposed: the variance, invariance, and covariance losses. The invariance loss is the same as the alignment loss (see Equation 2). The variance regularization forces the standard deviation of a batch (in the dimension axis) to be close to the value μ , preventing *collapse* (when embedding dimensions become useless). Let $\mathbf{d}_j(\mathbf{z}) \in \mathbb{R}^B$ be the vector composed of the values of a batch \mathbf{z} at dimension j . The variance regularization is:

$$\mathcal{L}_{\text{var}}(\mathbf{z}) = \frac{1}{D} \sum_{j=1}^D \max(0, \mu - S(\mathbf{d}_j(\mathbf{z}), \epsilon)), \quad (4)$$

where D is the number of dimensions of z_i , and S is the regularized standard deviation $S(x, \epsilon) = \sqrt{\text{Var}(x) + \epsilon}$.

The covariance regularization decorrelates the dimensions of the embedding, making them orthogonal:

$$\mathcal{L}_{\text{cov}}(\mathbf{z}) = \frac{1}{D_z} \sum_{i \neq j} (C(\mathbf{z}))_{i,j}^2, \quad (5)$$

where $C(\mathbf{z}) = \frac{1}{N-1} \sum_{i=1}^N (\mathbf{z}_i - \bar{\mathbf{z}})(\mathbf{z}_i - \bar{\mathbf{z}})^T$ is the covariance matrix of \mathbf{z} , and $\bar{\mathbf{z}} = \frac{1}{N} \sum_{i=1}^N \mathbf{z}_i$.

BYOL: Bootstrap Your Own Latent (BYOL) [6] employs two neural networks: the online and target networks. Both networks share the same architecture. In addition, BYOL employs an additional predictor network q which computes predictions $q(\mathbf{z})$. BYOL iteratively refines the representation of the online network by minimizing the mean squared error (MSE) between its predictions and the target’s projections. If f and f' denote the online and target networks, respectively, the loss function $\mathcal{L}_{\text{BYOL}}$ on the projections $\mathbf{z}^{(1)} = f(\mathbf{x}^{(1)})$, $\mathbf{z}^{(2)} = f'(\mathbf{x}^{(2)})$ is:

$$\mathcal{L}_{\text{BYOL}}(\mathbf{z}^{(1)}, \mathbf{z}^{(2)}) = \frac{1}{N} \sum_i \left\| \mathbf{z}_i^{(1)} - q(\mathbf{z}_i^{(2)}) \right\|^2. \quad (6)$$

The target network f' is not trained using directly the gradients of $\mathcal{L}_{\text{BYOL}}$, but it is updated with an exponential moving average of the weights of the online network.

Table 1: Out-of-domain datasets used for testing.

4. EXPERIMENTS

4.1 Data

We used a large private corpus of professionally recorded singing voice data containing approximately 25,000 tracks, totaling 940 hours of audio data. The dataset consists of isolated vocals of re-recordings of popular songs by 5,700 artists and includes a variety of singing styles, voice types, lyrics, and audio effects. We note that the actual number of singers is unknown, as the same artist might have been re-recorded by multiple singers. Therefore, we do not believe that this corpus is appropriate for supervised training. Additionally, we added 6 hours of source-separated vocals to the corpus. All samples were converted to mono 44.1kHz tracks with 16-bit encoding, and any silence lasting more than 1.3 seconds was trimmed to 1.3 seconds. Segments with less than 0.5% amplitude were considered silent, and segments with more than 0.5% amplitude lasting less than 0.2 seconds were silenced. The dataset was partitioned into three distinct sets with ratios of 80% for training, 10% for validation, and 10% for testing, with no artist allocated to more than one set. The length of a track is typically a few minutes.

Out-of-domain evaluation: Four datasets are used to test the out-of-domain generalization of the models. The summary of all datasets is shown in Table 1.

4.2 Experiment setup

We perform a series of experiments to determine the best SSL framework for singer representation learning:

- **CONT:** We train a model on the decoupled version of the contrastive loss $\mathcal{L} = \mathcal{L}_{\text{cont}}$ [35].
- **CONT-VC:** We train a model using $\mathcal{L}_{\text{cont}}$ (contrastive loss) with added variance and covariance regularization $\mathcal{L} = \mathcal{L}_{\text{cont}} + \mu \mathcal{L}_{\text{var}} + \nu \mathcal{L}_{\text{cov}}$ [40].
- **UNIF:** We train a model using the uniformity- alignment loss $\mathcal{L} = \mathcal{L}_{\text{align}} + \gamma \mathcal{L}_{\text{unif}}$ [4].
- **VICReg:** We train a model using the VICReg loss $\mathcal{L} = \lambda \mathcal{L}_{\text{align}} + \mu \mathcal{L}_{\text{var}} + \nu \mathcal{L}_{\text{cov}}$ [5].
- **BYOL:** We train a model on BYOL configuration, optimizing the MSE $\mathcal{L} = \mathcal{L}_{\text{BYOL}}$ [6].

The contrastive loss has been shown to yield good results in the literature [27, 31], but there is concern that it may break the semantic structure of the embeddings by pushing similar singers away in the representation space [4]. In the CONT-VC approach, the addition of variance

and covariance losses from VICReg is tested as a regularization method to mitigate this problem [21,40]. The UNIF approach attempts to optimize directly for uniformity of the space, which has shown links with linear separability [4] and potential for strong singer identification results. While VICReg claims to be an information-theoretic approach to general-purpose representation learning, it has not yet been thoroughly tested in the audio domain. Finally, BYOL is included in the study for comparison as it has shown promising results in several audio downstream tasks, claiming state-of-the-art [41].

4.3 Evaluation procedure

The models are first trained until the validation loss stops decreasing. Validation similarity metrics (Section 4.3.1) are tracked during training, and the best-performing model is selected. This model is evaluated on the test and on out-of-domain sets using cropped 4-second clips of singer recordings (with no overlapping segments). The embeddings h are evaluated in two tasks: singer/speech similarity and singer/speech identification. For simplicity, we refer to singer similarity/identification even when dealing with speech data such as with VCTK/NUS-48E datasets (see Section 5 for details).

4.3.1 Singer similarity

We evaluate singer similarity by measuring two metrics directly on the singer feature embeddings h : the Equal Error Rate (EER) and Mean Normalized Rank (MNR). The EER relates to singer verification. On the other hand, we relate the MNR to singer retrieval by computing the similarities between a query excerpt and a set of candidates. No training is performed for the similarity evaluation.

EER: The EER is a popular metric for verification systems. To compute the EER, the system is exposed to a set of trials consisting of true pairs (two segments coming from the same singer) and fake pairs (two segments coming from different singers), and a similarity metric is computed for both cases (in our case the cosine similarity). False positives (FP) and False Negatives (FN) can be computed by applying a threshold τ on the similarity metric, and the Detection Error Tradeoff (DET) is obtained by varying τ as a function of FP and FN. The EER is the error rate at which $FP = FN$. We compute the EER following the implementation available as part of the SupERB benchmark [42]². We sample 50,000 speaker pairs for computing the EER on the test set and 20,000 speaker pairs for out-of-domain.

MNR: Denote $q^{(1)}, q^{(2)}$ two query audio samples, coming from the same audio recording (and therefore the same singer) drawn at random at each trial. Let S be a set of N audio samples, drawn at random from a dataset, and $q^{(2)} \in S$. The MNR is [40]:

$$\text{MNR} = \frac{1}{K} \sum_{k=1}^K \frac{R(q_k^{(1)}, S_k)}{N}, \quad (7)$$

XLSR-53 [45] ⁶	300M	16	24X1024	Wav2Vec 2.0
Ours	5.0M	44.1	1000	EfficientNet-B0

Table 2: Number of network parameters, sampling rate in kHz (SR), the size of the feature embeddings (Dim), and the architecture backbone for the baselines and our models.

where $R(q_k^{(1)}, S_k)$ is the integer position (rank) of $q^{(2)}$ in the sorted list of cosine similarities between $q^{(1)}$ and the samples in S . We perform $K = 1000$ trials for $N = 512$.

Input sample rate: To ensure a fair comparison with the baselines, which operate on 16 kHz, the evaluation is done in two scenarios: at 16 kHz and 44.1 kHz. In the former, the 44.1 kHz inputs are downsampled to 16 kHz and upsampled back to 44.1 kHz before being fed to the models, removing energy above 8 kHz. In the latter, the trained models have access to the full frequency range of the input data.

4.3.2 Singer identification

To evaluate the linear separability of singer classes, we perform singer classification as a downstream task for singer identification on out-of-domain evaluations. We use 5-fold cross-validation to split the audio files of each singer into train, validation, and test subsets (4-fold for NUS-48E). A single feed-forward linear layer is trained with cross-entropy loss on the train subset to predict singer classes from embeddings extracted from frozen models. The best model is selected on the validation subset. Average metrics on the test set over all folds are reported. We limit this task to out-of-domain evaluations since these datasets contain multiple files per singer and the classes are balanced.

4.4 Baselines

In our experiments, we use as baselines three speaker verification networks: GE2E [43], Fast-ResNet34 [33] (hereafter referred to as F-ResNet), H/ASP [44]; and two large general purpose self-supervised models Wav2Vec-base [24], and XLSR-53 [45]. These models have been pre-trained on speech and either achieved state-of-the-art results or have been used for obtaining speaker representations for speech/singing voice synthesis tasks while being publicly available. We provide an overview of the baseline models in Table 2.

Since all baselines operate on 16kHz, we down-sample the test signals to 16kHz accordingly. For Wav2Vec-base and XLSR-53, we use adaptive average pooling as the temporal aggregation method for the frame-wise feature embeddings, and we employ a learned, weighted sum of the first three layers for the downstream

Table 3: EER and MNR (% , lower is better) measured on frozen model embeddings. Datasets that contain only singing voice are marked with *, and models which are not self-supervised are indicated with †. Results in bold are the best among all models, for both 44.1 kHz and 16 kHz input sample rates. Underlined results highlight the best on 16kHz input only. For Wav2Vec-base and XLSR-53, we use the embeddings of the first layer and aggregate them using average pooling.

classifier [42]. We empirically found that this approach boosts classification performance compared to using a single layer. Specifically, the first layers of these models are more effective for speaker verification [26] and are more correlated with speaker characteristics [46]. For singer similarity evaluations, we use only the first layer, as there is no training involved to yield weights for a weighted sum.

4.5 Training

To train our models, we used 4-second audio clips that were normalized, augmented, and converted to log-compressed mel-filterbanks with 80 mel bins, a window length of 2048, and a hop size of 512. This results in an FFT frame of 46.4ms and sliding windows of 11.6ms for 44.1 kHz audio. We initialized the EfficientNet-B0 backbone with pre-trained weights on ImageNet [40] and used the ADAM optimizer with a learning rate of 1e-4 and weight decay of 1e-5, with a batch size of 120. For contrastive loss, we used a temperature parameter of $\tau = 0.2$ [4], and whenever we used covariance regularization, we set $\nu = 100$. For variance regularization, we set $\mu = 25$. Additionally, for VICReg experiments, we used an invariance loss factor of $\lambda = 25$, and UNIF, we set $\gamma = 1$. For BYOL, we used a learning rate of 3e-5, a weight decay of 1.5e-6 and an initial moving average value τ of 0.99. We found through empirical analysis that these hyperparameters were effective for convergence and avoiding collapse.

In terms of data augmentation techniques, we applied Gaussian noise, gain with a minimum attenuation of -6 dB, and time masking with at most 1/8 of the clip being masked. We also used formant-preserving pitch shifting with Praat [47, 48] as a method of data augmentation, with the pitch shift ratio and pitch range ratio being sampled uniformly from U(1,3) and U(1,1.5), respectively, with a random choice on whether to take the reciprocal of the sampled ratios or not [46]. All augmentations had a probability of 0.5 of being applied. We avoided using naive pitch-shifting techniques that transpose the formants, which can significantly alter the singers’ timbre.

Table 4: Average linear classification accuracy on out-of-domain data (%) over K-fold cross-validation. Datasets that contain only singing voice are marked with *. The best scores are highlighted in bold and the best among the trained models (bottom 5 rows) are underlined. Models which are not self-supervised are indicated with †.

5. RESULTS AND DISCUSSION

Table 3 presents the results of singer similarity evaluation on both in-domain and out-of-domain test sets, reporting the best Equal Error Rate (EER) and Mean Normalized Rank (MNR) for trained models and baselines in all test datasets. Table 4 shows the accuracies for downstream singer identification task on out-of-domain datasets. We also share in supplementary material additional qualitative visual evaluations of the embeddings⁷, and release code and models to encourage reproducibility and facilitate its use in future projects⁸.

5.1 Results on pre-trained models on speech

The results indicate that models pre-trained on speech in a supervised manner (using speaker labels) exhibit good generalization to out-of-domain speech datasets. H/ASP achieves an impressive 0.28% EER on the VCTK, and all models score higher than 88% accuracy on VCTK, NUS-

⁷ <https://sites.google.com/view/singer-representation-learning>

⁸ <https://github.com/SonyCSLParis/ssl-singer-identity>

48E, and M4Singer datasets. Their similarity performance on singing voice datasets, however, is much worse than on speech, but the best models still score below 10% EER on NUS-48E and 12.31% and 14.21% EER on M4Singer for H/ASP and F-ResNet, respectively.

This suggests that important features of the singing voice can also be learned directly from speech. However, the results show the pre-trained models perform worse on heavily processed data that includes uncommon effects and vocal techniques. This is evident, in particular, in the last columns of Tables 3 and 4 (VocalSet), with all baselines scoring around 40% EER and from 20% to 40% worse accuracy when compared to the other datasets.

5.2 Results on Self-Supervised Models

Models trained with contrastive loss (CONT and CONT-VC) achieved the best EER and MNR on the test set. These models were able to learn highly discriminative features for the task of in-domain singer similarity. For instance, the CONT model had the lowest overall EER and MNR (2.16% and 0.48% respectively) on the test set.

It can also be seen in Table 3 that in-domain test performance did not necessarily translate to good generalization to out-of-domain data. By adding variance and covariance regularizations (CONT-VC), the model achieved better generalization to out-of-domain data on some datasets (such as the VocalSet, with approximately 1% EER difference). However, in the VICReg scenario, which has both regularizations but lacks the contrastive part, the results were worse. In fact, VICReg had the worst overall results of all the tested self-supervised frameworks. UNIF, while better than VICReg, also performed worse on average when compared to the other approaches.

CONT and BYOL achieved the best accuracy over all our trained models on singer identification (Table 4), achieving the highest scores of 77.42% and 81.01%, respectively (the VocalSet paper [38] reports 60-70% accuracy on a supervised singer identification task).

BYOL achieved the best generalization on similarity, performing best on out-of-domain data, even though its scores were worse on the in-domain test set. Interestingly, of all explored self-supervised techniques, BYOL is the only one that does not explicitly force any kind of feature distribution on the embedding space. In addition, BYOL was able to learn best how to leverage the information present at 16 kHz sample rate, with an EER of 5.88 on the test set. It also performed best on out-of-domain speech data (VCTK). In general, our models struggled with speech, performing generally better when they only had access to a reduced frequency band. This suggests that in speech, high-frequency information the models rely on hinders their ability to generalize.

44.1 vs 16 kHz: Using 44.1 kHz inputs consistently improved the similarity results on singing voice datasets (e.g., M4Singer) for all models, highlighting the models' ability to efficiently use high-frequency information. Moreover, most models showed a marked decline in the in-domain dataset results when tested with 16 kHz inputs (the CONT

model, for example, shows a drop from 2.16% EER to 6.39% EER). While the 16 kHz inputs could be considered out-of-domain, this effect shows that high-frequency information is important for the trained models to achieve better performance.

Comparison to baselines: The trained models show better results than baselines on in-domain test sets and the VocalSet dataset for singer similarity tests, although they fall behind F-ResNet and H/ASP on the mixed speech/singing dataset NUS-48E and VCTK. Nonetheless, on M4Singer, some self-supervised models outperformed the supervised baselines, with BYOL showing the best performance (12.28% EER and 3.77% MNR), and CONT and CONT-VC also being superior to F-ResNet.

The trained models have substantially better singer similarity results compared to Wav2Vec-base and XLSR-53. These results indicate the potential of training models on the proposed SSL tasks specifically on singing voice data. Further improvements could be made by fine-tuning the embeddings on verification tasks, as has been demonstrated in previous work on Wav2Vec 2.0 [49].

Moreover, BYOL outperformed Wav2Vec-base for both VocalSet and M4Singer on classification. Among all models, XLSR-53 achieved the best overall performance for singer identification of singing voice. However, is noteworthy that our models have significantly fewer parameters than the self-supervised Wav2Vec-base (19 times less) and XLSR-53 (63 times less).

6. CONCLUSION

In conclusion, we have shown that self-supervised learning is an effective approach for learning representations of singers. The self-supervised models trained on a large corpus of singing voice data demonstrated a performance that either matched or surpassed publicly available supervised speech models, without resorting to specialized architecture designs. Additionally, our models outperformed general-purpose self-supervised counterparts even with a significantly reduced parameter count. When applied to singer identification, our models exhibited superior performance over Wav2Vec-base on singing voice datasets but fell somewhat short in comparison to the considerably more expansive XLSR-53.

Furthermore, our results suggest that these models hold promise for singer identification and similarity downstream tasks. BYOL showed the most promise for generalizing to out-of-domain data, while the contrastive approaches were more effective for in-domain data.

However, we note that our models' representations do not yet fully capture a singer's identity when confronted with unique singing techniques, such as those found in the VocalSet [38]. This underscores the need for further research on robust SSL frameworks capable of accommodating such variations. Our findings also suggest that employing a higher sampling frequency can be advantageous for singing voice tasks, but optimal frequency for generalizing to both singing and speech tasks remains to be determined.

ABSTRACT

Self-supervised learning (SSL) has shown promising results in various speech and natural language processing applications. However, its efficacy in music information retrieval (MIR) still remains largely unexplored. While previous SSL models pre-trained on music recordings may have been mostly closed-sourced, recent speech models such as wav2vec2.0 have shown promise in music modelling. Nevertheless, research exploring the effectiveness of applying speech SSL models to music recordings has been limited. We explore the music adaption of SSL with two distinctive speech-related models, data2vec1.0 and Hubert, and refer to them as music2vec and musicHuBERT, respectively. We train 12 SSL models with 95M parameters under various pre-training configurations and systematically evaluate the MIR task performances with 13 different MIR tasks. Our findings suggest that training with music data can generally improve performance on MIR tasks, even when models are trained using paradigms designed for speech. However, we identify the limitations of such existing speech-oriented designs, especially in modelling polyphonic information. Based on the experimental results, empirical suggestions are also given for designing future musical SSL strategies and paradigms.

1. INTRODUCTION

Deep learning (DL) techniques have shown promising results in a wide range of auditory tasks, including speech and music information retrieval (MIR). However, the quantity and quality of labelled data is a bottleneck for developing algorithms with better generalisation in complex real-world settings for machine listening. To address this issue, self-supervised learning (SSL) such as BERT [1] has emerged

as a solution to leverage diverse and representative unlabelled data to train a deep feature extractor with better generalisation. By combining this pre-trained SSL encoder with a naive classifier, typically a multi-layer perceptron (MLP) or long short-term memory (LSTM) with limited hidden layers, the model can achieve strong or state-of-the-art (SOTA) performance in various downstream tasks including NLP [1–3], computer vision [4], and audio [5, 6], where well-labelled datasets are limited. For music, larger datasets can be more expensive due to copyright and annotation costs, making SSL essential for developing effective MIR systems. Investigating versatile SSL approaches in MIR can further improve the performance on many MIR tasks, benefitting the music industry, music education, and heritage preservation. Although SSL has significantly improved the performance of models in tasks such as speech recognition, sentiment analysis, and language modelling, its effectiveness in MIR remains largely unexplored.

There has been much work on SSL for audio representation learning, including speech, sound events or music. But most results are difficult to evaluate or fine-tune due to limited access to training data, pre-trained parameters or training codes. PANN [7] is trained on noisy/weak-label classification and does not provide promising results in music tasks such as pitch classification and instrument classification [8]. Besides, it can hardly be re-trained on music datasets given that the MIR community does not have a weekly labelled large music dataset. MusiCoder [9], Music PASE [10], and MAP-Music2Vec [11] use strategies mainly based on masked prediction, where training models predict the audio waveform manually-designed feature or learnable deep feature of input removed randomly from the ground truth. Such models trained on music are not open-sourced except MAP-Music2Vec, which provides pre-trained parameters on hugging-face¹. Jukebox [12] uses similar strategies for pop-song recording generation and demonstrates good potential for multiple MIR tasks [6]. But the training code for it is unavailable and is hard to fine-tune given its 6 billion parameters. MAP-MERT v0 [13] mimicks HuBERT [14], which regards the clustering results of audio as a pseudo label or pseudo spectrum to be reconstructed rather

*The authors contributed equally to this work.

† Corresponding authors.

¹ <https://huggingface.co/m-a-p/music2vec-v1>

than a cluster assignment. But it does not provide training codes for further model evaluation. Furthermore, there are some music SSL models based on instance discrimination. In this family of approaches, each instance is considered its class, and models are trained to distinguish among different instances. CLMR [15] is trained with a limited number of parameters and shows limited capacity [6]. PEMR [16] does not show promising results besides tagging and is not open-source for further evaluation.

Although not designed for MIR tasks, some speech SSL models provide promising results on music tasks, and their training codes are available for fine-tuning or re-training on musical audio. Mockingjay [17], and PASE [18] use masked waveform / audio-feature prediction for pre-training. COLR [19] uses EfficientNet with a limited number of parameters and is designed for general audio, though it has a promising result on instrument classification. SF-NFNet-F0 [20] also uses an architecture based on convolution neural networks, a SlowFast Normalizer-Free ResNet, for audio pre-training. Furthermore, apart from providing good results on automatic speech recognition (ASR), Wav2Vec2.0 [5], HUBERT and data2vec [21] also provide much better results on pitch estimation and instrumental classification than PANN, though they are still far from perfect [8]. All of the speech SSL models are helpful for music SSL model development.

Previous work on re-training speech SSL systems with music recordings is limited to the size of training datasets or model structure. Ragano et al. [22] re-trained wav2vec2.0 on music audio and improved performance on pitch estimation and instrument classification significantly. But the training set is less than 100 hours which may be less representative, and the downstream tasks are limited and not universal. MusiCoder and Music PASE can be regarded as re-training speech SSL models on music recordings, but the model performance is not promising. Besides, these models are evaluated with a limited number of downstream tasks, making the learned embedding less persuasive. SF-NFNet-F0 is trained on music recordings and provides better results on multiple music tagging tasks [23]. But its model architecture is based on CNN, without much room for further scale-up and longer sequence modelling.

The missing science in the previous studies is as follows. All of the existing models trained on music are either with a limited number of parameters and capacity for MIR tasks other than tagging or not open-source for further evaluation. Some of the systems developed on speech or general audio recordings demonstrate promising but not satisfying results on MIR tasks. Besides, previous investigations on the efficacy of applying speech-related SSL models to music recordings are limited by the size of the training set, not enough universality on the downstream tasks, or paying less attention to powerful transformer structures.

Our key contributions are four-fold: (1) exploring two speech-related SSL models based on transformer structures, data2vec and HuBERT, and comparing the results with those models pre-trained in speech recordings; (2) carrying out ablation studies for pre-training, thus providing more

intuition for further music SSL system design; and (3) systematically comparing the performance on 13 downstream tasks, which facilitates comprehensive model evaluation on a wide range of MIR tasks.

2. METHOD

In order to keep the pre-training and representation evaluation protocols comparable, we focus on adapting from the speech self-supervised learning frameworks that support direct audio input and end-to-end pre-training. Given our intent of exploring the influence of the pre-training design itself, we choose two SSL frameworks mainly distinguished by their self-supervised learning targets while sharing very similar training settings, including model architecture, training datasets, and evaluation protocols. In this section, we briefly describe the two selected SSL models – data2vec-1.0 [21] and HuBERT [14] – in the unified auto-encoding framework (cf. Fig. 1) and discuss the similarities and differences under music audio pre-training.

2.1 Music2Vec: Continuous Target Prediction

We adapt the pre-training paradigm from the speech version of the multi-modal framework data2vec-1.0 [21], where the prediction targets during pre-training are continuous representations. We refer to this continuous prediction model adapted with music recordings as Music2Vec.

Modified from the design of bootstrap your own latent (BYOL) [24], Music2Vec aims to predict continuous latent representations from the teacher model for the masked input audios, which is illustrated in Fig. 1a. The teacher model and student model share the same architecture, and the parameters of the teacher model are updated according to the exponential moving average of the student [21]. The student model takes the partially masked input and is asked to predict the average pooling of top- K layer outputs from the Transformer [25] in the teacher model. In contrast, the teacher model takes the unmasked input and provides contextual prediction targets in the pre-training.

Following the data2vec [5] setting, we train the Music2Vec of 95M parameters with a comparable 1k hours of music recordings. Since pre-trained speech models can barely benefit music representation learning [22], we instead train the base model from scratch to verify its effectiveness in modelling music audio recordings.

2.2 MusicHuBERT: Discrete Target Prediction

Another efficient speech SSL model, HuBERT [14], is chosen as the representative of discrete target prediction design. We referred to the music adaption version as MusicHuBERT. It takes masked music audios as input (Similar to Music2Vec) and predicts pre-processed discrete labels corresponding to the masked area, as shown in Fig. 1b. The discrete targets are pseudo labels provided by K-means that are trained on the MFCC features of the training audios. The number of clusters K of the K-means model is a hyperparameter, and all the centroids are assigned with randomly initialised embeddings and learned during the

Figure 1: Pre-training Paradigms of Selected Models. Both of the models are fed with masked audio inputs and predict given targets without supervised information.

MusicHuBERT pre-training. MusicHuBERT can also be trained for an extra n iterations, where K-means clustering is learned from model outputs’ previous iteration. We follow the original HuBERT [14] setting to train a model with 95M parameters of the same size as Music2Vec.

2.3 similarities & Differences of SSL frameworks

This subsection will examine the similarities and differences between the SSL frameworks mentioned above.

Both Music2Vec and MusicHuBERT are annotation-free and utilise SSL techniques; their most common characteristic is the training task of “reconstructing” information from masked inputs, making them auto-encoding models. During the denoising process, these models learn the semantics contained in the audio. Furthermore, they share similar model architecture designs, which are inherited from wav2vec-2.0 [5], wherein the audio is initially encoded by a multi-layer 1-D CNN feature extractor that maps a 16 kHz waveform to 50 Hz representations. The encoded tokens are then fed into a 12-layer transformer block with a hidden dimension of $H = 768$.

Regarding the differences in the designs, the most notable one is that Music2Vec is required to predict continuous latent variables, whereas MusicHuBERT predicts discrete pseudo-labels. The time cost of SSL target preparation bottleneck varies according to their mechanism. In Music2Vec, the pre-training consumes twice the model forward time since the target representations from the teacher model are inferred on-the-fly. In contrast, MusicHuBERT trains the K-means model and infers all the pseudo-labels before training, which requires high parallel processing ability when the dataset is scaled-up.

3. DATASET & EVALUATION

3.1 Training

We use a private dataset with 1000 hours of music audio recordings for pre-training; each sample is a 30s-long ex-

cerpt from pop-song or instrumental music. The size of the pre-training dataset is roughly the same as the pre-training for HuBERT-base and data2vec-audio-base models.

3.2 Evaluation

We evaluate the models on 13 downstream tasks, including timbre classification tasks such as genre and instrumental classification, singing, playing technique classification, singer classification, and music tagging; emotion-related tasks like music mood classification and regression; and note-related tasks such as pitch estimation, key detection; and sequential tasks like beat tracking.

Music Tagging is a multi-label classification task. We used MagnaTagATune (MTT) [26] and MTG-Jamendo [27] for this task, tag categories of which include genre, instrumentation, mood, and tempo (e.g. fast) etc. For both datasets, we limit the tag vocabulary to the 50 most common tags. We use all clips in MTT and MTG-Jamendo for evaluation. Since many of the audio recordings among 5.5k MTG-Jamendo excerpts are longer than the 30s, we averaged the multiple embeddings computed with a 30s sliding window as the overall embedding. The metrics are the macro-average of ROC-AUCs and the average precision (AP) / PR-AUC among all top-50 tags.

Key detection. We use a commonly-used subset of Giantsteps-MTG-keys [28] as the training and validation set following the data splitting [6], and Giantsteps (GS) [29] as the test set. The metric is a refined accuracy that gives partial credit to reasonable errors [30].

Genre classification. We report the multi-class classification accuracy of the GTZAN [31] dataset, along with ROC and AP on MTG-Genre for multi-label. We used the standard “fail-filtered” split [32] for GTZAN.

Emotion score regression. The Emomusic dataset [33] contains 744 music clips of 45 seconds, each reported on a 2-D valence-arousal plane after listening. We use the same dataset split as [6]. The evaluation metric is the determination coefficient (r^2) between the model regression results

and human annotations of arousal (EmoA) and valence (EmoV) [33]. We split the 45-second clip into a 5-second sliding window for inference and averaged the prediction.

Instrument classification. We use the Nsynth [34] and MTG-instrument datasets. The former is a multi-class task on 306k audio samples in 11 instruments with accuracy as an indicator. The latter is a subset of MTG-Jamendo, containing 25k audio tracks and 41 instrument tags; each track can contain multiple instruments and is evaluated on ROC and AP.

Pitch classification. Given these audios are short monophonic audio, this task is multi-class to determine which of the 128 pitch categories, and the accuracy is used as an evaluation metric.

Vocal technique detection. We use the VocalSet dataset [35], which is the only publicly available dataset for the study of singing techniques. The dataset contains the vocals of 17 different singing techniques in various contexts for a total of 10.1 hours. As the audio clips are divided into 3 seconds, the task only requires a judgment on the type of technique and not on the start and end of the technique. We used the same 10 different singing techniques as in [36] as a subset and used the same 15 singers as the training and validation sets and 5 singers as the test set. Since there is no accepted division between training and validation sets, we selected 9 singers as the training set and 6 singers as the validation set. All the 3-second segments originate from the same recording are allocated to the same part of the split (e.g. all in the testing set).

Singer identification is to identify the vocal performer from a given recording. We randomly divided the VocalSet dataset, which contains 20 different professional singers (9 female and 11 male), into a training set, validation set and testing set based on a ratio of 12:8:5, all containing the same 20 singers.

Beat tracking. We use an offline approach to the binary classification, i.e. the model can use the following information from each frame to help with inference. The model needs to output frame-by-frame predictions at a certain frequency and post-process them using a dynamic Bayesian network (DBN) [37], the same methods with supervised SOTA. The DBN is implemented using `madmom` [38]. The dataset we use is GTZAN Rhythm [39]. We also label the two adjacent frames of each label as beat, a common way of smoothing in beat tracking. The model is evaluated using the `f_measure` implemented in `mir_eval` [30], and the prediction is considered correct if the difference between the predicted event and the ground truth does not exceed 20ms. In this task, some models were trained on other datasets, and the full GTZAN set was used as the test set. For all cases, however, we use GTZAN-train as the training set and GTZAN-test as the test set.

Emotion Tagging. We use MTG-MoodTheme, another subset of MTG-Jamendo [27] that contains 18.5k audio tracks and 59 tags. Unlike Emomusic, this is a multi-label task, with ROC and AP as metrics.

4. EXPERIMENTAL RESULTS

We use the `fairseq` framework² from Meta to train MusicHuBERT and Music2Vec models. All the MusicHuBERT and Music2Vec models are trained for 400k steps with $8 \times$ NVIDIA A100-40GB GPUs. Training with 8 GPUs takes around 2 – 3 days. The experimental results are chiefly as follows.

Our findings suggest these SSL models pre-trained on speech can be helpful for MIR tasks, but pre-trained on music is generally more helpful, besides some exceptions. In section 4.2, we identify the strengths along with weaknesses of training strategies, revealing areas for further improvement. In section 4.3, we discuss the effect of hyperparameters in pretext tasks.

4.1 Pre-trained on Speech and Music

Table 1 demonstrates the performance of HuBERT³ and data2vec⁴ SSL models that were pre-trained on speech recordings and music recordings separately. Here, we only consider the SOTA performance trained with the same dataset train/valid/test split. All of the models are used as parameter-frozen feature extractors. The weighted sum of one output of the CNN tokeniser as well as the 12 outputs of all the transformer layers, are combined with an MLP as the back end. The MLP has only one single 512-dimension hidden layer. The learning rate of the probing is set to $1e-3$.

For the HuBERT model, the results pre-trained on speech recordings are comparable with SOTA on tasks like music tagging, beat tracking, pitch estimation and singing technique classification etc., and are surpassed by the results pre-trained on music audio on most of the downstream tasks besides pitch estimation on Nsynth and key detection on GS. For pitch detection, the data samples in Nsynth are a single note played by one single monophonic instrument, which is similar to speech data. So it is reasonable that HuBERT pre-trained on speech data is capable of modelling a single pitch. Although HuBERT surpasses the vanilla MusicHuBERT on GS and Nsynth-pitch, it is surpassed by the results of MusicHuBERT with an ablation study on pre-training hyperparameters (shown in Table 2).

For data2vec, the data2vec-audio results are also comparable with SOTA on many tasks and have a large gap on others, and overall surpassed by Music2Vec or its ablation study shown in Table 3 on most of the tasks as well. But the data2vec results of beat tracking on GTZAN-Rhythm and singer identification on Vocalset surpassed all Music2Vec. Vocalset includes singing of different phonemes with different singing techniques by different singers. The speech SSL system is capable of modelling diverse phonemes in ASR and various timbres of speakers but has less focus on timbre in speaking techniques you may find in opera. On the contrary, the music SSL models may focus more on phonemes (lyrics) and singing timbre (techniques) but include less focus on the singer itself. For beat tracking, we observe that the performance is reduced significantly when

the number of transformer layers increases from 0 to 12. This shows that the data2vec structure may not be useful for learning temporal information.

4.2 Pre-trained with Different Paradigms

From Table 1, we can tell that MusicHuBERT is more promising than Music2vec given that it provides better results in most of the downstream tasks, especially genre classification on GTZAN, emotion regression on EMO and beat tracking on GTZAN. But it is worse on single-pitch estimation on Nsynth, along with key detection on GS.

These phenomena suggest pre-training with the HuBERT paradigm is strongly correlated with the MFCC feature information used for k-means. Therefore, the quantisation results lack multi-pitch information, including harmony or chord modelling, that is essential to key detection. The following research can use the chroma feature to replace MFCCs⁵. On the contrary, the mask prediction for the deep feature in the data2vec pre-training paradigm is clearly better but still has much room for improvement compared to the SOTA. Although the deep feature still lacks sufficient harmonic information for key detection, it already contains enough information for single-pitch estimation, and the MFCCs may focus more on the timbre of instruments instead of the fundamental frequency. Apparently, Music2Vec can learn pitch information more freely. Besides, data2vec is generally a bit worse for tagging than Music2vec, and both are significantly worse on beat tracking compared to HuBERT and MusicHuBERT.

4.3 Ablation Studies on Pretraining Hyperparameters

Here, we carry out an ablation study of hyperparameter search under both pre-training paradigms. Given the time limitation, we did not extract features on MTG datasets and only calculated the results in another 9 downstream tasks.

4.3.1 Ablation Study on MusicHuBERT

We use the number of clusters $k=500$ and $k=2000$. For the case $k=500$, we increase the dimension of MFCC features from 13, which is commonly used in the speech community, to 20, which is widely used in sound event detection. Thus, the dimension of MFCCs combined with their delta features

and delta-delta features have 39 and 60 dimensions respectively. For the case of $k=2000$, we use the 768-dimension deep feature learned from the first iteration experiment to carry out the second iteration k-means.

From Table 2, we can see that MusicHuBERT with $k=2000$ is better than the $k=500$ case for most of the tasks. Given HuBERT is good for speech when $k=100$ or $k=500$, which is roughly the number of human phonemes, this implies music tokens or notes are much richer than speech and therefore need a larger number for quantisation.

The results on k-means for deep features are better than the vanilla MusicHuBERT besides genre classification on GTZAN, singer identification on vocalset, and singing techniques classification on vocalset. This implies the MFCCs features are good for modelling the human voice, regardless of speech or singing. The results of GTZAN may be due to the randomness as the dataset is very small.

Besides, increasing the dimension of MFCCs provides no significant difference among most of the tasks other than tasks on Nsynth and GS. Increased dimensionality for MFCC features can provide more detailed information on impulse response for a sound event. Thus, monophonic instrumental notes can be better modelled with 60-dimension MFCC features. Furthermore, the emotion regression also provides different results, but the average of the two metrics is nearly the same, providing no significant improvement.

4.3.2 Ablation Study on Music2Vec

We use audio files with 30s length, mask span length 10, mask probability 65%, target top-8 transformer layer the teacher model as a deep feature, and training step 400K as the vanilla setting. We conduct parameter searching and correlation analysis for Music2Vec pretraining, including masking strategy, training steps, the learning target layers, and recording length; the results are shown in Table 3.

We revise the masking strategy by changing the **mask span length** and **mask token probability** in the data2vec-audio-base setting. Mask token probability is the probability for each token to be chosen as the start of the span to be masked, the length of which can also be adapted for different data modalities. The results in Table 3 show that the other span value and other mask token probability provide a bit worse results on nearly all the tasks. This suggests that the data2vec hyperparameters for speech pre-training are generally helpful for music pre-training.

Given the fact that early transformer layer representations generally perform well on key detection and beat

tracking, we modify the **prediction target** provided by the teacher model. We change the prediction target in Music2Vec from the original one, that is, the average of the top-8 layer representations, to all the 12 layers. The results in Table 3 show that Music2Vec actually benefits, not only from the potentially preserved key information shown by a significant increase on GS but all the other tasks as well.

Furthermore, we use **audio length cropping** to shorten music excerpts since longer sequences are more difficult to model. Note that the combined audio length in a batch on a single GPU is not altered, and the hardware environment remains the same, making a single training batch contain a larger number of music samples when clips are cropped. Due to the position embedding in the SSL systems, the model can get information more than 5 seconds after pre-training on only 5-second music recordings. But the key detection provides worse results which may lead to the fact that a local key within a 5-second song may not be identical to the global key in the whole music sentence.

5. CONCLUSION & DISCUSSION

In this paper, we explore the music variants of two distinctive speech-related transformer-based SSL models, data2vec and HuBERT. Our findings suggest that pre-training with music recordings rather than speech can generally improve performance on a wide range of MIR tasks, even when the models and training are designed for speech. There are exceptions for data2vec, however, such as singer identification, the dataset of which is similar to the speech dataset used to pre-train. Thus, when resources are limited, our suggestion is to use speech pre-training models, given that they can provide helpful information about music already. Speech data can be beneficial if lacking a suffi-

cient vocal dataset with different singers, but one should use mainly music data if possible.

Furthermore, we can use the same speech training hyperparameters for masked span and masked probability in music pre-training. But some other hyperparameters, such as the number for pseudo label clustering, might be the shortage of pretext strategies. We identified some limitations of existing speech SSL systems, especially in the case of harmonic information and diversity of music notes. One suggestion is to emphasise key or harmonic in the pretext task for music SSL models by using more than just MFCC features. Also, the number of categories for quantisation in k-means should be much larger if necessary, given the number of pitch, chord, and timbre categories is much larger than the number of human speech phones. This diversity in music might be a bottleneck for both speech SSL systems to learn good music features. For one thing, the larger number of clusters for k-means in HuBERT is expensive to calculate, making it harder to scale up, preventing transformer-based models from reaching their potential for better performance and longer sequence modelling. In addition, it may not be easy for data2vec to jointly learn deeper features. We may need curriculum learning skills or manually-designed features to increase training stability.

Another general suggestion for pre-training recognises that batch size should be as diverse as possible. Given that the memory of one single machine is limited, it is a good idea to shorten the length of audio to be modelled at first, allowing for an increase in batch size, and then train another language model for long sequence modelling.

We believe the findings in this paper to be of value in understanding the potential for SSL speech models applied to music, and we have offered some general insights about music modelling that resulted from this study.

TRANSFORMER-BASED BEAT TRACKING WITH LOW-RESOLUTION ENCODER AND HIGH-RESOLUTION DECODER

Tian Cheng Masataka Goto

National Institute of Advanced Industrial Science and Technology (AIST), Japan

{tian.cheng, m.goto}@aist.go.jp

ABSTRACT

In this paper, we address the beat tracking task which is to predict beat times corresponding to the input audio. Due to the long sequential inputs, it is still challenging to model the global structure efficiently and to deal with the data imbalance between beats and no beats. In order to meet the above challenges, we propose a novel Transformer-based model consisting of a low-resolution encoder and a high-resolution decoder. The encoder with low temporal resolution is suited to capture global features with more balanced data. The decoder with high temporal resolution is designed to predict beat times at a desired resolution. In the decoder, the global structure is considered by the cross attention between the global features and high-dimensional features. There are two key modifications in the proposed model: (1) adding 1D convolutional layers in the encoder and (2) replacing positional embedding by the upsampled encoder features in the decoder. In the experiment, we achieved the state-of-the-art performance and showed that the decoder produced more precise and stable results.

1. INTRODUCTION

Beat tracking is an important task in Music Information Retrieval (MIR) area with a long history. The task is to predict beat times, a periodic sequence of time instants which people can tap along with, from musical pieces. The first attempt of beat tracking for polyphonic musical audio signals can date back to around 30 years ago [1]. In the past three decades, we see the techniques shifting from signal processing to machine learning. In the most recent deep-learning-based methods, sequence models have been used to produce beat probabilities for each input frame, with the final beat times detected by the HMM on the beat probabilities in the post-processing step. In these models, various sequence models have been used, including Recurrent Neural Network (RNN) [2–4], Temporal Convolutional Network (TCN) [5–7], and Transformers [8–10]. Convolutional Neural Networks (CNNs) are also commonly combined in the models for front-end feature embedding [9, 11, 12].

To produce good beat tracking results, the model needs to consider both local timing and global consistency. This brings a contradiction on choosing the temporal resolution. The problem of using low temporal resolution (i.e., low frame rate) is that we cannot predict beats with precise times. On the other hand, using high temporal resolution (i.e., high frame rate) results in long sequential inputs and imbalanced output labels. The current commonly-used 10ms temporal resolution enables an easy comparison on the results. With such high temporal resolution, the sequential inputs are already relatively long for the RNN, causing the gradient vanishing problem. Using TCN and Transformer helps to solve the gradient vanishing problem, while modeling long sequences can still be challenging. To model long sequences more efficiently, more compact models have been proposed, such as dilated self-attention [9] and linear Transformer [10]. Another problem caused by the high temporal resolution is the data imbalance issue between beats and no beats. Given the same tempo, the higher the temporal resolution is, the more the no-beat labels exist between the beat labels. In order to solve this problem, smoothed labels [7, 9, 13] and weighted loss functions designed for the data imbalance problem [14–16] are applied to achieve more efficient training. The above long sequence modelling issue and data imbalance issue can be more challenging if a higher temporal resolution than 10ms is needed. In fact, there are some commercial music applications that potentially require more temporally precise beat tracking for sample-wise audio editing/mixing/mashups based on beat timings and highly rigid music synchronization.

In order to tackle the contradiction between high and low temporal resolutions, we propose a novel beat tracking model based on the Transformer with low-resolution encoder and high-resolution decoder. With the low temporal resolution, the sequential inputs become shorter and the training data become more balanced, which makes the global structure easier to model by the encoder. At the same time, the beat time precision in the output can still be preserved by the decoder with the high temporal resolution. The Transformer is a good architecture for joining the two parts because the encoder and decoder are not required to be the same length, and features of different dimensions can be jointly learned by the cross attention in the decoder. We modify the original Transformer in several ways to make it work for beat tracking with the proposed combination of the encoder and decoder. First, we

stack 2D convolutional layers for feature learning from the spectral inputs and 1D convolutional layers inside the encoder layers for feature smoothing and dimension adjustment. Second, we use the upsampled encoder feature to replace the position encoding in the decoder. In the experiments, we produced results comparable to the state-of-the-art performance. The analysis of experimental results showed that the decoder not only produced more precise results, but also helped to recover the missing beats and to filter out unwanted peaks between beats, making the beat tracking more stable.

The rest of paper is organised as follows. Section 2 summarises the related work on Transformer-based beat tracking models and multi-scale models. In Section 3, we give a detailed description of the proposed model, especially focusing on the proposed modifications. Section 4 presents the experiments with ablation study, results, and attention visualisation. In the last section, we conclude the paper and show aspects for future improvements.

2. RELATED WORKS

2.1 Transformer in beat tracking

Recently, Transformers have been used for many MIR tasks with promising performance, such as music transcription [17–19], music tagging [20], and beat tracking [8–10]. In the SpectTNT model, Transformer encoders are used for modeling both the spectral and temporal features [8]. The model also combines the Temporal Convolutional Network (TCN) model for better beat tracking results. Since the Transformer is computationally expensive for long sequences, the inputs are divided in 6-second chunks to process. For modelling the long sequences efficiently, more compact Transformers have been applied, including the dilated Transformer in the Beat Transformer model [9] and the linear Transformers for singing beat tracking [10].

These existing methods are based on Transformer encoders, while in our model, we use both the encoder and decoder, which is an important contribution of this paper. By adding the decoder layers, we can set a more reasonable temporal resolution for the encoder input, more specifically, low-temporal-resolution inputs. In other words, in the proposed model, the temporal resolution of the encoder can be independent of the high temporal resolution of the beat tracking output. With the low-resolution encoder, we are able to model the sequences more efficiently and obtain more balanced training data.

2.2 Multi-scale structure

In the proposed model, we leverage features at different scales: low-dimensional features for modeling the global structure and high-dimensional features for predicting precise beat times. Such multi-scale structure has also been used in related domains. In our previous work, we proposed a multi-scale beat tracking model based on the Wave-U-Net, which learned features at different scales from waveform and spectral inputs with downsampling

Figure 1: The model architecture of the beat tracking model. The coloured parts indicate the modifications from the original Transformer.

and upsampling blocks [21]. Schreiber et al. achieved tempo estimation by concatenating multi-scale features learned from a series of convolutional layers with different filter size from 32 to 256 [22]. Sun et al. [23] propose a multi-scale structure for tempo estimation by downsampling/upsampling the feature to different scales and combining multi-scale features repeatedly.

3. MODEL ARCHITECTURE

The proposed model architecture is shown in Figure 1. Our model is based on the Transformer, consisting of both encoder and decoder layers. As we have already written, the key idea is to use a low-resolution encoder for modelling the global structure, depicted on the left side of the figure (starting from “Input_low” denoting the low-resolution input), and a high-resolution decoder for predicting beats more precisely, depicted on the right side of the figure (starting from “Input_high” denoting the high-resolution input).

To make it work for beat tracking, we make some modifications on the original Transformer. The modified parts are coloured in Figure 1, including adding 1D convolutional layers (“1D Conv”) in the encoder, replacing the positional embedding by upsampled encoder features (from “Upsampling Block”) in the decoder, and stacking 2D convolutional layers for feature learning from the spectral inputs (“2D Conv Block”) in both the encoder and decoder.

In the following subsections, we illustrate the proposed model in detail.

Network parameter	Setting
filter size	$3 \times 3, 3 \times 3, 3 \times 3, 1 \times 3$
maxpooling size	$1 \times 3, 1 \times 3, 1 \times 3$
activation function	ReLU

Table 1: Parameters used in the convolution block.

Encoder

3.1 Input features and 2D convolutional layers

We use the Mel-spectrogram as the input features. For the low-resolution encoder, we computed 80-dimensional Mel-spectrogram with a 22050 sample rate and a hop size of 1024, roughly corresponding to a 46 ms temporal resolution (more precisely, 46.44 ms). The high-resolution Mel-spectrogram is computed the same way but in a hop size of 256, roughly corresponding to 12 ms temporal resolution (more precisely, 11.61ms). The dimensions of the inputs are (T, 80) and (4T, 80), respectively, where T is the frame length of the low-resolution input. We choose such resolutions so that the low-resolution can still distinguish beat and no beat frames for fast-tempo pieces, and the high-resolution outputs can be easily compared to those of other methods. In the 2D convolutional block, we stack four 2D convolutional layers and three maxpooling layers for feature embedding, with details show in Table 1.

3.2 Encoder with 1D convolutional layers

The encoder consists of identical encoder layers which process the low-dimensional features. As shown on the left side in Figure 1, each encoder layer includes a multi-head attention sub-layer and a fully connected feed-forward network with residual connections. Before the encoder, we concatenate the features with the positional encoding. Since in the Transformer, the input dimension is not changeable within the encoder layers, we stack a 1D convolutional layer after the feed-forward network for feature smoothing and channel number adjustment.

3.3 Upsampling Block

Another important change of the proposed model is that we replace the original positional encoding by upsampled encoder features for the decoder. In the upsampling block, there are two upsampling layers with linear interpolation. The upsampled features are then concatenated with the high-dimensional features. We also stack a 1D convolutional layer to re-dimension the concatenated features. In the preliminary experiment, we confirmed that the original positional encoding does not work well and the upsampled features worked for indicating rough beat positions. The ablation study for this replacement is presented in Section 4.3.

3.4 Decoder

The decoder processes the high-dimensional features for predicting more precise beats. The decoder layer consists of three components. As shown on the right side in Figure 1, between the multi-head attention sub-layer and a fully connected feed-forward network, there is another multi-head attention sub-layer which computes the cross-attention between the low- and high-dimensional features. We use the decoder as a discriminative model for predicting the output based on the input, rather than a generative model as the original Transformer decoder. Hence we do not need to use the causal mask in the first multi-head attention sub-layer.

3.5 Output Layer and Post-Processing

As shown in Figure 1, we stack a dense layer with the sigmoid activation at the end of the decoder for producing beat outputs. Then, we apply the DBN from Madmom [2] for post-processing. We first take the nearest integer of frame per second (fps) for the post-processing, and then map the results to the original fps.

3.6 Complete Architecture

We apply random search to find the best hyperparameters for the model. We set up a grid of hyperparameter values according to Table 2, and randomly select a subset to compare. The decoder uses the same parameters as the encoder if not present. The finally chosen parameters are shown in bold.

4. EXPERIMENTS

4.1 Data

We train, validate, and test the proposed model by using the standard music datasets with beat annotations as shown in Table 3. For training and validation sets, all musical pieces are segmented into 30-second clips with 50% overlap. Segments from the same musical piece appear only in either the training or validation set to ensure that there is no overlap between the training and validation sets. Test results are obtained on the whole pieces without segmentation.

We do data augmentation for better tempo balance. We follow the strategy in [7] to generate input features for less

Usage	Datasets
training only	Beatles [24], Harmonix [25], 5 RWC datasets [26, 27], tapcorrect [28]
8-fold cross-validation	Ballroom [29, 30], Hainsworth [31], SMC [32]
testing only	GTZAN [33, 34]

Table 3: The usage of the standard datasets for beat tracking evaluation.

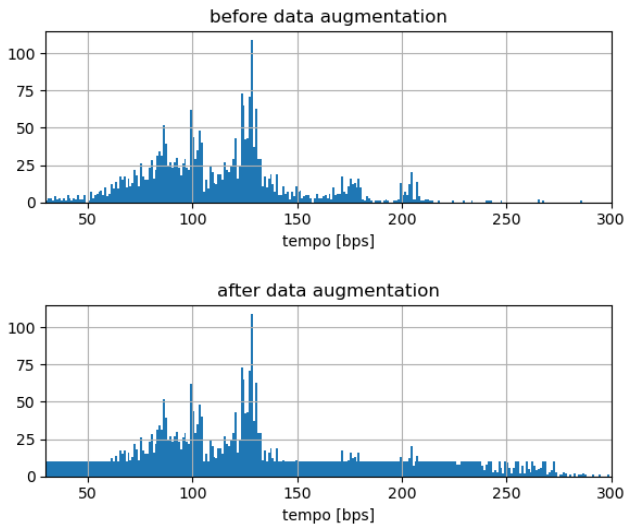

Figure 2: The tempo distribution before and after the data augmentation for the model training.

representative tempos by changing the hop size when computing the mel-spectrogram. The tempo distribution before and after the data augmentation is shown in Figure 2.

Inspired by [9], we also process the input mel-spectral features by Harmonic Percussive Source Separation (HPSS) and obtain the original mel-spectrogram S , the harmonic part H , and the percussive part P . In the preliminary experiment, we compare two way of using HPSS: one way is as data augmentation which triples the training data (i.e., we can use all of S , H , and P with the same beat annotations); the other way is to concatenate three parts, S , H , and P , as the more informative input features. Since the results showed that using HPSS as the data augmentation works better, we decided to take that way.

4.2 Training

In order to train the model effectively, we compare three training methods as shown in Table 4. The first method is training the model (i.e., both the encoder and decoder) from scratch.

For the other two methods, we first temporarily stack a dense layer at the end of the encoder and pre-train the encoder only with the low-resolution labels. Then we initialize the encoder with this pre-trained model and start train-

Method	Initialization	Encoder parameters
1	None	Trained with decoder
2	Pre-trained encoder	Not trainable in training decoder
3	Pre-trained encoder	Trainable in training decoder

Table 4: Three training methods (the third method was the best).

ing the decoder. The second method trains the parameters of the decoder only, by freezing the parameters of this pre-trained encoder. The third method trains the parameters of both the encoder and decoder after the above initialization of the encoder.

We choose the third method for training the model because it worked best in our preliminary experiments. The model is trained with binary cross-entropy by using the RMSprop optimiser [35] with a learning rate of 0.0002. The batch size is set to 16 for pre-training the encoder, and 4 for training the whole model.

4.3 Ablation Study

To illustrate the influence of replacing the positional encoding by the upsampled encoder features in the decoder, we show the differences on the training with and without the proposed modification (replacement) in Figure 3. We see that using the upsampled encoder features decreased the validation loss slightly and decreased the training loss in a large degree in comparison to using the positional encoding. This shows that the modified model can learn better from the training data and generalise well in the validation set, resulting in better beat tracking results.

4.4 Evaluation

We evaluate the proposed method with three standard metrics: F-measure with a tolerance window of 70ms, continuity-based metrics CMLt (tracking accuracy on the correct metrical level), and AMLt (tracking accuracy with alternate metrical levels allowed) [24].

4.4.1 The proposed method

In order to validate our model design, besides results on the decoder outputs, we also show results on the pre-trained encoder outputs. In Table 5, “Encoder (Th)” indicates the results obtained by applying a threshold of 0.1 without using the DBN. “Encoder” and “Decoder (Proposed)” results are processed by the DBN in the post-processing step, with the encoder outputs linear interpolated. If we compare the results of “Encoder (Th)” and “Encoder”, we observe that the DBN post-processing step increased the performance in all the four datasets, especially for the continuity-based results (CMLt and AMLt). Furthermore, if we compare them with the “Decoder (Proposed)” results, which corresponds to the proposed model, we see performance further increased on the Ballroom, SMC, and GTZAN datasets.

Figure 3: The training and validation losses for training the decoder with the original positional embedding or with upsampled encoder features.

Method	F-measure	CMLt	AMLt
Dataset: Ballroom			
Encoder (Th)	90.7	80.1	85.7
Encoder	93	87.4	96.1
Decoder (Proposed)	95	91.1	96.4
Beat trans [9]	96.8	95.4	96.6
TF trans [8]	96.2	93.9	96.7
TCN [7]	96.2	94.7	96.1
Dataset: Hainsworth			
Encoder (Th)	84.4	66.7	81.8
Encoder	88.2	81	93.4
Decoder (Proposed)	87	76.2	93.6
Beat trans [9]	90.2	84.2	91.8
TF trans [8]	87.7	86.2	91.5
TCN [7]	90.4	85.1	93.7
Dataset: SMC			
Encoder (Th)	53.9	32.9	45.6
Encoder	55	45.8	64.1
Decoder (Proposed)	55.4	45.1	65.6
Beat trans [9]	59.6	45.6	63.5
TF trans [8]	60.5	51.4	66.3
TCN [7]	55.2	46.5	64.3
Dataset: GTZAN			
Encoder (Th)	87.1	72.8	85.5
Encoder	87.8	78.5	93.7
Decoder (Proposed)	88.4	80.8	94
Beat trans [9]	88.5	80	92.2
TF trans [8]	88.7	81.2	92
TCN [7]	88.5	81.3	93.1

Table 5: Testing results for comparing the proposed method with three state-of-the-art beat tracking models [7–9]. The GTZAN dataset is held out for testing only; other datasets are used in the 8-fold cross-validation. (Th) means results obtained with a threshold of 0.1 without using the DBN post-processing step.

In order to understand the effect of the proposed decoder better, we show the outputs examples from the pre-

trained encoder and the decoder in Figure 4. We can see that the encoder outputs are large at beat times, which is benefit from the more balanced training data in shorter sequences. On the other hand, the decoder outputs are small and even (i.e., more stable), as we expected. As we design, the decoder basically predicts the beat times at a higher resolution in comparison to the encoder. The decoder also helped to recover missing beats as shown in the 5th example, where some beats are missing in the encoder output but they are recovered in the decoder output. Moreover, the decoder helped to filter out peaks between beats as shown in the 3rd example, where peaks are more regularly placed in the decoder output. With the above effects, using the proposed decoder generally improved results except for the Hainsworth dataset. For the Hainsworth dataset, we see the CMLt decreased, but the AMLt remained the same level, which means that the decrease on the performance is caused by phase and octave errors. Since the peaks from the decoder are even, in some cases it would be more difficult for the DBN to exclude the peaks between beats.

4.4.2 Comparison to state-of-the-art beat tracking models

As shown in Table 5, results of the proposed model (“Decoder (Proposed)”) were comparable to the state-of-the-art results obtained by three beat tracking models [7–9], despite not the best. Since our goal is not to achieve better performances than all the state-of-the-art models, these results are satisfactory since we can show the high performances of the proposed model with different temporal resolutions. We see noticeable gap on the CMLt in comparison to other methods, which means the proposed model encountered more phase and octave errors. We hope this could be improved by including related topics in the multi-task learning as in [7, 9]. In addition, for the testing-only dataset GTZAN, the F-measures achieved by thresholding the encoder outputs (“Encoder (Th)”) are better than what we expected, given the fact that it did not use the DBN post-processing step.

(a) Encoder outputs

(b) Decoder outputs

Figure 4: Output examples from the pre-trained encoder and the decoder for five different pieces. The ground-truth beat annotations are indicated by lines pointing down.

4.5 Attention Visualisation

In order to understand how low- and high-dimensional features are jointly learned, we show the cross attention matrix between low- and high-dimensional features in the second decoder layer in Figure 5. We found that for high-dimension features at beat times (frames), it got attention at each beat on the low-dimensional features. For no-beat times (frames), all attentions were drawn to the frames after the corresponding beat times, which formed horizontal lines in this figure. With such attentions, the final high-dimensional beat outputs were predicted with the captured global beat structure considered.

5. CONCLUSIONS AND FUTURE WORK

We present a novel Transformer-based model for beat tracking. The proposed model consists of both en-

Figure 5: Cross attention matrix between low dimensional features and high dimensional features in the decoder layer.

coder layers and decoder layers which work on low- and high-dimensional features, respectively. We obtained beat tracking performances which are comparable to the state-of-the-art beat tracking results. The experimental results showed that the proposed model worked well as designed: with the low-dimensional (low-temporal-resolution) encoder for capturing the global beat structure and high-dimensional (high-temporal-resolution) decoder for predicting more precise beats. Thus, the proposed Transformer-based encoder and decoder structure succeeds in providing a new framework for handling multi-scale features for beat tracking. Beyond beat tracking, the advantage of this framework can be summarized as follows.

- The encoder and decoder do not require inputs to be the same length (same temporal resolution), they can be used to handling features at different scales, which enables us to sample the features with more reasonable time resolutions.
- We can make use of features at different scales jointly learned by the cross attention in the decoder.

We therefore believe that this framework is also adaptable for other MIR tasks, such as musical structure boundary detection.

As the analysis of our experimental results showed, phase and octave errors are relatively high in our results. As future work, we would like to tackle the problems by combining downbeat tracking and tempo estimation in the proposed model by using multi-task learning. In addition, we also plan to use our model to produce beat outputs in a higher temporal resolution, which is demanded by some practical music applications as we discussed in Section 1. Yet another advantage of our model is that such precise beats can be achieved by using transfer learning with a higher-temporal-resolution input for the decoder.

ABSTRACT

The objective of pattern-matching topics is to gain insights into repetitive patterns within or across various music genres and cultures. This approach aims to shed light on the recurring instances present in diverse musical traditions. The paper presents a study analyzing folk songs using symbolic music representation, including melodic sequences and musical information. By examining a corpus of 400 monophonic Slovenian tunes, we are releasing annotations of structure, contour, and implied harmony. We propose an efficient algorithm based on suffix arrays and bit-vectors to match both music content (melodic sequence) and context (descriptors). Our study reveals that certain descriptors, such as contour types and harmonic “stability” exhibit variations based on phrase position within a tune. Additionally, combining melody and descriptors in pattern-matching queries enhances precision for classification tasks. We emphasize the importance of the interplay between melodic sequences and music descriptors, highlighting that different pattern queries may have varying levels of detail requirements. As a result, our approach promotes flexibility in computational music analysis. Lastly, our objective is to foster the knowledge of Slovenian folk songs.

1. INTRODUCTION

Music pattern analysis in the field of Music Information Retrieval (MIR) is extensively studied. The challenges of this topic extend beyond algorithms, encompassing diverse music forms, representation (signal, symbolic, or textual), music content, and cultural metadata.

1.1 Content and Context in Ethnomusicology

Ethnomusicologists analyze recordings, live performances, and transcriptions (in various notations) to understand the composition of music. While transcriptions reveal the *what* of the music, cultural context is essential for comprehending the *how* and *why* behind these musical structures.

Initiated by Merriam [1], and many others [2–7], the music is to be observed *in* culture (in his later work, *as* culture), or as a multi-dimensional object, a direct consequence of the organization of social structures, and vice versa. Some studies [4, 6, 8–10] have primarily compared folk tunes based on their music content. In others, including the Slovenian Folk Song Collection [11], the categorization of the collection is organized according to the elements, such as lyrics and other textual content.

Considering *music material*, it can be explored as a general outline for music analysis [12], or through specific music descriptors, such as melodic contour (the melodic arch shape) [13]. Recent studies have expanded the use of descriptors to analyze folk songs, incorporating a broader range of attributes. De la Ossa [14] suggests basic music descriptors be included, such as scale types, range, several levels of rhythmic information, and so on. *Cantometrics*, introduced by Lomax [15, 16], proposed 37 descriptors, (almost) independent from usual Western music theory. His idea of representing datasets as a digital “Global Jukebox” was recently completed. [17–19]. Computational methodologies encourage us to process more data, including multiple layers of music *content*, and *context* as descriptors (music and/or metadata). Serra [20] exposed the presence of musical entities (performer, music, instrument, etc.) that “are linked by various types of relationships,” which contribute to the understanding of music as a whole. Conklin and Neubarth also stressed the importance of non-musical information, such as region and genre [21], extended Densmore’s and observed (super)area and (super)type information [22]. These non-musical phenomena, although limited, were always correlated with different types of music content (rhythm, melody, pattern, and antipattern [23]) of folk songs. Although focusing on musical content, especially on cadences, van Kranen-

burg also considers lyric, perceptual information, as well as other information [24–26].

1.2 Pattern Inference and Matching

Music pattern searching or matching is most commonly approached from a music analysis perspective [12, 27–30], by addressing music structures, such as melody, harmony, and rhythm. Previous contributions focused on a single or a couple of features or the computational representations and matching of multi-feature music patterns. The Mongeau-Sankoff algorithm [31] simultaneously explores multidimensional music features, as it defines the distance between any two melodies depending on the pitch, tonal contour and rhythmic structure. The pattern similarity is ranked by the number of transformations, including consolidation and fragmentation.

Other dynamic programming methods for melodic sequence alignment were proposed [6, 32, 33], as well as other methods on the general melodic or pitch-related queries [33–36]. Some research added the rhythmic [37], or, especially with multipart music, the harmonic information [38]. In another solution, Marsden adapts the *hierarchical or tree structures* for representing and comparing melodies [39]. Lartillot, conversely, matched melodic sequence (or motives) by using *heterogeneous patterns* [30], whose occurrences can be located through multiple parametric dimensions – including contextual ones, such as implied harmony.

1.3 Motivation and Contents

These studies indicate that a melodic pattern is not isolated from other musical elements, such as a phrase, rhythmic or harmonic structure, ornamentation, and so on. While most distinguish between *music material* and *cultural metadata*, we instead split the first into *melodic sequence* and *descriptors* (see Table 1). Our objective is that *melodic phrase should never be detached from its context*. Hence, we focus on segmented melodic phrases that never lose their identifier (connecting them to all supplementary (meta)data), nor their position within a tune (first, middle, last). This enables the *tune description by phrase position, contours, labels, and rough harmonic tendencies*, and to easily access and apply any combination of other (meta)data information to the pattern-matching process.

In Section 2 we introduce the corpus as well as our annotation methodology on metadata and descriptors, including structure, contour, and implied harmony. Section 3 introduces a pattern-matching algorithm that utilizes suffix arrays (for all melodies) and bit arrays (a selection of descriptors) to return matched results based on melodic *content* and controlled descriptor context. Sections 4 and 5 discuss the implementation and the results of examples of combined melody/descriptor queries, and Section 6 provides concluding remarks and addresses open perspectives.

2. THE ANNOTATED CORPUS OF SLOVENIAN FOLK SONGS

2.1 The Corpus

We are expanding the digital world of folk songs ([17, 40–42] and others) with a limited selection of tunes from the largest collection of Slovenian folk songs – SLP, *Slovenske ljudske pesmi*, which consists of 5 critically edited physical books, issued between 1970 and 2007 [11, 43–46]. Tunes belong to *narrative song* genre (Figure 1) or hybrids between narrative and lyric genres (resemble narrative form, but much shorter). These are divided into types (by lyric resemblance) and their variants.

The fifth and last book [11] was edited and issued by the Slovenian Ethnomusicological Institute (Research Centre of the Slovenian Academy of Sciences and Arts, consecutively mentioned as GNI), which later digitized (OCR-ed pdf, musicXML, sib) by Matija Marolt and Matevž Pesek (FRI, University of Ljubljana). Most tunes are transcriptions of field recordings collected members of the institute, and external colleagues, such as Franc Kramar (1890–1959), Josip Dravec (1912–1996), and Stanko Vraz (1810–1851). Most tunes were collected and/or transcribed between the 1950s and 1970s. The earliest two (notated) transcriptions date back to 1819 and 1839, while the most recent transcription was completed in 2001. Together, there are 650 tune variants of 54 types and belong to family fates and conflicts topic, which represents about 34% of all Slovenian ballads [11]. Some tunes have one or two, while the most popular have 100+ variants (*Infanticide Bride*, *A Widower at His Wife’s Grave*, *Step-mother and an Orphan*, and *Convicted Infanticide*). which mostly belong to Styria (166), followed by Upper Carniola (133) and Lower Carniola (99) regions.

Out of those, 418 are transcribed as monophonic, 218¹ as homophonic, and 8 as mixed. About 70% were performed by a solo female singer. Instrumentally-accompanied examples are very rare. All tunes were transposed to G (major/minor) by the editors. Recent annotations include special notation symbols indicating deviations, such as slight disparity in pitch (higher/lower), duration (shorter/longer), and more [11].

2.2 Descriptors and Corpus Annotation

Out of the 418 monophonic tunes, 18 were excluded due to incomplete score information or incompatible encoding. Our final corpus contains 400 monophonic tune variants with detailed manual annotations, made by the first author and reviewed by all contributors. An average tune has about 9 bars and 30 notes. *Phrase boundaries* were annotated by curating the output of a simple heuristic relying

¹ Some melodies may have been harmonized by the annotator, making it unclear which singing line represents the original tune. This is common in transcriptions by Franc Kramar (1890-1959). The opposite can be true for monophonic transcriptions.

Figure 1. Tunes from the SLP corpus with structural, contour, and implied harmony annotations. (Top) *The Death of the Bride Before Her Wedding*, 9th variant of tune type 239(A), transcribed by GNI in 1960. The first phrase (F), labeled A has a convex (↗↘) contour, whereas the second phrase has a horizontal-descending (→↘) contour as the first pitch of B phrase is about at the average compared to consecutive pitches of the phrase. Starting (upbeat) and ending implied harmonies (H_S, H_E) can be clearly labeled as a tonic, even though the strong beat on the first full measure is a D pitch. (Bottom) *The Widower at His Wife's Grave*, 44th variant of tune type 252, transcribed by Franc Kramar in 1913. Phrases A and B are approximately repeated as phrases A' and B', with changes in melody, contours, and harmonic functions. Harmonically, the first phrase starts on a clear dominant but is somewhat ambivalent at the end. The second phrase is the most stable on a tonic. The rest is slightly more ambivalent between the two degrees again, while, at the very end, the tune concludes on a tonic. (Right) A few descriptors that are associated with these tunes (see Table 1).

on pauses and punctuation marks, yielding 1502 phrases (median of 4 per tune, min. 2, max. 8).

Musical descriptors, listed in Table 1, describe either the full tune or phrases. The descriptors can carry both, *non-musical* and *musical* information.

Tune metadata⁴ relies on transcribers' information, and the format aligns with the original sources, with some conversions made for data analysis convenience [11]. Tune phrases were annotated with *descriptors* across the following categories:

- *Phrase position.* This central annotation category establishes the relationship between other descriptors. Each phrase is annotated with a sequence number and position, such as first, middle, or last.
- *Structure.* Each phrase is assigned a label that describes the repetition of its melodic material within the verse. The first label is always A, followed by A, A', A+ (similar to B), A(X) (refrain-like A), or B. The same alphabetical progression is applied to subsequent phrases. The tunes have an average of 2.82 different labels (1 to 6 with symbols or 4 with letters only) and infrequent repetitions (Table 2). Each label appears only 1.34 times on average per tune.
- *Implied Harmony.* Using Western harmony to describe folk songs may be biased and controversial, but it is likely that Slovenian folk tunes and their transcribers have been exposed to the Western music system to some extent [47]. Approximate functions of tonic (T) or dominant (D) were annotated for about 60% of

phrase beginnings and 50% of endings, with ambiguous cases marked as “?”. To evaluate the validity of individual annotations, the inclusion of scale information (the count of distinct pitch classes) is provided.

- *Contour.* Diverging from only comparing the unreliable note-to-note melodic representation of oral music tradition, we use Huron's 9 types of melodic arches [13] (the most frequent being the convex contour ↗↘), where the starting and ending MIDI pitch value is compared against an average value of all intermediate MIDI pitch values.

3. MATCHING MELODY WITH DESCRIPTORS

3.1 Pitch and Descriptor Representation

Each tune is subdivided into *phrases* as *pitch sequences* with *descriptors*, which are considered as a set of n phrases $P = \{p_1, p_2, \dots, p_n\}$, and m phrase descriptors $\Delta^1, \dots, \Delta^m$. Each descriptor Δ^t has a finite set of values $V(\Delta^t)$. A phrase p_i is associated with a *descriptor sequence* $d_i = (d_i^1, d_i^2, \dots, d_i^m)$, where each d_i^t is in $V(\Delta^t)$.

For example, the following options:

$$\left\{ \begin{array}{l} \{\Delta^1, \dots, \Delta^5\} = \{\text{POS}, \text{LBL}, \text{CT}, \text{H}_S, \text{H}_E\} \\ V(\text{POS}) = \{\text{F}, \text{L}, \text{M}\} \quad V(\text{H}_E) = \{\text{T}, \text{D}, ?\} \\ V(\text{LBL}) = \{\text{A}, \text{B}\} \quad V(\text{H}_E) = \{\text{T}, \text{D}, ?\} \\ V(\text{CT}) = \{\nearrow\searrow, \rightarrow\searrow, \nearrow, \dots\} \end{array} \right.$$

can describe phrase 239.9.A.1 (Figure 1) as:

$$p_{239.9.A.1} = gbddgdcbag \quad d_{239.9.A.1} = (\text{F}, \text{A}, \nearrow\searrow, \text{T}, \text{T}).$$

⁴ Metadata was collected for all 650 songs, including polyphonic compositions.

<i>Non-musical Metadata</i>	
tune ID	▷ Type, variant, other
type title	▷ Title or label
region	▷, ★ Region
annotator	▷ Name of the initial collector/transcriber
year	▷, ★ Year ² of initial annotation.
singer	▷, ★ Singer sex and ensemble size
lyric	▷, ★ First line ³ , first verse, structure
<i>Musical Descriptors</i>	
POS	★ Phrase position (First, Middle, Last)
NUM	★ Phrase number (1, 2, 3, 4, ...)
LBL	★ Phrase label (A, B, C, ...)
SYM	★ Phrase symbol (A [?] , A [?] , A ⁺ , ...)
CT_SPEC	◇ Huron's contours (↗, ↘, ↗↘, ↘↗, →, ↗→, ↘→, →↗, →↘)
H _S	★ Starting harmony (T, D, ?, ...)
H _E	★ Ending harmony (T, D, ?, ...)
TS	◇ Time signature (simple duple/triple ...)
SCALE	◇ Scale (8, 7, 6, ...)
<i>Musical Content</i>	
MEL	Melodic sequence (example: <i>gbddg</i>)

Table 1. Metadata, musical descriptors, and musical content. Manual annotations were done for phrase boundaries and descriptors marked with ★, while computed descriptors are marked with ◇. Descriptors marked with ▷ were collected by the initial transcribers and/or the GNI. Other descriptors, such as general contour, tone set, and leading tone, are also present in the dataset but not discussed here.

3.2 Melody and Descriptor Pattern Matching

The goal of *melody-and-descriptor matching* is to find all phrases (associated with their descriptors) matching in both the given *pitch pattern* and selected variation of *descriptor pattern*.

A *pitch pattern* pp is also a sequences of pitches. It matches a phrase p_i when pp is a factor of p_i , matching note-to-note. This definition currently permits no kind of deviation. For example, $pp = dcb$ matches $p_{239.9.A.1} = gbddg dcb ag$.

A *descriptor pattern* is $dp = (dp^1, \dots, dp^m) \in (V(\Delta^1) \cup \{\star\}) \times \dots \times (V(\Delta^m) \cup \{\star\})$, where ★ is a “don’t-care” symbol. It determines which descriptors are

NP	instances		
2	20% (78)	AB (60)	AA (18)
3	6% (23)	ABC (11)	ABB (6)
4	65% (261)	ABCD (112)	ABAB (45)
5	2% (8)	–	–
6	6% (24)	ABCD CD (7)	AABABA (5)
8	1% (6)	ABCBCBCB (2)	–

Table 2. Out of 400 tunes, sorted according to the number of phrases (NP), the most common structure “ABCD” is present in 28% of all tunes. Label variants are ignored (A[?] is considered as A). There are no tunes with 7 or more than 8 phrases. Unique structures (–) are not reported.

to be checked, and matches a descriptor sequence $d_i = (d_i^1, \dots, d_i^m)$ if, for every $t = 1 \dots m$, either $dp^t = \star$ or $dp^t = d_i^t$. For instance, the descriptor pattern $dp = (\star, A, \nearrow \searrow, \star, \star)$ checks if the phrase label matches A, and contour matches $\nearrow \searrow$, but ignores the phrase position and harmonic functions. Thus dp matches $d_{239.9.A.1} = (F, A, \nearrow \searrow, T, T)$ but does not match $(F, B, \nearrow \searrow, T, D)$.

3.3 Algorithm

For this matching problem, we first retrieve phrases and positions from a suffix array, in linear time, then filter these matches with bit-wise operators.

Pitch sequence matching with suffix array. Pitch sequences of P are concatenated to one sequence, separated by a symbol, such as $S_P = p_1 \$ p_2 \$ \dots p_n \$$. An index data structure such as a compressed suffix array is computed and stored to retrieve all occurrences of a pitch sequence. When a query is matched at position k in S_P , the corresponding phrase p_i and its position in p_i is retrieved using a (pre-computed) bit-vector \overline{S}_p , and functions $rank_1(x, k)$ and $select_1(x, k)$ (respect. the number of occurrences of 1 in the prefix of length k of a bit-vector x , and the index of the k -th 1 in x). The bit-vector $\overline{S}_p = b_1 \dots b_{|S_P|}$ is defined as $b_i = 1$ if $S_P = \$$, otherwise $b_i = 0$. Hence, the query occurs in phrase p_i at position j (within p_i) with $i = rank_1(\overline{S}_p, k)$, and $j = k - select_1(\overline{S}_p, i)$. Retrieving the list of phrases and positions of a query, pitch sequence q of length m is done in time $O(m + occ)$, where occ is the number of occurrences of q in S_P provided that $rank$ and $select$ operations are performed in constant time.

Descriptor pattern matching with bitwise operators.

Each descriptor Δ^t can be represented by b^t bits, with $b^t = \lceil \log_2 |V(\Delta^t)| \rceil$, and each value $v \in V(\Delta^t)$ is associated to a bit-vector \overline{v} . Each descriptor sequence $d_i = (d_i^1, d_i^2, \dots, d_i^m)$ is then stored as a bit-vector $\overline{d}_i = \overline{d}_i^1 \dots \overline{d}_i^m$. A descriptor pattern $dp = (dp^1, dp^2, \dots, dp^m)$ is associated to two bit-vector masks $\mu(dp) = \mu^1 \dots \mu^m$ and $\pi(dp) = \pi^1 \dots \pi^m$, where

$$\begin{cases} \mu^t = \pi^t = 0 \dots 0 \text{ (} b^t \text{ bits)} & \text{if } dp^t = \star \\ \mu^t = 1 \dots 1 \text{ and } \pi^t = \overline{dp^t} & \text{otherwise.} \end{cases}$$

Then, a descriptor pattern dp matches one descriptor d if and only if $(\overline{d} \text{ xor } \pi(dp))$ and $\mu(dp) = 0$. For example, if $dp = (\star, A, \nearrow \searrow, \star, \star)$, then

$$\begin{aligned} \overline{d_{239.9.1.A}} &= 00 \cdot 0 \cdot 0010 \cdot 01 \cdot 01 \\ \mu(dp) &= 00 \cdot 1 \cdot 1111 \cdot 00 \cdot 00 \\ \pi(dp) &= 00 \cdot 0 \cdot 0010 \cdot 00 \cdot 00 \end{aligned}$$

$$\begin{aligned} \overline{d_{239.9.1.A}} \text{ xor } \pi(dp) &= 00 \cdot 0 \cdot 0000 \cdot 01 \cdot 01 \\ \overline{d_{239.9.1.A}} \text{ xor } \pi(dp) \text{ and } \mu(dp) &= 00 \cdot 0 \cdot 0000 \cdot 00 \cdot 00 \end{aligned}$$

Checking whether a descriptor dp matches a descriptor d is done in $O(1)$ time, provided that the bit-vectors fit in one machine word.

	$\nearrow \searrow$	\searrow	\nearrow	$\searrow \nearrow$	$\nearrow \rightarrow$	$\searrow \rightarrow$
First	24%	16%	30%	15%	6%	1.2%
Middle	36%	21%	15%	8%	10%	1.3%
Last	44%	32%	2%	5%	4%	11%
Total	35%	23%	16%	9%	7%	1.5%

Table 3. We show the most frequent Huron’s contour types according to phrase position. Regarding general contour (data not shown), first phrases are mostly ascending (53%), while middle and last phrases are predominantly descending (63% and 89% respectively).

4. IMPLEMENTATION AND AVAILABILITY

The descriptors and the algorithm were implemented in Python using `music21` [48] for music data manipulation, `bitarray` library for descriptors matching and a C++ library `sdsl-lite` [49] (used in Python with `pysdsl` library) for melodic matching. From the latter, we used `rank` and `select` methods, and `BitVector` and `SuffixArrayBitcompressed` classes. On a standard laptop from 2022, building suffix arrays and bit vectors on 1502 phrases takes less than 0.5s. A single suffix array takes 49.4 KB, and bit vectors 1.7 KB. The longest melody/descriptor queries take about 100 ms. The annotations and the code are available on a git repository through open licences (Open Database License, Database Contents License, GPLv3+) at algomus.fr/data and algomus.fr/code. We are collaborating with partners in Slovenia to prepare the release of 400 melodies and additional ethnomusicological research.

5. RESULTS AND DISCUSSION

Almost all tunes (84%) in our collection revolve around a minimum of six distinct pitch classes, indicating the likely utilization of Western major/minor scales and modes. Approximately 67% of the tunes fall within the range of a major sixth (M6) to an octave (P8). Additional statistics in the annotated corpus examine phrase positions (Section 5.1). Specifically, the analysis focuses on the prevalent tune subtype 286.T1, annotated for melodic similarity. Findings from combined melody and descriptor queries are presented in Section 5.2.

5.1 Descriptors and Phrase Positions

The 400 tunes consist of 1502 phrases, split into first (400), middle (702), and last (400) positions. The labels, contours, and implied harmonies are strongly influenced by the phrase positions, as evident from Tables 2, 3, and 4. In general, phrases are convex or descending (see Table 3), while the *first phrases* are mostly ascending or convex, and less harmonically stable at their ends than beginnings. Conversely, the *last phrase* is almost never ascending, and more harmonically stable at its ends than beginnings. The *middle phrase* group is more divided and is more unstable.

		T	D	? _T	? _D	?
First	H _S	25%	54%	9%	<1%	12%
	H _E	22%	27%	15%	7%	29%
Middle	H _S	16%	36%	14%	6%	28%
	H _E	21%	16%	18%	6%	40%
End	H _S	19%	32%	10%	5%	34%
	H _E	60%	<1%	20%	None	19%
Total	H _S	19%	40%	11%	5%	25%
	H _E	32%	15%	18%	5%	32%

Table 4. Starting (H_S) and ending (H_E) harmonic functions in relation to phrase positions demonstrate a consistent pattern. Phrases typically initiate on a dominant (D) and conclude on a tonic (T). However, there is ambiguity with the functions ?, ?_T, and ?_D, as they can be interpreted as either T or D, which arises from the influence of previous and following pitch values or bars, making the exact annotation spot unclear.

Figure 2. Two variants (out of 34) of the subtype 286.T1 with similar melodies with short melodic patterns in coloured squares.

We assume that the contrasting beginnings and endings of each verse offer pitch orientation for the singers, given the repetitive structure of narrative songs. The contour relationship between the first, middle, and last phrases supports the notion that “what goes up is likely to come down,” as proposed by Huron [13].

5.2 Case Study: Subtype 286.T1, *Infanticide Bride*

Our dataset includes 103 monophonic variants of the widely known “Infanticide Bride” theme in European folk song tradition. Subtype 286.T1 consists of 34 tunes selected for their melodic similarity (Figure 2), which often exhibit similar patterns, such as the *fad* as a start middle phrase pattern or the *bag* as a last phrase ending pattern.

We have developed combined melody/descriptor queries to represent certain phrases of subtype 286.T1. These queries are evaluated as a binary classification problem: Can we accurately identify the 34 initial phrases of 286.T1 and distinguish them exclusively from others?

Pattern design and matching. Table 5 demonstrates that simple melody queries with 1 to 3 notes achieve reasonable recall rates (50%-80%) but limited precision. Refining the queries with descriptors improves precision and relevance,

leading to enhanced F_1 measures. The *ddb* melody query alone produces 93 matches, but 75 of them are “false positives” unrelated to the first phrase of 286.T1 tunes. Incorporating a phrase position descriptor (F, first) improves the query, while adding relevant contour (\nearrow) and starting harmonic information further enhances specificity. This comprehensive query results in only 2 false positives, achieving a precision of up to 0.88, with minimal sensitivity loss. The *ag* pattern in the last phrase, characterized by a convex contour and a harmonic ending, is a noteworthy example. Given the enhanced harmonic stability typically found in verse endings, the inclusion of the $H_S T$ as a stable harmony descriptor proves to be effective in this context. Including too many or irrelevant descriptors leads to poor results. For instance, the *cbb* pattern is primarily found at the end of the middle phrase. However, requiring a stable harmonic framework ($H_E T$) for middle endings reduces precision, as it is less common in those positions (Table 4). Another interesting instance is the *fad*, occurrences of which are almost evenly split into two contours. If we matched (*fad*, $M, \nearrow \searrow$ or $\nearrow \rightarrow$), we would get 23 true positives and a precision of 0.82 with a recall of also 0.82. The algorithm should be extended to accommodate the matching of a subset of multiple descriptors within the same category, rather than solely relying on one descriptor.

Patterns as building blocks. Melody/descriptor patterns have versatile applications beyond classification. In our case, the most effective queries incorporate position descriptors, indicating that we should view phrase *building blocks* as patterns. It is noteworthy, that studying the “false positives” (matches outside of 286.T1) is expected to yield intriguing results, shedding light on the transmission of music material among tunes and vice versa. For instance, the *ag* pattern in the last phrase, exhibiting a $\nearrow \searrow$ contour and ending with $H_E T$, is not only specific to 286.T1 but also appears in 14 tunes of type 252 (*A Widower at His Wife’s Grave*). The shared section of the melodic line in the two tunes has identical descriptors, although its positions may vary (scores not shown). Comparing outcomes across multiple corpora would provide insight into the unique musical characteristics of (Slovenian) folk songs.

5.3 Discussion

Our study explored tune structures and melodic patterns, finding that combining melodic content with descriptors provides valuable insights into the characteristics of Slovenian folk songs. However, not all descriptors fit universally to describe all content, and vice versa. In contrast to the usual transferability of folk song melodies, our case study indicates that the melody of 286.T1 was not easily transferable, possibly due to its popularity in multiple regions. Further inter- and intra-corpus research is needed to investigate this distinctive characteristic. We also show, that individual melodic extracts alone lack the specificity required for a comprehensive description of a full phrase or tune. Strong correlations were found for descriptors

Query (melody + descriptors)			TP	FP	FN	Prec.	Rec.	F_1
<i>d</i>	None	1 (34)	28	1191	6	0.02	0.82	0.04

Table 5. Evaluation of melody/descriptor queries seen as classification queries intended to match phrases 1, 3, and 4 of the melodic tune subtype 286.1 (34 first and last phrases, 33 third phrases) against all 1502 phrases of the dataset. We computed True Positives (TP), False Positives (FP), False Negatives (FN), and from those, precision, recall, and F_1 -score. Bold values are discussed in the text.

like contour. Expanding the dataset is needed to comprehensively explore the relationship between lyrics and melodies, including the observed descending shape in the last phrase, potentially reflecting or corresponding with speech characteristics [50, 51].

6. CONCLUSION AND PERSPECTIVES

By integrating descriptor information into melodies, we gain a deeper understanding of the observed music. Our findings indicate a strong dependency of many descriptors on phrase positions, and that combining melody and descriptors enhances precision compared to using melody alone. Our algorithm efficiently matches melodies and descriptors, which can be extended beyond our proposed selection. Lastly, we released annotations of Slovenian folk songs, a yet underrepresented corpus in the MIR community.

Our current plans primarily involve releasing the corpus of these tunes, accompanied by comprehensive ethnomusicological commentary. In addition, future work should prioritize improving the algorithm’s usability for non-computational users, expanding the existing annotations of descriptors, and implementing the capability to perform combined query searches with approximate matching for melodies and descriptors. Our study (and corpus) may be used as supporting data for new algorithms of phrase segmentation, tune structure analysis, and harmony tasks including semi-automatic annotation.

Acknowledgements. We extend our gratitude to Matija Marolt, Matevž Pesek, and current as well as past members of the Institute of Ethnomusicology ZRC SAZU for their pivotal role in digitizing and curating the corpus from field recordings, notations and notes. We also appreciate the valuable input and comments provided by Dinh-Viet-Toan Le and the Algomus team, Patrick E. Savage and the members of Comp Music Lab, and the anonymous reviewers, which greatly contributed to the development of this paper.

HOW CONTROL AND TRANSPARENCY FOR USERS COULD IMPROVE ARTIST FAIRNESS IN MUSIC RECOMMENDER SYSTEMS

Karlijn Dinnissen

Utrecht University, The Netherlands

christine.bauer@plus.ac.at

ABSTRACT

As streaming services have become a main channel for music consumption, they significantly impact various stakeholders: users, artists who provide music, and other professionals working in the music industry. Therefore, it is essential to consider all stakeholders' goals and values when developing and evaluating the music recommender systems integrated into these services. One vital goal is treating artists fairly, thereby giving them a fair chance to have their music recommended and listened to, and subsequently building a fan base. Such artist fairness is often assumed to have a trade-off with user goals such as satisfaction. Using insights from two studies, this work shows the opposite: some goals from different stakeholders are complementary. Our first study, in which we interview music artists, demonstrates that they often see increased transparency and control for users as a means to also improve artist fairness. We expand with a second study asking other music industry professionals about these topics using a questionnaire. Its results indicate that transparency towards users is highly valued and should be increased.

1. INTRODUCTION

Music is most consumed on streaming services nowadays [1]. These services often have music recommender systems (MRS) integrated to provide personalized recommendations to users. Unfortunately, those systems might disadvantage some artists due to biases in the data, the system, and society. This could lead to unfairness for artists, e.g., through reduced visibility and opportunities [2–5].

To mitigate such issues, it is essential to understand and involve the stakeholders affected by MRS, and assess whether we are solving the right problems [6]. However, researchers have rarely directly reached out to these stakeholders inquiring how exactly they are affected, and what they value and desire in these systems. Limited work has been done on the user side, e.g., interviewing users about fairness in recommender systems (RS) in general [7], diversity in MRS [8], and the impact of MRS on listeners [9].

Work considering the artists' view is equally scarce. Exceptions are two interview-based studies on artists' perspective on fairness in MRS [10], and on playlists in music streaming services [11]. Moreover, to date, no research consults other music industry professionals. Such indirect stakeholders are often ignored when designing and evaluating systems such as MRS, even though these systems affect them as well [12]. In the case of MRS, some professionals come into direct contact with streaming services and embedded MRS, e.g., when working in a publishing or concert booking role. More indirectly, the success of a professional in an artist's team depends on that of the artist, which in part depends on streaming services.

This work focuses on two topics that are not described in existing artist-focused work: (i) *transparency* for users and (ii) giving more *control* to users. These topics emerged unprompted in interviews with artists (Study 1), which aimed to understand what artists consider to be fair in music streaming services and embedded MRS, and which role artists envision for music streaming platforms with regard to fairness, diversity, and transparency. While the general results of this study are described in Dinnissen & Bauer [13], in the work at hand, we zoom in on transparency and control for users because artists frequently mentioned these concepts as a means to increase artist fairness. This suggests that—contrary to what is often suggested [14–16]—there is not necessarily a trade-off between user and artist goals; they could even be complementary. Inspired by these insights, we subsequently query industry professionals through a questionnaire (Study 2).

We address the following research questions (RQs):

- **RQ1:** How do (i) artists and (ii) other music industry professionals view the current level of transparency and control for users on music streaming services?
- **RQ2:** Which role do artists see for user transparency and control in improving artist fairness?
- **RQ3:** What are artists' user interface (UI) suggestions to improve transparency and control?

This work offers insight into several perspectives on transparency and control of MRS for users. Artists think both should be increased and give concrete UI suggestions to achieve this. Industry professionals agree that transparency for users should be increased but offer a more nuanced view on control. We emphasize two key points: (i) user and artist goals should not always be viewed as

trade-offs, as some can be complementary, and (ii) directly involving a diverse set of stakeholders is essential in music information retrieval (MIR) research and development, to integrate their values and needs adequately.

2. RELATED WORK

2.1 Fairness in Music Recommender Systems

Fairness in MRS is increasingly receiving attention in the RS and MIR research communities [17, 18], as music streaming services and their integrated MRS significantly influence the music landscape [19]. One challenge here is that fairness is a human judgment value with many definitions and factors at play that do not directly translate into RS evaluation metrics [3]. Hence, research generally focuses on specific, often demographics-based fairness dimension(s) [5], such as nationality (e.g., [20]) and gender (e.g., [4, 21]). Here, a system is generally considered fair on a dimension if it upholds *group fairness*, a concept in which several groups of people are defined (e.g., based on their nationality), and the system should not give anyone a lesser experience based on their belonging to one group.

Fairness research in the music domain covers users (i.e., consumers), artists (i.e., item providers), or both simultaneously (for an overview, see [2]). Frequently mentioned issues for artists are *popularity bias*, a phenomenon where already popular items are recommended more often than others (e.g., [22, 23]), and the *item cold-start problem*, denoting difficulty in accurately recommending new items due to lack of previous interactions (e.g., [24]). These issues particularly affect new or less well-known music acts. For users, goals such as satisfaction are often considered rather than their fairness desires. Still, users indicate that in RS in general, provider fairness is important to them [7].

Other stakeholders to consider are platforms offering MRS [25, 26], music labels [27], and other music industry professionals who come into contact with or are impacted by music streaming services (e.g., concert bookers, artist managers, event producers). To the best of our knowledge, no work directly addresses the latter stakeholder group's view on how their values should be integrated into MRS.

2.2 Transparency for Users

Like fairness, RS transparency is increasingly valued by users and item providers alike [10, 28], with its societal relevance resulting in EU-wide legislation [29]. Transparency is often offered through interpretable or explainable RS, which can educate users on inner RS workings [7, 30]. To properly gauge RS fairness, transparency is considered a prerequisite. In Sonboli et al. [7], users indicate desiring insight into the fairness goals of organizations that offer RS. Ferwerda et al. [31] show that MRS users were more satisfied if they perceived a playlist as fair (here, focusing on artist popularity), even if they could not identify which playlist was more fair according to objective measures.

Insight into the inner workings of MRS, and therein considered fairness dimensions, could be offered on multiple levels and with different amounts of detail [30, 32]. On

the broadest level, music streaming services could share relevant business rules. On an abstract RS model level, global explanations can show overall tendencies on different dimensions (including fairness) [33]. Local model explanations are also possible, e.g., on the level of specific songs, artists, or playlists [33–35]. Different user personalities and cognition needs should be considered here [36], ideally allowing users to choose the type of explanations [7]. When promoting lesser-known artists, persuasive explanations might increase how users rate their recommendations [16]. However, users indicate they do not want to be (unintentionally) manipulated through explanations, even in a fairness context [7]. Finally, visualizations might also bring model logic to light [32], though textual explanations might be more effective in the MRS domain [34]. Yet, such transparency-enhancing functionality has rarely been implemented into user-facing parts of music streaming services, especially on the model level.

2.3 Giving Users Control

User control is considered an essential quality of an effective RS, as it positively affects user trust and satisfaction [28]. While transparency can provide insight into fairness, control gives users the agency to change their recommendations based on their values and goals, which could include fairness. Users indicate they want to choose whether they want more personalized recommendations that might be less fair for item providers, or less personalized in favor of fairness [7]. In the music domain specifically, research on user control often aims at exploration, discovery, or diversification tasks (e.g., [8, 32, 37–41]), with no works to date focusing on fairness. Still, if users' listening behavior becomes more diverse (i.e., they start engaging with a broader range of music items), this could also contribute to artist fairness if that range includes less popular or historically underrepresented artists [15, 42].

Like transparency, user control can be implemented on different system levels in a MRS. Literature differentiates between low-level control on recommendation data level (playlist, play and like buttons, rating), middle-level control on user profile level (e.g., with tags or sliders), and high-level control on algorithm parameter level [32]. When enabling such functionality, the extent to which a user can take control should be personalized to keep cognitive load and complexity at an acceptable level [32, 37].

Even though research demonstrates how users can be given control and how this contributes to recommendation acceptance and user satisfaction, in practice, users typically have little control in widely used MRS. Essentially, RS providers are in the main position to control the system, and with it, the items recommended [43, 44]. In the music industry, some item suppliers (e.g., major labels) may be in a strong position to shift the control to their side [43].

3. METHODS

We employed two studies: Study 1 with artists and Study 2 with other music industry professionals. Here, we describe

Code	Age	Gender	Audience reach	Genre
P1	26–35	Male	Local	Hip-Hop
P2	26–35	Male	National	Rock/Pop
P3	26–35	Male	Local	Rock/Punk/Metal
P4a,b	26–35	Male	Local (a) National, Local (b)	Hardcore/Rock/Blues (a), Indie/Metal (b)
P5	26–35	Male	Internat.	Dance
P6	18–25	Non-binary	Local	Pop
P7a,b	46–55	Female (a), Male (b)	National	Alt. Pop
P8a,b	56–65	Female	N/A	Folk/World
P9	18–25	Non-binary	Local	Rock/Pop/Folk
P10	26–35	Male	Local	Neoclassical
P11	36–45	Female	Local	80’s Alt. Synthpop
P12	18–25	Female	Local	Metal
P13	26–35	Female	(Inter)nat.	Indie-pop Alt.
P14	36–45	Male	National	Many

Table 1. Study 1 self-reported participant information.

both studies’ methods and outline our analysis approach.

3.1 Study 1: Interviews with Artists

We conducted 14 interviews with currently active music artists in the Netherlands from January to March 2022. We reached out to new participants until we reached a high level of thematic saturation [45]. For music groups, we offered the opportunity to join the interview with two members. This resulted in 3 interviews with two members and 11 interviews with individual artists (Table 1).

The research setup was based on the one used by [10], starting with a metadata questionnaire and a short presentation about MRS. Then, we conducted a semi-structured interview (52 minutes on average). Questions, outlined in detail in Dinnissen & Bauer [13], covered a broad range of topics: transparency for artists, artist control over recommendations, reaching an audience, popularity bias, diversity, gender balance, influencing users’ behavior, localization, repertoire size, royalty distribution, and impact of the COVID-19 pandemic. By using open questions, we encouraged an open conversation rather than a predefined one, leaving space for artists to add insights.

We recorded, transcribed, and pseudonymized the audio of the interviews. We used a Qualitative Content Analysis [46] for which we based the annotation scheme on the codes used in [10] (deductive) and then adapted the codes based on the interview content (inductive). Three annotators coded the transcripts, with two inter-annotator sessions indicating a high level of inter-annotator agreement. In the work at hand, we focus on the interview parts related to transparency and control for users. Therefore, we analyze results under respective codes ‘Transparency’ (top-level)—‘Towards user’, and ‘Control’ (top-level)—‘For users’. As mentioned in Section 1, neither topic was explicitly addressed in the questions. Both organically came up when discussing experiences and fairness.

3.2 Study 2: Questionnaires

To reach a considerable sample of music industry professionals, we used questionnaires as our data collection ap-

proach in Study 2.¹ We collected 35 responses, all filled in on tablets, from attendees at Eurosonic Noorderslag, a major European conference for music industry professionals held in January 2023.² 12 participants identified as women, 22 as men, and 1 participant refrained from stating their gender. Participants were from 7 European countries. When asked about their current professional role(s), participants indicated education (10), technology (7), event production (6), bookings (5), research/science (4), marketing/PR (4), artist (3), legal/policy (3), artist representation (2), and other (7). 11 participants indicated more than one role, and ‘artist’ was not the sole role for any participant.

In the questionnaire, we address the wide variety of topics from Study 1, this time from several points of view (i.e., artist, MRS user, and participants’ own as an industry professional). For this work, again, we focus on the questions that relate to transparency and control for users (see Table 2). We used a 5-point Likert-scale answering format and also offered the options to indicate ‘Don’t know / prefer not to answer’, skip a question if desired, and add comments. For the topics at hand, no comments were added. As one participant skipped all four questions on these topics, we present results for 34 participants.

4. RESULTS AND DISCUSSION

We outline the results of our studies going from our research questions. Insights from both Study 1 and Study 2 are used to answer RQ1, whereas RQ2 and RQ3 zoom in further on the results of Study 1.

4.1 RQ1: Transparency & Control for Users

For RQ1, we present insights from artists and other music industry professionals about current transparency and control for users within music streaming services.

Transparency—Artist view. All participants indicated using music streaming services both as a consumer and artist, distinguishing clearly between those two roles in their answers. In some cases, their views as an artist were similar to those from a user perspective. On transparency, they remarked that MRS deployed in streaming services are opaque to both artists and users. Here, we focus on the latter, which came up in several interviews despite no question being dedicated to this point of view. Opaqueness of MRS towards users was often stated as a fact: “As a user [...] you really have no idea what is recommended to you. You are kind of cool with all of it because they do a pretty good job, those algorithms.” (P6)

Artists called for more transparency on especially fairness objectives and diversity in recommendations. Some also noted that if users lack insight into MRS, they have no way of knowing whether and how their taste is being influenced: “It would be proper for a platform to show how it works, and that you as a listener would also... know? [...] As I think it influences [...] our listening behavior—which is not necessarily our taste—a lot.” (P13)

¹ Study 2 materials can be accessed at [47].

² <https://esns.nl/en/>

Transparency—Music industry professional view.

From Study 2, we show results for 34 industry professionals for the two questions dedicated to user transparency (Table 2, Q1+2). Responses on whether personalized MRS are transparent to users were spread ($SD = 1.37$), with 32% of participants somewhat agreeing, but also 26% of participants strongly disagreeing. Participants tend toward a negative view ($Mean = 2.79$) on current transparency towards users, displaying similar tendencies as artists.

A stronger consensus can be found on whether personalized MRS should be made more transparent. Here, no participants opted for (slightly) disagree; only one participant chose the neutral option, and the other participants either somewhat agreed (56%) or strongly agreed (41%). This shows a clear, almost unanimous call for more transparency of MRS, mirroring this call from artists in Study 1.

Discussion. From these results, we deduce that both stakeholder groups highly value transparency for users in MRS, think it is currently lacking, and desire improvement. All in all, artists mainly focus on system-level information (versus, e.g., song-level), which could be shared through global explanations [34]. As in Sonboli et al. [7], artists mention an educational component, noting users do not know how MRS work, which objectives are incorporated, and how MRS influence their listening behavior.

Control—Artist view. In Study 1, the topic of control for users frequently surfaced when artists discussed their own experiences as streaming service users: being unhappy with their recommendations, and having no options to modify them: *“Truly every week [certain act] is added to my Release Radar, every week I dislike it, I disliked [their profile], and it still appears every week. How?”* (P2)

“You start [on YouTube] with a very small band, and eventually you always end up, let’s say, at... Metallica, at Rock Im Park, you know. So I never find that useful.” (P3)

Increased user control was not only mentioned as a solution to such problems, but also as a means to generally improve MRS by allowing users to provide more information on their preferences: *“I know plenty of people who really enjoy listening to the same music all the time and especially don’t want to hear anything new. [...] If they’d solely be presented with a lot of different styles, they’d probably think: ‘that’s it, I’ll go somewhere else, this is too much for me’. So it would be very cool if you could indicate [yourself], from zero to ten, ‘I am very experimental’.”* (P4a)

Nevertheless, some artists viewed actively searching for specific music on streaming services as effectively also ‘taking control’: *“If I want to listen to super obscure Hip-Hop or something, then there are [play]lists for that. You do need to know those exist [...], but they contain all kinds of new things I didn’t know about before.”* (P1)

P2 did note that not all users know how to find such lists or want to put in such effort: *“I feel like people very often simply listen to what they are told. [...] 30 years ago, radio dictated what people could listen to in the car, so people just listened to that, and now Spotify is doing it.”* (P2)

Control—Music industry professional view. Resulting from Study 2, we show responses from 34 participants

in Table 2 (Q3+4). Contrary to artists, industry professionals were less unanimously negative about the current extent to which users can control their recommendations in MRS. Regarding users’ influence on general recommendations, participants were divided on the topic, with 38% indicating being somewhat or strongly dissatisfied, and 41% indicating they were somewhat or strongly satisfied.

On the extent to which users can influence their personal playlists, participants responded slightly more positively ($Mean = 3.38$), with 29% indicating they were somewhat or strongly dissatisfied, and 56% indicating they were somewhat or strongly satisfied. Overall, dissatisfaction with current user control seems less pronounced in this stakeholder group than for artists.

Discussion. Artists expressed dissatisfaction with current control over recommendations, as well as the lack of agency for users to change them. Some works (e.g., [44]) suggest that streaming services’ business interests are a possible reason for limited control. Still, the added value artists see for increased control aligns with frequently discussed user goals, such as exploration [37, 39, 41] and discovery [32]. The industry professionals’ view was more nuanced, with about half of the participants being satisfied with the extent to which users can currently control MRS.

4.2 RQ2: Role of Transparency & Control in Improving Artist Fairness

For RQ2, we focus on why artist fairness could be improved by increasing transparency and control for users, according to our participants. As this emphasis was initiated by participants from Study 1 but out of scope for Study 2, we focus on insights from Study 1.

Artists mainly mentioned transparency towards users in the context of algorithmically generated and ‘curated’ (i.e., created by an editor) playlists. These could be created with specific fairness goals in mind, which should be clearly communicated to the user. Such playlists could counter biases in MRS by presenting the user with more diverse music, e.g., highlighting music from (historically) underrepresented artists. P7b mentioned this could also be a way to highlight older repertoire, and P9 noted: *“An older album can, of course, still be new to someone.”* (P9)

However, P8a+b and P13 remarked that solely offering playlists with a designated fairness goal would not bring any lasting shift in user behavior: *“If you put all [women] in one list, then it is a list again. Then it effectively becomes some kind of subgenre, while gender actually transcends genre, and... it should not be an issue at all anyway.”* (P13)

A second suggestion was giving insight into all current playlists regarding certain ratios such as artist gender or ethnicity. With such insights, users could be made more aware of current inequalities, and make more informed and fairer decisions based on their own values: *“I think it is important for creators that users know what they are choosing. [...] Such transparency is missing completely. So I think it would be better if [streaming services] were transparent, like: all [play]lists contain this many women, this many men, this many black people, this many white peo-*

No.	Question	Min	Max	Median	Mean	SD
Q1	For users of streaming services, I feel like it is clear for which reason(s) specific music is recommended to them.	1	5	3	2.79	1.37
Q2	For users of streaming services, I feel like it is important to make it more clear for which reason(s) specific music is recommended to them.	3	5	4	4.38	0.54
Q3	For users of streaming services, I am happy with the extent to which they can influence which music is in their general recommendations.	1	5	3	3	1.26
Q4	For users of streaming services, I am happy with the extent to which they can influence which music is in their personalized playlists.	1	5	4	3.38	1.19

Table 2. Questionnaire responses (1 = ‘Strongly disagree’, 5 = ‘Strongly agree’).

ple, this many... and they would do this for all lists. End of story. And all of them would do it.” (P8a)

Other than more transparency, giving users more control over their recommendations was also suggested as a way to address unfairness issues. When discussing popularity bias and cold start problems, several participants suggested letting users manually adapt their playlists or general recommendations. Users could then, e.g., indicate they want to receive more songs that they have not listened to before: “Ideally, I would like to see not one band name I already know. As a small artist, I would appreciate that a lot as well, as it would make chances a little higher you’d maybe be recommended for once.” (P3)

Alternatively, users could indicate their preferred level of adventurousness: “Maybe it would be nice to make a specific setting for [more music outside of usual taste], ‘I feel adventurous’ or something like that.” (P6)

As a final insight, we note that most artists desired stronger measures, such as actively making playlists more diverse or balanced. P8a remarked that if users are given the choice, only those who already wish to contribute to a balanced and diverse music landscape would use such functionality: “[Recommending more diverse music] should just be a standard, [...] because else, it just won’t happen. Because that’s not the way people are. We are herd animals! We do what we know! And we also do what we know if we say: ‘I want to discover something new’. [...] It is a choice you think suits you. [...] So if you offer it as a choice, you will keep fishing in the same pond.” (P8a)

P13 also suggests offering more balanced playlists to start with: “[I would prefer] a playlist which contains a certain number—that it is more balanced.” (P13)

P5 remarked this could be achieved while taking user type (e.g., inclination towards diverse music) into account, and adapting recommendations based on that: “So it might start with... 30, 33%, and if it is a hit, the percentage becomes higher, and if [the more diverse songs are] skipped, it becomes lower... something like that.” (P5)

Discussion. Artists identified a connection between transparency for users and artist fairness. They indicated that users need insight into how MRS work to make informed decisions matching their fairness needs, which literature suggests could benefit artist fairness [7, 31]. Even though persuasive explanations might increase users’ satisfaction with lesser-known artist recommendations [16], we note that such persuasion is not necessarily appreciated [7].

Artists especially emphasized insight into platform fair-

ness goals (confirming results for RS in general [7]), and fairness metrics within playlists. To some extent, playlist channels intended to address fairness are currently offered: e.g., Spotify’s *EQUAL* [48] and Deezer’s *Women’s Impact* [49] initiatives both aim to combat gender disparity, while other curated playlists are dedicated to a certain niche, e.g., Tidal’s *Diversity & Tradition: New Black Americana* [50]. However, while dedicating playlists to an underrepresented group addresses the overall fairness issue, each standalone playlist is not necessarily a fair one, as it features only one group. Lastly, we note that collecting data on, or giving users insights into, sensitive attributes such as gender and ethnicity, is a debated topic [51].

Concerning giving users more control, artists noted it would help increase fairness on certain aspects if desired. This corresponds to previous findings [7], where users expressed their wish to adapt personalized RS on diversity aspects. Control over diversity in MRS could also contribute to artist fairness if less popular or (historically) underrepresented artists are recommended as a result [15, 42]. Still, some artists believed that increased control alone would not make a significant impact, as they expected that only users whose listening behavior is already diverse would increase their playlists’ diversity.

4.3 RQ3: UI Suggestions

For RQ3, we cover concrete ideas for implementing transparency- and control-enhancing UI functionalities, as brought up in Study 1. These came up when discussing (desired) artist fairness improvements, and integrating those in a manner that users would perceive positively. Ideas focused on influencing either MRS in general, or specific streaming service pages (e.g., playlists).

Artists mentioned some approaches to increase transparency and agency for users simultaneously. Those could be implemented on: (1) a user profile page, where users can modify their general recommendations, and (2) specific playlists so that users could modify recommendations within each playlist. For example, P6 and P11 mentioned sliders to adapt, e.g., how many new artists versus established artists should be recommended, or whether songs should be new to the user: “Perhaps just a percentage, a slider, saying how many recommended songs you’d know already, and how many you wouldn’t know, which you could adjust according to which mood you’re in.” (P6)

P7a+b and P11 suggested adding tags or filters so that

users could indicate what they want to be recommended, e.g., only songs from a specific genre or region: “*As if you are logging in from France, for example.*” (P7b)

Lastly, P10 mentioned addressing users through a prompt suggesting to increase the listener-artist connection. This could be achieved by proposing that the user visits the profile of artists they often listen to but have not yet looked up. Prompts could also suggest trying something more adventurous: “*Let’s say someone is listening to the same things constantly, after one week you could also say: ‘hey, [user], is it time for something else?’ [...] And then you could indicate: ‘nah, I don’t really feel like it, go back to what I was listening to, let’s just play The Beatles and The Rolling Stones again’... Or you like it.*” (P10)

Discussion. Our results offer a first insight into transparency- and control-increasing design for MRS, from the artist’s perspective. As a whole, artists focused on control in their answers rather than on transparency-increasing design or explanations. They mainly focused on mid-level controls on user profiles, playlists, or through prompts, rather than low- and high-level controls [32]. These responses correspond to previous research (e.g., sliders [32,37–39] and tags [32]) but had not yet been noted in an artist fairness context. From the user perspective, such controls could help influence MRS to better fit the current user goals and mindset (i.e., focused, open, or exploratory) [52]. In Sonboli et al. [7], users emphasize the importance of design practices to promote fair treatment. From the streaming services’ side, new functionality by YouTube Music might address the need for more control by allowing users to customize radio channels, e.g., by indicating what percentage of songs should be new to the user [53]. Deezer has also introduced a ‘Country Selector’ allowing users to switch the ‘home country’ on which their music and shows recommendations are based [54]. Regarding transparency, Spotify recently introduced an AI-generated ‘DJ’ feature offering personalized playlists with item-based explanations [55]. Further new functionalities and redesign should be extensively researched and tested to minimize user change aversion [56], and to verify whether they correspond with other stakeholder values.

5. CONCLUSION

5.1 Insights for the MIR Community and Beyond

Our work contributes insights into artists’ and music industry professionals’ perspectives on MRS transparency towards users. Our results suggest neither stakeholder is positive about the current transparency, despite its importance in MIR systems [18]. “*Transparency can serve to empower artists and listeners to challenge AI systems*” [18]. In the literature, there is a strong agreement that transparency is fundamental for MIR [5, 17, 18] and MRS specifically [10, 36], which is supported by our findings. Our results also show that the transparency towards users is considered insufficient and requires improvement.

Regarding control, artists indicate clearly that they desire increased user control over MRS, deeming the current

level insufficient. They argue that the combination of transparency toward users and giving them control will, in turn, help increase fairness for artists, which is a novel and complementary view going beyond existing work. By contrast, music industry professionals are interestingly divided on this matter, for which the cause is yet to be explored.

On a broader level, we learn that there is not necessarily a trade-off between user, item provider, and industry goals (as extensively discussed in multi-stakeholder systems research): indeed, there is some overlap. In our work’s context, users, artists, and other music industry professionals essentially want the same (i.e., more transparency and control for users) for similar reasons (i.e., better artist fairness and more recommendation diversity), though our study does not deliver insights concerning industry professionals’ reasoning. Hence, it is imperative that MIR involves different stakeholders to understand better what the various actors need and value, and integrates those needs and values in MRS. While trade-offs will keep existing, we need to delve into, and focus on, overlaps and joint goals.

Our work also contributes UI suggestions addressing control and transparency. We note that making only user-facing design changes is insufficient; they should be supported by MIR measures (e.g., data enhancement for retrieval and filtering, fair ranking). We emphasize the significance of combining algorithms and UI research alike.

Concluding, in MIR research, we need to support artists better. Taking a multi-stakeholder approach will accelerate this because some goals and needs are complementary. Essentially, supporting users (in transparency and control) can help artists (in terms of fairness).

5.2 Limitations and Future Work

One constraint of this work is that we aim for exploration with our sample and therefore do not offer an exhaustive, generalizable overview. In future work, both studies could be extended with participants from different cultural, musical, and professional backgrounds to paint a more generalizable overall picture. The perspectives of streaming service providers and other additional stakeholders could also be further addressed. Additionally, as we did not explicitly address transparency and control for users in Study 1, we might have missed views from participants where those topics did not come up. Still, this ensures that responses were spontaneous and unprompted. Lastly, Study 2 mostly contained closed questions that did not allow in-depth analysis, though participants had the possibility to add remarks in the optional free text fields.

A promising future direction is to implement the suggested UI functionalities in a music streaming service, and compare user behavior to that in a system without such functionalities. It would be especially worthwhile to conduct user studies evaluating those functionalities with various stakeholder groups and measure differences in perceived transparency, control, and fairness of such a system. Such a study should cover what RS should deliver if a user indicates not wanting fair recommendations, and how to personalize any fairness-aimed explanations to user needs.

6. ACKNOWLEDGEMENTS

We thank all participating artists and music industry professionals for sharing their invaluable insights. We also express our gratitude to all who supported us in recruiting participants, and especially to Marloes Vredenburg and Isabella Saccardi, both of whom helped conduct Study 2.

TOWARDS A NEW INTERFACE FOR MUSIC LISTENING: A USER EXPERIENCE STUDY ON YOUTUBE

Ahyeon Choi Eunsik Shin Haesun Joung Joongseek Lee Kyogu Lee
Department of Intelligence and Information, Seoul National University

{chah0623, esshin, gotjs3841, joonlee8, kglee}@snu.ac.kr

ABSTRACT

In light of the enduring success of music streaming services, it is noteworthy that an increasing number of users are positively gravitating toward YouTube as their preferred platform for listening to music. YouTube differs from typical music streaming services in that they provide a diverse range of music-related videos as well as soundtracks. However, despite the increasing popularity of using YouTube as a platform for music consumption, there is still a lack of comprehensive research on this phenomenon. As independent researchers unaffiliated with YouTube, we conducted semi-structured interviews with 27 users who listen to music through YouTube more than three times a week to investigate its usability and interface satisfaction. Our qualitative analysis found that YouTube has five main meanings for users as a music streaming service: 1) exploring musical diversity, 2) sharing unique playlists, 3) providing visual satisfaction, 4) facilitating user interaction, and 5) allowing free and easy access. We also propose wireframes of a video streaming service for better audio-visual music listening in two stages: search and listening. By these wireframes, we offer practical solutions to enhance user satisfaction with YouTube for music listening. These findings have wider implications beyond YouTube and could inform enhancements in other music streaming services as well.

1. INTRODUCTION

In recent years, the music streaming industry has witnessed a significant surge in popularity, with market leaders such as Spotify, Apple Music, and Amazon Music dominating the market [1]. Alongside this trend, YouTube has solidified its position as a prominent platform for diverse video content, including documentaries, daily vlogs, entertainment shows, and more. As users flocked to YouTube for various types of content, the platform naturally became a hub for music-related videos as well. Users now have easy access to a wide range of music video content on

YouTube, contributing to the growing trend of consuming music through video formats [2].

Indeed, YouTube delivers a distinctive multi-sensory experience by showcasing a vast variety of music-related videos such as music videos, live performances, curated playlists with visual artworks, and cover performances, enabling users to enjoy music through a fusion of visual and auditory elements. Despite Spotify's global prominence based on subscribers, YouTube has seen an increasing number of users turning to its platform for music consumption [1, 3]. This trend is evident in regions like South Korea [4, 5] and Latin America [6], where YouTube dominates as a preferred music platform.

Given YouTube's current dominance in music consumption, there's a need for a more comprehensive investigation into this behavior and patterns. Earlier studies have explored YouTube's role as a streaming service [7], compared its usability with Spotify [3], and analyzed music consumption behavior on YouTube [8]. However, the elements contributing to YouTube's rise as a primary music platform and the actual levels of user satisfaction are still not fully understood, indicating a need for further user-focused research.

Thus, this study aims to conduct in-depth interviews with music consumers on YouTube, examining their behavior, comparing the advantages and disadvantages of using YouTube as a music consumption tool with other music streaming services, and reevaluating YouTube's standing as a tool for music consumption. Additionally, we propose a new interface design that enhances the usability of music-related searches and listening. This research was conducted independently by our team, with no financial backing or data provided by YouTube or any associated organization. With our study, we aim to contribute to the ongoing conversation on YouTube's role as a music platform and offer insights into developing an innovative interface that elevates the user's music listening experience.

2. RELATED WORK

In the field of music information retrieval (MIR), research on music streaming services includes studies on improving recommendation algorithms [9–11], understanding user behavior and patterns of use [12–16], and studying user experiences and interfaces [17–21]. These studies aimed to enhance overall user satisfaction and engagement with music streaming services by providing personalized recommendations, improving the user interface, and identify-

ing the factors that influenced user behaviors and preferences.

Compared to other music streaming services, research on music consumption through YouTube has only recently gained attention due to the platform’s relatively late recognition as a music consumption platform. Early studies on YouTube’s music videos have revealed that music is the most consumed content category on YouTube, and researchers have classified the types of YouTube’s music content while analyzing their differences [7]. Furthermore, [3] reported that YouTube is used as frequently as Spotify and is perceived as superior to Spotify in terms of its shareability and accessibility.

As YouTube’s influence in music consumption grows, recent research has examined three types of online music practices according to the role YouTube plays: default, soundtracking, and complementary platforms [8]. Authors report that one of the main results is that YouTube’s music videos are listened to, rather than watched. However, the significance of visual elements in music listening can differ based on the genre or content. Additionally, it is worth mentioning that the participants in the study reported only occasional use of YouTube for music, which may limit the generalizability of the findings to other contexts, such as frequent YouTube users.

Therefore, this study aims to examine the usage behavior of users who use YouTube more than three times a week in everyday situations, report on the characteristics of the subject group, and classify the content used. In addition, we draw out advantages and disadvantages through usability tests to newly consider the role of YouTube as a music-listening tool. Moreover, the study proposes interface improvement measures to fill the research gap on "how to improve the music listening environment through YouTube." Considering the diverse range of devices used to access YouTube, including mobile devices, PCs, tablets, and TVs, we primarily focus on the mobile device, taking into account its widespread usage among participants.

3. METHODS

3.1 Participant

We recruited 27 Seoul National University students (12 males, 15 females) aged 18 or older (mean=23.40, sd=3.13). Our recruitment focused on participants who listen to music on YouTube at least three times a week while excluding those who rely solely on YouTube Music without using YouTube. This approach allowed us to concentrate on the distinct characteristics of consuming music through videos on YouTube, which encompass both visual elements and audio. Participants were compensated with a cash payment of KRW 10,000. Ethics approval was obtained from the Institutional Review Board of SNU.

3.2 Study Design

Informed by previous studies’ methodologies and the specific needs of our research, we designed our interview in two stages: a preliminary questionnaire [22, 23], followed

Phase	Requirements
A Verbal Interview	Asking about participants’ music listening habits and preferences along with the motivation to use YouTube.
Usability Test	Comparison of YouTube and other music streaming services and feedback on the interface of YouTube for searching and listening to music.
UI proposal	Propose YouTube interface design for music listening freely, and explain yourself.

Table 1. Three steps of semi-structured interview

by a semi-structured interview [22–24] that includes a brief ice-breaking session [25]. The preliminary questionnaire collects demographic data and music consumption habits of the participants, such as their academic majors, relationship with music, frequency and duration of YouTube use for music, and specific contexts of YouTube music consumption (excluding YouTube Music). Additionally, we also sought information regarding their subscription to YouTube Premium or usage of YouTube Music.

Following an ice-breaking session, the semi-structured interview proceeded with three main segments (Table 1). First, we explored participants’ regular music consumption habits, such as frequency, platform preference, and content preferences. Second, participants were asked to demonstrate the process of searching and listening to music on YouTube, which allowed for a natural exploration of the platform’s advantages and disadvantages in comparison to other music streaming services. Third, participants utilized empty interface templates on iPad to design a new interface for music searching and listening, enabling them to customize the screen ratio, functions, buttons, and more. Each interview, lasting roughly 30-40 minutes, was recorded and transcribed using NAVER Clova Note, with participant consent.

3.3 Analysis

We identified the overarching themes and trends of the participants’ responses and organized the data accordingly. The data were categorized into the following topics: primary streaming service, weekly listening time, music listening type, preferred music genres or content on YouTube, situations YouTube is used for music listening, reasons for using YouTube as a music consumption tool, music search methods on YouTube, criteria for video selection, advantages and disadvantages of YouTube compared to other services, and a summary of interface proposal sessions.

We generated a list of keywords for the qualitative analysis, which includes the advantages and disadvantages of using YouTube for music listening and user interface proposals from interviewees. To validate our classifications and identify commonalities, we repeated the process of analysis and consensus-building three times among the researchers similar to the analysis process in [22, 26, 27]. Grounded theory [28] and content analysis [29] were also

used as a guide throughout the process of keyword generation. We also referred to previous qualitative studies in the field of MIR [8, 15, 24, 26, 27] to guide our data analysis, as well as to ensure consistency in our reporting and citation practices. Finally, we thoroughly reviewed the keyword lists to extract the main findings of how YouTube is used as a music consumption tool by the participants based on the method of theme analysis [30].

To better understand the participants' interface design proposals, we compared the proposals from the participants and reviewed the summary of the interface designing sessions. From this process, we synthesized useful design implications and arrived at wireframe designs for the music search and listening screens.

4. RESULT

4.1 Behavior and Characteristics of Music Consumption on YouTube

As the current study investigates interview data from a sample of 27 users, it is important to take into account the unique characteristics of this group. Therefore, information concerning the participants' music consumption behaviors and preferences was gathered through preliminary surveys and interviews. The results showed that participants typically used YouTube about five times per week (mean = 4.89, sd = 1.93), for a total of approximately five hours (mean = 5.35, sd = 3.76), to listen to music while engaging in various activities, such as studying, relaxing, commuting, and exercising. No one specialized in music. The majority of participants used the free version of YouTube and did not subscribe to YouTube Premium. Additionally, some participants supplemented their music listening with other platforms such as YouTube Music, Melon, Spotify, and Genie.

Participants enjoyed a diverse range of music genres on YouTube. The top five genres mentioned most frequently were OST (original soundtrack of movies or dramas, 13 times), pop (12 times), K-pop (11 times), classical music (7 times), and indie music (7 times). Other genres mentioned in order of frequency include J-pop, ballads, old-fashioned music (mid-20th-century Korean pop and ballads), jazz, rock, band music (with live instrumentation and elements of rock, pop, and indie), new age, hip-hop, EDM, and R&B. Music content can be broadly divided into three categories: 1) Official music content such as music videos, 2) Live music content such as performances, concerts, festivals, and 3) User-generated content such as playlists and cover videos. In terms of frequency of mention, the order was 3-2-1 (27 times, 25 times, 8 times) respectively.

4.2 Advantages of using YouTube for music listening

Alongside our anticipation that YouTube serves as an audiovisual music listening tool, we found that YouTube possesses various strengths compared to other streaming services (Table 2). Musical diversity was the most frequently mentioned category, with two main points: the availability of non-official music in addition to official

Category	Keyword	Freq	Total
Musical Diversity	official soundtrack + α	14	23
	playlist	9	
Convenience	familiarity	4	15
	accessibility	4	
	subscription fee	4	
	Customizing	3	
User Interaction	recommendation	10	13
	comments	3	
Visual Contents	thumbnail	6	10
	video	4	
etc.	etc.	1	1

Table 2. Pros. keywords of usability test

releases, and the diversity of playlist content compared to other streaming services.

With streaming services, I can only listen to official releases, but with YouTube, I can listen to not only official releases but covers and other user-generated content. (P11)

Unlike other services, YouTube's diverse playlists prevent repetitive listening by offering a wide range of songs within similar genres. (P26)

Also, convenience was mentioned as an advantage, with familiarity, accessibility, no subscription fee, and user customization.

I use it because I'm used to it. I've used Melon and YouTube Music before, but I settled with YouTube because it was more convenient. (P12)

Since YouTube is free, there's no need to pay for other services. (P8)

As for user interaction, most users mentioned the recommendation algorithm itself and the ability to view other users' opinions through comments.

The recommendation algorithm is good. I often find great new songs through it. (P17)

It's good to be able to see other people's opinions and sympathize by reading comments. (P4)

Lastly, the visual content of thumbnails and videos was mentioned as an advantage.

I can use both sight and sound when listening to music with videos. (P4)

When I play playlists with thumbnails, like at a housewarming party, it adds to the atmosphere, and it's good for interior purposes too. (P6)

While we initially expected the inclusion of visual elements to be a significant advantage of YouTube, the participants' usage patterns proved more diverse. Some appreciated the visual components, while others turned to YouTube strictly for audio during activities like work or sleep (P2, P5, P22, P23, P24). These observations align with prior research [8], showing the varied ways users utilize YouTube for music. Although some mentioned listening to audio with the screen off (P7, P23, P24), we ex-

Category	Keyword	Freq	Total
User Interaction	comments	12	21
	recommendation	9	
Manipulation	button / tap	10	17
	display ratio	7

	log information	3	
Underutilization	replay	5	8
	volume control	3	
Contents Quality	sound quality	5	6
	video quality	1	
etc.	(video) data size	4	6
	etc.	2	

Table 3. Cons. keywords of usability test

cluded this aspect from our analysis as it’s a feature exclusive to YouTube Premium subscribers.

4.3 Disadvantages of using YouTube for music listening

The inconveniences and disadvantages of listening to music on YouTube were categorized into seven major themes (Table 3). The most frequently mentioned inconvenience was related to user interaction, with many complaints about the inconvenience of filtering the desired information while exploring recommended videos and comments.

In other music streaming services, genre separation is clearly done, but YouTube recommends based on the videos you watch, so there is a tendency to lean towards a specific genre. (P26)

When watching music videos and reading comments, it’s hard to find South Korean users’ reactions when most comments are in foreign languages. (P11)

The second most frequently mentioned disadvantage was related to screen manipulation, such as fixed thumbnails, the ratio of videos, and accidental button presses.

It would be nice if I could reduce the screen ratio. I want to watch the small screen when exercising or doing other things. (P8)

There are cases where I accidentally press the Shorts button and the music stops. (P22)

Regarding playlists, users complained about not having timestamps for individual songs, the content of playlists made by others, the process of creating playlists themselves, and the mixes provided by YouTube.

It’s inconvenient to switch to another song if there is no timestamp in the playlist. (P18)

Since playlists are made by others, there are few cases where all songs suit my taste, and there are mediocre

songs in between. (P18)

It’s inconvenient to save songs one by one in my library. It feels slow every time I press the save button, and it is a hassle to press the button several times to save. (P27)

Lastly, some users mentioned the lack of information about album or song information and lyrics, as well as the lack of log information about previously watched videos as a disadvantage.

It’s hard to find album or song information, and it’s frustrating not knowing the information of the concert I am watching. (P7)

When I use the autoplay function, it is hard to find which song I thought I liked. (P17)

Despite the existence of autoplay and volume control features on YouTube, user complaints arose from a lack of information about these functions. Some users viewed them as drawbacks, unaware of their existence or location. Specifically, enabling autoplay requires navigating to the settings, while fine-tuning volume necessitates physical device button use. This complexity may have heightened user frustration and dissatisfaction.

I wish there is a autoplay button. (P12)

I want to make minute adjustments, but even if I increase the volume level by just one, the volume suddenly becomes too loud. (P16)

The quality of the content is related to the audio or video quality. Some responses showed low reliability in audio quality when used for music listening.

There are cases where the sound quality is poor in content uploaded by individual users. (P12)

Aside from that, there were four mentions of concerns about mobile data usage due to large video data size (P2, P9, P11, P25), one mention of discomfort with provocative titles (P23) and experiencing an error when randomly playing saved videos (P14). There were nine mentions related to ads or background playback (P2, P5, P6, P8, P9, P12, P17, P19, P25), but these were excluded from the analysis since they can be resolved with a YouTube premium subscription.

4.4 User Feedback for Interface Improvements

We analyzed users’ explanations and drawings of the searching and listening screens, categorizing their demands for interface improvement into three categories: addition, modification, and deletion. These categories, along with relevant quotes, provide specific descriptions of users’ interface improvement suggestions.

The first is to request the addition of new information or functions that are currently absent on YouTube, such as a new button or tab, new sorting and filtering criteria, or more information about contents and songs.

It would be great if there was a detailed search button under the search bar, where you could search by year, album, composer, etc. (P7)

It would be nice if I can choose options between "all videos recommended" and "music-related recommendations" in the recommendation section. (P9)

The second is to modify the existing functions or configuration of YouTube to increase operability and efficiency when searching and listening to music, such as changing the ratio of various spaces on the interface or changing the positions of existing buttons and information.

It would be great if the thumbnail (album cover) could be smaller, and the title, artist, etc. could be displayed next to it. (P12)

It would be nice to adjust the ratio of the comment box and recommended videos so that you can view them together. (P4)

Lastly, there were cases where demands were made to remove things from the existing YouTube interface that are not directly related to music searching or listening.

We don't need the buttons for uploading videos on the bottom menu bar. It would be great if we could freely configure this menu bar. (P15)

If we could hide the buttons we don't use often and press the detailed button to show them, it would be neat. (P19)

5. FINDINGS AND DISCUSSION

5.1 Role of YouTube as a music streaming service

Users desire an improved interface for YouTube to maximize its potential as a music consumption tool. We have identified five key roles that YouTube plays in music listening, and based on this, we propose design implications to enhance the user experience.

5.1.1 Exploring musical diversity

YouTube offers users a wide variety of musical genres, artists, and songs to discover and explore, including rare or unreleased music not found on other streaming services. Users can also enjoy various versions of the same song through covers or live performances by different artists. **Design Implication:** To improve search efficiency, music content should be categorized by genre, artist, and mood, and album information such as lyrics should be provided to reduce the need to search for information on other platforms.

5.1.2 Sharing unique playlists

YouTube creators can create and share playlists, simplifying the search process and enabling them to select playlists based on keywords like mood or activity (e.g. warm spring day, driving playlist). **Design Implication:** Playlists should provide song and timeline information, and allow users to switch to the next song with a button. Allowing users to customize songs within the playlist, such as adding or removing them, and saving these changes, would enhance the playlist's functionality.

5.1.3 Providing visual satisfaction

By offering sensory satisfaction beyond just videos, YouTube's visual content enhances the music listening experience. Users appreciate being able to observe the musicians' expressions, gestures, and style, and sometimes even watch music videos solely for visual gratification like repetitive animations or thumbnail images paired with the music. **Design Implication:** The screen size and ratio of the video should be customizable based on the content's characteristics and users' listening environment. For example, users would like the option to decrease the video screen size in public settings or enlarge it to focus on a particular idol member or musician's finger movements.

5.1.4 Facilitating user interaction

YouTube's likes, dislikes, subscriptions, and comments features enable users to interact with the platform and foster a sense of community, resulting in a more engaging music listening experience. Additionally, the recommendation algorithm lets users explore new content and see how others react to music, which is a key motivation for users to use YouTube. **Design Implication:** Users should be able to sort and filter recommendations and comments based on various criteria, such as timeline, keyword, lyrics or the most frequently mentioned, to expand YouTube's social function. Pinning specific comments that users like or refer to frequently could also reduce search time.

5.1.5 Allowing free and easy access

YouTube's accessibility, cost-effectiveness, and cross-device compatibility make it a convenient option for users to listen to music in various situations. This versatility has led some users to cease subscribing to other streaming services. Primarily, the appeal lies in the free access to a diverse library of music videos, live performances, covers, and user-generated content, resonating with users disinclined to pay for music subscriptions. **Design Implication:** While device-specific interfaces are important, consistent usability is crucial to prevent user confusion or inconvenience.

It is crucial to acknowledge that while some of the proposed features (e.g., album and artist filters, lyrics, smaller screen mode) have already been implemented in the YouTube Music App, users still rely on YouTube to access a diverse range of music videos that are not available on the YouTube Music App. Therefore, our design implications hold the potential to differentiate YouTube from YouTube Music by catering to the experience of video streaming alongside music consumption.

5.2 UI for Audio-Visual Music Streaming Platform

Taking into account the role of YouTube as a music streaming service, the needs of its users, and the interface designs of typical music streaming services, we have developed an ideal wireframe for an audio-visual music listening platform. It consists of two stages: (a) searching and (b) listening screens (Figure 1).

Figure 1. A Wireframe of youtube UI for music listening

(a) Searching To display diverse music content tailored to users’ interests, we added 1) advanced search functionality to the top keyword search bar, allowing users to filter by era, genre, artist, and other details. Additionally, we added 2) a button to easily add multiple videos to a user’s playlist, and 3) reduced the thumbnail size to show more videos on one screen. Next to the thumbnail, we included 4) information about the songs in the video, and if the video is a playlist, we added 5) a timeline and information about the included songs. Finally, we made 6) the bottom menu buttons customizable, allowing users to remove buttons when they feel unnecessary and create their own menu.

(b) Listening While maintaining the current structure of the interface, we adjusted the layout and added new features to enhance the music listening experience. 1) Adding a toggle button that allows users to exchange between video watching and music listening. Users can use their fingers to 2) zoom in or out of the video to adjust its size. Previously, users had to click the video to access playback and skip buttons, but we located 3) the playback bar and related functions at the bottom of the video. We also made the 4) repeat button more visible. We added 5) a toggle button to expand or shorten album information or lyrics, and made 6) comments expandable in a similar manner, with a function for users to pin comments they want to keep visible. We added 7) a filtered recommendation feature to suggest reduced-size videos based on specific user-selected filters. This allows for easier exploration of related content through horizontal scrolling.

The findings of this research hold potential for application across a variety of streaming services. Features such as advanced search functions, customizable menus, and enhanced playlist capabilities can improve user engagement and satisfaction. Effective presentation of music-related information enriches the listening experience, while additional functionalities such as video zoom or comment

pinning foster a personalized user experience. These findings can significantly benefit YouTube, as well as aid other music streaming platforms like Spotify, Apple Music, and Amazon Music, and video streaming services including music videos, like Bilibili and Vimeo, in optimizing their interfaces according to their unique characteristics and users’ needs.

6. CONCLUSION

This study explored the music listening behaviors of YouTube users and analyzed the advantages and disadvantages of YouTube as a music streaming service. We proposed new interface wireframes to improve usability and re-examined YouTube’s role as a tool for music listening. Undoubtedly, there are constraints in actualizing the proposed interface fully on YouTube. Nevertheless, some suggestions on improving visual satisfaction, comment exploration, and toggle button to exchange the interface between video watching and music listening mode could be considered in designing the overall interface of video streaming platforms.

Our study has limitations depending on the small sample size of Korean users, and it is essential to consider several important factors. Firstly, our interface design primarily focused on mobile environments, which may limit its direct applicability to other devices like PCs and TVs. Secondly, the relatively narrow age range and educational levels of our participants may affect the generalizability of our findings. Thirdly, the absence of comparative studies on similar video platforms and services hinders our understanding of YouTube’s performance as a video streaming service. However, these limitations present opportunities for future research to explore and address the diverse needs of users across different devices, demographics, and video services. Overall, our study provides valuable insights and paves the way for further advancements in user-centered design for music streaming services.

FILOBASS: A DATASET AND CORPUS BASED STUDY OF JAZZ BASSLINES

Xavier Riley

Centre for Digital Music

ABSTRACT

We present FiloBass: a novel corpus of music scores and annotations which focuses on the important but often overlooked role of the double bass in jazz accompaniment. Inspired by recent work that sheds light on the role of the soloist, we offer a collection of 48 manually verified transcriptions of professional jazz bassists, comprising over 50,000 note events, which are based on the backing tracks used in the FiloSax dataset. For each recording we provide audio stems, scores, performance-aligned MIDI and associated metadata for beats, downbeats, chord symbols and markers for musical form.

We then use FiloBass to enrich our understanding of jazz bass lines, by conducting a corpus-based musical analysis with a contrastive study of existing instructional methods. Together with the original FiloSax dataset, our work represents a significant step toward a fully annotated performance dataset for a jazz quartet setting. By illuminating the critical role of the bass in jazz, this work contributes to a more nuanced and comprehensive understanding of the genre.

1. INTRODUCTION

The role of the double bass (also known as the string bass or upright bass) in jazz is nearly ubiquitous as a time keeper, outliner of harmony and as an occasional soloist. A key function is to play “walking bass”, where the harmony of the song is outlined by playing chord tones on strong beats and linking them with arpeggio, scale or chromatic movements on the remaining beats in the bar. This style has emerged as a way to provide a rhythmic and harmonic foundation to support a soloist. We believe that the harmonic techniques that performers use to outline chord changes could provide important information for enhanced understanding of jazz from an MIR perspective, e.g. for generative models. Due to the relatively simple rhythmic vocabulary, this style lends itself to algorithmic approaches which reduce the problem to beatwise pitch predictions, as discussed in Section 2. However, we recognize that this is a simplified view of bass performance, as bass lines also

contain rhythmic subtleties and other nuances which serve to increase the interest and texture of the music over time.

The FiloSax dataset [1] addressed a need for high quality annotations [2] to enable downstream tasks like automatic music transcription, score layout and performance analysis. Building on this, we address the need for similarly high quality data relating to the double bass as used in jazz, by turning our attention to the backing tracks used to create that dataset. The backing tracks are taken from the Aebersold series¹ and include performances by professional musicians.

Given the high quality of the bass playing on these tracks, we provide fine-grained annotations to allow for detailed stylistic and harmonic analysis. We believe that this represents the first large scale dataset to include detailed performance timing for jazz bass, which in turn should allow for more realistic generative modelling applications and better results for automatic transcription models. The transcriptions have been carried out using a semi-automatic pipeline which we describe in Section 3. Each note was checked manually and additionally proof-read by a professional jazz bassist. We also publish the extracted audio stems together with the transcriptions using the SoundSlice platform² to allow for easy browsing and evaluation³. Audio, MIDI and MusicXML artefacts along with the code to produce our analysis are available to download via the same site.

2. RELATED WORK

Despite the important role of bass in the jazz genre, study of this subject has often relied on fully manual transcriptions which are extremely labour intensive to produce (see [3] for an example). To address the need for data on a larger scale, important work was led by Abeßer et al. into automatic transcription of bass lines in a jazz context [4–6]. One of the motivations for their work was the idea that accurate bass transcriptions may be used to derive information about the harmony of a song, which in turn could aid with the task of automatic chord estimation. This resulted in 41 automatic bass transcriptions (with manual verification) as part of the Weimar Jazz Dataset [7] (WJD). These are beat-wise pitch transcriptions, meaning that they are only a partial annotation of the performance, omitting in-

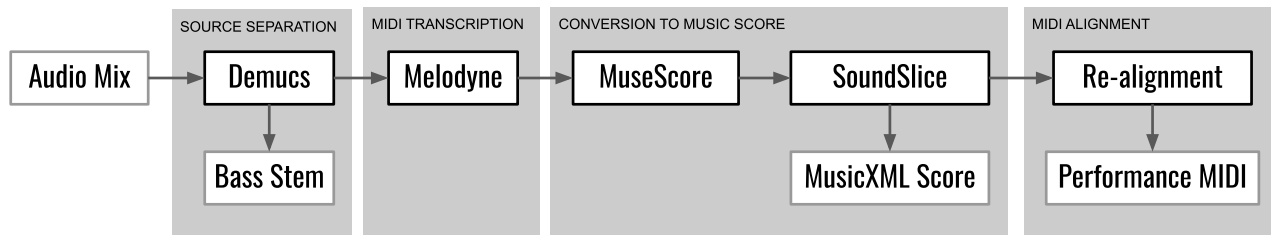

Figure 1. Flow diagram describing the main stages of the proposed method.

formation about rhythmic details, which may limit the use of this dataset in some downstream tasks such as performance analysis or generative modelling. Recent releases of the WJD dataset have included a further 415 fully automatic transcriptions of the bass notes for each beat.

The RWC-Jazz database [8] (a subset of the widely cited RWC dataset) provides audio and aligned MIDI annotations for 5 pieces, which have multiple recordings across a number of different instrument groupings which include bass. Bass is included on 37 recorded tracks which total around 3 hours of audio, however the audio is synthesised from samples of isolated notes and is mixed rather than provided as individual audio stems. This allows for accurate alignment at the expense of some realism in terms of articulation and dynamic range.

Formal research into walking bass has also focused on rule-based generation for modelling bass performances [9]. By incorporating rules described in instructional materials for learning jazz bass, the authors were able to construct a hidden Markov model (HMM) which produced musically relevant results according to subjective listening tests. The authors mention a lack of training data for this task and also note that they were unable to model anything beyond beat-wise pitch estimation.

Outside of the jazz genre, Araz [10] describes a pipeline for transcribing bass lines from electronic music. This approach relies on source separation to extract a bass stem before transcribing it to quantised MIDI. This approach assumes that the music is recorded at a fixed tempo, which is usually the case for electronic genres however this is not usually the case for jazz performances. The MedleyDB [11] dataset provides a large corpus of multitrack audio recordings. Of these, 71 have been annotated and resynthesised using the process described in [12] to produce the MDB-bass-synth dataset. This dataset is primarily aimed at training and evaluating framewise pitch estimation (f0) methods. We also note the IDMT-SMT-Bass dataset [13] which provides individual recordings of each note on an electric bass with a variety of playing techniques. This may be a good basis for a synthetic dataset to approach similar tasks. A summary of the available datasets is shown in Table 1.

3. METHODOLOGY

We now describe the process used to create the dataset which is summarised in Figure 1. We would like to em-

phasise that the work was carried out by the main author, a semi-professional bassist, and later checked and verified by another professional jazz bassist. Despite the use of automatic methods, every note was checked manually at least twice as a result. While this process was expensive in terms of time spent, the resulting increase in accuracy will provide a solid foundation for future methods.

3.1 Audio Recordings

All of the 48 backing tracks in this dataset are recorded in a standard format using professional jazz musicians. Details of the performers are shown in Table 2. They feature a jazz trio (piano, bass and drums) with bass panned to the left, drums panned centrally and piano panned to the right. This allows for convenient separation of bass and drums by using a single channel of audio. We are able to further isolate this single channel to obtain a bass stem using the Demucs source separation tool [14]. The producers of these tracks (Aebersold) have a catalogue of over 1300 tracks recorded in a similar fashion, which means that this approach could be applied to additional tracks in the future.

3.2 Transcription

For the initial transcription of performance MIDI, we opted to use the commercial program Melodyne⁴, specifically their “Melodic” detection algorithm. This is more typically used for editing vocal performances, however the pitch tracking and note segmentation proved to be broadly accurate for the separated bass stems. The program also offers a convenient interface to edit onsets and pitches manually in cases where the automatic analysis was judged to be incorrect. Each of the 48 scores were loaded into Melodyne and manually corrected where necessary.

To produce a score from the performance MIDI we employed a multi-step process. The first step was to import the existing downbeat annotations from the FiloSax dataset into Melodyne. We then used the “Make tempo constant” feature of Melodyne to produce a new file in which variations in the tempo were removed and the note positions rescaled accordingly. For those without access to Melodyne, we note that a similar result could be achieved using the `adjust_times` function from the PrettyMIDI library [15].

Todd Coolman	3	3952	1954
Tyrone Wheeler	6	5474	1965
Wayne Dockery	1	1050	1941

Table 2. Details for each bassist in the dataset

From this constant tempo version, we export a MIDI file from Melodyne and then import this into MuseScore 3⁵ using their MIDI import procedure. This was found to work better when the tempo was made constant first. This yields a score representation, however the variations in timing can produce non-idiomatic representations in the score which need to be corrected. This was done by exporting MusicXML and performing the final corrections using the SoundSlice platform, which allowed the transcription to be edited with reference to the synchronized audio from the original bass stem. Chord annotations are then copied from the FiloSax metadata and all 48 scores were checked by a professional jazz bassist to ensure accuracy and readability.

Finally, we used the alignment method proposed by Nakamura et al. [16] to realign the final score representation to the original MIDI performance data. This step is necessary to obtain a 1-to-1 correspondence in note annotations between score and performance MIDI. However, after working with these annotations we found that the timing information in the performance MIDI produced by Melodyne was not of sufficiently high quality. This resulted in issues when evaluating automatic transcription methods (see 5). To improve the alignment quality further, we align the MIDI to the model activations of a pre-trained guitar transcription model following the work of Maman and Bermano [17]. The realigned MIDI outputs are included in the final dataset.

⁵<https://musescore.org/en>

3.3 Repeated Passages

During the construction of the original FiloSax dataset, one of the objectives was to capture a consistent amount of saxophone data for each track. Since the original backing tracks varied in length, the authors edited the original backing tracks to repeat certain sections (usually complete choruses) in order to meet their criteria. This impacts the production of this dataset in that some passages are repeated exactly, however they were transcribed by treating them as a complete performance. This may lead to slight variations in how the rhythmic figures are notated which may be an issue for certain downstream tasks, for example introducing a bias in generative models. We recognise this and will provide instructions on how to remove the repeated sections if desired. Otherwise we provide transcriptions for each track in its entirety to allow for easy alignment with the existing FiloSax data.

3.4 Double Stops, Grace Notes and Ghost Notes

The source material used for this dataset is predominantly monophonic in nature, however the performers do make use of double stops (polyphony) in some places. We have transcribed these in the score and alignments but we also provide a monophonic version of the dataset with a view to ease of use in downstream tasks. The use of effects such as grace notes (extremely short notes) or ghost notes (where the string is partially or fully dampened to produce a percussive sound) is prevalent throughout the dataset and these can be viewed as an important aspect of the style. A guiding principle for producing the score representation is that they are readable by a sufficiently experienced bassist. With this in mind, we have notated ghost notes where these can be clearly heard on the recording however in cases where these effects were judged to be subtle or fleeting we have omitted them. We understand that this approach could be seen as subjective but we did so to prioritise the goal of making a readable and idiomatic score output over a completely consistent yet less readable score.

3.5 “Common Practice” versus Real Performance

The backing tracks used to create this dataset were originally conceived as practice aids for instrumental soloists. As such, the performances on these tracks could be viewed as a sort of “common practice” of jazz accompaniment. The performers focus on outlining chord changes and rhythms clearly to allow the soloist to focus on their role. This aspect of the data makes it a valuable example for studying how these accompaniments are constructed.

However, they may not be entirely representative of performances from live or studio recordings, as musicians may be more inclined to take musical risks in those settings. For this reason, the figures that we derive in our later analysis might not be fully representative of live or studio performance. A comparison is a potential area for exploration in future work.

3.6 Dataset Contents and Distribution

The final dataset comprises 48 tracks with contents as follows: Melodyne project files, audio mixes, isolated bass stems (from source separation software), performance-aligned MIDI with velocity information, and music scores in MusicXML format. We also include metadata which was compiled as part of the FiloSax dataset which includes timings for chords, sections, beats and downbeats.

As discussed in [1], the backing tracks themselves are subject to copyright restrictions so we are unable to release these. However, we provide instructions on how to obtain the files from the original provider. All other assets (including the source-separated stems) will be made freely available to researchers.

4. ANALYSIS

We now present a corpus analysis of the data in which we demonstrate the potential for insights on a musical level. As a starting point, we seek to answer some queries about the harmonic and rhythmic functions of a typical walking bass line as represented in the data. A number of commercial jazz bass methods from different authors are summarised in [3] which we will refer to where appropriate. All analyses which follow were derived from the dataset by converting note-level information to a Pandas [18] dataframe using the Music21 Python library [19]. The queries used to perform the analysis will be released alongside the dataset.

4.1 Chord Degrees Used in Bass Line Construction

As jazz performance is a cultural practice, a strict set of rules for bass line construction has not been established. However, given the size of the proposed dataset we can start to provide a quantitative analysis of the choices made by performers during their improvisations.

Concerning the question of which chord degrees are favoured by the player, we analyse the function of each note in the dataset as it relates to the chord being played underneath it. In Figure 2 we see that bassists will favour the root note of the chord when constructing walking bass lines, as these are used in 32.7% of all notes played. This is rather basic from a musical perspective, but we can now point to data that bolsters existing empirical observations. When we examine the note played at each new chord change event, we see from Figure 2 that the use of chord roots is even more prevalent, with the proportion rising to 67.9% of the total. This reflects the role of the bass in outlining the harmony of the song.

Figure 2. Global distribution of chord degrees

4.2 Use of Rhythmic Fills versus Quarter Note Pulse

In his educational method book, bassist Ron Carter [20] describes the process of adding rhythmic interest, or “fills”, to a line. However, he cautions the student “not to overdo” their use before advising that: “personal tastes and judgement will govern this area of your playing”. We can make an attempt to quantify this more precisely by examining what percentage of measures in the dataset contain a simple set of 4 quarter notes, and which deviate from this. We find that 62.81% of measures are indeed 4 quarter notes. While this is not a substitute for developing good taste, knowing this percentage might help in guiding a more analytical player.

4.3 Deriving Common Patterns

The annotations in this dataset also allow us to examine sequences of chord degrees that are commonly used in bass line construction. Over the 6400 chord symbols annotated, 3900 distinct patterns of chord degrees over chords are played. The 5 most common patterns for a chord lasting 4 beats are shown in Table 3. From these we can see a preference towards using tones from major and minor triads (i.e. 1, b3, 3 and 5). Given that the root movements in jazz are often perfect 4ths apart, we see that a number of the patterns approach the 4th via tones or semitones (i.e. from b3, 3, b5 or 5). This analysis of patterns only considers the chord degree, however a more detailed examination of patterns including sequential ideas and motifs is a subject of future work.

4.4 Semitone and V-to-I Approaches

In “Creating Jazz Basslines”, author Jim Stinnet emphasises the use of semitone approaches. This is where target notes which fall on strong beats or chord changes are preceded by a note which is a semitone above or below the target (described in [3]). In this dataset we observe that this is indeed common, with ascending and descending semitones being the most often used intervals overall as shown in Figure 3. For notes which land on chord changes, semi-

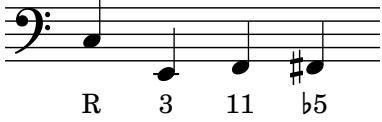

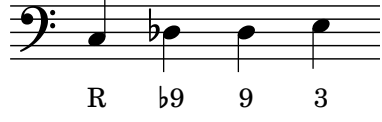

Pattern	Count	% of total
 R 9 \flat 3 3	360	4.6%
 R 3 11 \flat 5	195	2.5%
 R \flat 9 9 3	113	1.43%
 R \flat 7 13 \flat 13	113	1.43%
 R 3 13 5	111	1.41%

Table 3. The five most common chord degree n-grams for 7898 chord instances lasting 4 or more beats. Examples are notated in C major for illustration.

tone approaches are even more prevalent. We summarise the most common intervals to approach chord changes (target tones) in Table 4.

In the “Walking Basics” by Fuqua, Zisman, and Sher (described in [3]), the authors advocate the use of V to I movements for students however our data suggests that this is relatively uncommon in practice (9.66% ascending a perfect fourth and 4.30% descending). This is an interesting example of an idea that seems intuitive in theory (V to I is a strong bass movement for walking bass) but is not reflected in practice.

4.5 Step, Leap or Staying Put?

As we have seen in Section 4.1, in the majority of cases the performer will aim to play root notes when a new chord arrives but this leaves the question of how these root notes are typically connected together into a musically pleasing line. From the data, we can examine whether performers tend to use step-wise motion (tones and semitones), larger intervallic leaps (minor thirds or greater) or whether they choose to repeat a note. Looking at Figure 3 we see that there is a slight preference toward using step-wise motion (the largest group at 47.5%). Viewing the interval distribution plot we can also see that intervallic leaps are slightly more likely when the line is ascending especially for the interval of 5 semitones which corresponds to a perfect fourth.

Approach	Interval to target	Count	% of total
$D\flat \searrow C$	-1	4318	26.75
$B\sharp \nearrow C$	+1	3384	20.97
$B\flat \nearrow C$	+2	1921	11.90
$G \nearrow C$	+5	1560	9.66
$C \rightarrow C$	0	1172	7.26
$G \searrow C$	-7	694	4.30
$D \searrow C$	-2	656	4.06

Table 4. The most common intervals used to approach a chord change (totalling 16141 events). For illustration all approaches are shown relative to a target tone of C.

Figure 3. Distribution of intervals, grouped as step-wise movements (2 semitones or less), leaps (3 or more semitones) or repeats (no change from the preceding note).

4.6 Melodic Contour

The performer has a number of parameters available when improvising a bass line, one of which is the direction of the line. Sigi Busch (summarised in [3]) refers to the idea of “voice leading” within a bass line to link important chord tones while maintaining a direction, but none of the other methods summarised in [3] advise on how to choose directions or when to change them. Referring to the data now, we can see in Figure 4 that a high number of changes in direction is preferred, with the mean length of a sequence before a change falling at 2.46 notes. Intriguingly, the distribution of sequence lengths exhibits a power law. This phenomenon has been observed in several cases when analysing symbolic music corpora [21] but to our knowledge this is the first evidence in relation to walking bass lines.

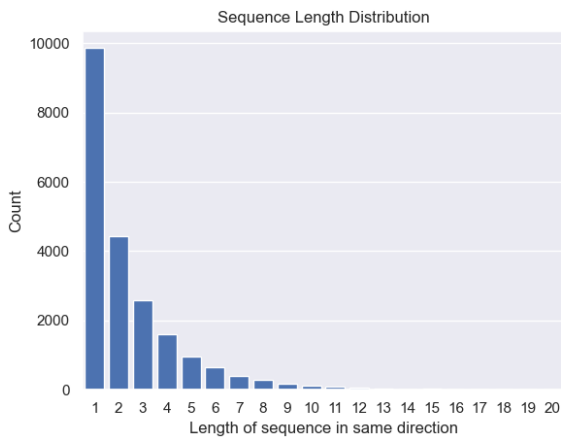

Figure 4. Sequence length (number of intervals) of lines maintaining a constant direction.

	CREPE Notes	Basic Pitch	Melodyne
R_{no}	74.11 ± 12.09	81.28 ± 6.26	79.52 ± 14.77
P_{no}	71.81 ± 13.33	51.40 ± 6.28	78.48 ± 15.41
F_{no}	72.89 ± 12.68	62.73 ± 5.55	78.95 ± 15.02
O	78.77 ± 2.68	65.24 ± 4.51	87.94 ± 3.91

Table 5. Automatic note transcription results for FiloBass, showing mean scores and standard deviation for Recall, Precision, F-measure and Overlap. Only onsets were evaluated and a timing tolerance of 50ms was used.

5. AUTOMATIC TRANSCRIPTION BASELINE

Using the accurate alignment data we have collected, we provide initial results for automatic note transcription — a bass line baseline. An exhaustive appraisal of transcription accuracy is beyond the scope of this work but we hope these results will encourage the use of this dataset in related future work.

We use the `mir_eval` [22] library to calculate precision, recall, F-measure and overlap scores. A default threshold of 50ms was used and only onset timings were considered. This is due to the difficulty of assessing offsets, as described in [23]. Three methods are examined for this task; the “Basic Pitch” package described in [23], the “CREPE Notes” method proposed in [24] and the commercial software Melodyne using the “Melodic” algorithm. The results from Melodyne were not manually corrected for this evaluation. Results for all methods are shown in Table 5. We see from these results that the proprietary commercial software outperforms the best research solutions for this dataset, however a significant amount of work is required to correct the remaining errors. During this work we also appreciated the Melodyne UI for note editing during our manual correction process. We note that similar projects in future may benefit from open source tools that allow a more streamlined note correction workflow.

6. DISCUSSION AND FUTURE WORK

In collating a dataset and performing a corpus analysis with reference to jazz bass methods, we hope to have provided

useful insights into the role of the bass in jazz. The analysis provided here is not exhaustive however, and we hope that future research can reveal more about the mental model that performers use when constructing their bass accompaniment. In particular we hope to examine the role of timing, dynamics and use of sequential ideas in further work. We are also interested in pairing the FiloBass data with the FiloSax data for further analysis. The relationships between bass line and melody in a jazz setting could be explored further, with a view to developing more realistic generative models for both bass lines and solos.

We believe that the dataset has a wide number of potential uses beyond musicological analysis. Recent work on automatic music transcription (AMT) has highlighted that performance can be improved as more data is made available [2] and this dataset can help to address this need.

An additional task which we hope to address in future is that of automatic chord estimation (ACE). Following the hypothesis of Abeßer et al. [4], we believe that this data could be used to train a system to estimate chords from the bass line directly. Chord estimation is a particularly challenging task in the jazz setting due to the rich harmonic vocabulary so novel approaches here may be welcome.

The scores which were produced as part of this data should also be valuable to researchers, as they provide a potential source of training data and evaluation for monophonic score processing tasks. In particular, they will be useful for rhythmic parsing (quantisation), automatic score layout and related sub-tasks such as spelling of accidentals.

7. CONCLUSIONS

We present FiloBass: a new dataset for jazz bass lines. Making use of the detailed annotation data, we are able to demonstrate a quantitative approach to reinforce traditional musicological analysis of the role of the bass in jazz performance.

Through examination of this dataset we demonstrate that a number of rules put forward in jazz bass method books are supported by larger scale data. These can be summarised as follows: the root note of the chord is usually played on the first beat of a new chord; this root is approached via a semitone step where possible; the rhythm comprises a quarter note pulse most of the time; a balance is maintained between ascending and descending contours. We are aware though, that any analytical project of this sort cannot be truly comprehensive and can only offer a guide to the performer. The musical context and the taste and experience of the musician will determine when to follow the “default” most likely path and when to choose a different route.

ABSTRACT

In this paper, we propose four different approaches to quantify similarities of compositional texture in symbolically encoded piano music. A melodic contour or harmonic progression can be shaped into a wide variety of different rhythms, densities, or combinations of layers. Instead of describing these textural organizations only locally, using existing formalisms, we question how these parameters may evolve throughout a musical piece, and more specifically how much they change. Hence, we define several distance functions to compare texture between two musical bars, based either on textural labels annotated with a dedicated syntax, or directly on symbolic scores. We propose an evaluation methodology based on textural heterogeneity and contrasts in classical Thema and Variations using the TAVERN dataset. Finally, we illustrate use cases of these tools to analyze long-term structure, and discuss the impact of these results on the understanding of musical texture.

1. INTRODUCTION

The term *texture* is used at various levels of description in the music domain. Initially related to the description of sound features, it is also used in symbolic representations of music to describe musical streams through a variety of concepts characterizing the volume and the organization of basic score elements such as notes and voices, which encompass high-level concepts such as monophony and polyphony¹ [1–4]. Between these two extremes, elements of musical texture include layers, voices, melodic or rhythmic patterns, articulation and instrumentation [2,5]. Huron interestingly summarizes it in three main ideas [3]: (1) the density of musical elements, (2) the diversity or inhomogeneity of elements, and (3) the overall sonic activity. The first two can be included in the notion of *compositional*

¹ Polyphony, as a type of texture, has a stronger meaning than “the simultaneous presence of possibly more than one note”. Here, it implies “two or more lines moving independently” [1]. Similarly, monophonic texture is not restricted to single melodies, but designates the presence of a unique musical line – possibly with note doubling or parallel motions.

texture, as opposed to orchestral (or timbral) texture [6]. Compositional texture, which is the object of study of the present work, is mostly embedded in the symbolic score. It is worth noting that some models of texture only focus on a particular musical dimension. Nordgren’s categorization for instance deals with the vertical dimension only, with note doubling and spacing [7]. Conversely, other approaches focus on the time dimension, as a *complement* to harmony, as in [8], or [9] for style-transfer. Figure 1 shows multiple versions of the same musical theme, which is shaped into different compositional textures.

We aim at quantifying the differences of compositional texture in piano music. Previous studies provided local descriptions of texture [10–12]. Here, we question how textural dimensions may evolve through a whole piece of music. This objective requires the elaboration of dedicated tools to compare textures, more precisely to assess the distance, or dissimilarity, between two given textural configurations.

A number of Music Information Retrieval (MIR) tasks involve the search of similarities at various scales, from pattern detection [13, 14] to genre classification [15, 16]. In the audio domain, music similarity lies at the center of content-based recommender systems [17, 18]. At the level of the musical score, music similarity has also been extensively studied on specific musical notions such as melody [13–15, 19–22], rhythmic pattern [23, 24], or chord and harmonic progressions [25–27]. Classical approaches for computing similarities include edit-distance on string-based representation, or geometric distance on pianoroll-like representations [28]. New latent embeddings of music also emerged from development of deep neural networks, as well as metric learning methods, like [29]. Although measures of music similarity may ultimately reflect some similarities in the perception of music [30, 31], we compare textural information based on symbolic music scores only. In particular, we focus here on studying different representations of texture in order to build interpretable dissimilarity measures.

In this work, we propose distance functions to quantify textural dissimilarity between musical bars from piano scores. We first detail four types of textural distance (Section 2). Then, we introduce estimators of textural heterogeneity and contrast, for longer musical extracts, and propose a dedicated methodology to evaluate our distances, using a dataset of Thema and Variations (Section 3). Finally, we provide use cases of such distances, especially in the context of form or structure analysis (Section 4).

Figure 1: Examples of different textures from *Ten Variations in G on ‘Unsere dumme Pöbel meint’* by W. A. Mozart (K. 455, 1784). A textural annotation, following the syntax defined in [10], is provided for each example. The melodic contour (circled in red) is shared among the variations, but the overall compositional texture changes. a. The theme is introduced in monophonic texture: three voices merge into a single musical idea, in parallel octave motions; b. There are now only two notes sounding at the same time: the vertical density decreases. But horizontal density is increased by sixteenth notes; c. A more homophonic texture: three or four threads, mostly synchronous; d. Here, we identify two layers of melody and accompaniment. In these last three bars, the harmony changes, but compositional texture is exactly the same.

2. DEFINING DISTANCES FOR COMPOSITIONAL TEXTURE

The distances that are designed in this paper aim at comparing compositional texture at the scale of individual musical bars. We focus on (polyphonic) piano scores of the Western Classical repertoire, with no voice separation.

2.1 Distances based on textural labels

Textural annotations have been produced in [6] for piano music, on Mozart’s sonatas. For each annotated bar, a label enclose two levels of textural information: on the one hand, a set of keywords that indicate the presence of certain properties of the overall textural configuration, or in one of its layer (like parallelism, melodic or harmonic roles...); on the other hand, a vertical structuration of the musical content into main textural layers and sublayers [10]. We propose two distance functions based on this information.

2.1.1 Distance between textural elements

The first distance is based on a set of binary *textural elements* which have been defined in [6, section 3.2]. These indicators express the presence of atomic textural characteristics in a musical bar. They include specific functions of the musical layers: melodic (M), harmonic (H), or static (S), relationships between voices: homorhythmy (h), parallel (p) or octave (o) motions, as well as characteristic musical figures such as sustained (τ) or repeated (ε) notes, scale motives (s), oscillations (b), sparse horizontal density (⊔) and neat changes of texture in the bar (,).

A musical bar a is therefore abstractly represented by a vector $texel(a)$ which comprised of the 12 textural elements from its label. The distance function d_{texel} returns the Hamming distance between the vectors. It is an integer between zero and 12 that corresponds to the number of textural elements that differ between two bar annotations:

$$d_{texel}(a, b) = \sum_{i=1}^{12} |texel_i(a) - texel_i(b)|$$

where a and b are two musical bars, and $texel_i(\cdot)$ the binary value of the i^{th} textural element of a given bar.

2.1.2 Textural diversity and density

At a higher level of description, textural annotation of piano scores mainly focus on grouping threads² of notes into distinct musical layers. Examples 1.a and 1.d both have three threads, but they are organized differently. In 1.a, they merge into a single layer. On the contrary, in 1.d, the threads are divided in 2 main textural layers: its texture is more *diverse* than 1.a without being thicker.

This grouping of threads is formalized in [10] under the terms of *density* (number of threads, of simultaneous sounding notes; the thickness or *density-number* in [2]) and *diversity* (number of distinct layers). These two dimensions allow to embed any textural label in the planar textural space represented in Figure 2 (left).

The *density-Diversity* distance d_{dD} separating two bars is defined as the Euclidean distance between their labels in this space. In previous examples, the first bar of 1.a and 1.d respectively have density-diversity coordinates of (3,1) and (3,2), resulting in a distance of 1.

Note that this distance only takes into account the vertical dimension of compositional texture (as in [7]). A drawback of restricting textural analysis to only two dimensions is that it is less sensitive to small textural fluctuation: as an example, the 1164 labels released by [6] only use 17 distinct combinations of density and diversity values. Nevertheless, this condensed description allows an interpretable

² The term ‘thread’ designates the most atomic elements that can be combined into musical ‘layers’ [5, p.65].

Figure 2: Schematic representations of textural spaces proposed respectively by Couturier et al. [6] (left) and Huron [3] (right). In both case, areas of the space are matched to *main types* of texture [1, 4]. The boundaries are not strict, though. The four examples of Figure 1 are also represented in these spaces.

approach for high-level analysis, as it reflects main textural strategies (see Figure 2).

2.2 Score-based distances

The distances defined in Section 2.1 are based on manually-annotated textural labels. Such textural annotations are however rarely available as their production requires substantial time and expert knowledge. In contrast, this section presents two distance functions that can systematically be computed on encoded musical scores.

2.2.1 Adapting Huron’s textural space

Another two-dimensional textural space has been proposed by Huron in [3]. It is used in this article to categorize full musical pieces among *main types* of texture (see also [1]): polyphony, monophony, homophony and heterophony, represented on Figure 2. Instead of analyzing the quantity and grouping of musical threads (see Section 2.1.2), it relies on the relationships between them: the proportions of *onset synchronization* and *semblant motions*.

The original study used a pre-existing separation of voices in the pieces (such as Bach’s Inventions and Sinfonias) to compute these features. For both of them, we provide an estimation of the value in the interleaved polyphonic case – i.e. without separation of voices. Note that it is not always possible to find a valid and unique voice separation in piano scores [32]. The details of the implementation, out of the scope of the article, can be found in the dedicated repository¹. They are:

- The ratio of *onset synchrony* quantifies the degree of homorhythmy of the note onsets. A value of 1 indicates a perfect synchronization of note onsets, which is the case in monophonic (see Figure 1.a) or homophonic (chordal or hymnal) textures. This value decreases if note onsets happens while other notes are sustained. For example, 1.b has a value of 0.25: in this case, only one onset over four is fully synchronous.

¹ Available at <http://algomus.fr/code>.

- The ratio of *semblant motions* estimates to what extent the directions of pitch motions are similar. This feature has its maximal value in the case of monophony, once again, whereas the presence of multiple concurrent layers with opposite motions will reduce its value.

We use these dimensions to build a new distance d_{huron} (the *Huron distance*) between two bars, which is obtained by summing their differences of *onset synchrony* values and *semblant motions* values, using our implementation in the polyphonic interleaved case. This corresponds to the Manhattan distance between their respective coordinates in this textural space.

2.2.2 Features of density

We present a last set of three distances based on low-level textural features, focusing on vertical and horizontal density. On the one hand, vertical density refers to the thickness of the texture, the number of simultaneous notes – similarly to the density evoked in Section 2.1.2. On the other hand, horizontal density describes the volume of successive notes, and their position in time. For both dimensions, we use a value of volume and a value of dispersion:

- `vert_avg`: average thickness, in number of notes. After slicing the bar into successive pitch sets, we count the number of pitches in each slice, weighted by their duration.
- `vert_std`: standard deviation of the number of pitches in each onset of one or more notes.
- `horiz_avg`: average number of onsets per beat. The duration of one beat is inferred from the bar time signature.
- `horiz_std`: standard deviation of the regularity of onsets, i.e. around the average duration between successive onsets.

We use Manhattan distance to compare two vectors of features, computed on two target bars. We define and test three variants of this distance: based on the two horizontal features only (d_h), on the two vertical ones (d_v), or on all the four (d_{hv}).

2.3 Implementation details and release

The features are extracted from the musical scores using intermediate Tab-Separated Values (TSV) files, which contain a list of notes (see [33]). The code¹, in Python, includes a converter to this format from both Humdrum `**kern` [34] and musicXML formats, using music21 Python library [35].

3. EVALUATING TEXTURAL DISTANCES

3.1 Dataset

To evaluate the relevance of the distances proposed in the previous section, we use bars from classical *Thema*

and variations. [36] emphasizes the links between musical variations in general, and musical similarity. In the genre of Thema and variations, a theme is reproduced in short sections with various changes of (textural) parameters, but in a way that allow to recognize the original melodic contour and/or harmony; as in Figure 1. This structure has the advantage of providing both dissimilar examples (in distinct variations), and similar examples (in the same variation).

Although no explicit mention of textural homogeneity within variations has been found in musicological literature, authors more often insist on the higher contrast between distinct variations [37, p.570]. The genre of Thema and variations provides “the largest esthetic spectrum” [38], and this variety of content is valuable in our case. We rely on this fundamental assumption for the rest of the paper: *on average, a musical bar is more similar – in texture – to a bar from the same musical phrase, than to any other bar in another variation or piece.*

We use the TAVERN dataset [39], which consists in 27 sets of thema and variations by Mozart (10) and Beethoven (17). The variations are already segmented into structural phrases, totalling 1060 of them in the whole dataset. We take those phrases as structural units in which we use the score-based distances defined in section 2.2. Further annotations of texture would be required to apply label-based distances on this dataset.

Remark. The texture of phrases can vary within the same variation, to a lesser extent – this is generally the case in bipartite or tripartite variations, which is a common structure in this context [37, 38]. Changes of mode (major/minor) often occur, in general at least once per set of variations. This change is not considered as textural, but it is often accompanied by changes of other musical parameters that are in the scope of texture, so it would still add valuable information.

3.2 Heterogeneity and contrast

To evaluate textural dissimilarities on full musical extracts, we introduce two indicators:

- *heterogeneity*: the heterogeneity (h_d) within a single set of bars corresponds to *the average distance between pairs of distinct bars from the set*, for a given distance function d .
- *contrast*: the contrast (c_d) between two sets of bars is defined as *the average distance value between pairs of bars from the two extracts*, for a given distance function d .

More formally, we have:

$$h_d(S) = \text{avg}_{\forall (m_i, m_j) \in S^2, i \neq j} d(m_i, m_j)$$

$$c_d(S_1, S_2) = \text{avg}_{\forall m_i \in S_1, \forall m_j \in S_2} d(m_i, m_j)$$

where avg is the arithmetic mean operator, S , S_1 and S_2 are sets of bars, and m_i , m_j denote bars/measures in those sets.

Figure 3: Schematic representation of the computation of heterogeneity of a specific phrase (arcs above) and contrast (links between the bars of phrase P and all the other bars outside P, in the corpus T). Our evaluation metric is the average value of this ratio for all the phrases of the corpus.

The heterogeneity is a measure of dispersion: a lower value means that samples in the extract are more similar between each other (given a distance d). We specifically ignore the comparisons of a bar with itself to reduce the influence of the size of S .

Let us illustrate those two indicators for the descriptor-based distance d_{hv} (Section 2.2.2) using examples Figure 1.a and Figure 1.d. We note $S_a = \{\text{bars of Figure 1.a}\} = \{a_1, a_2\}$ and $S_d = \{\text{bars of Figure 1.d}\} = \{d_1, d_2, d_3\}$. In S_a , the heterogeneity is simply equal to the distance between its two bars: small differences occur in horizontal density, but not in vertical density. We obtain a value of 0.6. To compute the *heterogeneity* in S_d , we have three possible unordered pairs of bars to compare ($\{d_1, d_2\}$, $\{d_1, d_3\}$ and $\{d_2, d_3\}$); however, the texture in these bars is precisely the same regarding d_{hv} , resulting in a value of zero of heterogeneity. The inequality $h_d(S_a) > h_d(S_d)$ can be interpreted as “ S_a is more texturally heterogeneous than S_d , with regards to distance d ”. The contrast c_d between S_a and S_d is 1.825. In general, the inequality $h_d(S_a) < c_d(S_a, S_d)$ means that a bar in S_a is, on average, more similar to other bars in S_a than bars in S_d .

3.3 Evaluation methodology

We evaluate how heterogeneous the texture is within each phrases of the TAVERN dataset, compared to the rest of the corpus. Under the assumption exposed in Section 3.1, we assess the quality of a textural distance d by looking for the lowest *average Relative Heterogeneity* on TAVERN phrases (T):

$$\text{aRH}_T(d) = \text{avg}_{\forall P_i \in T} \left(\frac{h_d(P_i)}{c_d(P_i, T \setminus P_i)} \right)$$

where T is the set of all the phrases in TAVERN dataset, P_i is the i^{th} phrase of the dataset, and d is a textural distance function between individual musical bars.

This process is schematized in Figure 3. For a given phrase, if the ratio between intra-phrase heterogeneity and inter-phrases contrast is very low, it means that the extract is rather homogeneous, and that this texture – or whatever the distance d represents – is rather specific to this extract compared to the rest of the corpus. If this ratio is above 1, it means that the bars in this phrase are more similar to other

Distance	d	$\text{aRH}_T(d)$
Horiz. and Vert. density features	d_{hv}	0.51
Horizontal density features	d_h	0.39
Vertical density features	d_v	0.64
Huron’s textural space	d_{huron}	0.72
Comparison: Pitch class content	d_{pc}	0.80

Table 1: Evaluation of textural distances using the *Average Relative Heterogeneity* on phrases of the TAVERN dataset ($\text{aRH}_T(d)$), to minimize.

bars outside the phrases than between themselves. Put differently: a value below 1 show that intra-phrase distances (heterogeneity) are smaller than inter-phrases comparison (contrast with the corpus). The value of $\text{aRH}_T(d)$ is the average of this ratio on all the phrases of the corpus.

Remarks. We could directly compute values of *contrast* or *heterogeneity* on reference data, using different textural distance d_i and opt for the most convincing values. However, these values are not directly comparable if they are based on different distances: they are average values of specific distances, and thus follow their respective – and possibly very different – order of magnitude. Also note that the *contrast* is not a distance function (or metric) because the contrast between the same set of bars could be different from zero – if its bars that are not all the same. The functions presented in Section 2 *are* metrics, applied to different representations of texture in a musical bar.

3.4 Results

The results, for all score-based distances, are shown in Table 1. Using the distance based on all density features (d_{hv}), the aRH_T of 0.51 indicates that a musical bar is, on average, a twice more similar to bars in the same phrase than to the rest of the corpus. The use of horizontal density features alone (d_h) improves this value (0.39), highlighting the importance of the time dimension to discriminate between textures.

For comparison, we integrate an additional distance (d_{pc}) that describe not textural but harmonic content – computing Euclidean distance between pitch-classes profile. Its aRH_T of 0.80 is still below 1, which means that intra-phrase d_{pc} -values (heterogeneity) are smaller than inter-phrase comparison (contrast with the corpus); this is not surprising in tonal music. But most importantly, this evaluation metric value is higher than for all other textural distances. This gap contributes to validate the use of Thema and Variations as a source of empiric ground truth examples of textural similarities.

3.5 Links between distances

In Table 2, we display correlations between all the distances defined in Section 2. They are computed on all dis-

	d_{hv}	d_h	d_v	d_{huron}	d_{dD}	d_{texel}
d_{hv}	1.00	"	"	"	"	"
d_h	0.95	1.00	"	"	"	"
d_v	0.33	0.05	1.00	"	"	"
d_{huron}	0.10	0.10	0.05	1.00	"	"
d_{dD}	0.19	0.03	0.53	0.03	1.00	
d_{texel}	0.10	0.06	0.14	0.01	0.20	1.00

Table 2: Spearman correlation between textural distances as defined in Section 2, evaluated on all pair of bars in three Mozart piano sonatas (K. 279, K. 280, K. 283).

	d_{hv}	d_h	d_v	d_{huron}	d_{dD}	d_{texel}
Horizontal density (time dimension)	×	×				×
Vertical density (thickness)	×		×		×	×
Semblant motions, parallelism				×		×
Roles of layers (melody, acc. ...)						×
Main types of texture (see Fig.2)				×	×	
Computed on symbolic scores	×	×	×	×		
Computed on annotated labels					×	×

Table 3: Summary of the distances defined in Section 2, and the different dimensions of compositional texture that they take into account.

tinct pairs of bars among 1160 from Mozart piano sonatas (K. 279, K. 280, K. 283), for which we have both textural annotations [6] and encoded scores [33]. We use Spearman correlation, that depicts similarities of rankings of these values.

Huron-space distance (d_{huron}) and texel distance (d_{texel}) seem independant from other distances. We explain it by the fact that our distances focus on different dimensions of texture, summarized in Table 3. In particular, d_{texel} covers a wide range of abstract concept and is the only function that deals with the roles of layers, which is difficult to approximate using low-level features. Otherwise, we find that using horizontal density features only (d_h) gives a very similar behavior than using all four density features (d_{hv}) – with a correlation of 0.95. Although Density-Diversity distance (d_{dD}) and vertical-feature distance (d_v) deal with very different level of abstraction, they correlates positively (0.53), as they both focus on the vertical dimension of texture.

Figure 4: Textural dissimilarities between the phrases of *Ten Variations in G* on ‘*Unsere dummer Pöbel meint*’ by W. A. Mozart (K. 455, 1784). Intersections are colored according to *contrast* values using d_{hv} distance (Section 2.2.2), and *heterogeneity* of phrases on the diagonal (Section 3.2). The phrases are scaled according to their size in number of bars (totalling 338 in the whole piece). The most similar extracts are shown in dark blue, whereas light green indicates higher dissimilarity. – We identify blocks of consecutive similar variations, such as (1,2,3) or (5,6,7); inner structure of variations may reveal contrasting segments in the case of Variation 4; Variation 9 is very contrasted due to the alternation between chordal texture and fast melodic lines; the penultimate phrase comes back to the original texture of the Thema.

4. USE CASES FOR STRUCTURE ANALYSES

4.1 Long-term textural dissimilarities

The *contrast* defined in Section 3.2 can be used as a dissimilarity measure between any sets of bars, from individual pieces to entire corpora. It may also emphasize the relationships between sections, or phrases, of a given piece of music. Figure 4 shows an example of self-similarity matrix based on textural contrast between phrases of a piece in Thema and Variations form. Beyond the case of Thema and Variations, the contrast measure gives an overview of the piece macrostructure, and may even link thematic material up to transposition, such as recapitulation parts in sonata form. More generally, the proposed distances can lead to promising and original approaches for automatic structure segmentation.

4.2 Short-term textural changes

In this paper, we assume lower textural heterogeneity within phrases of thema and variations. But in the general case, changes of textures may occur in the middle of a phrase. Following the intuition that in-phrase texture changes mostly occur in openings and endings of phrases in the TAVERN dataset, we evaluate d_{hv} using the same methodology as in Section 3.3, but systematically ignore

the last bar of each phrase of the corpus. We find that $aRH_T(d_{hv})$ decreases from 0.51 to 0.42. When removing each first bar instead, it drops to 0.34. In comparison, removing the second or third bar of the phrases increases the original value of $aRH_T(d_{hv})$ to respectively 0.55 and 0.54. This shows that the ‘core’ of phrases have slightly more textural homogeneity, and most importantly that openings and endings are less similar to the middle of phrases. Typical examples are transitional melodies and final chords in cadences – which often contrast with the rest of the phrase. We believe that our distance can be used to study more precisely these local changes of texture within short sections.

5. CONCLUSION AND FURTHER WORKS

The textural distances proposed in this paper give promising perspectives for the computation of multi-level similarities in symbolic music. On the one hand, comparing textural labels allows to rely on expert data, which is already known as texturally meaningful. This information already carries a lot of abstraction, but it is costly to produce in practice and can lead to a certain amount of subjectivity [40]. Moreover, the low amount of available annotations hinders our ability to evaluate the quality of these distances. On the other hand, using symbolic features that can be computed automatically is more practical, and also more objective. In further work, we plan to investigate the best features to use at a more global scale, as well as their relative contribution.

Although the proposed distances are drawn at the level of musical bars, we elaborated a more global dissimilarity measure to compare sets of several bars, and highlight textural contrast between and within structural sections of musical pieces. This measure made possible a quantitative evaluation of textural distances on a corpus of Thema and Variations, based on the assumption that texture is more dissimilar between two distinct variations, and more homogeneous within single variations.

Our distances capture different facets of compositional texture, at different levels of abstraction (see Table 3). Focusing on more atomic and independent textural aspects can enhance the precision and the interpretability of our analyses. However, ensuring a proper disentanglement of such dimensions remains a major challenge. Integrating Thema and variations in the evaluation methodology is a step further to link theoretical models of texture to concrete, and somewhat intuitive, examples. It contributes to a better understanding of some models of texture, but also of musical texture itself.

A potential continuation of this work is to broaden the scope of our experiments to other repertoires. We believe that the tools introduced in this paper are easily extendable to other styles of written polyphonic music, or to other instruments. In the meantime, the present experiments on Western classical piano music already offer promising opportunities of quantitative analyses of texture with regards to genre, style, form or harmony.

6. ACKNOWLEDGMENT

We want to thank Jean-Paul Chehab for fruitful discussion at the beginning of the project. We also thank Dinh-Viet-Toan Le, Alexandre D’Hooge and the rest of the Algomus team, as well as the anonymous reviewers for their constructive feedback. This research is partly funded by Région Hauts-de-France and by Agence Nationale de la Recherche (ANR), project TABASCO ANR-22-CE38-0001.

ABSTRACT

As corpora of digital musical scores continue to grow, the need for research tools capable of manipulating such data efficiently, with an intuitive interface, and support for a diversity of file formats, becomes increasingly pressing. In response, this paper introduces the Digital Musicology Corpus Analysis Toolkit (`DiMCAT`), a Python library for processing large corpora of digitally encoded musical scores. Equally aimed at music-analytical corpus studies, MIR, and machine-learning research, `DiMCAT` performs common data transformations and analyses using dataframes. Dataframes reduce the inherent complexity of atomic score contents (e.g., notes), larger score entities (e.g., measures), and abstractions (e.g., chord symbols) into easily manipulable computational structures, whose vectorized operations scale to large quantities of musical material. The design of `DiMCAT`'s API prioritizes computational speed and ease of use, thus aiming to cater to machine-learning practitioners and musicologists alike.

1. INTRODUCTION

Given the proliferation of large corpora of digital scores (e.g., [1–4]), the computational challenges of analyzing symbolically encoded staff notation loom large in Digital Musicology and MIR. In principle, any symbolic music encoding is equally amenable to algorithmic processing, to the extent that it is consistent and comprehensive. In practice, however, the *visual* efficiency of staff notation—which conglomerates tonal, rhythmic, metric, articulatory, and other musical parameters in context-dependent and position-dependent symbols—is inversely related to its *computational* efficiency. Analyzing large collections of digital scores is thus hindered not only by the sheer volume of data involved, but also by the intrinsic complexity of the representations comprising musical structures. [5, 6]

To address such challenges, we present the Digital Musicology Corpus Analysis Toolkit (`DiMCAT`), which uses

dataframes [7–9] to disentangle pertinent score features within tabular representations, providing an interface for processing and analyzing large collections of dataframe-structured score data. `DiMCAT` supports MusicXML, MEI, Humdrum, and MuseScore (see Section 3.1), among other formats, and provides an expandable range of music analysis functionalities, including feature extraction, similarity analysis, and visualization. Addressed to Digital Musicology and MIR communities alike, its purpose is to provide a user-friendly interface for “distant-reading” staff-notated score corpora, and for utilizing score data in machine-learning pipelines. Efficiency at scale was among our primary design goals, an aspect which is only growing in importance as corpus sizes have continued to grow (e.g., [3]), with scores, rather than MIDI encodings, increasingly used to train large computational models (e.g., [10]).

In this paper, we describe the design and implementation of `DiMCAT` and argue for its usefulness through trials with various corpora. First, in Section 2, we outline a rationale for the representation of staff notation as dataframes, and for the underlying data-relational mindset. Section 3 presents the library design from a user’s perspective, covering such topics as data loading (Section 3.1) and the slice/group/analysis pipeline (Section 3.2). Evidence of ease-of-use in musicological research is provided in Section 4, and a comparison to extant libraries is made in Section 5.

2. UTILIZING DATAFRAMES TO REPRESENT SCORES

Dataframes were first introduced in 1990 as part of the statistical programming language S [7] and later ported to its descendant R [11]. Since then, they have become ubiquitous in the data science and machine learning communities, with a multitude of supplementary frameworks released across the spectrum of programming languages, often aiming to overcome performance problems associated with large dataframes (e.g., `modin` [12]). The wide adoption of dataframes can be attributed to their versatility, convenience, and operational principles, which resemble those of relational databases, spreadsheets, and nested arrays [9, 11–13]. `DiMCAT` encodes all score information within dataframe objects provided by either `pandas` or `modin`, with support for additional libraries (which we refer to as “backends”) planned in future versions.

Table 1: Ludwig van Beethoven, *String quartet op. 18/6*, 4th movement (“La Malinconia”), measure number (**mn**) 44. The measure contains the section break after the slow introduction and is composed of two incomplete measure units with counts (**mc**) 44 and 45. The new 3/8 time signature (**timesig**) of the latter is introduced by a 3/16 upbeat, mathematically completing the 2/4 meter of the former. The dataframe represents notes and rests from beat 2 onwards. Its index (bold values on the left) comprises left-closed, right-open intervals which express the start and end points of each event on the score’s timeline, measured in quarter notes. Each column has a name (**bold**) and a data type (*italic*). The first eight columns contain temporal information (see Section 2.1). The columns **staff** and **voice** determine a notational layer. The last four columns express pitch-related information (**tpc** is tonal pitch class, expressed as the distance from C measured in perfect fifths) and are empty for rows representing rests. Special columns are omitted (e.g., ties, tremolos, or grace notes).

2.1 Representing staff notation as dataframes

Most encoding standards symbolically represent staff notation in hierarchical fashion. This includes most non-XML plaintext formats—at least those capable of encoding multiple staves, such as Lilypond, ABC, or Humdrum’s `**kern`—as well as XML-based standards. Table 2 shows a selection of tags in order of hierarchical nesting, from outermost to innermost, for three common XML-based standards. The table reveals that these standards recognize almost the same types of score elements, albeit located at different levels within the document tree. Among these elements are staves, measures, textural layers (‘voices’), chords (understood as groups of notes sharing a stem) and, finally, notes. For certain features, such as tempo and dynamic markings, the choice of hierarchical anchor is to some extent arbitrary: a tempo marking, for instance, might be attached to a specific measure or to a chord within that measure. DiMCAT’s approach to the unified modeling of diverse hierarchical representations consists in traversing them and grouping score elements of the same type in the same dataframe. This obviates mapping the particularities of each standard into a common score model, a process which would either inherit a degree of arbitrariness, or resort to error-prone estimations in order to eradicate it.¹

DiMCAT disentangles the underlying score hierarchy by grouping elements in five distinct categories, which we refer to as “facets”. These are:

- notes and rests (“events”, including ties, tremolos, grace notes, etc.)
- performance details (“control events”; tempo, dynamics, slurs, lyrics, articulation, etc.);
- measures (“flow control”; measure durations, staves, repeat indications, *fine*, etc.);

¹ Such a mapping, employed for example by the `music21` score processing library [14], is rather suitable when a complete model of the score needs to be maintained for further processing.

MuseScore	MEI	musicXML	
<Score>	<music> ...	<score-partwise>	<score-timewise>
<Staff>	(<part> ...)	<part>	<measure>
<Measure>	<measure> ...	<measure>	<part>
<Voice>	<staff> ...		<note>
<Chord>	<layer> ...	<staff>, <voice>	
<Note>	(<chord> ...)	<note>	

Table 2: Synopsis of XML tag hierarchies in three widespread XML-based score models. Models differ mainly in the placement and naming of score elements (<layer> being equivalent to <voice>). In the MEI column, ellipses (...) suggest that any number of hierarchical levels may be nested, and parentheses mark optional layers. MusicXML has two distinct organizational strategies (partwise or scorewise), which converge at the note level.

- analytical annotations (“labels”; chord changes, form labels, algorithmic outputs, etc.);
- metadata.²

A facet is the raw, original representation of a category of score elements from which specific, homogeneous “features” can be derived. In its simplest form, a feature is a subset of a facet in terms of rows and/or columns. For example, the `NotesAndRests` facet (shown in Table 1) comprises the `Rests` feature from which all rows and columns about notes have been removed. Other features offer variants requiring simple transformations. For instance, the `Notes` feature may be requested with tied note heads fused into single note events, with metrical weights added, or with pitches expressed as scale degrees (for an example, see Listing 2). Other features require more substantial computational analysis on a set of features or

² Note that visual details such as beaming are not loaded by default whenever they are deemed irrelevant for a distant-listening setting.

facets, and necessitate the invocation of an `Analyzer` (see Section 3.2.3).

Our approach thus projects different hierarchical score representations into a paradigm similar to that of relational databases. Structural relations previously expressed by the underlying score hierarchy are now expressed via IDs (for example, the columns ‘staff’, ‘voice’, and ‘mc’ in Table 1). In addition, all objects (except metadata) are unambiguously located on the score’s musical timeline by means of timestamps. As Table 1 shows, each facet and feature includes five columns expressing timestamps in three partially redundant ways. Timestamps expressed by means of ‘mc’ (the strict count of measure-like units from the beginning of the piece, regardless of their actual length or displayed measure number), along with ‘mc_onset’ (the location within a measure-like unit, represented as a fraction of a whole note) serve a crucial function. Given the actual durations of the measure-like units, ‘mc’ and ‘mc_onset’ determine ‘qstamp’, an object’s offset from the beginning of the piece in quarter notes. In addition, `DiMCAT` provides ‘mn’, the measure numbers actually found in score engravings, which are in principle non-unique and based on longstanding editorial conventions [15]. Analogously to ‘mc_onset’, these units warrant ‘mn_onset’ positions, required for computing metrical weights consistent with the respective meter (in the column ‘timesig’).

2.2 Operations on `DimcatResource` objects

To facilitate the processing and analysis of potentially large collections of notated music, `DiMCAT` aggregates facets (as well as features or analysis results) drawn from multiple pieces in a single dataframe, a `DimcatResource`. This approach enables vectorized operations on entire datasets, thus achieving higher performance in comparison to an equivalent sequence of single-dataframe operations. For additional speed when using very large corpora, `DiMCAT` can delegate dataframe operations to a distributed-computing backend such as `modin`, which allows for automatic partitioning and parallel processing [12]. `DimcatResources` natively serialize into ZIP archives accompanied by a Frictionless descriptor file [16] allowing for type-safe data validation and loading with external tools. Furthermore, the “frictionless” design allows `DiMCAT` to treat a descriptor file with its included metadata (column descriptions, file genesis, versioning information) as if it was the described resource itself, and to load the actual data into memory no earlier than required. The loaders described in the following section have the purpose of pre-processing the data to be analyzed, and storing it in a self-contained format that can also be easily served on the web.

3. LIBRARY DESIGN

This section describes `DiMCAT`’s design and API,³ which parallel familiar routines of musicological research: con-

³ The complete API and documentation can be found at <https://github.com/DCMLab/dimcat>. In addition to pydocs, we provide Jupyter Notebook-based interactive tutorials.

structing a corpus (loading and filtering, Section 3.1), organizing relevant corpus data (slicing and grouping), and running algorithms on this selection (analyzing, and plotting (Section 3.2)).

3.1 Loading Data

`DiMCAT` defines loaders which parse and store score data for a variety of symbolic encoding standards with the aid of external libraries.⁴ This is typically achieved by discovering the relevant files on disk or (from the web) and producing the homogeneous representation (the dataframes presented in Section 2.1) in parallelized fashion, while also compressing and storing the loaded data on disk for later use. Once data has been pre-processed and stored along with its metadata, `DiMCAT`’s default loader is capable of determining which score features are present, and of “lazily” loading them into memory whenever needed for processing. Apart from decreasing the memory footprint, this principle makes it possible to verify, before proceeding, whether the features required for a processing pipeline are actually available (see below). The extracted `Facet` objects remain by design as faithful as possible to the original data in terms of presence and naming of detected elements. Names and types of facet fields are standardized only in relation to the above-mentioned timeline columns, which are necessary for alignment. `Feature` objects, on the other hand, are comprehensively standardized upon extraction to guarantee type safety. Less specialized analyzers such as `Counters` also allow for the processing of `Facets`, and users who frequently work with custom `Features` drawn from nonstandard elements may contribute appropriate extensions to the codebase in the spirit of community-driven development.

Once loaded, the data is represented internally by the `Dataset` class and its various subclasses (see the complete documentation for details). `Dataset` objects are `DiMCAT`’s main drivers and the object type users interact with the most. They grant centralized access to all available dataframes (`Facets`, `Features`, and `Results`), depending on the current stage of computation. These objects in turn enable type-specific transformations and visualizations.

3.2 The Analysis Pipeline

Conceptually, every action performed by `DiMCAT` is a sequence of `PipelineStep` objects which, having been chained together, accept a `Dataset` object, perform a transformation or analysis on it, and return a new data object. In practice, this chaining is not entirely arbitrary, since some computations require data in specific formats (for example, the `CrossEntropy` analyzer requires equal-shaped probability vectors). All pipeline steps can be expressed as, and instantiated from, associative arrays of type `DimcatConfig` which are stored together with a `Dataset`’s descriptor to make the pipeline generation reproducible.

⁴ These currently include `ms3` [17] and `music21` [14], with `Verovio` [18] planned to be added in the future.

Each step in a `Pipeline` is fundamentally an instance of one of the following three classes⁵: `Slicers` accept data and partition it into chunks of various sizes—for example, sections between repeat signs, segments under the same guitar chord, or 8th-note-long slices. Slices never cross the boundaries of a piece of music. `Groupers` accept data and group it in formally specified categories—for example, segments with the same chord label, or pieces composed in the same decade. Unlike slices, groups often contain information from across the corpus. `Analyzers` are the heart of the library, performing the actual computation once the data has been sliced and grouped.

Many questions in music corpus studies involve comparisons between groups with a degree of commonality, e.g., between groups of pieces by the same composer, or of segments such as sonata development sections [19]. By combining slicers, groupers and analyzers, music researchers will find in `DiMCAT` an intuitive language for addressing pressing questions in the field.

3.2.1 Slicers

`Slicer` objects invoke one particular feature to compute segmentation boundaries. For example, a `NoteSlicer` invokes the `Notes` feature and stores its timestamps (e.g., note onset positions) as slice markers within the resulting `SlicedDataset`, interpreting them as time intervals. The newly returned dataset will slice any facet or feature subsequently requested, inserting an additional index level or column for slice boundaries (any element spanning over a slice boundary will be split or duplicated). In principle, any feature (e.g., double bar lines, dynamic indications, or the results of a key finder) can serve as the slicing criterion. The properties of the feature used as criterion can then be used for grouping the resulting slices (e.g., slicing a dataset using the results of a key-finding algorithm enables the subsequent grouping of slices by mode; see the following section).

3.2.2 Groupers

Applying a `Grouper` to a dataset is tantamount to binning pieces or slices based on a membership criterion. As a result, any facet or feature requested from a `GroupedDataset` is provided with a prepended index level of group identifiers. This enables both choosing a larger unit of analysis (by analyzing entire groups rather than each contained piece or slice, see the following section) and comparing groups of analysis results (for an example, see Section 4.2).

Frequently used groupers include the `CorpusGrouper`, the `StaffGrouper`, and the `ModeGrouper` (grouping pieces, events, and key slices, respectively). Groupers may also use metadata as criterion: for instance, the `YearGrouper` groups pieces based on their composition dates. Grouping is a computationally cheap operation because it is performed using dataframe indices.

⁵ That is without considering auxiliary pipeline steps such as `Writers` which never result in a different dataset type.

3.2.3 Analyzers

`Analyzers` are at the heart of the `DiMCAT` library. Based on its configuration, an analyzer will take one particular or all available features from the `Dataset`, perform the analysis on the minimal unit provided by the `Dataset` (slice or piece), and return an `AnalyzedDataset`. Results can be `Feature` objects (with timestamps) or `Result` objects (without timestamps), both of which are `DimcatResources` (see Section 2.2) and provide suitable methods for retrieving, displaying, transforming, and plotting analysis results. In addition, they allow the combination of piece or piece-slice analysis results into those corresponding to higher units of analysis, e.g., piece results into group results. This makes it possible, by applying several groupers to the same `AnalyzedDataset`, to regroup and recombine individual results. `DiMCAT` currently uses the `plotly` library for creating interactive plots and provides reasonable (but non-binding) defaults for combining grouped results in one figure. The main types of analyzers are `Counters`, `Comparisons` and `ClusterAnalyzers`, `Transformations`, and `RangeAnalyzers`.

The base `Analyzer` class is designed to be easily extensible; additional analyzers can be created by the community without knowledge of the deeper layers of the code. Contributors only need to understand the structure of the features that the new analyzer accepts as input, and select or implement the appropriate result type. Thereafter they implement the new object's serialization `Schema`⁶ and one of the methods that performs the actual analysis on a slice-, piece-, or group-specific dataframe. The method `combine()`, used for aggregating two result objects into one—for example, by adding result vectors—only needs to be implemented if no superclass is available to inherit it from. Optional methods include `check()` (for rejecting a dataset or feature if it doesn't fulfill certain criteria), `pre_process()` (for performing analyzer-specific feature transformations), and `post_process()` (for cleaning up the results object, for example by filling in missing values). A new analyzer constructed in this fashion is guaranteed to work with `DiMCAT`'s pipeline architecture.

The basic `Counter` counts the number of rows of any facet or feature (e.g., notes or chord labels). More versatile counters aggregate counts or durations based on the values contained in a given column (e.g., pitch classes), value combinations between several columns (e.g., pitch class–duration pairs), or n-grams (e.g., pairs of successive dynamic indications). Results can be transformed (e.g., by normalizing), various properties can be calculated and returned (e.g., the distributions' entropies), and plots can be generated.

`Comparison` analyzers perform pairwise comparisons on the slices, pieces, or groups represented by a given feature or result, such as the sliding-window autocorrelation of a feature's inter-onset-intervals, the Jaccard similarity between chord vocabularies, or the cross entropy between key profiles. They typically store their result as a

⁶ See details in the documentation.

confusion matrix, plotted by default as a heatmap. The results of comparisons lend themselves to subsequent application of `ClusterAnalyzers`, which use common algorithms such as k-means to compute groups that can reveal relations between the features under comparison [20, 21].

Transformations apply a function or fit a model in order to translate a feature into a different representation. Examples include analyzers that fit a Gaussian mixture model to a distribution, tokenize pitch events for use in a neural network, or transform pitch-class profiles into Fourier coefficients (as demonstrated in Section 4.1).

`RangeAnalyzers` are useful in cases where only minima and maxima (or the range) of numerical features are relevant. Examples include the line-of-fifths segment covered by a pitch class distribution [22] or the historical timespan covered by a dataset based on composition dates.

Finally, there are many specific analyzers, such as the `PitchClassVectors` analyzer featured in Section 4.1; they perform an analysis or transformation (here, aggregating durations) on one particular feature (here, `Notes`) under a range of specific configuration values (here, for example, type and format of pitch classes). A full list of analyzers is available in the documentation.

4. EXAMPLES

In this section, we present a few examples of musicological questions that can be easily answered using `DiMCAT` (provided the requisite data is available).

4.1 Fourier analysis of pitch class vectors

```

1 D = Dataset.load("debussy_piano")
2 D_analyzed = Pipeline(
3     [WindowSlicer(quarters_per_slice=1.0),
4     PitchClassVectors(),
5     DiscreteFourierTransform()])
6 ).process(D)
7 df = D_analyzed.get_result()
8 df.sample(5)

```

Listing 1: Pipeline for slicing a dataset by quarter-note windows, computing pitch class vectors and applying the Discrete Fourier Transform.

The Discrete Fourier Transform has seen frequent applications to musical structures, in particular pitch-class sets [23–28]. It belongs in a broader class of techniques which require, in our terms, a “slicing” of the score, such as a chordal reduction or a fixed-window segmentation. For example, as part of a corpus study using the Discrete Fourier Transform [29], `DiMCAT` was used to create enharmonic pitch class vectors for all 2-hand piano compositions by Claude Debussy. Listing 1 demonstrates the simplicity with which this analysis can be expressed as a `DiMCAT` pipeline. In the first line, the data is loaded from a local directory. Then the pipeline is created and processed. In the pipeline, a slicer first slices all pieces at every quarter note, then an analyser creates vectors of aggregated pitch class durations for each slice. Finally, the DFT analyser is run on each vector and the result obtained. A sample of

the results, with coefficients 0 through 6 given as complex numbers, is shown in Table 3.

4.2 Evaluating key segments

```

1 D = Dataset.load("dcml_corpora.datapackage.json")
2 D_sliced = Pipeline(
3     [KeySlicer(),
4     ModeGrouper()])
5 ).process(D)
6 F = DimcatConfig("Notes", format=SCALE_DEGREES)
7 D_sliced.get_feature(F).plot_grouped() # plot 1
8 D_grouped = CorpusGrouper().process(D_sliced)
9 D_grouped.plot_grouped() # plot 2

```

Listing 2: Plotting common dataset transformations (plotting parameters omitted). Plots shown in Figure 1.

Given a score dataset with local-key annotations created by human analysts or an automatic key finder, a researcher might wonder how key segments in the major and minor mode are distributed over the corpora contained in the dataset, and how the tonal pitch-class profiles compare between the two modes. This second example relies on a dataset that includes key annotations⁷ and demonstrates the power and ease-of-use of `DiMCAT` pipelines, even without using any analyzers. The `KeySlicer` used in Listing 2 is set up by default to slice the dataset by annotated modulations, and warns the user about pieces for which no local key information is available. The pipeline proceeds by applying the `ModeGrouper` to create one group per mode which, in the present dataset, amounts to a minor-key and a major-key group. Requesting the `Notes` feature from a `Dataset` processed in this fashion, we may retrieve and plot a representation that reflects the grouping, as shown in the upper bar chart in Figure 1. The lower plot demonstrates that the slicing criterion itself may also provide meaningful insights into a dataset. It can be produced by applying a `CorpusGrouper` to the processed `Dataset` and plotting the groups. (Without the corpus grouper, the plot would show the major-minor ratio for the entire dataset—that is, the result of the mode grouper).

5. COMPARISON WITH OTHER LIBRARIES

Other analysis libraries also lend themselves to the analysis of datasets of symbolic music encodings. In this section we compare `DiMCAT` to other open-source libraries which maintain note names (pitch spelling) and support multiple staves and analytical annotations. Several among them likewise utilize dataframes.

The Humdrum Toolkit was one of the first frameworks for computer-aided music analysis, and is still used for the analysis of Humdrum and kern files across the range of programming languages to which it has been ported. The R package `humdrumR` [30] ports the Humdrum Toolkit into R. While it provides support for computationally efficient dataframes, and includes R’s inherent plotting capabilities, like Humdrum itself it cannot import more modern, and arguably more common, symbolic-encoding formats such as musicXML without the use of error-prone converters.

Table 3: Sample rows from a dataframe containing the seven first DFT coefficients gained from quarter-note-window pitch class vectors. The first three columns represent a multi-index indicating corpus, file name, and slice interval (expressed as `qstamp`, see Table 1); they make it possible to trace the result back to the score.

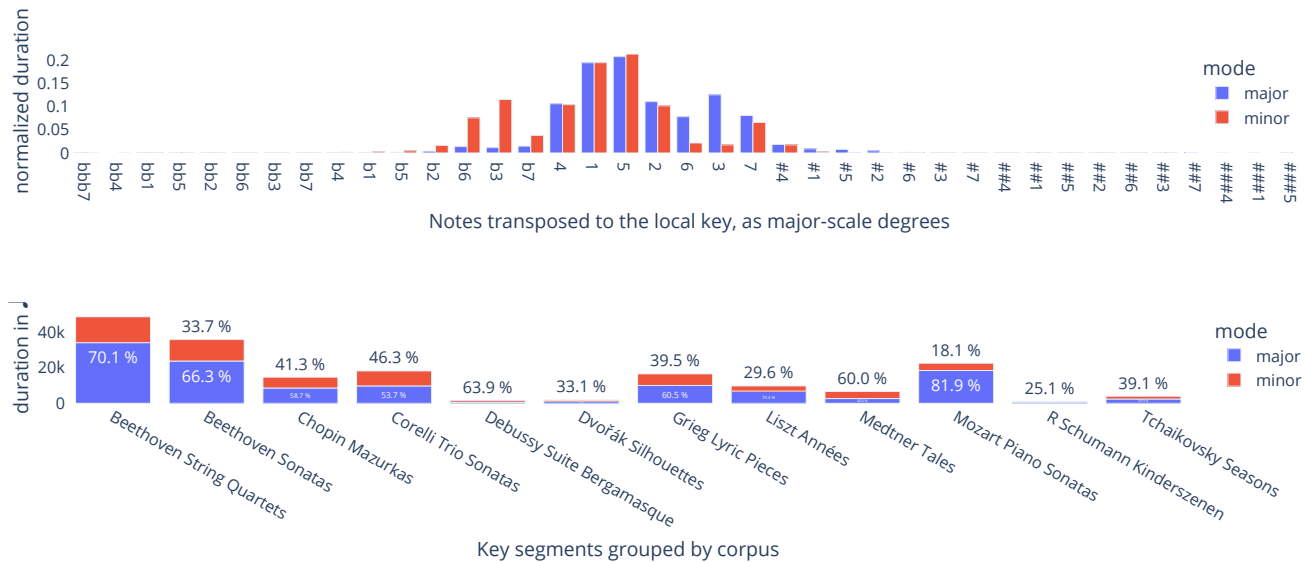

Figure 1: The two plots produced by the code shown in Listing 2.

MUSIC21 [14] is a large Python library capable of importing all relevant music formats, transforming them into a comprehensive hierarchical model of the score. Relying on an elaborate object model, it provides methods for creating and manipulating the elements of a music score. However, its design renders it computationally demanding [30, 31] for large corpora, and it provides only few methods designed specifically for corpus analysis.

Several Python libraries follow a similar approach to DiMCAT’s, analyzing and making available score information in the form of dataframes. These include the VIS-framework [32] and CRIM intervals [33] (both focusing on intervallic successions and sonorities), CAMAT [31] (basic pitch statistics), and musif [34] (with a focus on global features of entire scores). Among them, only [31] introduces its own score parser (for MusicXML), with the remaining ones invoking music21. [34] also includes the MuseScore parser ms3 [17] and therefore exposes an architecture that is as easily extensible as ours.

Although DiMCAT can, in principle, provide any algorithm that operates on successions or sets of pitch events, its focus on “distant listening” makes it less suited for close-reading studies than some of the aforementioned alternatives. Indeed, its distinguishing feature is the newly introduced *Slice-Group-Analyze* paradigm, designed for inquiries in which the corpus, rather than the individual score, is the primary research object. To this end, DiMCAT

provides mechanisms for studying the statistical properties of potentially very large amounts of musical material by iteratively applying sequences of segmentation and grouping algorithms with a high degree of combinatorial freedom. From this point of view, the “slice” serves as an additional operational level between “note” [31–33] and “piece” [34].

6. CONCLUSION

In this paper we have introduced DiMCAT, a Python library capable of parsing, transforming, and analyzing annotated music score data in a range of symbolic-encoding formats, and to do so efficiently at scale. The library stores data as dataframes, a ubiquitous structure in the fields of digital humanities and data science. DiMCAT emphasizes traceability (results can reliably lead to the original score elements) and reproducibility (version identifiers are systematically applied to code and data). Thanks to an interface that masks its inner workings, the functionality of the library is usable and extensible by musicologists with limited programming experience.

DiMCAT is released under the GPL-3.0-or-later License, and we intend to continue adding further music analyzers, inviting feedback, requests, and contributions from the community.

7. ACKNOWLEDGEMENTS

This research was supported by the Swiss National Science Foundation within the project “Distant Listening – The Development of Harmony over Three Centuries (1700–2000)” (Grant no. 182811). This project is being conducted at the Latour Chair in Digital and Cognitive Musicology, generously funded by Mr. Claude Latour.

ABSTRACT

We propose multiple methods for effectively training a sequence-to-sequence automatic guitar transcription model that uses tokenized music representation as an output. Our proposed method mainly consists of 1) a hybrid CTC-Attention model for sequence-to-sequence automatic guitar transcription that uses tokenized music representation, and 2) two data augmentation methods for training the model. Our proposed model is a generic encoder-decoder Transformer model but adopts multi-task learning with CTC from the encoder to speed up learning alignments between the output tokens and acoustic features. Our proposed data augmentation methods scale up the amount of training data by 1) creating bar overlap when splitting an excerpt to be used for network input, and 2) by utilizing MIDI-only data to synthetically create audio-MIDI pair data. We confirmed that 1) the proposed data augmentation methods were highly effective for training generic Transformer models that generate tokenized outputs, 2) our proposed hybrid CTC-Attention model outperforms conventional methods that transcribe guitar performance with tokens, and 3) the addition of multi-task learning with CTC in our proposed model is especially effective when there is an insufficient amount of training data.

1. INTRODUCTION

Automatic guitar transcription is a challenging task that has gained significant attention in the field of music information retrieval due to its potential applications in music analysis, performance evaluation, and transcription of music compositions. Despite recent advancements in the field, there are still several challenges that need to be addressed. One of the major challenges in automatic guitar transcription is the difficulty in extracting relevant features from the audio signal. The variations in timbre, pitch, and playing style make it difficult to distinguish individual notes accurately [1, 2].

Multiple methods exist for representing musical notation suitable for employment in a DNN framework. Two

Figure 1. Examples of a pianoroll (upper) and tokenized music representation (lower).

of the popular methods are pianoroll and tokenized musical representation. Figure 1 shows a visualization of the differences between pianoroll and tokenized music representations. Note that each can be converted from one to another. Pianoroll is a visual representation of music that uses a grid-like structure to display the timing, pitch, and duration of notes in a piece. Tokenized music representation is a type of symbolic music representation that breaks down a music signal into small, discrete tokens, which can be analyzed and processed as a sequence of tokens to extract relevant musical features such as pitch, duration, and timing. Recent studies have shown that using tokenized music representation over pianoroll can better learn the temporal dependency between different musical events [3]. Using tokenized music representation along with sequence-to-sequence models is particularly effective and have the potential to improve the performance of automatic music transcription model [1, 4]. However, these models also face several challenges such as the lack of training data [1].

The field of automatic speech recognition (ASR) has provided inspiration for improving automatic music transcription models, as both face similar challenges, including the need to extract relevant features and handle complex temporal and frequency relationships [5]. In the field of ASR, various techniques and models, such as connectionist temporal classification (CTC) [6], Transformer [7] models, data augmentation, transfer learning, and multi-task learning, have shown promising results [8, 9] and can potentially aid the performance of an automatic guitar transcription system.

CTC and attention are two popular techniques used in sequence-to-sequence models for various tasks. CTC is

Toda, "Sequence-to-Sequence Network Training Methods for Automatic Guitar Transcription with Tokenized Outputs", in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

an efficient method for training models with an unknown alignment between input and output sequences. It can handle variable-length input and output sequences. However, it does not explicitly model dependencies between input and output sequences [10]. Attention, on the other hand, allows the model to selectively focus on different parts of the input sequence, improving the accuracy of the model on tasks that require complex dependencies. However, attention mechanism is too flexible in the sense that it allows extremely non-sequential alignments, making it relatively difficult to train [8].

In an attempt to improve the performance of an ASR system, researchers have also explored hybrid models that combine CTC and attention mechanisms [8]. The authors reported that the addition of CTC solves the misalignment issues and improves robustness and achieves fast convergence.

Although models such as Conformer-Transformer have been successful in ASR tasks [11], these were not used in guitar transcription mainly due to a lack of training data available. To resolve this issue, we propose data augmentation techniques and a hybrid CTC-Attention model suited for a guitar transcription system¹ that utilizes tokenized music representation and show the effectiveness of the proposed methods. Our contributions are summarized as follows.

- We propose two data augmentation methods for training a sequence-to-sequence model that utilizes tokenized music representation.
- We propose a hybrid CTC-Attention model for automatic guitar transcription.
- We conduct experimental evaluations to confirm the effectiveness of our proposed methods and prove that both the data augmentation techniques and the proposed model enhance guitar transcription performance.

2. RELATED WORK

2.1 Automatic guitar transcription

There have been many successful automatic guitar transcription systems [1, 12–15]. Some of them are based on audio signal processing to estimate the tablature score from a guitar sound signal [12]. Also, approaches that employ probabilistic models have been proposed in some automatic guitar transcription tasks. In [14, 15], a two-step method was employed, where the first step involves determining the pitch of each played note, and the second step involves computing the optimal finger positioning by combining the estimated pitch with physical limitations of feasible fingerings. Since this approach processes information in a sequential manner, information cannot flow from downstream components to upstream ones, making it difficult to be jointly optimized [16].

Most of the recent state-of-the-art systems were mainly based on end-to-end deep neural network (DNN) models since end-to-end DNN models have the advantage of the ability to jointly optimize the whole model, showing better results compared to multi-step approaches [13]. Wiggins et al. proposed a convolutional neural network (CNN)-based model architecture [13] that estimates the frame-wise fingering position of a guitar performance. In our previous work [17], a self-attention mechanism was introduced along with CNN to better capture long-term relations and estimate the fingering position in both frame-level and note-level. We proved the effectiveness of the self-attention mechanism used in the guitar transcription model. However, since the proposed systems in [13] and [17] do not detect onset, the output can not be interpreted into reproducible forms such as music score or MIDI.

2.2 Automatic music transcription using tokens

Recently, the use of generic encoder-decoder Transformer architecture has shown its potential in automatic music transcription tasks. Howthorne et al. proposed a generic Transformer architecture for an automatic piano transcription [4]. The proposed method takes mel-spectrogram of audio and autoregressively generates a token sequence. The tokenization method used in this work is similar to how MIDI file stores its note sequences. The vocabulary consists of `note`, `velocity`, and `time` tokens, with the addition of an end-of-sentence (EOS) token for ending the sequence. In this tokenization method, the timing of each note is represented with absolute time location within the segment, quantized into 10 ms bins. This kind of tokenization method which represents the time of a note in location as opposed to the time shift from the previous note was reported to work better [18].

Chen et al. proposed a multi-objective generic Transformer model that not only predicts token sequences but also frame-level onsets, offsets, and pitch activation [1]. In the original paper of [1], the authors report that although the proposed model is a generic Transformer model that generates a sequence of tokens, introducing multi-task learning with frame-level labels, i.e., the pianoroll representation, lowers the performance of the token-wise prediction from the decoder, but improves frame-level estimation performance compared to frame-level guitar transcription model proposed in [19]. The authors also mentioned that the lower performance of the model without multi-task learning (that only predicts token sequence) could be attributed to the insufficient size of the training set to learn a dependable language model for the decoder.

3. PROPOSED METHOD

3.1 Hybrid CTC-Attention model for tokenized guitar transcription

3.1.1 Tokenization

As for the tokenization method, we use a slightly modified version of revamped MIDI-derived events (REMI) [20].

¹ Source code available:

<https://github.com/KimSehun725/seq2seqGuitarTranscription>

Figure 2. Overview of our proposed model architecture.

Since our main interest is to accurately transcribe a performance with pitch and timing information, we excluded velocity tokens and chord tokens from the original REMI. Excluding these tokens makes the total sequence shorter, making it easier to pass the restriction of CTC (token sequence length must be shorter than input sequence length), and easier to train. The tokenization method we used in our proposed approach includes the following vocabulary:

Blank [1 category] Used to represent the blank token when using CTC. This token gets dropped when decoding the final prediction when applying CTC.

Position [16 categories] Indicates the location in a bar quantized into 16th note. This token is placed to indicate the start position of a note.

Pitch [45 categories] Each class represents the pitch ranging from E1 to C5. This token is placed after the Position token to indicate the pitch of a note.

Duration [16 categories] Represents the duration ranging from the 16th note to a bar in 16th note increments. This token is placed after the Pitch token to indicate the duration of a note.

Bar [1 category] Token used to denote the start of a bar.

SOS, EOS [2 categories] Used to represent the start and end of a token sequence. These tokens are used for training and inferencing with the Transformer decoder.

3.1.2 Encoder

Figure 2 shows the overview of the proposed model architecture. We will refer to the left side of the figure as encoder and the right side as decoder from here on out.

The structure of the encoder of our proposed model is largely inspired by our previous automatic guitar transcription model proposed in [17], with some modifications for generating a token sequence and conditioning with BPM information. The encoder structure can be divided into three main parts: a convolution stack, a Conformer encoder, and an output layer for generating a token sequence to which CTC can be applied later.

The convolution stack has 2D convolution, max pooling, dropout layers, and a linear layer. Input features go through two convolution blocks with 2D convolution, batch normalization, and an activation function. Latent features are then subsampled by max pooling and refined by another convolution block and max pooling layer. Lastly, a linear layer is added to reduce dimension. Three dropout layers prevent overfitting after max pooling and the final linear layer.

The Conformer encoder closely follows the Conformer block architecture proposed in [21]. The Conformer encoder mainly consists of self-attention modules, convolution modules, and feed-forward modules. For the input to the Conformer encoder, first, we concatenate the output from the convolution stack and the given BPM information of the input segment. Then, the concatenated feature goes through a linear transformation layer, which is omitted from Figure 2 for simplicity. We concatenate BPM information to the output of the convolution stack because the problem formulation of our method is estimating a sequence of tokens based on both acoustic features and BPM information.

Finally, the output layer is a simple linear transformation layer with softmax function at the end for generating CTC token outputs. Unlike the model that predicts frame-level activation probability (pianoroll) from the encoder [1], the encoder of our proposed model generates the probability of token sequence, which we can directly calculate the loss between the output and the ground truth token sequence by calculating CTC loss [6].

During inference, we first apply argmax to the encoder outputs, then repeating tokens get merged. Then, the blank token gets removed to obtain the final output.

3.1.3 Decoder

The structure of the decoder in our proposed model is roughly the same as the ones used in ASR tasks or other symbolic music transcription tasks such as in [1, 4]. The decoder consists of multiple Transformer decoder blocks stacked in serial. The Transformer decoder block consists of a masked self-attention module, a cross-attention module, and a feed-forward module.

The decoder is trained and validated with a teacher forcing scheme where the token is predicted one step ahead without self-attention looking ahead by masking the self-attention with a diagonal mask in a non-autoregressive manner. During inference, we only give a start-of-sentence (SOS) token at first, and autoregressively generate the following tokens by selecting the most probable tokens at each timestep. The generation stops when the decoder gen-

erates an end-of-sentence (EOS) token.

3.1.4 Multi-task learning

Our proposed method is a multi-objective model with both the CTC output from the encoder and the output from the decoder. Therefore, we define a custom loss function for backpropagation.

First, we define the CTC loss \mathcal{L}_{CTC} as

$$\mathcal{L}_{CTC} = - \sum_{\mathbf{y} \in \mathcal{B}} \log p(\mathbf{y}|\mathbf{x}), \quad (1)$$

where \mathcal{B} is the set of all possible output sequences including blank symbols, \mathbf{x} is the input sequence, and $p(\mathbf{y}|\mathbf{x})$ is the probability of generating the output sequence \mathbf{y} from the encoder given the input sequence \mathbf{x} . The CTC loss is calculated by summing the negative log probabilities of all possible output sequences \mathbf{y} that can be generated from the ground truth sequence. The loss encourages the model to learn to generate the correct output sequence while accounting for possible alignment errors between the input and output sequences.

Next, we define the cross-entropy loss as

$$\mathcal{L}_{CE} = - \frac{1}{N} \sum_{i=1}^N \sum_{j=1}^C \mathbf{y}_{ij} \log(\hat{\mathbf{y}}_{ij}), \quad (2)$$

where N is the number of samples, C is the number of classes, \mathbf{y}_{ij} is a binary indicator of whether sample i belongs to class j , and $\hat{\mathbf{y}}_{ij}$ is the predicted probability from the decoder of sample i belonging to class j .

The total loss function of our system \mathcal{L}_{total} can be expressed as

$$\mathcal{L}_{total} = \alpha \mathcal{L}_{CTC} + \mathcal{L}_{CE}, \quad (3)$$

where α is the hyperparameter for controlling the weight of \mathcal{L}_{CTC} .

3.2 Data augmentation

When using a tokenization method whose time resolution is in units of musical lengths, training a model to generate a sequence of tokens requires a large amount of data to properly model the language structure of the tokenization method and the concept of musical length. However, unlike musical instruments such as the piano, which have a significant amount of publicly available training data, the guitar lacks sufficient data for training. The goal of the proposed data augmentation methods is to scale up the amount of data used in the training process.

3.2.1 Bar overlap

In the field of automatic music transcription, splitting a musical excerpt into multiple segments is common, especially with the models that use the attention mechanism since the attention mechanism has a space complexity of $O(n^2)$ with respect to sequence length n . There have been many attempts to train a network by cutting musical pieces into exact lengths in seconds. However, there have been only a few attempts to handle music pieces by cutting them

into the same musical length, e.g., 4 bars [17]. When cutting a musical piece into segments whose length is in units of bars, the most naive way of cutting it would be to cut without overlap so that the timing of the start of a segment is the end of the previous one. This results in obtaining $l_{excerpt}/l_{segment}$ segments, assuming that $l_{excerpt}$ is dividable by $l_{segment}$, where $l_{excerpt}$ denotes the bar length of a musical excerpt, and $l_{segment}$ denotes the bar length of a segment. This method was done in our previous work [17].

We propose a method that creates more segments when cutting musical excerpts, by overlapping segments, i.e. sliding a window with a hop length shorter than the window length. This results in obtaining $l_{excerpt}/l_{overlap} - (l_{segment} - 1)$ where $l_{overlap}$ denotes the bar length of the overlap.

3.2.2 Synthetic audio-MIDI pair

With the goal of training a model to properly learn how to generate the token sequence by reliably training the language model for the decoder with a large amount of data, we propose a method that can synthetically create an audio-MIDI pair dataset from MIDI-only data. We generate synthetic audio data by utilizing an oscillator such as a sinusoidal oscillator or a square wave oscillator. This results in obtaining an audio-MIDI pair with its audio being perfectly aligned with the matching MIDI, yet with unnatural timbre. With the synthetically generated audio-MIDI pair dataset, we pretrain the model before training with real-world data. This results in the decoder being trained as a reliable language model for tokenization method, and the model having preliminary knowledge regarding extracting pitch and timing information.

It is possible to use the method to produce an endless amount of data theoretically, by applying it to either a publicly available MIDI dataset or automatically generated MIDI from an automatic symbolic music generation model such as [20,22,23] since the method generates audio-MIDI pair data solely from MIDI.

3.3 Implementation details

Regarding the network settings for the encoder and decoder of our proposed model, we set the number of attention heads and the number of sequential Conformer blocks to 8 and 6 respectively. For the Transformer decoder, the number of attention heads and the number of sequential blocks are set to 4 and 4 respectively. The dimension of both the Conformer encoder and the Transformer decoder is set to 128. We implement the Conformer encoder using the ESPNet2 framework [11]. We use the leaky ReLU activation function [24] throughout the encoder, except for the activation functions in the Conformer encoder and the final output layer.

For the implementation of tokenization, we use MidiTok [25], but slightly modify the original implementation as mentioned in Section 3.1.1. As for the learning rate, we use a cyclic learning rate scheme [26]. The base learning rate is set to $1e-5$, the max learning rate is set to 0.001, the number of training iterations in the increasing half of a cy-

Attention only	-	-	0.784±0.014	0.345±0.021
Proposed	0.666±0.047	0.307±0.025	0.804±0.015	0.336±0.021

Table 2. Estimation metrics for our proposed model, compared with a baseline model and a model without multi-task learning with CTC. For all metrics, we report the mean and standard deviation over the entire dataset. All the experiments were done by applying both of the proposed data augmentation methods. Note that the baseline model does not have TER from the encoder output because the encoder output is pianoroll-like frame-level annotation, not tokens.

Model	Decoder output	
	F1	TER
Attention only + BO	0.114±0.046	1.520±0.378
Proposed + BO	0.630±0.196	0.497±0.176

Table 3. Estimation metrics for simulating the situation where only a small amount of training data is available by not pretraining with synthetic audio-MIDI pair data. We only show the results of the output from the decoder for simplicity.

cle is set to 4 epochs, and the same for the decreasing half. We made the peak learning rate decreases by a rate of 0.9 after each cycle. For the optimizer, we employ Rectified Adam (RAdam) [27]. Finally, we set the weight α which is used in the loss function, to 0.2.

4. EXPERIMENTAL EVALUATION

4.1 Experimental conditions

As for the MIDI data used in the pretraining phase, we used data from Classical Guitar MIDI Archives [28]. We filtered out the data that did not have the properties that we want such as having a time signature other than 4/4 beat or changing tempo over time. As a result, we obtained a total of 1232 minutes of data. We used square wave oscillator to make the synthetic audio, and split the dataset for training/validation/testing with a ratio of 0.9:0.05:0.05.

For the data used in the finetuning phase, we used the GuitarSet [29]. GuitarSet is a dataset for guitar transcription research containing 360 audio recordings, totaling approximately 3 hours. Since the dataset was recorded by six players, we left the recordings of one player for testing and used the rest of the data for training and validation. We rotated the test player to evaluate the methods with a six-fold cross-validation method. For both the pretraining data

and finetuning data, we cut the tracks into segments with 4 bars, with 1 bar hop length.

Regarding the input of the network, first, we resampled the audio to 22050 Hz, then we converted the audio to a constant-Q transform (CQT) [30] with a hop length of 256 points, 24 bins per octave spanning over 8 octaves, resulting in a total of 192 frequency bins.

We evaluated the proposed methods in three points: 1) the effectiveness of data augmentation methods, 2) the performance of the model, 3) the effectiveness of introducing CTC in the proposed model when there is only a small amount of training data available. For the experiment measuring the effectiveness of the data augmentation techniques, we compared the metrics of 1) using GuitarSet only and not using bar overlap, 2) only applying bar overlap, 3) pretraining the model with synthetic audio-MIDI pair dataset without bar overlapping, and 4) using both bar overlapping and pretraining.

For the model comparison, we compared our proposed model with 1) the model proposed in [1] which refer to as baseline hereafter, 2) our proposed model without the use of CTC ($\mathcal{L}_{total} = \mathcal{L}_{CE}$) which we refer to as attention only model from here on out, and 3) our proposed model.

Regarding the network settings of the baseline model [1], we followed the settings described in the original paper, except we input a 4-bar-long acoustic feature to the network and use the same tokenization method as our proposed method.

4.2 Evaluation metrics

Since the output of our proposed model is a sequence of tokens that can be converted into pianoroll, we used different evaluation metrics for pianoroll domain and token domain.

In the pianoroll domain, we used precision, recall, and F1 score. If the output is a sequence of tokens, we decode the token sequence to pianoroll to calculate precision, recall, and F1 score. In the token domain, we used token er-

Figure 3. Comparison of the speed in learning alignments between acoustic features (horizontal axis) and tokens (vertical axis). The training was done using only the GuitarSet.

ror rate (TER), which is calculated similarly to word error rate (WER) which is a widely used metric in the research field of ASR and natural language processing (NLP). The only difference is that every element is a token index instead of a word in WER. The TER can be calculated as

$$\text{TER} = \frac{S + D + I}{S + D + C}, \quad (4)$$

where S is the number of substitutions, D is the number of deletions, I is the number of insertions, and C is the number of correct tokens.

The reason why we introduce TER as an evaluation metric is that we want to compensate for the mismatch between the metrics used in pianoroll domain and human perception. For instance, if we only evaluate the system in the pianoroll domain, the outputs with the notes that are shifted for a consistent amount of time will have very low scores. However in the same case, if we use TER as an evaluation metric, only the `position` tokens will lower the metric, not penalizing for the shifted notes as much.

4.3 Results

The result of the experiment comparing the effectiveness of the data augmentation methods is shown in Table 1. The result shows that both data augmentation methods are effective in raising the estimation performance of the proposed model. By comparing the effectiveness of bar overlapping and pretraining, pretraining shows slightly better results in the output from the decoder but worse in the output of the encoder.

The result of the experiment comparing the performance of the models mentioned in Section 4.1 is shown in Table 2. The result shows that our proposed model outperformed the baseline model and the proposed model without utilizing CTC (attention only) in both F1 score and TER. Upon comparing the estimation results of the attention-only model with the proposed model, it is evident that the latter produced superior results, thereby indicating that the

Figure 4. A sample of transcription result from our proposed model. TP, FP, and FN denote true positive, false positive, and false negative respectively.

inclusion of CTC considerably improves transcription performance.

The result of the experiment simulating a situation with a small amount of training data available is shown in Table 3. We simulated this situation by only using the GuitarSet for training. The result shows that the model with attention only performed very poorly when there is only a small amount of data. However, our proposed model which utilizes multitask learning with CTC outputs from the encoder performs better compared to attention only model. This indicates that employing multi-task learning with CTC is highly effective when there is an insufficient amount of data. Figure 3 shows the attention alignments between acoustic features and tokens. We observed that despite being trained for 64 epochs, the attention only model failed to acquire a reasonable alignment, whereas the suggested model achieved to acquire the desired alignments early on in the training process. The performance difference between the attention only model and the proposed model is likely to be attributed to the difference in the difficulty of learning the correct alignments.

While we did not include the outcomes of using solely synthetic audio-MIDI pair data for both training and testing in any of the tables, it is worth stating that during the pretraining phase of the experiment utilizing the proposed model and data augmentation methods, the output of the decoder with the test data yielded an F1 score of 0.959 and TER of 0.029. This indicates that the amount of data used in the pretraining was sufficient enough to train a reliable language model for the decoder.

5. CONCLUSION

In this paper, we proposed two data augmentation methods for training sequence-to-sequence networks that used tokenized music representation as output, and a hybrid CTC-Attention model for automatic guitar transcription. We confirmed that 1) both of the data augmentation methods are highly effective in training the sequence-to-sequence models when there is an insufficient amount of data, 2) our proposed hybrid CTC-Attention model outperforms conventional methods that transcribe guitar performance with tokens, and 3) the addition of multi-task learning with CTC in our proposed model is especially effective when there is an insufficient amount of training data.

ABSTRACT

In this paper, we address the problem of pitch estimation using Self Supervised Learning (SSL). The SSL paradigm we use is equivariance to pitch transposition, which enables our model to accurately perform pitch estimation on monophonic audio after being trained only on a small unlabeled dataset. We use a lightweight ($< 30k$ parameters) Siamese neural network that takes as inputs two different pitch-shifted versions of the same audio represented by its Constant-Q Transform. To prevent the model from collapsing in an encoder-only setting, we propose a novel class-based transposition-equivariant objective which captures pitch information. Furthermore, we design the architecture of our network to be transposition-preserving by introducing learnable Toeplitz matrices.

We evaluate our model for the two tasks of singing voice and musical instrument pitch estimation and show that our model is able to generalize across tasks and datasets while being lightweight, hence remaining compatible with low-resource devices and suitable for real-time applications. In particular, our results surpass self-supervised baselines and narrow the performance gap between self-supervised and supervised methods for pitch estimation.

1. INTRODUCTION

Pitch estimation is a fundamental task in audio analysis, with numerous applications, e.g. in Music Information Retrieval (MIR) and speech processing. It involves estimating the fundamental frequency of a sound, which allows to estimate its perceived pitch. Over the years, various techniques have been developed for pitch estimation, ranging from classical methods (based on signal processing) [1–4] to machine learning approaches [5, 6].

In recent years, deep learning has emerged as a powerful tool for a wide range of applications, outperforming classical methods in many domains. This is notably true in

MIR, where deep learning has led to significant advances in tasks such as music transcription [7–9], genre classification [10–12], and instrument recognition [13–15]. Pitch estimation has also benefited greatly from deep learning techniques [16, 17]. However, these deep learning models often require a large amount of labelled data to be trained, and can be computationally expensive, hindering their practical applications in devices with limited computing power and memory capabilities. Additionally, these models are often task-specific and may not generalize well to different datasets or tasks [18]. Therefore, there is a need for a lightweight and generic model that does not require labelled data to be trained. We address this here.

We take inspiration from the equivariant pitch estimation [19] and the equivariant tempo estimation [20] algorithms which we describe in part 2. As those, we use a SSL paradigm based on Siamese networks and equivariance to pitch transpositions (comparing two versions of the same sound that have been transposed by a random but known pitch shift). We introduce a new equivariance loss that enforces the model to capture pitch information specifically.

This work has the following **contributions**:

- we formulate pitch estimation as a multi-class problem (part 3.1); while [19, 20] model pitch/tempo estimation as a regression problem,
- we propose a novel class-based equivariance loss (part 3.1) which prevents collapse; while [19] necessitates a decoder,
- the architecture of our model is lightweight and transposition-equivariant by design. For this, we introduce Toeplitz fully-connected layers (part 3.4).

We evaluate our method on several datasets and show that it outperforms self-supervised baselines on single pitch estimation (part 4.4.1). We demonstrate the robustness of our method to domain-shift and background music, highlighting its potential for real-world applications (part 4.4.2).

Our proposed method requires minimal computation resources and is thus accessible to a wide range of users for both research and musical applications. In consideration of accessibility and reproducibility, we make our code and pretrained models publicly available¹.

2. RELATED WORKS

2.1 SSL to learn invariant representations.

Siamese networks. Most common techniques for SSL representation involve Siamese networks [21]. The underlying idea is to generate two views of an input, feed them to a neural network, and train the network by applying a criterion between the output embeddings. Various techniques have been developed for generating views².

Collapse. However, a major issue with these methods is “collapse”, when all inputs are mapped to the same embedding. To address this, various techniques have been proposed. One of the most common is SimCLR [22] which also uses negative samples to ensure that embeddings are far apart through a contrastive loss. Additionally, several regularization techniques have been developed that minimize a loss over the whole batch. Barlow Twins [23] force the cross-correlation between embeddings to be identity, while VICReg [24] add loss terms on the statistics of a batch to ensure that dimensions of the embeddings have high enough variance while remaining independent of each other. On the other hand, [25] explicitly minimize a loss over the hypersphere to distribute embeddings uniformly. Furthermore, incorporating asymmetry between inputs has been shown to improve performance. [26, 27] uses a momentum encoder, while [28] and [29] add a projection head and a stop-gradient operator on top of the network, with [28] also using a teacher network. Finally, [30] incorporates asymmetry to contrastive- and clustering-based representation learning.

Application to audio. While originally proposed for computer vision, these methods have been successfully adapted to audio and music as well. For example, [31], [32], and [33] respectively adapted [22], [23], and [28] to the audio domain. By training their large models on AudioSet [34], they aim at learning general audio representations that are suited for many downstream tasks. More specifically, [35] successfully adapts contrastive learning to the task of music tagging by proposing more musically-relevant data augmentations.

2.2 SSL to learn equivariant representations.

The purpose of the methods described above is to learn a mapping $f : \mathcal{X} \rightarrow \mathcal{Y}$ that is *invariant* to a set of transforms $\mathcal{T}_{\mathcal{X}}$, i.e. so that for any input $\mathbf{x} \in \mathcal{X}$ and transform $t \in \mathcal{T}_{\mathcal{X}}$

$$f(t(\mathbf{x})) \approx f(\mathbf{x}) \quad (1)$$

However, recent approaches [36–38] try instead to learn a mapping f that is *equivariant* to $\mathcal{T}_{\mathcal{X}}$, i.e. that satisfies

$$f(t(\mathbf{x})) \approx t'(f(\mathbf{x})) \quad (2)$$

where $t' \in \mathcal{T}_{\mathcal{Y}}$ with $\mathcal{T}_{\mathcal{Y}}$ a set of transforms that acts on the output space \mathcal{Y} . In other words, if the input is transformed, the output should be transformed accordingly. Representation collapse is hence prevented by design.

Equivariant representation learning has mostly been applied to computer vision and usually combines an invariance and an equivariance criterion. E-SSL [36] trains two projection heads on top of an encoder, one to return projections invariant to data augmentations while the other predicts the parameters of the applied data augmentations. [37] predicts separately a semantic representation and a rotation angle of a given input and optimizes the network with a reconstruction loss applied to the decoded content representation rotated by the predicted angle. Finally, SIE [38] creates a pair of inputs by augmenting an input and learns equivariant representations by training a hypernetwork conditioned on the parameters of the augmentation to predict one embedding of the pair from the other.

Application to audio. Finally, a few successful examples of equivariant learning for solving MIR tasks recently emerged [19, 20]. In particular, [20] introduces a simple yet effective equivariance criterion for tempo estimation while preventing collapse without any decoder or regularization: pairs are created by time-stretching an input with two different ratios, then the output embeddings are linearly projected onto scalars and the network is optimized to make the ratio of the scalar projections match the time-stretching ratio within a pair.

2.3 Pitch estimation.

Monophonic pitch estimation has been a subject of interest for over fifty years [39]. The earlier methods typically obtain a pitch curve by processing a candidate-generating function such as cepstrum [39], autocorrelation function (ACF) [40], and average magnitude difference function (AMDF) [41]. Other functions, such as the normalized cross-correlation function (NCCF) [1, 2] and the cumulative mean normalized difference function [3, 42], have also been proposed. On the other hand, [4] performs pitch estimation by predicting the pitch of the sawtooth waveform whose spectrum best matches the one of the input signal.

Recently, methods involving machine learning techniques have been proposed [5, 6]. In particular, CREPE [16] is a deep convolutional network trained on a large corpus to predict pitch from raw audio waveforms. SPICE [19] is a self-supervised method that takes as inputs individual Constant-Q Transform (CQT) frames of pitch-shifted inputs and learns the transposition between these inputs. It achieves quite decent results thanks to a decoder that takes as input the predicted pitch and tries to reconstruct the original CQT frame from it.

Finally, some works [43, 44] aim at disentangling the pitch and timbre of an input audio, thus predicting pitch as a side effect. In particular, DDSP-inv [45] is a DDSP-based approach [46] that relies on inverse synthesis to infer pitch in a self-supervised way.

3. SELF-SUPERVISED PITCH ESTIMATION

3.1 Transposition-equivariant objective

We focus on the problem of monophonic pitch estimation and model it as a classification task. Our model is com-

² The most common technique involves randomly applying data augmentations to inputs to create pairs of inputs that share semantic content.

Figure 1. Example of k -transpositions. Visually, \mathbf{y} and \mathbf{y}' are just translated versions of each other. The sign of k and its absolute value respectively indicate the direction and the distance of the translation.

posed of a neural network f_θ that takes as input an audio signal \mathbf{x} and returns a vector $\mathbf{y} = (y_0, \dots, y_i, \dots, y_{d-1}) \in [0, 1]^d$, which represents the probability distribution of each pitch i . y_i represents the probability that i is the pitch of \mathbf{x} . We propose here to train f_θ in a SSL way. For this, similarly to [22, 24, 26, 28, 29], we use data augmentations and Siamese networks.

Given \mathbf{x} , we first generate $\mathbf{x}^{(k)}$ by pitch-shifting \mathbf{x} by a known number k of semitones. Then, both \mathbf{x} and $\mathbf{x}^{(k)}$ are fed to f_θ which is trained to minimize a loss function between $\mathbf{y} = f_\theta(\mathbf{x})$ and $\mathbf{y}^{(k)} = f_\theta(\mathbf{x}^{(k)})$.

Definition. For two vectors $\mathbf{y}, \mathbf{y}' \in \mathbb{R}^d$ and $0 \leq k < d$, \mathbf{y}' is a k -transposition of \mathbf{y} if and only if for all $0 \leq i < d$

$$\begin{cases} y'_{i+k} = y_i & \text{when } 0 \leq i < d - k \\ y'_i = 0 & \text{when } i < k \\ y_i = 0 & \text{when } i \geq d - k - 1 \end{cases} \quad (3)$$

Similarly, for $-d < k \leq 0$, \mathbf{y}' is a k -transposition of \mathbf{y} if and only if \mathbf{y} is a $-k$ -transposition of \mathbf{y}' .

The concept of k -transposition is illustrated in Figure 1. Note also that for a vector $\mathbf{y} \in \mathbb{R}^d$, exists at most one vector $\mathbf{y}' \in \mathbb{R}^d$ that is a k -transposition of \mathbf{y} . We can therefore refer to \mathbf{y}' as the k -transposition of this vector \mathbf{y} .

Equivariance loss. We then design our criterion based on the following assumption: the probability of \mathbf{x} to have pitch i is equal to the probability of $\mathbf{x}^{(k)}$ to have pitch $i+k$, i.e. y_i should be equal to $y_{i+k}^{(k)}$ ³. In other words, if $\mathbf{x}^{(k)}$ is a pitch-shifted version of \mathbf{x} , their respective pitch probability distributions should be shifted accordingly, i.e. $\mathbf{y}^{(k)}$ should be the k -transposition of \mathbf{y} .

We take inspiration from [20] to design our equivariance loss. However, in our case, the output of our network f_θ is not a generic representation but a probability distribution. We therefore adapt our criterion by replacing the learnable linear projection head from [20] by the following deterministic linear form:

$$\begin{aligned} \phi : \mathbb{R}^d &\rightarrow \mathbb{R} \\ \mathbf{y} &\mapsto (\alpha, \alpha^2, \dots, \alpha^d) \mathbf{y} \end{aligned} \quad (4)$$

where α is a fixed hyperparameter⁴.

³ For example, if $k = 2$ semitones, the probability of \mathbf{x} to be C4 is exactly the probability of $\mathbf{x}^{(k)}$ to be a D4, and the same holds for any pitch independently of the actual pitch of \mathbf{x} .

⁴ We found $\alpha = 2^{1/36}$ to work well in practice.

Indeed, with this formulation, for any k if \mathbf{y}' is a k -transposition of \mathbf{y} then $\phi(\mathbf{y}') = \alpha^k \phi(\mathbf{y})$. Hence we define our loss as

$$\mathcal{L}_{\text{equiv}}(\mathbf{y}, \mathbf{y}^{(k)}, k) = h_\tau \left(\frac{\phi(\mathbf{y}^{(k)})}{\phi(\mathbf{y})} - \alpha^k \right) \quad (5)$$

where h_τ is the Huber loss function [47], defined by

$$h_\tau(x) = \begin{cases} \frac{x^2}{2} & \text{if } |x| \leq \tau \\ \frac{\tau^2}{2} + \tau(|x| - \tau) & \text{otherwise} \end{cases} \quad (6)$$

Regularization loss. Note that if $\mathbf{y}^{(k)}$ is the k -transposition of \mathbf{y} then $\mathcal{L}_{\text{equiv}}(\mathbf{y}, \mathbf{y}^{(k)}, k)$ is minimal. However, the converse is not always true. In order to actually enforce pitch-shifted pairs of inputs to lead to k -transpositions, we further add a regularization term which is simply the shifted cross-entropy (SCE) between \mathbf{y} and $\mathbf{y}^{(k)}$, i.e. the cross-entropy between the k -transposition of \mathbf{y} and $\mathbf{y}^{(k)}$:

$$\mathcal{L}_{\text{SCE}}(\mathbf{y}, \mathbf{y}^{(k)}, k) = \sum_{i=0}^{d-1} y_i \log \left(y_{i+k}^{(k)} \right) \quad (7)$$

with the out-of-bounds indices replaced by 0. The respective contribution of $\mathcal{L}_{\text{equiv}}$ and \mathcal{L}_{SCE} is studied in part 4.4.3.

Invariance loss. $\mathcal{L}_{\text{equiv}}$ and \mathcal{L}_{SCE} allow our model to learn relative transpositions between different inputs and learn to output probability distributions \mathbf{y} and $\mathbf{y}^{(k)}$ that satisfy the equivariance constraints. However, these distributions may still depend on the timbre of the signal. This is because our model actually never observed at the same time two different samples with the same pitch.

To circumvent this, we rely on a set \mathcal{T} of data augmentations that preserve pitch (such as gain or additive white noise). We create augmented views $\tilde{\mathbf{x}} = t(\mathbf{x})$ of our inputs \mathbf{x} by applying random transforms $t \sim \mathcal{T}$.

Similarly to [35], we then train our model to be invariant to those transforms by minimizing the cross-entropy between $\mathbf{y} = f_\theta(\mathbf{x})$ and $\tilde{\mathbf{y}} = f_\theta(\tilde{\mathbf{x}})$.

$$\mathcal{L}_{\text{inv}}(\mathbf{y}, \tilde{\mathbf{y}}) = \text{CrossEntropy}(\mathbf{y}, \tilde{\mathbf{y}}) \quad (8)$$

Combining the losses. For a given input sample \mathbf{x} and a given set of augmentations \mathcal{T} ,

- we first compute $\mathbf{x}^{(k)}$ by pitch-shifting \mathbf{x} by a random number of bins k (the precise procedure is described in section 3.2);
- we then generate two augmented views $\tilde{\mathbf{x}} = t_1(\mathbf{x})$ and $\tilde{\mathbf{x}}^{(k)} = t_2(\mathbf{x}^{(k)})$, where $t_1, t_2 \sim \mathcal{T}$;
- we compute $\mathbf{y} = f_\theta(\mathbf{x})$, $\tilde{\mathbf{y}} = f_\theta(\tilde{\mathbf{x}})$ and $\tilde{\mathbf{y}}^{(k)} = f_\theta(\tilde{\mathbf{x}}^{(k)})$.

Our final objective loss is then:

$$\begin{aligned} \mathcal{L}(\mathbf{y}, \tilde{\mathbf{y}}, \tilde{\mathbf{y}}^{(k)}, k) &= \lambda_{\text{inv}} \mathcal{L}_{\text{inv}}(\mathbf{y}, \tilde{\mathbf{y}}) \\ &+ \lambda_{\text{equiv}} \mathcal{L}_{\text{equiv}}(\tilde{\mathbf{y}}, \tilde{\mathbf{y}}^{(k)}, k) \\ &+ \lambda_{\text{SCE}} \mathcal{L}_{\text{SCE}}(\tilde{\mathbf{y}}, \tilde{\mathbf{y}}^{(k)}, k) \end{aligned} \quad (9)$$

We illustrate this in Figure 2. To set the weights λ_* we use the gradient-based method proposed by [48–50].

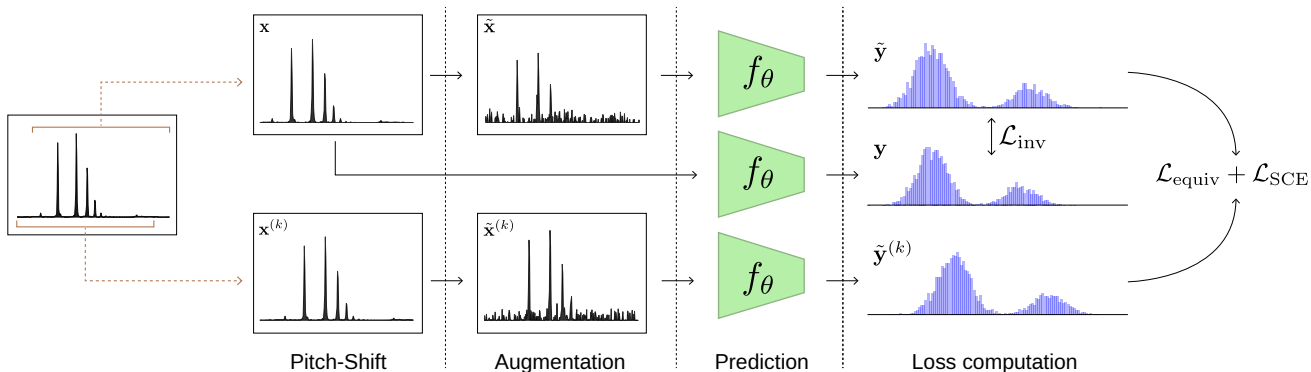

Figure 2. Overview of the PESTO method. The input CQT frame (log-frequencies) is first cropped to produce a pair of pitch-shifted inputs $(x, x^{(k)})$. Then we compute \tilde{x} and $\tilde{x}^{(k)}$ by randomly applying pitch-preserving transforms to the pair. We finally pass x, \tilde{x} and $\tilde{x}^{(k)}$ through the network f_θ and optimize the loss between the predicted probability distributions.

3.2 Audio-frontend

The inputs x are the individual frames of the CQT. We have chosen the CQT as input since its logarithmic frequency scale, in which bins of the CQT exactly correspond to a fixed fraction b of pitch semitones, naturally leads to pitch-shifting by translation. CQT is also a common choice made for pitch estimation [17, 19, 51].

To compute the CQT, we use the implementation provided in the nnAudio library [52] since it supports parallel GPU computation. We choose $f_{\min} = 27.5$ Hz, which is the frequency of A0 the lowest key of the piano and select a resolution of $b = 3$ bins per semitone. Our CQT has in total $K = 99b$ log-frequency bins, which corresponds to the maximal number of bins for a 16kHz signal.

3.3 Simulating translations.

To avoid any boundary effects, we perform pitch-shift by cropping shifted slices of the original CQT input frame as in [19]⁵. From a computational point of view, it is indeed significantly faster than applying classical pitch shift algorithms based on phase vocoder and resampling.

3.4 Transposition-preserving architecture

The architecture of f_θ is illustrated in Figure 3. It is inspired by [17]. Each input CQT frame is processed independently: first layer-normed [53] then preprocessed by two 1D-Conv (convolution in the log-frequency dimension) with skip-connections [54], followed by four 1D-Conv layers. As in [17], we apply a non-linear leaky-ReLU (slope 0.3) [55] and dropout (rate 0.2) [56] between each convolutional layer. Importantly, the kernel size and padding of each of these layers are chosen so that the frequency resolution is never reduced. We found in practice that it helps the model to distinguish close but different

Figure 3. Architecture of our network f_θ . The number of channels varies between the intermediate layers, however the frequency resolution remains unchanged until the final Toeplitz fully-connected layer.

itches. The output is then flattened, fed to a final fully-connected layer and normalized by a softmax layer to become a probability distribution of the desired shape.

Note that all layers (convolutions⁶, elementwise nonlinearities, layer-norm and softmax), except the last final fully-connected layer, preserve transpositions. To make the final fully-connected layer also transposition-equivariant, we propose to use **Toeplitz fully-connected layers**. It simply consists of a standard linear layer without bias but whose weights matrix A is a Toeplitz matrix, i.e. each of its diagonals is constant.

$$A = \begin{pmatrix} a_0 & a_{-1} & a_{-2} & \cdots & a_{-n+2} & a_{-n+1} \\ a_1 & a_0 & a_{-1} & \ddots & \ddots & a_{-n+2} \\ a_2 & a_1 & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ a_{m-1} & \cdots & \cdots & \cdots & \cdots & a_{m-n} \end{pmatrix} \tag{10}$$

Contrary to arbitrary fully-connected layers, Toeplitz matrices are transposition-preserving operations and only have $m + n - 1$ parameters instead of mn . Furthermore, they are mathematically equivalent to convolutions, making them straightforward to implement.

⁶ Convolutions roughly preserve transpositions since the kernels are applied locally, meaning that if two transposed inputs are convolved by the same kernel, then the output results will be almost transpositions of each other as well

⁵ Specifically, we sample an integer k uniformly from the range $\{-k_{\max}, \dots, k_{\max}\}$, then generate two CQT outputs, denoted as x and $x^{(k)}$, where x is obtained by cropping the input CQT at indices $[k_{\max}, K - k_{\max} - 1]$, and $x^{(k)}$ is obtained by cropping the input CQT at indices $[k_{\max} - k, K - k_{\max} + k - 1]$, with K the total number of bins of the original CQT frame and $k_{\max} = 16$ in practice (see Figure 2).

Model	# params	Trained on	Raw Pitch Accuracy	
			<i>MIR-1K</i>	<i>MDB-stem-synth</i>
SPICE [19]	2.38M	private data	90.6%	89.1%
DDSP-inv [45]	-	<i>MIR-1K / MDB-stem-synth</i>	91.8%	88.5%
PESTO (ours)	28.9k	<i>MIR-1K</i>	96.1%	94.6%
PESTO (ours)	28.9k	<i>MDB-stem-synth</i>	93.5%	95.5%
CREPE [16]	22.2M	many (supervised)	97.8%	96.7%

Table 1. Evaluation results of PESTO compared to supervised and self-supervised baselines. CREPE has been trained in a supervised way on a huge dataset containing in particular *MIR-1K* and *MDB-stem-synth*. It is grayed out as a reference. For DDSP-inv, we report the results when training and evaluating on the same dataset.

3.5 Absolute pitch inference from \mathbf{y}

Our encoder f_θ returns a probability distribution over (quantized) pitches. From an input CQT frame \mathbf{x} , we first compute the probability distribution $f_\theta(\mathbf{x})$, then we infer the absolute pitch \hat{p} by applying the affine mapping:

$$\hat{p}(\mathbf{x}) = \frac{1}{b} (\arg \max f_\theta(\mathbf{x}) + p_0) \quad (11)$$

where $b = 3$ is the number of bins per semitones in the CQT and p_0 is a fixed integer shift that only depends on f_θ . As in [19], we set the integer shift p_0 by relying on a set of synthetic data⁷ with known pitch.

4. EXPERIMENTS

4.1 Datasets

To evaluate the performance of our approach, we consider the two following datasets:

1. *MIR-1K* [57] contains 1000 tracks (about two hours) of people singing Chinese pop songs, with separate vocal and background music tracks provided.
2. *MDB-stem-synth* [58] contains re-synthesized monophonic music played by various instruments.

The pitch range of the *MDB-stem-synth* dataset is wider than the one of *MIR-1K*. The two datasets have different sampling rates and granularity for the annotations.

We conduct separate model training and evaluation on both datasets to measure overfitting and generalization performance. In fact, given that our model is lightweight and does not require labelled data, overfitting performance is particularly relevant for real-world scenarios, as it is easy for someone to train on their own dataset, e.g. their own voice. However, we also examine generalization performance through cross-evaluation to ensure that the model truly captures the underlying concept of pitch and does not merely memorize the training data.

4.2 Training details

From an input CQT (see part 3.2), we first compute the pitch-shifted CQT (see part 3.3). Then two random data augmentations $t_1, t_2 \sim \mathcal{T}$ are applied with a probability of 0.7. We used white noise with a random standard deviation between 0.1 and 2, and gain with a random value

picked uniformly between -6 and 3 dB. The overall architecture of f_θ (see part 3.4) is implemented in PyTorch [59]. For training, we use a batch size of 256 and the Adam optimizer [60] with a learning rate of 10^{-4} and default parameters. The model is trained for 50 epochs using a cosine annealing learning rate scheduler. Our architecture being extremely lightweight, training requires only 545MB of GPU memory and can be performed on a single GTX 1080Ti.

4.3 Performance metrics

We measure the performances using the following metrics.

1. *Raw Pitch Accuracy* (RPA): corresponds to the percentage of voiced frames whose pitch error⁸ is less than 0.5 semitone [61].
2. *Raw Chroma Accuracy* (RCA): same as RPA but considering the mapping to Chroma (hence allowing octave errors) [61].

RCA is only used in our ablation studies.

4.4 Results and discussions

4.4.1 Clean signals

We compare our results with three baselines: CREPE [16], SPICE [19] and DDSP-inv [45]. CREPE is fully-supervised while SPICE and DDSP-inv are two SSL approaches. To measure the influence of the training set, we train PESTO on the two datasets (*MIR-1K* and *MDB-stem-synth*) and also evaluate on the two. This allows to test model generalization.

We indicate the results in Table 1. We see that PESTO significantly outperforms the two SSL baselines (SPICE and DDSP-inv) even in the cross-dataset scenario (93.5% and 94.6%). Moreover, it is competitive with CREPE (-1.7% and -1.2%) which has 750 times more parameters and is trained in a supervised way on the same datasets.

4.4.2 Robustness to background music

Background noise and music can severely impact pitch estimation algorithms, making it imperative to develop robust methods that can handle real-world scenarios where background noise is often unavoidable.

We therefore test the robustness of PESTO to background music. For this, we use the *MIR-1K* dataset, which contains separated vocals and background tracks

⁷ synthetic harmonic signals with random amplitudes and pitch

⁸ i.e. distance between the predicted pitch and the actual one

Model	Raw Pitch Accuracy (<i>MIR-1K</i>)			
	clean	20 dB	10 dB	0 dB
SPICE [19]	91.4%	91.2%	90.0%	81.6%
PESTO				
$\beta = 0$	94.8%	90.7%	79.2%	50.0%
$\beta = 1$	94.5%	94.2%	92.9%	83.1%
$\beta \sim \mathcal{U}(0, 1)$	94.7%	94.4%	92.9%	81.7%
$\beta \sim \mathcal{N}(0, 1)$	94.8%	94.5%	93.0%	82.6%
$\beta \sim \mathcal{N}(0, \frac{1}{2})$	94.8%	94.5%	92.9%	81.0%
CREPE [16]	97.8%	97.3%	95.3%	84.8%

Table 2. Robustness of PESTO and other baselines to background music with various Signal-to-Noise ratios. Adding background music to training samples significantly improves the robustness of PESTO (see section 4.4.2).

and allows testing various signal-to-noise (here vocal-to-background) ratios (SNRs).

We indicate the results in Table 2. As foreseen, the performance of PESTO when trained on clean vocals (row $\beta = 0$) and applied to vocal-with-background considerably drop: from 94.8% (clean) to 50.0% (SNR = 0 dB)⁹.

To improve the robustness to background music, we slightly modify our method to train our model on mixed sources. Instead of using gain and white noise as data augmentations, we create an augmented view of our original vocals signal $\mathbf{x}_{\text{vocals}}$ by mixing it (in the complex-CQT domain) with its corresponding background track $\mathbf{x}_{\text{background}}$:

$$\mathbf{x} = \mathbf{x}_{\text{vocals}} + \beta \mathbf{x}_{\text{background}} \quad (12)$$

Then, thanks to \mathcal{L}_{inv} , the model is trained to ignore the background music for making its predictions.

The background level β is randomly sampled for each CQT frame. The influence of the distribution we sample β from is depicted in Table 2. This method significantly limits the drop in performances observed previously and also makes PESTO outperform SPICE in noisy conditions.

4.4.3 Ablation study

Table 3 depicts the influence of our different design choices. First, we observe that the equivariance loss $\mathcal{L}_{\text{equiv}}$ and the final Toeplitz fully-connected layer (eq.(10)) are absolutely essential for our model not to collapse. Moreover, data augmentations seem to have a negligible influence on out-of-domain RPA (-0.2%) but slightly help when training and evaluating on the same dataset (+1.2%).

On the other hand, it appears that both \mathcal{L}_{inv} and \mathcal{L}_{SCE} do not improve in-domain performances but help the model to generalize better. This is especially true for \mathcal{L}_{SCE} , whose addition enables to improve RPA from 86.9% to 94.6% on *MDB-stem-synth*.

Finally, according to the drop of performances in RPA and RCA when removing \mathcal{L}_{inv} , it seems that the invariance loss prevents octave errors on the out-of-domain dataset.

⁹ It should be noted that the difference between the 96.1% of Table 1 and the 94.8% of Table 2 is due to the fact that we do not apply any data augmentation (gain or additive white noise) when $\beta = 0$.

	MIR-1K		MDB	
	RPA	RCA	RPA	RCA
PESTO baseline	96.1%	96.4%	94.6%	95.0%
<i>Loss ablations</i>				
w/o $\mathcal{L}_{\text{equiv}}$	5.8%	8.6%	1.3%	6.1%
w/o \mathcal{L}_{inv}	96.1%	96.4%	92.5%	94.5%
w/o \mathcal{L}_{SCE}	96.1%	96.5%	86.9%	93.8%
<i>Miscellaneous</i>				
no augmentations	94.8%	95.4%	94.8%	95.2%
non-Toeplitz fc	5.7%	8.7%	1.2%	6.1%

Table 3. Respective contribution of various design choices of PESTO for a model trained on *MIR-1K*.

5. CONCLUSION

In this paper, we presented a novel self-supervised learning method for pitch estimation that leverages equivariance to musical transpositions. We propose a class-based equivariant objective that enables Siamese networks to capture pitch information from pairs of transposed inputs accurately. We also introduce a Toeplitz fully-connected layer to the architecture of our model to facilitate the optimization of this objective. Our method is evaluated on two standard benchmarks, and the results show that it outperforms self-supervised baselines and is robust to background music and domain shift.

From a musical perspective, our lightweight model is well-suited for real-world scenarios, as it can run on resource-limited devices without sacrificing performance. Moreover, its SSL training procedure makes it convenient to fine-tune on a small unlabeled dataset, such as a specific voice or instrument. Additionally, the resolution of the model is a sixth of a tone but could eventually be increased by changing the resolution of the CQT. Moreover, despite modelling pitch estimation as a classification problem, we make no assumption about scale or temperament.

These features make our method still a viable solution, e.g. for instruments that use quartertones and/or for which no annotated dataset exists. We therefore believe that it has many applications even beyond the limitations of Western music.

Overall, the idea of using equivariance to solve a classification problem is a novel and promising approach that enables the direct return of a probability distribution over the classes with a single, potentially synthetic, labelled element. While our paper applies this approach to pitch estimation, there are other applications where this technique could be useful, such as tempo estimation.

Moreover, modelling a regression task as a classification problem can offer greater interpretability as the output of the network is not a single scalar but a whole probability distribution. Finally, it can generalize better to multi-label scenarios.

Our proposed method hence demonstrates the potential of using equivariance to solve problems that are beyond the scope of our current work. In particular, it paves the way towards self-supervised multi-pitch estimation.

6. ACKNOWLEDGEMENTS

This work has been funded by the ANRT CIFRE convention n°2021/1537 and Sony France. This work was granted access to the HPC/AI resources of IDRIS under the allocation 2022-AD011013842 made by GENCI. We would like to thank the reviewers and meta-reviewer for their valuable and insightful comments.

ABSTRACT

Throughout history, a consistent temporal and spatial gap has persisted between the inception of novel knowledge and technology and their subsequent adoption for extensive practical utilization. The article explores the dynamic interaction and exchange of methodologies between musicology and computational music research. It focuses on an analysis of ten years' worth of papers from the International Society for Music Information Retrieval (ISMIR) from 2012 to 2021. Over 1000 citations of ISMIR papers were reviewed, and out of these, 51 later works published in musicological venues drew from the findings of 28 ISMIR papers. Final results reveal that most contributions from ISMIR rarely make their way to musicology or humanities. Nevertheless, the paper highlights four examples of successful knowledge transfers between the fields and discusses best practices for collaborations while addressing potential causes for such disparities. In the epilogue, we address the interlaced origins of the problem as stemming from the language of new media, institutional restrictions, and the inability to engage in multidisciplinary communication.

1. INTRODUCTION

In 2005, Cook [1] critically addressed the prospects and difficulties of collaborations between Music Information Retrieval (MIR) and musicology, many of which were revisited by Downie in 2009, further examining their implications and potential advancements [2]. With the emergence of empirical research methods and advancements in technology, music research has encompassed multiple academic fields, leading to a transformation in the structures of these disciplines, including Music Information Retrieval (MIR) and contemporary musicology. Given their multidisciplinary nature, the categorization of either is becoming increasingly arbitrary. However, for the purpose of

the clarity of further arguments in this paper, we classify “traditional” and humanities-centred music research fields (musicology, music theory, ethnomusicology, etc.) under the umbrella term “musicology.” Conversely, we use the term “MIR” to encompass all fields that engage in natural-sciences-based (typically computational) research related to music, such as acoustics, informatics, physics, mathematics, engineering, and more¹.

Despite the significant impact of both fields in broadening our understanding of music, unresolved issues highlighted by Cook continue to hinder their collaboration to this day [1]. In recent years, a growing number of musicologists, along with humanities researchers in general, have shown a preference for working with digital materials rather than physical ones [3], but the application of computation to research can be approached at various levels. There are *general-purpose software*, such as word processors or spreadsheet editors, and *music-oriented software*, such as Sibelius, Finale, and Audacity; there are *programming music/MIR platforms and libraries*, such as Humdrum [4], music21 [5], Librosa [6] and Essentia [7] and then there are *methods and algorithms* as developed by the MIR community, for example [8–11] and others (see [12] for a detailed review). While computer usage is prevalent among many researchers there are fewer musicologists who adopt or contribute to similar methodologies. However, through new media and computational advancements, music and our relationship to it are changing [13]. Given the expansion of what is deemed significant in the “realm of music,” it raises the question of whether familiarity with computational languages is becoming a prerequisite for its exploration.

Computational methods assist researchers in handling larger and more varied datasets, but, would musicologists agree that “working with [these] datasets [have] open[ed] up new areas of musicology?” [1] Or, has this shift evoked new areas of research, which are (almost) independent from the musicological domain? The goal of this paper is to ask *to what extent the MIR contributions (in the frames of ISMIR) resonate throughout the musicological community*. The very results of these particular analyses may also

¹ Our labels are arbitrary categories for rough orientation, considering disciplines like music cognition that fit into both/neither category.

highlight some of the core issues of miscommunication between the two domains.

We start by outlining the “ready-made” arguments of collaboratory issues of the fields (Section 1), followed by a methodology introduction for a bibliographical study of ten years of ISMIR papers (2010–2021) and their citations, where we present some empirical results (Sections 2 and 3). As an example of “good collaboratory practice”, we detail four examples, where ISMIR findings were later used by/for a musicological audience through datasets, methodologies, and tool and/or code (Section 4). In conclusion, we discuss the results, examine potential reasons for the outcomes, and draw on theories of play and media studies to support our findings (Section 5).

2. THE WEB OF ARGUMENTS

Numerous authors have explored the advantages and/or drawbacks of interdisciplinary research in the realm of music. We acknowledge the tensions within musicology without delving into the detailed evolution of historic musicology, ethnomusicology, and systematic (empirical) musicology, as these topics have already been extensively covered ([14]). We focus on the development of (pro and con) arguments, generally raised in the 2000s and 2010s.

2.1 Years 2000–2010: Enticement Versus Restraint

The critical discussions began with the emergence of more empirically-centred approaches, mostly labelled as systematic musicology. Following the iconic question “Who stole systematic musicology?”, Leman [15] observed, that even systematic musicology had no longer belonged to “itself.” Conversely, transdisciplinary musicology gained traction among engineering departments (MIR, sound processing), as and neuroscientists and psychologists, who developed a growing interest in the study of *music*.

Amidst the rapid growth of music-related technology production, papers in the early 2000s addressed contemporary musicology, its redefinition, and future methodologies and goals. For some, technologies were viewed as a natural extension for quantitative, big-data, and empirical music analyses [1], while others thought of music research as an interdisciplinary ground of “somewhat equal” sub-disciplines, including musicology and MIR. Addressing the benefits of these collaborations, [16, 17], many authors highlighted the benefits of multidisciplinary projects in expanding the boundaries of isolated disciplines for more comprehensive outcomes. In contrast, others warned that in “an era in which interdisciplinarity has become a kind of mantra, verbally subscribed to by nearly everyone, disciplines continue to police their own boundaries [18].” A similar opinion was shared by Parncutt [14], and Leman, who stressed that, even though they like talking about interdisciplinary projects, “it was very rare that researchers went beyond the boundaries of their own disciplines [15].” Additionally, knowledge transfers are anything but fluid

among computational scientists and musicologists, thus the ideas expand poorly, if at all [19], hence, they must be improved [12]. The scepticism towards unconditionally welcoming the emerging collaboratory changes thus remained. In 2009, [2] reflected on interdisciplinary dynamics during the first 10 years of ISMIR, highlighting its shortcomings, such as the inability to communicate the produced tools to the user (performer, musicologists, ...), favouring low-level over high-level features and audio over other symbolic music representations, and so forth.

2.2 Years 2010–Today: The Quest for Consensus

The scepticism and critiques were not far-fetched nor properly addressed, as Urberg later noticed that the methodological visions of “fundamentally-renewed” music research, had “not [yet] taken over the majority of musicological scholarship [20].” Nonetheless, he imposed that the methodology of research has already shifted, as there is an ascending trend of new research tools and digitized (music) data representations, a lot of them consciously used by musicologists. So what seems to be the problem?

Finding balance in methodology, data collection and interpretation. Still in the second decade of the 21st century, when the introduced arguments began to overlap, Inskip et al. [25] conducted a survey in order to answer this question. The study suggests that “[...] efforts should be made into supporting the development of their digital skills and providing usable, useful and reliable software created with a ‘musicology-centred’ design approach.” Otherwise, the “data richness will lead to information overload [26].” As Dahling expressed in 2012, there are many tools for music collection and analysis, of which many “suffer from various shortcomings, such as specificity to a certain repertoire or approach, lack of robustness and flexibility, flawed user interfaces, or output is difficult to interpret [26].” A similar concern has been expressed by others, such as [27] and [28], or, for textual analysis [29]. All of them advocate not only for a more *accessible and flexible computational methods*, but also express the need understand *what these methods do and how*. Alongside epistemological confusion and other (methodological) drawbacks, a similar problem was stressed by Aucoeur and Bigand. Their dialogue-style paper revealed the flaws and prospects for collaborations between MIR and music research (specifically music cognition) [30]. In Drucker’s words, “the humanities are not a mere afterthought, simply studying and critiquing the effects of computational methods. [Their theory] can provide ways of thinking differently [31].” In a different light, the latter was also implied by [32].

Cyclical collaboration vs discontinuity. Following Downie’s call for improvements [2], some authors discussed *refined measurements* that need to be considered regarding data collection and interpretation, for “obtaining or accessing *high-quality datasets* remains a serious hurdle, especially on a large scale [33].” These hurdles limit the (digital) quality of music research, but not only that. All

Claim/link to musicology	ISMIR papers	Examples of claim
None, “musicolog” is only present in one of the references	147 (42.7%)	
Application of musicological concepts, by only explaining citation, or apply musicological concepts, or hinting towards the possibility of musicological application.	81 (23.6%)	[21] “In order to select relevant low-level features, we refer to <i>musicology</i> papers such as [...] which suggest that arousal is related to features including rhythm density, note density, key, dynamic, tempo, etc.” [22] “We assume that the music tradition is known, and that the rhythm class (tāla) of the piece is from a set of known (from <i>musicological</i> literature) tālas.”
Some claim of musicological utility.	114 (33.7%)	[23] “[...] retaining the rest of the presented framework, e.g. for an analytical ontology of musicological terms supporting the use of digital score annotations to illustrate points in scholarly musicological arguments.” (see Section 4) [24] “These features can serve as inputs to machine learning algorithms, or they can be analyzed statistically to derive musicological insights.” (see Section 4)

Table 1. Links and/or claims regarding musicology in 342 ISMIR papers from 2012 to 2021 where “musicolog” occurs.

music cannot be collected and/or represented in the same manner, and it is not feasible to investigate and discuss it within identical methodological frameworks [28,34]. They believe that this perspective should be considered not only by musicologists but should also be of equal importance for the field of MIR. Schüler and Huron argued that mutual *theoretical awareness* is essential for musicologists and MIR researchers [19,35]. Methodological tools should not be confused with philosophical worldviews [35], and due to the importance of theory *and* “practice”, there must exist a *cyclical collaboration* between the disciplines [27]. Humanities scholars express concern about detached interpretation and the prioritization of “facts” and algorithmic success in studies [28, 29]. Thus, the algorithms must be transparent enough for the scholars to actively participate in the building blocks of their framework and methods. “[I]n the long run, the most ‘useful’ computational analyses will be the ones which are interactive, confronting a human user with the results of computational analysis and allowing that user to modify or intervene in the procedure to arrive at an acceptable or interesting result [28].”

From a more critical standpoint, Becker asks whether “our failure [is] due to our own shortcomings in not becoming thoroughly versed in the protocols and expectations of another discipline? Or, was the failure due to too stringent protocols and expectations for publication in a [...] journal?”, concluding that some disciplinary barriers may be unbreachable due to rigid institutional formations [18]. Leman, conversely, sees the “failure” of collaboration in the notion of the absence of “concrete planned goal at long term, except some vague idea of what all these research activities are up to [15].” Although no firm solutions have been introduced, some humanities authors [29, 36, 37] offered partial theoretical frameworks. Our methodology, inspired by the latter (e.g., Moretti’s *Distant Reading*), will be introduced in the following section.

3. METHODOLOGY AND RESULTS

In this section, we discuss the filtering process of ISMIR 2012–21 to examine *whether* and *how* such papers were used in musicological studies. We also provide statistics and information on data availability.

3.1 Article Selection and Filtration: Which papers claim to have some musicological utility?

We downloaded all 1055 ISMIR papers² from the past 10 years (2012–2021)³ and converted the .pdf files to .txt files. We retrieved 342 articles which included the root “musicolog”, meaning the article contained words like “musicological,” “musicology”, and “ethnomusicologist”⁴. Next, we reviewed these 342 papers to determine their musicological implications, categorizing them into 3 categories (see Table 1 for examples and details). Subsequently, we focused on the 114 ISMIR papers that claimed some musicological relevance and the citations, if any.

3.2 Citations Analysis: Were the papers later used “in musicology”?

To study how and if these 114 papers may have had an impact on musicology, we identified 907 citations of them through Google Scholar. The median of all citations per cited paper is 16. The most cited paper was cited 208 times, while 10 were never cited. We retrieved almost all of these citations⁵ and sorted the citing papers by these two (slightly ambivalent) categories.

- ① *Is any “citorator” a musicologist?* As “musicologists”, we classified researchers with a Master’s or PhD degree in a “musicological” research field or most of their activity was mostly conducted in a musicological environment (see Introduction). Together, there were 210 citations to 67 unique ISMIR papers that corresponded with this category.
- ② *Does the citing paper appear in a musicological journal/conference?* Here, we focus on venues instead of in-

² <https://www.ismir.net/conferences/>

³ Due to time constraints, we couldn’t thoroughly analyze all ISMIR papers. Instead, we focused on the impact of early 2000s ideas on the MIR and musicology collaboration, exploring new tools, and acknowledging changes due to improved technology and online publication accessibility.

⁴ We acknowledge potential exclusions of articles using terms like “music research,” “music theory,” or “music history”, and that ISMIR papers may hold musicological significance without explicitly stating so.

⁵ About 20 were excluded due to inaccessibility of the article or lack of information, among which 6 belong to centred dataset.

		70 citations in total

Table 2. Somewhat musicology-centred journals/conferences/books/institutions, in which ISMIR papers were cited 143 times. The venues marked with (*) have both, musicology/MIR goals.

dividuals, because researchers with musicological backgrounds can have a strong root in MIR as well, while musicological journals mainly target and publish works of primarily musicologically-motivated research activity. We defined “musicological venues” by their primary motivation and targeted audience (Table 2), some of them also have (secondary) MIR motivations (* in Table 2). ISMIR was fully excluded, with the intention to show to which extent these contributions manage to “leave” the ISMIR community. Together, there were 143 citations in rather musicologically relevant publications to 55 ISMIR papers.

From here, we focus on the 143 citations, as the rest either focused on the MIR audience only (was published in technical, science, MIR conference) or did not imply the musicological utility.

3.3 Filtered Citations Analysis: What is the type of citation/utility?

We sorted the 143 citations (or 114 unique citing articles) of previously mentioned 55 ISMIR papers, focusing on *if and how* the first use the latter.

- ✗ *Only referencing the ISMIR paper.* 92 citations only reference 43 ISMIR papers. The authors referenced the article, because it was relevant to the topic, however, their contribution was not actually used.

The other 51 citations cited *and somewhat used* 28 ISMIR contributions⁶, split into the following types:

- ✓ *Dataset* (10 citations to 5 ISMIR papers): The author(s) of citation (partially) used the dataset, presented in cited ISMIR paper.

⁶ Certain ISMIR papers were referenced and utilized in various contexts, and/or classified under multiple utility categories.

Figure 1. Distribution of the papers reported in this study among the years. Left. (a) 114 ISMIR papers with “musicolog” root and claiming to have some musicological utility; (b) from which 43 ISMIR papers *cited* in musicological venues; (c) from which 28 ISMIR papers *actually used* at least once. Right. (d) 143 citations in 51 citing papers (of the 43 ISMIR papers) from musicological venues; (e) from which 87 citations (74 unique citing papers) with at least one musicologist as an author; (f) from which 35 (or 31 unique citing papers) with *actual usage* (of the 28 ISMIR papers). Even for citations, the considered year is the year of the original ISMIR paper.

- ✓ *Methodology* (22 citations to 17 ISMIR papers): The author(s) of citation (partially) used the methodology, presented in cited ISMIR paper.
- ✓ *Code/Tool* (19 citations to 13 ISMIR papers): The author(s) of citation (partially) used the code and/or tool, presented in cited ISMIR paper.

3.4 Statistics on these Papers and Citations

About 10% of ISMIR articles mention “musicolog” every year. As expected, most recent papers are not cited (Figure 1). Despite the limited 10-year time span, papers that received at least one citation showed an average gap of three years between publication and the first citation. If we consider the 81 “older papers” published between 2012 and 2018, about the third of them have been *actually used* at least once in another study.

The list of musicological venues is also revealing (Table 2): The conference that most frequently included ISMIR’s contribution was DLfM, a community that started as a satellite event of ISMIR and that “provides a forum for *musicians, musicologists, librarians, and technologists* to share findings and expertise⁷.” It is followed by JNMR, which “publishes *systematic, scientific and technological research* on music, musical processes and musical behaviours, including popular, cultural and canon music”⁸. The majority of the 143 citations (see Figure 1) appear in journals/conferences with a clearly stated inclination to MIR and/or digital humanities ((* in Table 2) and include several MIR scientists.

⁷ <https://dlfm.web.ox.ac.uk>

⁸ <https://www.tandfonline.com/journals/nnmr20>

Among 51 citations that used ISMIR papers, 16 papers were (partial) self-citations, meaning there was at least one common author. However, in 12 cases, new team members were involved (often from outside the initial institution), and in 4 cases, a new musicologist was present.

3.5 Data Availability

The annotated data on the 114 papers, which claim to have some musicological utility, and the one of 143 citing papers of the 28 papers are available on a git repository through open licences (Open Database License, Database Contents License) at algomus.fr/data.

4. FOUR EXAMPLES OF KNOWLEDGE AND IDEA TRANSFERS

51 citations in musicological venues were thus *used* one of the 28 ISMIR papers through its dataset, methodology, code and/or tool. We focused on four of these stories: In the qualitative observation, we picked examples that describe the type of utility of ISMIR contribution.

Despite some self-citations, promising collaborations were observed *within* research teams integrating interdisciplinary dynamics between musicology and MIR. These teams included both computer/MIR scientists and “conventionally” trained musicologists.

Tool: VIS Framework. In an ISMIR 2014 paper, researchers from the Distributed Digital Music Archives & Libraries Lab at McGill University introduced the VIS Framework, a Python library for music analysis together with a case study on counterpoint patterns in symbolic music scores [38]. The library was further used and cited by the same group in “musicological” venues, such as a study on encoding and translation issues published in DLfM [39]. Two PhD theses from the Schulich School of Music (McGill University) also used the framework. First proposed a computer-assisted approach to the study of interval-succession treaties [40], while second studied the tonality practice of seventeenth-century Italian composers in trio-sonatas [41] and used VIS to extract features. The VIS GUI was found to be essential in making the analysis task easier for non-computational scientists.

Dataset: The Story of Jingju. The Music Technology Group (UPF, Barcelona, Spain) includes the ethnomusicologist, Repetto. His ISMIR 2017 paper with Serra introduced JMCS, of collection of scores or Jingju (also called “Beijing Opera”) [42]. Two citing DLfM 2017 papers⁹ analyzed the melodic syllabic contours in JMCS [43, 44], each paper including another member of the MTG joining the two authors of the ISMIR paper.

Multidisciplinary environments have been created by MIR and music teams globally, fostering collaboration

with external groups, attracting more scientists, and expanding opportunities for obtaining PhD positions from both sides. The following story exemplifies how a multidisciplinary group can attract new collaborations.

Methodology/Tool: The Lohengrin TimeMachine. An ISMIR 2017 paper by Weigl and Page, from the University of Oxford, presented an update on the MELD framework [23], used to *encode information of and about music* (e.g., digital representations of notation, audio, contextual information) inside MEI. MELD has been cited by 25 other papers. One of the “MELD applications”, the Lohengrin TimeMachine was presented at DLfM in 2021 [45] by Lewis and Page, as well as Dreyfus, an American musicologist who was previously not involved with the MIR community. In his late career, he was appointed at the University of Oxford – but in the music department. The application explored a few extracts of Wagner’s Lohengrin through scores, motives, orchestration, structure, texts, audio/video, musicological analysis, etc. It offers interesting representations to a wider audience of both musical knowledges but also on the very methodology of the musicological research. This citation is also a good example of the time it may take to cross domains (here, 4 years).

Tool: Mindfulness and Music Performance Study . In ISMIR 2017, researchers from IRCAM presented the PiPo plugin, designed for data stream processing in various domains including interactive audio processing and MIR. This API-based tool facilitates the extraction of low-level descriptors from audio and motion data streams [46]. A 2021 citing paper in *Psychology of Music*, from a completely independent group, in Israel, examined whether short-term mindfulness meditation activity would improve music performance (vocal skills) regarding pitch intonation, dynamics transmission, and vocal resonance [47]. They use the PiPo tool in the processing phase, using PiPo modules for the automatic segmentation of markers by onset (time-tagged frames) for low-level descriptor extraction (pitch, dynamics, timbre ...). Focusing on music psychology, this application doesn’t qualify as a musicological study. However, it showcases how MIR methods can be applied to humanities-based music research. Interestingly, out of the 114 ISMIR papers examined, this is the only one reused in a “musicological” context independently of the original authors.

5. DISCUSSION AND CONCLUSION

While ISMIR is not exclusively focused on musicology, certain researchers who publish at ISMIR assert their impact on the field. Our examination of the last five years as well as a ten-year period of ISMIR reveals that the majority of these contributions seldom make their way into musicological or humanities scholarship. Out of the 28 ISMIR papers, which have been cited and used, the majority of them are partly self-cited, and/or are “re-used” within the same group, lab etc. Somehow, *we did not find a single example*

⁹ DLfM was a satellite event of ISMIR at that time, meaning the papers and their citations appeared (and were likely prepared) simultaneously.

of independent musicological application of ISMIR 2012-2021 contributions in a traditional musicological journal.

We are aware that our study has some biases. To broadly observe how MIR and other music research interact, we should explore the utility dynamics both ways (ISMIR to musicology, *and* musicology to ISMIR), as well as analyze roots other than “musicolog” in multiple venues (both MIR and music) and thoroughly explore the organizers, institutions, and authors. There are also time¹⁰ and space¹¹ variables, which could have had an impact on the results. Research and collaboration cannot always be measured solely by points or numbers. Non-citable research and pedagogical activities at universities are valuable components that may not be easily quantifiable. In some cases, tools or datasets may be used for inspiration without being cited in the final report. Similarly, ISMIR-presented tools may be employed without direct citation, with references made to non-ISMIR contributions or other sources.

Various technologies have undoubtedly made their way to musicologists, inspiring the creation of a quasi-common ground with IT and other domains. However, further efforts are necessary to establish a consistent circulation of knowledge. While some are managing this challenge (see Section 4), most still struggle.

This *struggle* could be understood through theories of the game (or play) by Huizinga [48] then Caillois [49]. They discuss how the games we play are not only those of “leisure” (sports, video games, ...) but also “law and order, commerce and profit, craft and art, [...] and science. All are rooted in the primaevial soil of play [48].” Caillois considers day-to-day games people play in the light of competitive examinations and economic competition [49], and his six rules very much resemble the scientific atmosphere. Like play, it is 1. *not obligatory to participate* in science, which 2. *must be conducted* (or “played”) in an environment, *pre-defined in time and space*. 3. The strategy (research development) is left to the *individual ideas* 4. and is generally locked in an infinite loop of “*unproductivity*” (meaning, it is largely being developed and executed and re-executed within itself). Both (games and science) follow *conventional rules* and take place in 6. “*make-believe*” world, which is accompanied by a special *awareness of a second reality*. For example, this may as well be the daily shift from one’s research to mundane events. Games (or science) can only be played *when all parties are in agreement with the particular rules*.

Several of these may be incompatible between the MIR and musicology, one of them being, as mentioned in [50], the language of new media (similar idea in [13]). As later elaborated by [51] and [52], this language has, “in the process of epochal technological change” never been immediate, but instead adopted “through a process of transition [52].” Since the majority of new technologies (or

languages) for music analysis “skipped” the transitional era, and are, for an average musicologist, incomprehensible or non-intuitive (algorithmic codes), the computational products “do not manage to address them [musicologists] in an intelligible way.” There seems to be a “clear disconnect between how MIR tasks are designed to evaluate systems, and how end users are supposed to use those systems [...] [making them] difficult and costly to implement [12]”. Consequently, the results, produced by such processes also become unusable, as the “involvement in the wheel of algorithms is indispensable for musicological research [13, 52].” It is this kind of disruption alone, that can disable the multidisciplinary game.

Reflecting on our discussion in Section 2, Huron, imposed the obligation for both parties (MIR and musicology) to familiarize themselves with each other’s methodologies [35]. Additionally, [30] highlights the importance of knowing which parts of whose methodology are to be used for a fruitful collaboration. Leman suggests solving the gap by inducing multi-modality, introducing context-based approaches into empiricism [15]; and a more reserved Parncutt, explains that the wall is set by the feeling of superiority on both sides [14], and so on. Still, the rules of the playground must first reach consensus (starting with the transition towards a common “language”). And this is where these “common grounds” come to light. ISMIR in itself is a multidisciplinary environment, however, most of the participants (deriving from natural rather than humanities or social sciences), already play by similar rules (or speak the same language). Consequently, the multidisciplinary activity within MIR remains rather limited and, despite numerous surveys [12] has yet been unable to properly address all of the (reasons for) constraints mentioned by [2] about 14 years ago. As seen in 3.4, the most cited papers in musicological venues are derived from DLfM and JNMR. This is not a coincidence, as these are “institutions”, whose “rules” derive from a compromise between both disciplines, as well as the majority of yearly contributions, manage to speak the language of both. It hence makes sense, that one of the mentioned papers addressing these matters [30] is structured as a *dialogue*, as it is exactly that, finding a practical working consent among (the two) sciences, that can endorse a fertile collaboration. Merely adapting to each other’s rules seems like trying to simultaneously play football and handball, where similar “material” surely cannot and will not bring a consensus between the two games. The successful examples (Section 4) and mentioned discussions, should be considered to help us advance our fundamental goals on institutional grounds and go beyond both MIR and musicology. In the process of transductive ergomimesis, “new digital media drastically reposition the people” [13] and repeatedly evoke new (motor) skills and techniques, professions, and multidisciplinary actions (see also [53]). The change is hence indispensable for the two fields, “but we’ve got to put in place the [institutional] conditions to make it actually happen” [1]. It seems that it is, in the end, this game (digital) musicologists may want actually want to play.

¹⁰ The contributions we examine may be applied in the future.

ABSTRACT

Supervised music source separation systems using deep learning are trained by minimizing a loss function between pairs of predicted separations and ground-truth isolated sources. However, open datasets comprising isolated sources are few, small, and restricted to a few music styles. At the same time, multi-track datasets with source bleeding are usually found larger in size, and are easier to compile. In this work, we address the task of singing voice separation when the ground-truth signals have bleeding and only the target vocals and the corresponding mixture are available. We train a *cold diffusion* model on the frequency domain to iteratively transform a mixture into the corresponding vocals with bleeding. Next, we build the final separation masks by clustering spectrogram bins according to their evolution along the transformation steps. We test our approach on a Carnatic music scenario for which solely datasets with bleeding exist, while current research on this repertoire commonly uses source separation models trained solely with Western commercial music. Our evaluation on a Carnatic test set shows that our system improves Spleeter on interference removal and it is competitive in terms of signal distortion. Code is open sourced.¹

1. INTRODUCTION

Music source separation (MSS) is a core task in the field of music information retrieval (MIR) in which the aim is to automatically separate the different sources in a musical mixture. In this work, we focus on separating the singing voice. In recent years, impressive performance for this difficult and highly undetermined problem has been achieved through the use of deep learning (DL) approaches [1]. Traditionally, MSS models operate on time-frequency representations [1–3], and more recently on waveforms [4, 5], however, the latter are prone to introduce artifacts to the estimated sources. While the combination of both domains

has also shown impressive performance [6, 7], these models tend to be large in size and require extensive amounts of computational power, especially for the training stage.

Supervised MSS approaches, which currently lead the field, require fully-isolated multi-track recordings for the target sources. Data of this kind are scarce and constrained to few musical repertoires [8] because recording these at high quality without bleeding is expensive. One solution is to synthesize the signals [8–10], however, these datasets may not be fully realistic and may produce domain mismatch. On the other hand, multi-track datasets with source bleeding, where the track corresponding to a source is contaminated by the leakage from other sources, are easier to build, since these may be compiled through a less complex process, and can be recorded in live performances. We observe large multi-track datasets with bleeding for diverse domains in the literature [11–14], therefore, dedicated MSS systems to be trained with these would be beneficial. In fact, MSS in the presence of bleeding has recently gained interest: a dedicated leaderboard for this problem – albeit in a slightly different context than here – has been included in the Music Demixing Challenge 2023 [15].

In this work, we propose to address the MSS problem for a repertoire that lacks clean isolated tracks: Carnatic Music (CM). The computational analysis of CM has received growing attention in recent years [16]. MSS is a useful pre-processing step in many computational research pipelines on CM. However, researchers use the available models in the literature, typically the pip-installable version of Spleeter [3] – some examples being [17–22] –, which is trained on a large private dataset, presumably including few or no CM examples. Despite not having information on that latter matter, we make the assumption because the 4/5-stem Spleeter models target an instrument arrangement not applicable to CM (vocals, bass, drum, piano, and other), and CM is rarely recorded stem-by-stem in a studio. The domain mismatch between repertoires here may hinder the generalization given the unseen instruments and playing/singing techniques. That may also produce a negative effect on the analysis of the separated sources, as well as on further processes such as melody estimation or pattern recognition. Existing works focusing on CM have pointed out the domain mismatch problem for related tasks currently lead by data-driven models [23].

We propose an MSS model to be trained using the Saraga dataset [11] which is, to the best of our knowledge,

¹ <https://github.com/MTG/carnatic-separation-ismir23>

the largest open dataset for the computational analysis of Indian Art Music (IAM). Saraga comprises multi-track audio data recorded in live performances and is larger in size (≈ 36 h) than the rest of the real-audio MSS datasets in the literature. However, in all multi-track audio signals in Saraga, there is bleeding from the rest of the sources. Our goal is to use the real-world data with bleeding in Saraga to train an MSS model for this domain, while proposing a strategy to output clean isolated signals, even though no bleeding-free signals are available for development.

To achieve so, we train a *cold diffusion* model, followed by unsupervised clustering on the resulting output. Cold diffusion has shown promising results in recovering data samples from a given distribution that have been iteratively perturbed, in T steps, using a deterministic signal [24–26]. We apply said process to iteratively convert the amplitude spectrogram of a mixture to that of a target source with bleeding. This yields a separation as good as the target source with bleeding in the training data. To address this issue, we take advantage of all the intermediary cold diffusion steps to further improve the output. In doing so, we rely on the fact that the energy of the target source, which is predominant, will evolve differently throughout the transformation than the energy of the source bleeding. Note that this process is cumbersome in a single-step non-diffusion separation system, given the overlapping between vocal and accompaniment at various time–frequency bins.

The key contribution of this study is an MSS system that can be developed solely using data with bleeding. With regards to that, solely the mixture and the target source containing bleeding from other instruments are required. Given its relevance to the repertoire, we focus on separating the singing voice. Also, the proposed model is adaptable: the user may choose to be more restrictive with interferences – at the expense of loss of vocal quality – or vice versa. We put special emphasis on being able to characterize the ubiquitous instruments in CM, to reliably remove the interferences from the singing voice. In a computational musicology context, that would improve the musicologically-relevant research done on the separated vocal signal.

2. METHOD

Our separation pipeline assumes the existence of m , the audio signal of the mixture, and the target source with bleeding s^b which is contained in the mixture, while we may not have the remaining sources at hand. In our case, s^b is the singing voice with source bleeding. We present a two-step method to estimate the isolated source \hat{s} by only having m and s^b during training, and solely m during inference.

- (1) **Cold diffusion process:** we aim at running a cold diffusion process to recursively convert the magnitude spectrogram of a mixture M into the magnitude spectrogram of the singing voice with bleeding \hat{S}^b .
- (2) **Unsupervised mask estimation:** Note that step (1) can only yield estimations as good as the source with bleeding S^b used as ground truth. Toward refining

Figure 1. The **spectrogram cold diffusion** transforms, in T steps, a mixture M into a target source with bleeding S^b .

these estimations, we build the final estimation mask by clustering the frequency bins using the entire cold diffusion process to understand how the energy of each bin is evolving during the transformation.

2.1 Feature extraction

2.1.1 Spectrogram cold diffusion

We propose an approach inspired by diffusion models, a class of generative models that define a Markov chain of T steps to iteratively convert samples from a given data distribution into Gaussian noise while learning to conduct the reverse process [27]. The model learns to generate a sample of the given input data distribution from a random sample of noise. Recently, deterministic signals have been successfully used in place of Gaussian noise for the diffusion process [24–26], a technique known as *cold diffusion*.

In [25], the authors apply a transformative cold diffusion process for SVS, using the mixture as the perturbation signal to gradually convert a singing voice to the corresponding mixture, while learning to conduct the reverse process, yielding improved separations for the evaluated model. The process operates in the waveform domain. Here, we propose an updated version of the cold diffusion paradigm in [25] to apply it in time–frequency domain. The cold diffusion process begins at X_0 which is the target data point at inference, in our case S^b , and ends at X_T , in our case M . Let α_t be the perturbation schedule to control the amount of perturbation added at each step and therefore determining the intermediate states of the variable X_t , being t the cold diffusion step. We define α_t as a 1D vector of linearly spaced values from 1 to 0, and of length T . We compute any step in the cold diffusion process as:

$$q_t(X_t|M, X_0) = \alpha_t X_0 + (1 - \sqrt{\alpha_t})M \quad (1)$$

The process is depicted in Figure 1. In other words, the proposed cold diffusion process gradually converts the amplitude spectrogram of the singing voice with source bleeding into the corresponding mixture, while at inference we aim at reverting said transformation. The use of cold diffusion is motivated by the successful attempts to iteratively transform two-dimensional signals using a diffusion process through a U-Net [24], a well-known network for source separation [2, 3]. Moreover, we can train the model in a supervised fashion, which may lead to more consistent performance than unsupervised procedures. Approaches to

extract features from the spectrograms for clustering [28] are a problem on its own, which in this context may be hindered by source bleeding and the musical and spectral characteristics of CM instruments, e.g. violin or tanpura.

Note that given Eq. 1, the singing voice stays predominant, while the accompaniment gradually increases – in the direction of the cold diffusion process – or decreases – in the direction of the inference process–. This equation is also aimed at amplifying the energy difference throughout the steps between the singing voice and accompaniment frequency bins, and that explains why X_0 and M have different trajectories assigned. The weighting $(1 - \sqrt{\alpha_t})$ applied to the mixture M ensures larger steps at the start of the inference process, while more fine-grained estimations are performed at the latter steps [27], aiming at obtaining more refined separation outputs. Note also that the expected inference input of a singing voice extraction model – in our case corresponding to X_T – is a mixture. Given the expressions in Eq. 1, the perturbation M ensures that $X_T = M$, otherwise the said condition is not given.

2.1.2 Reverse process

The reverse process iteratively removes the deterministic perturbation, aiming at reaching S^b receiving the corresponding mixture M as input. We directly chain the model estimations, so that the model input at a particular step t is the raw prediction of the model at the previous step $t + 1$ (note that the reverse process begins from step T to reach step 1). Therefore, given a trained model D with parameters θ , the reverse process can be defined as follows:

$$r_t(\hat{X}_{t-1}|X_t) = D_\theta(X_t, t) \quad (2)$$

This process is iteratively performed for $t = [T, T - 1, \dots, 1]$, using M as input corresponding to X_T .

2.1.3 Training algorithm

We aim at training a model that learns a mask K_t for each diffusion step t so that $X_t * K_t = \hat{X}_{t-1}$. For each t , we predict a different mask that transforms the signal into the next step in the reverse process until we reach \hat{X}_0 , which ideally is as close as possible to S^b . Given Eq. 1, we effectively optimize the model using the following objective [27]:

$$L(\theta) = \|X_{t-1} - D_\theta(q_t(X_t|M, X_0), t)\|^2 \quad (3)$$

where X_{t-1} is the known next step in the reverse process computed following $q_t(X_t|M, X_0)$, whereas the model D_θ predicts the next step \hat{X}_{t-1} based on $q_t(X_t|M, X_0)$, the step t , the mixture M , and the input of the cold diffusion process X_0 , corresponding to S^b .

We employ a U-Net to learn the reverse process, which has been shown useful for the problem of MSS [2]. We use a U-Net with 7 levels of depth and 4 residual blocks at each level. Both frequency and time dimensions are encoded and then expanded by a factor of 2. The last layer is a sigmoid in order to output the mask K_t of values $\in [0, 1]$, which is multiplied by the input X_t to get \hat{X}_{t-1} . We estimate masks instead of spectrograms to obtain a more consistent and linear evolution of the bins energy. Estimating

spectrograms may lead to unstable removal of accompaniment, which adds complexity to the proposed approach. To inform the network about the current diffusion step t in the reverse process, we encode it using a 16-dimension sinusoidal positional vector [29]. Said embedding is processed through two dense layers of 64 units. Next, the embedded t is projected to the corresponding channel size at each level of depth of the U-Net and added to the input of each residual block. We inject the time-step embedding to all residual blocks in the encoder, decoder, and bottleneck.

2.1.4 Inference

In standard diffusion models, the output of the last step is considered to be the cleanest signal. We argue that we can achieve better separation by studying how the time-frequency bins evolve throughout the inference process.

We run inference using the trained D_θ to automatically convert an input M to a predicted S^b while capturing and stacking all intermediate representations, in order, in a feature matrix $\hat{X}_{T, \dots, 0}$. These features are sized $I \times J \times T$, where I is time size, J number of frequency bins, and T is the number of cold diffusion steps, and represent how the iterative transformation of the magnitude spectrogram of M changes over the cold diffusion steps until reaching predicted S^b . We normalize the features by dividing all $\hat{X}_{T, \dots, 0}^{(i,j)}$ – being (i, j) the coordinates of a given frequency bin in $\hat{X}_{T, \dots, 0}$ – by $\max(\hat{X}_{T, \dots, 0}^{(i,j)})$. Therefore, the energy vectors are studied on the same scale.

2.2 Unsupervised mask estimation

The final mask estimation is performed on top of the cold diffusion feature matrix $\hat{X}_{T, \dots, 0}$, as seen in Figure 2. Existing works use diffusion models to generate features or embeddings for downstream tasks [30], however, to our best knowledge, this is the first attempt to use an entire diffusion process rather than relying only on the output signal.

Note that in the proposed cold diffusion paradigm, we iteratively convert the accompaniment into bleeding – much lower in presence but not removed –, while preserving the cleanest possible voice. Therefore, the energy of the time-frequency bins $\hat{X}_{T, \dots, 0}^{(i,j)}$ across the diffusion steps fluctuates less for the voice than for the accompaniment, which is iteratively lowered by the model. To this end, we propose to cluster the frequency bins based on the evolution of these in $\hat{X}_{T, \dots, 0}$. Clustering techniques have been previously used in a separation context [28, 31, 32], aiming at grouping the components belonging to the same source.

We use K-means clustering to automatically create groups of frequency bins associated with sources, given the computed features $\hat{X}_{T, \dots, 0}$. For example, if a binary separation mask is desired, one may use two clusters and multiply by 0 the clustered bins belonging to the accompaniment, while leaving the rest unchanged. For a soft mask, we consider more than two clusters, and the bins classified in the middle clusters may be shared between the singing voice and other sources, as seen in Figure 2, where we use three clusters. In our case, ideally, the cold diffusion process iteratively reduces the energy of accompaniment bins

Figure 2. The **unsupervised mask estimation** step clusters the frequency bins given vector $\hat{X}_{T,\dots,0}$, which stores the evolution from mixture M to the predicted source with bleeding \hat{S}^b . The example in this figure uses $C = 3$, being C the number of clusters. The cluster with centroid with lower value is considered the *accompaniment cluster* and assigned 0 in the mask and removed, while the furthest cluster to that is the *vocal cluster* and assigned value 1, so values are left untouched. The bins in the *shared clusters* (we have more than one shared cluster for $C > 3$) are weighted given w^F . Therefore, the user can navigate, given parameter F , through the interference/artifacts trade-off. Using larger C (i.e. considering more clusters) delivers a more granular masking.

while preserving the singing voice. Therefore, the features per bin $\hat{X}_{T,\dots,0}^{(i,j)}$ have higher values for those corresponding to the singing voice. In this case, the centroid of the closest cluster to the voice centroid has the largest L1 norm. We can then sort the clusters by the L1 norm of the centroid.

Having the clusters ordered, a weight $\in [0, 1]$ must be assigned to each cluster to create the soft mask. Rather than normalizing the cluster centroids, we discover that it is desirable to assign a balanced weighting to the clusters. Thus, we define w , a 1D array linearly spaced values $\in [0, 1]$ of length C , which is the number of clusters. Note that 0 and 1 are both included to directly give a weight of 0 to the *accompaniment cluster* and 1 to the *vocal cluster*, which are the two furthest clusters. Now let F be an integer representing weight factor that is used to control how restrictive we want to be with the intermediate clusters. Given w and F , we compute the final cluster weight array as w^F . For an $F > 1$, we are being more restrictive, especially with the clusters closer to the accompaniment one, and the bigger we set F , the more restrictive we are. When evaluating the clustering, we experiment with various parameter configurations. However, C and F may also be given by the users to control the trade-off between interference and artifacts depending on their needs. Intuitively, the more clusters are considered and removed, we obtain an output with less interference from other sources, at the expense of a loss of quality from the target source.

To take advantage of the first separation run given by the cold diffusion process, we multiply the final mask with the last step of the inference process \hat{X}_0 , or \hat{S}^b . Preliminary results confirmed that this is beneficial over masking the input mixture, and it does not imply added computational expense since \hat{X}_0 is contained in the features $\hat{X}_{T,\dots,0}$.

Note that the use of the cold diffusion process allows the development of differentiable operations for estimating the final separation mask in the context of bleeding. We

observed that clustering is not feasible when using a one-step prediction, e.g. two spectrograms do not yield enough information to study the energy change between a vocal and an accompaniment frequency bin.

3. EXPERIMENTS

3.1 Experimental setup

We perform our experimentation using $q_t(X_t|M, X_0)$ with $T = 8$. Generative diffusion typically uses larger T , e.g. 1000 [27]. Using large values for T in this context produces two consecutive steps in the process practically identical, and the optimization of the model becomes extremely complex. We compute the STFT of m and s^b with window size 1024 and hop 256, at a sampling rate of 22050Hz. We use ADAM optimizer with a learning rate of 2^{-4} and batch size of 8, and we run the training process for 1M steps.

The larger in time the input mixture spectrograms are, the more bins to cluster for the final mask estimation. While using an oversized spectrogram may lead to a complex clustering problem given the variations in playing intensity, few points may hinder the estimation of the clusters. Given the improvisatory nature of CM, we propose to use chunks of 3 seconds in order to be robust to the recurrent changes in intensity and dynamics of the performers.

Since we operate on magnitude spectrograms, we require the phase information to reconstruct the estimated audio signals. Here we reuse the phase from m , which is not ideal but it is fast and broadly used in the MSS [2].

3.1.1 Objective evaluation

We evaluate the models on a real-audio test set we record for the purpose of this work. It includes $\approx 2h$ of music and two different singers (male and female). Bleeding-free tracks for violin, mridangam, and tanpura are also available. We split the tracks into chunks of 30s, slightly mod-

ifying the mixing parameters to enrich the diversity in the dataset. The tracks are mixed with the assistance of an audio engineer. The testing set is made available for reproducibility and further MSS research.

MSS is commonly evaluated objectively using the BSS_Eval metrics [33]: (1) SDR: overall quality, (2) SIR: intrusiveness of the other sources in the estimated source, and (3) SAR: quality of the estimated source. For particular music genres SDR may not correlate with perceptual quality [34–37]. Thus, we run a subjective evaluation in which we contrast the two dimensions captured by the objective evaluation: interference removal (SIR) and signal quality (SAR). This is a common experimental setup in perceptual evaluation of MSS [38]. Therefore, we put more emphasis on these metrics on our objective evaluation as well, rather than comparing solely SDR. Note that our method allows for selecting the desired level of interference at the expense of signal artifacts. Therefore, we aim at covering two scenarios: creative tasks e.g. practicing or mixing, and analysis tasks, e.g. melody estimation.

In a first experiment we compare our system using three different configurations with a baseline U-Net model trained with raw Saraga as regular MSS models are. A second experiment is intended to compare our system with: (1) our cold diffusion model skipping the unsupervised clustering mask estimation, and (2) Spleeter [3], a widely used model in the literature, also in computational analysis works for CM. We include this comparison considering that Spleeter is trained using a much larger dataset with an unknown distribution. To the best of our knowledge, no Carnatic-specific separation models are available in the literature. In the latter experiment we report the absolute SIR and SAR difference of our models w.r.t. the alternatives aiming at providing an intuitive comparison in terms of interference removal and vocal signal quality. We compute the global MSS metrics [15] for all testing samples using the latest `museval` version [39], and we compute the median to be robust to extreme cases in the testing set.

3.1.2 Perceptual evaluation

Despite the efforts to enhance the variety within our testing set, it is restricted in size and all recordings are obtained from the same source. This is added to the fact that the objective metrics in [40] may not always correlate with the perceptual quality of MSS estimations [34]. For these reasons, we run a perceptual test with subjects including samples from the non-multi-track recordings in Saraga (≈ 17 h) – which were not included in the training set for our models, and ensuring there are no overlapping artists – and from the private collection of the Dunya database [41]. We first randomly sample 50 recordings from the said data collections, and we extract the singing voice from a randomly selected 30s chunk for each recording. Using the mixture as reference, we manually collect 6 examples from the batch of separations ensuring that the test includes different audio qualities, gender balance, and tonic diversity.

We design an online survey based on the MUSHRA framework [42]. We request the participants to rate, from 1

	C	F	SDR	SIR	SAR
Baseline	-	-	6.10	10.71	8.16
Ours	3	1	5.88	13.69	6.72
Ours	4	2	5.12	14.94	5.57
Ours	5	3	4.56	15.84	4.68

Table 1. Comparison of the baseline with three configurations for our system. C is no. of clusters and F the weight factor. Results are given in dB.

to 5, the vocal quality and the intrusiveness of other sources *separately*. The participants are shown the mixture as a reference and two stimuli: our system with $C = 5$ and $F = 4$, and Spleeter. The test includes a tutorial stage with examples – these are not shown during the actual test and are not passed through any of the evaluated models – to make sure the participants have the difference between distortion and intrusiveness from other sources clear. We randomize the order of the stimuli at each example, to prevent the order from having an impact on the ratings. The proposed subjective evaluation follows closely the ITU-T P.835. We include a short survey in the test to collect information on the expertise of the subjects on MSS and CM.

For each testing example, we compute the mean and standard deviation of all rankings. We finally report the mean and standard deviation over the 6 excerpts. The deviation serves as an indicator of the sparsity of the opinions.

3.2 Results

3.2.1 Objective results

We first compare, on our testing set, our system with $T = 8$ and three different cluster configurations with the baseline U-Net separation model. Results are shown in Table 1. The baseline system is more prone to leak other sources in the estimated vocals given the source bleeding in the training data, while it better preserves the quality of the target source. On the other hand, our system further eliminates the CM instrumentation from the input signal. However, additional masking comes with a drawback and especially in the case of CM where all instruments are pitched and tuned in the same tonic. That produces an important overlap, especially between vocals and violin. Therefore, by removing more interference, we are penalizing the quality of the singing voice.

Related to the latter observation, we confirm the adaptability of our system. The more clusters we consider and remove, we achieve better interference removal at the expense of a loss of vocal quality. However, as seen in Table 1, this is translated into worse SDR values. In the perceptual evaluation we study how these metrics correlate with the perceived quality of the estimations.

In Table 2 we report the difference in SIR and SAR (denoted, respectively, SIRd and SARd), first between two versions of our system (with and without clustering), and second between our system and Spleeter. Using roughly all tested configurations, our system is able to outperform the

		No clustering		Spleeter [3]	
		SIR	SAR	SIR	SAR
		9.39	10.28	14.21	10.95
Comparison of our system with $T=8$					
Config		vs. No clustering		vs. Spleeter [3]	
C	F	SIRd	SARd	SIRd	SARd
2	1	+4.70	-3.43	+0.14	-4.09
3	1	+4.31	-3.56	+0.52	-4.22
3	2	+5.46	-4.49	+0.64	-5.16
4	2	+5.55	-4.71	+0.72	-5.38
4	3	+6.41	-5.53	+1.60	-6.20
5	2	+5.61	-4.69	+0.78	-5.35
5	3	+6.45	-5.59	+1.63	-6.26
5	4	+7.14	-6.25	+2.32	-6.91

Table 2. SIR and SAR difference of our full system with (1) our system with no un-sup. mask estimation and (2) Spleeter. Results given in dB, + indicate that we improve. On top, we provide the absolute metrics of the alternatives for reference. C is no. of clusters and F weight factor.

alternatives in terms of interference removal, better characterizing and cleaning the Carnatic accompaniment from the singing voice, suggesting that we are taking advantage of the in-domain data despite the bleeding. Note also the SIR improvement – more than 4dB in the worst case – that the unsupervised masking provides on top of the last step of the cold diffusion model, which can only estimate, at most, the vocals with bleeding. That is the problem of using data with bleeding for training supervised MSS systems.

However, our system tends to perform worse in signal quality. This may be given by frequency components of the singing voice that are being removed while performing the unsupervised mask estimation, especially those living in the bins shared with other sources. On the other hand, Spleeter maintains a more complete singing voice despite being more prone to interference. We perceptually note that our estimations are *dryer*, while Spleeter is able to better capture components such as reverb and high-frequency details. This may be explained by the much larger training dataset comprising several different vocal styles and effects. In our case, given the proposed schedule and diffusion steps, these components may be partially living on the shared clusters and therefore negatively affected as we use a more restrictive parametrization.

Note the small difference in SAR between our system with no clustering-based masking and Spleeter. Said observation suggests that the cold diffusion process preserves the vocal quality roughly as Spleeter achieves so. That may also explain why masking the last cold diffusion step \hat{X}_0 provides an improved output over masking the mixture M .

3.2.2 Perceptual results

We run the MUSHRA test on 25 subjects. From the population, $\approx 44\%$ of the subjects have mid-to-high expertise

	Mean Opinion Scores (MOS)	
	Vocal quality	Vocal isolation
Ours ($C=5, F=4$)	2.80 ± 0.29	3.72 ± 0.31
Spleeter [3]	3.73 ± 0.17	1.97 ± 0.19

Table 3. Comparison between our system and Spleeter [3] on a perceptual test. Min=1 / Max=5, the higher the better.

in MSS, while $\approx 48\%$ have listened CM at least once.

The results of the MUSHRA test (see Table 3) on the intrusiveness of other sources – or how well the vocals are isolated – present a notable correlation with the SIRd in Table 2, suggesting that our model is able to better eliminate the Carnatic instruments from the separated singing voice. Another relevant aspect that we observe is that while Spleeter is still leading on source quality, the scores are more balanced between both models than what the SARd metrics in Table 2 suggest. That may be an indicator that the singing voice components erroneously removed by our model – which notably penalize metrics-wise – are not notably perceivable to the naked ear. All deviations of participant rankings per example are < 1 , suggesting that generally there is a disagreement of 1 point at most. Additionally, we run the Wilcoxon signed-rank test for paired data on each example, observing for all cases a p-value < 0.05 , indicating that the subject ratings were not given randomly.

4. CONCLUSIONS

We present a system that uses an entire cold diffusion process as features to perform singing voice separation when no isolated ground-truth sources are available, and we solely have the mixture and the target source with bleeding at hand for training. The cold diffusion process, which iteratively transforms a mixture into the target source with bleeding, allows for unsupervised clustering to build the final separation masks. We run our approach on the Saraga dataset, a large Carnatic collection of multi-track audio with bleeding. Despite being trained solely using these data, our model is able to better eliminate the Carnatic instruments from the singing voice than Spleeter, the most commonly used model in computational research for this repertoire, which is trained on a much larger private dataset of clean signals. Albeit the source separation metrics suggest that our system performs worse in terms of vocal distortion, perceptual tests on a dedicated test set suggest that the proposed system trained with noisy and considerably fewer data than Spleeter is competitive with the said system. This will allow to scale up our system since new in-domain data with bleeding are easier to compile than clean data, especially for under-represented music cultures.

As further research, we propose to investigate different schedules, while exploring more sophisticated clustering techniques, aiming at improving source distortion. We also aim at running the proposed pipeline for the other available instrument tracks in Saraga: violin and mridangam.

5. ACKNOWLEDGEMENTS

This work was carried out under the projects Musical AI - PID2019-111403GB-I00/AEI/10.13039/501100011033 funded by the Spanish Ministerio de Ciencia, Innovación y Universidades (MCIU) and the Agencia Estatal de Investigación (AEI). We would also like to acknowledge the 25 subjects that took the perceptual test and Xavier Lizarraga for the assistance on mixing the testing set.

UNVEILING THE IMPACT OF MUSICAL FACTORS IN JUDGING A SONG ON FIRST LISTEN: INSIGHTS FROM A USER SURVEY

ABSTRACT

When a user listens to a song for the first time, what musical factors (e.g., melody, tempo, and lyrics) influence the user's decision to like or dislike the song? An answer to this question would enable researchers to more deeply understand how people interact with music. Thus, in this paper, we report the results of an online survey involving 302 participants to investigate the influence of 10 musical factors. We also evaluate how a user's personal characteristics (i.e., personality traits and musical sophistication) relate to the importance of each factor for the user. Moreover, we propose and evaluate three factor-based functions that would enable more effectively browsing songs on a music streaming service. The user survey results provide several reusable insights, including the following: (1) for most participants, the melody and singing voice are important factors in judging whether they like a song on first listen; (2) personal characteristics do influence the important factors (e.g., participants who have high openness and are sensitive to beat deviations emphasize melody); and (3) the proposed functions each have a certain level of demand because they enable users to easily find music that fits their tastes. We have released part of the survey results as publicly available data so that other researchers can reproduce the results and analyze the data from their own viewpoints.

1. INTRODUCTION

When a user listens to a song for the first time on a music streaming service and it matches her taste, she may listen to it until the end or add it to her favorites or a playlist. On the other hand, if the song does not match the user's preferences, she may stop playing it partway through [1,2]. By accumulating logs of such listening behaviors, music streaming services can estimate users' music preferences and implement functions such as recommendations [3,4].

However, when a user first listens to a song and decides whether or not she likes it, which musical factors influence the decision? For example, one user may like a song because of its lyrics, another may like it because of its melody, and third may like it because of the sound of a musical instrument. Several prior studies investigated

people's preferred musical factors [5–7]. However, those studies targeted songs that the study participants already liked and investigated the reasons for liking those songs in terms of factors that were specific to the songs. Accordingly, when a participant answered that she liked a certain song because of its lyrics, it was unclear that she would always judge whether she liked or disliked a song because of its lyrics. Thus, despite those studies, there is a lack of research on the musical factors that influence people's judgment on whether they like a song on first listen. This lack of research motivates our first research question:

RQ1 When people listen to a song for the first time and judge whether they like it, which musical factors affect this judgment, and to what extent?

To more deeply understand how people interact with music, the effects of users' personality traits and musical sophistication on their music preferences and listening behaviors have also been studied [5,8–21]. For example, it has been reported that people with high openness tend to show a preference for folk music [16] and that musical sophistication positively influences recommendation acceptance [20]. Following such studies, we address the second research question:

RQ2 How do people's personality traits and musical sophistication affect the importance of each musical factor in judging whether they like a song?

If a certain musical factor influences judgments about song preferences, it would be useful to propose practical examples of its engineering use. In fact, proposed improvements to the functions of music streaming services from user study results have provided useful insights to the music information retrieval (MIR) community [22–35]. Hence, we investigate a third research question:

RQ3 What are the implications of musical factors for the functions of music streaming services?

To address these research questions, we targeted 10 musical factors and conducted a questionnaire-based online user survey involving 302 participants. Our main contributions can be summarized as follows.

- We reveal that the factors of *melody* and *singing voice* have large influences on music preference judgment, whereas the factor of *danceability* has a small influence.
- From a psychological perspective, we show that both personality traits and musical sophistication affect the importance of the various musical factors. Given these results, we discuss the possibility that the important factors for a particular user could be estimated from the user's listening behaviors on a music streaming service.

- From an engineering perspective, we propose three functions that would enable users to effectively browse songs by leveraging musical factors, and we show that each function has a certain level of demand.
- We have made the English translation of the survey questionnaire and the survey results publicly available on the web to support future studies¹.

2. RELATED WORK

2.1 Musical Factors

Understanding why people listen to music has been of interest to researchers. One typical research direction focuses on the motivation to listen to music in daily life. The main reasons include emotional reasons such as relaxation [18, 36–39] and relief [40, 41]. People also listen to music to concentrate and to pass time [42].

Another research direction investigates the reasons for listening to specific preferred songs in terms of musical factors. Greasley et al. [6] conducted interviews about participants’ music collections. Among the main reasons why the participants liked their collections were musical factors such as the lyrics and instruments. Sanfilippo et al. [7] asked participants to sample two songs from their music library on a listening device and answer questions such as “why do you enjoy listening to the track?” The participants often answered the questions by using a vocabulary of musical factors. Boyle et al. [5] investigated the influence of musical factors on young people’s pop music preferences. Each participant listed his/her three favorite pop songs and rated the importance of various musical factors in liking those songs. The results revealed that melody, mood, and rhythm had large influences. Although these studies investigated the influences of musical factors, they focused on only songs that the participants already liked. Our study is different in that we focus on the musical factors that people emphasize when they listen to a song for the first time. Since there is a vast number of songs that people have not yet listened to, investigating such factors is beneficial to support finding songs that match their preferences.

2.2 Personal Characteristics

In the music domain, user’s preferences, interests, and behaviors are influenced by personal characteristics. In particular, many studies have investigated the influences of personality traits measured by the Big Five Inventory [8–14, 16, 17, 43–47]. For example, personality has significant associations with genre preferences [11, 13, 14, 16, 43] and audio preferences [47]. It also influences the desired level of diversity in a recommended song list [46]. Ferwerda et al. [45] revealed that when a user browses for music, the preferred taxonomy (mood, activity, and genre) depends on the user’s personality. Such personality-based results can be used for personalization. In fact, several studies have shown increased recommendation quality when personality is incorporated [48–51]. Musical sophistication is another typical personal characteristic that influences

music preferences. For example, musically sophisticated users listen to more diverse songs on both the artist and genre levels [52], are more familiar with the songs in a recommended song list [53], and prefer a less personalized playlist [19]. These findings can also be used to improve music recommendations and user interfaces. Following those studies, we investigate the influences of personality traits and musical sophistication on the importance of musical factors, and we suggest how its results can be used to improve the recommendations.

2.3 Design and Function Proposals

For user studies on music listeners’ needs, preferences, and behaviors, it is common to not only report the results but also propose designs and functions to improve music services by applying the results [22–35]. Such proposals have provided reusable insights for the MIR community. Examples of these proposals include song recommendations according to the user’s attention level [27], support for remote co-listening with a friend [31], and support for users to add their interpretations of lyrics [33]. Inspired by those prior studies, we propose three functions that enable music streaming services to leverage musical factors. Whereas the above studies only proposed designs and functions, we also conducted a user study to evaluate users’ willingness to use the proposed functions.

3. PARTICIPANTS

We recruited participants for our user study via an online research company in Japan. We limited the participants to those who were Japanese and listened to music an average of at least one day per week via any music streaming service. The participants answered our questionnaire through a web browser. We paid about 13.21 USD (1,750 JPY) to each participant. Although 354 participants answered the survey, to make the analysis results more reliable, we removed the answers from 52 participants who submitted improper responses to a free-response question. The remaining 302 participants were diverse in both gender and age range: 147 male (10s: 4; 20s: 31; 30s: 33; 40s: 44; 50s: 35) and 155 female (10s: 9; 20s: 39; 30s: 35; 40s: 34; 50s: 38). Hereafter, we report the results obtained from the 302 participants including section 6.

4. INFLUENCE OF MUSICAL FACTORS

4.1 Musical Factors

Referring to prior studies on people’s favorite songs [5–7, 54], we targeted the following 10 musical factors that may influence a person’s judgment of liking or disliking music on first listen: *melody, singing voice, rhythm, lyrics, mood, tempo, harmony, sentiment, instruments, and danceability*. Although these 10 factors are not completely independent each other (e.g., there would be relatively high correlation between *mood* and *sentiment*), we adopted them to analyze as many factors as possible. In this study, all of these factors were determined entirely from the music. That is, we did not consider social factors that depend on the context of the music or the listener (e.g., the artist’s image, the popularity of music, and whether music was introduced by a

Figure 1. Importance distributions of musical factors (x-axis: number of participants).

friend). Rather, as this is an initial study on the influence of musical factors for judging a song on first listen, we leave the investigation of such social factors for future work.

4.2 Procedure

For each musical factor, we first showed the participants the factor’s name, its meaning, and a question. In the case of *instruments*, for example, we showed the following description to represent its meaning: “*Instruments* means the type of instruments used in the piece and their sounds.” Similarly, we showed the following question: “How important is the *instruments* in judging whether you like or dislike a song on first listen?” The possible answers were “not important,” “hardly important,” “somewhat important,” “important,” and “very important.” When the answer for a factor was “not important” or “hardly important,” the participant was asked to respond freely on why it was unimportant. On the other hand, when the answer was “somewhat important,” “important,” or “very important,” the participant was asked to respond freely with at least one criterion for judging that he/she liked or disliked a song according to the factor. The 10 musical factors were displayed in a random order to each participant.

Note that in this survey, we asked the participants to answer the questions without actually listening to music to avoid answer bias caused by the music they listened to for the survey. Instead, they were asked to imagine daily situations where they listen to a song for the first time and rate the importance of each factor. This type of survey, which involves imagining a certain situation, is an established survey method in the MIR community [27, 31, 55–59].

4.3 Results

Figure 1 shows the importance distribution for each factor. We can see that the importance was high for *melody* and *singing voice*; in fact, paired Wilcoxon signed-rank tests with Bonferroni correction revealed that their medians (i.e., 4) were statistically higher than the medians of the remaining eight factors at $p < 0.01$. Among the remaining eight factors, more than half of the participants gave a rating of 3, 4, or 5 for *rhythm*, *lyrics*, *mood*, *tempo*, *harmony*, and *sentiment*. To more deeply understand the relationships between factors, we show the Spearman’s rank correlations between them in Figure 2. There were high (> 0.4) correlations between *rhythm* and *tempo*, *mood* and *sentiment*, and *melody* and *singing voice*. Although *lyrics* had a relatively high average importance, it had low (< 0.3) correlations with all other factors. *Danceability*, which had

Figure 2. Spearman’s rank correlations of importance between musical factors.

the lowest average importance, showed a similar tendency.

For each factor, to analyze the free responses on criteria for liking a song, we manually grouped the responses. Because we allowed the participants to give more than one criterion, each participant’s response could be assigned to more than one group. Similarly, we grouped the responses on criteria for disliking a song and reasons for the unimportance of certain factors. Here, we omit the reasons for unimportance, because the most common response for all factors was “I am not interested in this factor.” On the other hand, the criteria for liking or disliking a song were diverse, as seen in Table 1, which lists the top three criteria for each factor in terms of the group size. Many criteria involved opposite terms for liked and disliked songs: in the case of *tempo*, for example, participants who gave “fast” as a criterion for liking a song tended to give “slow” as a criterion for disliking a song. In addition, the second column indicates that, for all factors, more participants gave criteria for liking a song than for disliking a song, which means that it was more common to have criteria for liking a song than to have criteria for disliking a song. An interesting application of this finding would be to use criteria for liking a song in explainable recommendation. For example, when a song is recommended to a user who emphasizes *melody*, she may be more willing to listen to it if it appears with an explanation such as “this song is recommended to you because the melody is easy to remember.”

The results in Figure 1 are somewhat similar to those reported by Boyle et al. [5] (e.g., *melody* and *rhythm* had high importance, while *danceability* had low importance). Nevertheless, we provide three contributions that are distinct from their results: (1) our results are more generalized, because we did not focus on a specific genre and age group, whereas they focused on young people’s pop music preferences; (2) we analyzed the correlations between factors and the criteria for each factor; and (3) we will publish the survey results on the web to support later studies.

5. INFLUENCE OF PERSONAL FACTORS

5.1 Personality Traits

Procedure. We measured the participants’ personality traits in terms of five aspects (i.e., *openness*, *conscientiousness*, *extraversion*, *agreeableness*, and *neuroticism*) by using the 29-item Big Five Inventory (BFI) on a 7-point scale (1: strongly disagree - 7: strongly agree) [60]. We used the BFI because of its popularity in past studies [8–14, 16, 17, 43–47] compared to other traits such as

Table 1. Top three criteria for judging “like” and “dislike,” for each musical factor. Each number in parentheses indicates the number of participants who responded with the corresponding criterion.

Factor		1st	2nd	3rd
Melody	Like (265)	Easy to remember (35)	Easy to sing or hum (33)	Feels comfortable (28)
	Dislike (193)	Too loud (18)	Difficult to sing or hum (16)	Feels uncomfortable (15)
Singing voice	Like (261)	Specific type (beautiful, powerful, soft, etc.) (74)	Voice to my liking (54)	Feels comfortable (51)
	Dislike (203)	Feels uncomfortable (50)	Specific type (raspy, piercing, etc.) (47)	Voice not to my liking (28)
Rhythm	Like (237)	Groovy (53)	Feels comfortable (23)	Rhythm to my liking (19)
	Dislike (167)	Rhythm not to my liking (17)	Slow (16)	Not groovy (15)
Lyrics	Like (218)	Sympathetic (71)	Inspirational (41)	Positive (10)
	Dislike (164)	Unclear meaning (41)	Lack empathy (30)	Pedestrian (26)
Mood	Like (219)	Cheerful (51)	Fits my mood/situation (25)	Calm (21)
	Dislike (162)	Gloomy (32)	Too loud (29)	Feels uncomfortable (12)
Tempo	Like (220)	Fast (40)	Groovy (29)	Feels comfortable (24)
	Dislike (163)	Slow (48)	Fast (31)	Feels uncomfortable (15)
Harmony	Like (174)	Feels comfortable (43)	Beautiful (23)	Harmonious (22)
	Dislike (116)	Feels uncomfortable (25)	Monotonous (7)	Inharmonious (6)
Sentiment	Like (163)	Positive (33)	Inspirational (30)	Sympathetic (25)
	Dislike (114)	Negative (32)	Evokes no emotion (12)	Doesn't fit my mood/situation (7)
Instruments	Like (146)	Include specific instruments (24)	Fit the song (17)	Feel comfortable (15)
	Dislike (102)	Too loud (24)	Feel uncomfortable (11)	Don't fit the song (7)
Danceability	Like (66)	Body moves naturally to music (13)	Groovy (11)	Rhythmic (9)
	Dislike (46)	Not groovy (6)	Gloomy (5)	Rhythm is bad (4)

opinion leadership [15].

Results. Table 2 lists the Spearman’s rank correlations between the personality traits and the importance of each musical factor. *Openness* had significant correlations with as many as seven factors. That is, participants with higher *openness* had more diverse criteria for judging whether a song fits their taste. This result is similar to a previous finding that people with high *openness* tended to listen to more diverse songs in terms of genres [16]. Similarly, *extraversion* also had significant correlations with many factors, particularly, *danceability*. This result echoes a report that people with high *extraversion* tended to listen to songs with high danceability on a music streaming service [51]. *Conscientiousness* was the only trait that had a significant correlation with *sentiment*. Both *agreeableness* and *neuroticism* had significant correlations with as few as two factors. These results are similar to a previous finding that those traits showed significant correlations with few genres [16].

Prior studies correlated personality traits with genre preferences and music audio preferences [16, 47]. For example, people who often listen to folk music were found to have high *openness* [16]. As seen in Table 2, people with high *openness* emphasize *lyrics*; accordingly, for a user who often listens to folk songs, it would be helpful to recommend songs according to the similarity of lyrics.

5.2 Musical Sophistication

Procedure. To measure the musical sophistication, we used the following nine questions on a 7-point scale.

1. InstExp: I engage in regular, daily practice of a musical instrument (1: never - 7: ≥ 10 years).

- DanceExp: I engage in regular, daily dancing (1: never - 7: more than 10 years).
- NoticeBeat: I can tell when people sing or play out of time with the beat (1: strongly disagree - 7: strongly agree).
- NoticeTune: I can tell when people sing or play out of tune (1: strongly disagree - 7: strongly agree).
- LsnMusic: I listen to music (1: < 15 minutes per day - 7: ≥ 4 hours per day).
- LsnNew: I listen to music that is new to me (1: < 1 song per month - 7: ≥ 31 songs per month).
- ViewLyrics: I view lyrics while listening to music (1: < 1 song per month - 7: ≥ 31 songs per month).
- Karaoke: I sing karaoke (1: < 1 time per year - 7: ≥ 4 times per week).
- AttEvt: I attend live music events as an audience member (1: < 1 time per year - 7: ≥ 11 times per year).

Questions 1, 3, 4, 5, and 9 derive from the Goldsmiths Musical Sophistication Index (Gold-MSI) [61]. In addition, we asked four questions of our own (questions 2, 6, 7, and 8). For questions 5-9, we asked the participants to give the average frequencies of those behaviors.

Results. Table 3 lists the Spearman’s rank correlations between musical sophistication and the importance of each musical factor. Overall, many of the results matched our intuition. For example, DanceExp had a significantly high correlation with *danceability*; participants who were sensitive to beat and tune deviations emphasized audio-based factors such as *melody*, *singing voice*, and *harmony*; and ViewLyrics had the highest correlation with *lyrics*. It is also convincing that participants who often sang karaoke emphasized *lyrics*; those who often attended live music

Table 3. Spearman’s rank correlations between musical sophistication and the importance of each musical factor (N=302). Significant correlations are shown in bold (*: $p < 0.05$; **: $p < 0.01$; ***: $p < 0.001$).

Figure 3. Overview of the three proposed functions. In the user study, these images were presented to the participants.

events emphasized both *lyrics* and *danceability*; and InstExp had a significant correlation with *harmony*. Table 3 also indicates certain high correlations that are not obvious (e.g., between LsnMusic/LsnNew and *lyrics* and between LsnNew and *danceability*).

Certain metrics, such as LsnMusic, LsnNew, and ViewLyrics, can be computed for each user on a music streaming service [59,62,63]. Thus, the results in Table 3 can also be used to increase the confidence in estimating the importance of each factor to a user without explicitly asking the importance. For example, if a user often listens to folk music (i.e., the user would have high *openness* as has been reported by Ferwerda et al. [16]) and new songs, we can estimate from the results in Tables 2 and 3 that *rhythm* is one of the user’s important factors. Hence, the user would be more likely to accept recommendations by recommending songs according to the similarity of their rhythms.

6. FUNCTIONS BASED ON MUSICAL FACTORS

In section 4, we showed that certain musical factors influence a person’s judgment of liking or disliking a song on first listen. Following those results, in this section, we propose three functions, illustrated in Figure 3, that could enrich and diversify the music listening experience on streaming services. Then, we investigate the usefulness of these functions from the results of a user study.

6.1 Functions

6.1.1 Function 1: Registration of Factor Importance

With this function, shown in Figure 3 (a), users register the importance of each of the 10 musical factors on a 5-point scale when judging whether they like or dislike music on first listen. It is not necessary to register the importance of all factors. For example, the importance of *rhythm* is not registered in Figure 3 (a). The registration process only needs to be done once, and the registered information can be changed later.

This function supports the users as follows. Suppose that a user is listening to her favorite song *s*. The user has registered *lyrics* as “very important” and *tempo* as “hardly

important.” Hence, among songs that are new to this user, we can recommend songs that have various tempos and similar lyrics to *s*. By listening to the recommended songs, the user can find new favorite songs.

6.1.2 Function 2: Evaluation of Songs by Factors

This proposed function allows users to rate their song preferences on a factor-by-factor basis, as shown in Figure 3 (b). The ratings are not mandatory: users only need to rate the songs that they want to rate. In addition, they do not need to rate songs in terms of all 10 factors. For example, in the figure, the user does not rate *mood*. For each song, by computing the average value of all users’ rating results for each factor, we can display others’ evaluations (averaged ratings) like those shown in Figure 3 (b).

This function supports the users as follows. Suppose that a user is interested in an artist named “Betty,” and that *danceability* is an important factor for the user. Then, songs by “Betty” can be sorted and displayed in order of the averaged ratings for *danceability*. This enables efficient discovery of songs that match the user’s preferences.

6.1.3 Function 3: Presentation of Factor Information

With this function, information on factors that a user wants to know for a song is displayed as shown in Figure 3 (c). The information on each of the 10 factors can be automatically estimated by using techniques from existing studies [64–70]. Thus, unlike the two previous functions, this one does not require the user to input any information.

This function supports the users as follows. When a user checks a list of newly released songs, usually only basic information such as the artist and title is displayed for each song. In contrast, our proposed function can display information on the musical factor for each song. For example, if the user prefers slow-tempo songs with piano, she can listen only to such songs by referring to the displayed information on *tempo* and *instruments*. This allows the user to efficiently find songs that match her preferences among a vast number of new songs.

Table 4. Top three free-response reasons for “reasonably willing” or “willing” to use each of the proposed functions. Each number in parentheses indicates the number of participants who gave that reason.

	Function 1: registration of factor importance	Function 2: evaluation of songs by factors	Function 3: presentation of factor information
1st	Easy to find music that fits my taste. (46)	Would like to refer to others’ evaluations. (22)	Easy to find music that fits my mood/situation. (27)
2nd	Helpful for listening to new songs. (33)	Easy to understand others’ evaluations. (14)	Easy to find music that fits my taste. (26)
3rd	Looks interesting to use. (11)	Easy to find music that fits my taste. (13)	Helpful for listening to new songs. (16)

Figure 4. Distribution of the willingness to use each of the proposed functions (x-axis: number of participants).

6.2 Procedure

For each function, we showed the participants an overview of the function and examples of the user support that the function would enable as we described in section 6.1². The participants were asked to indicate their willingness to use the function, on a 5-point scale (“unwilling,” “not very willing,” “undecided,” “reasonably willing,” and “willing”), if it were implemented on the music streaming service that they used regularly. They were also asked to provide free responses on their willingness. The three functions were displayed in a random order to each participant.

6.3 Results

Figure 4 shows the answer distribution for each function. Functions 1 and 3 were more positively received than function 2. To analyze the results, we manually grouped negative responses (i.e., the free responses for “unwilling” and “not very willing”). As we had anticipated, a reason of “I do not need the function” was common for all three functions. Regarding function 2, although we explained that the ratings were not mandatory, a response of “It is tedious to rate songs” was also common. This is why the distribution for function 2 was more biased in the negative direction. Here, note that our goal was not to propose functions that all participants would be willing to use. Rather, we sought to confirm that the proposed functions would have a certain level of demand; accordingly, the results in Figure 4 indicate that we achieved our objective.

We also manually grouped the positive responses (i.e., the free responses for “willing” and “reasonably willing”). Table 4 lists the top three responses in terms of the group size for each function. We can see that, in general, the participants tended to appreciate functions that would make it easy to find music that fits their taste (all functions) and easy to listen to new songs (functions 1 and 3). The responses for function 2 also indicate that they were interested in referring to other users’ evaluations of a song. We can also see that the participants felt it was valuable to be able to find music according to their mood or situation (function 3). These responses provide reusable insights for later studies: when researchers or streaming services pro-

pose a new function, such user demand could serve as a useful guideline for its design.

If function 3 were implemented on a music streaming service, it might be difficult to estimate the information for all factors because of the platform’s resource limitations. In such a case, a possible solution would be to decrease the number of displayed factors according to the results shown in Figure 2. For example, *rhythm* information could be omitted, because *tempo* has a high correlation with *rhythm*, and users who emphasize *rhythm* could thus refer to *tempo* information instead. In contrast, *lyrics* should not be eliminated because it has low correlations with the other factors, and there would not be no alternative factor for users who emphasize *lyrics*.

7. CONCLUSION

In this paper, we conducted an online user survey involving 302 participants. The reusable insights obtained from our user survey can be summarized as follows.

- We showed that the *melody* and *singing voice* are important for most participants. Because there were trends in the criteria for each factor, as seen in Table 1, the criteria could be used to increase the explainability of song recommendations, as discussed in section 4.3.
- Personality and musical sophistication influence the importance of each musical factor. As discussed in sections 5.1 and 5.2, these results would be useful for estimating which factors are important to a user from the user’s listening behaviors on a streaming service.
- The evaluation results for our proposed functions show that there is a certain demand for functions that enable users to browse songs according to musical factors. The reasons for each function’s demand in Table 4 could provide guidelines for other researchers and services to propose novel factor-based functions.

Finally, we acknowledge a limitation of this paper in that all the participants in our user study were Japanese. Because peoples’ music preferences and listening behaviors, as well as music itself, vary widely from country to country [26, 71–76], not all of the findings reported here can be generalized. Nevertheless, we believe that our study provides a worthwhile contribution to the MIR community as a first step toward understanding how musical factors influence whether people like a song on first listen. At the same time, the above limitation can guide future work such as investigating the differences in important musical factors among countries and cultures. The publicly available dataset of results from our user study will enable researchers not only to perform such comparisons but also to analyze and compare results from different viewpoints.

² We leave it as future work to actually implement these functions and conduct a long-term user study on them including how to visualize the information.

ABSTRACT

The historical development of medieval plainchant melodies is an intriguing musicological topic that invites computational approaches to study it at scale. Plainchant melodies can be represented as strings from a limited alphabet, hence making it technically possible to apply bioinformatic tools that are used to study the relationships of biological sequences. We show that using phylogenetic trees to study relationships of plainchant sources is not merely possible, but that it can indeed produce meaningful results. We develop a simple plainchant substitution model for Multiple Sequence Alignment, adapt a Bayesian phylogenetic tree building method, and demonstrate the promise of this approach by validating the resultant phylogenetic tree built from a set of Divine Office sources for the Christmas Vespers against musicological knowledge.

1. INTRODUCTION

Gregorian chant is the universal sacred liturgical monody of the Roman Catholic church, which exerts strong control over this musical tradition. There is an authoritative edition of chant: if singers from multiple countries and continents sing together, each from their print of liturgical books, they should encounter no conflicts in performance. However, this was not always so. During the five hundred years of notated Gregorian chant manuscript culture, between Guidonian staff notation and the introduction of the post-Tridentine printed liturgical books, rarely was a chant melody written exactly the same in two sources.¹ Despite its stated role as a unifying element of the Roman Catholic church, Gregorian chant was a diverse tradition.

The diversity of Gregorian chant, both in terms of repertoire and melody, has been a staple of musicological study

¹ See cf. a sample of melodies of an antiphon: <https://cantusindex.org/id/004237>

of plainchant [1, 2]. Already the relative importances of chronology, geography, and *cursus*² are, aside from select topics such as the Cistercian reform, not well understood. Recent chant scholarship thrives on the large-scale digitization effort centered around the Cantus Index network of databases [3], and there are ongoing efforts to apply digital methods to the problem of chant transmission such as the DACT project.³

In this pilot study, we present a novel pipeline to model the relationships between chant sources using tools from bioinformatics: we adapt multiple sequence alignment and phylogenetic tree inference for chant melodies. We qualitatively evaluate the method on a dataset of sources for Christmas Eve vespers.⁴

2. RELATED WORK

The study of melodic dialects of chant has a long tradition, most prominently in the distinction proposed between “West Frankish” and “East Frankish” chant [4], as has the theory of chant melody in general (i.a. the centonization hypothesis [5, 6] and its criticism [7], [8, pp. 74-75]), but has not yet been performed with computational models at the scales that these enable. The fact that the diversity within chant melodies is a subject worthy of study is further reinforced by the debate on early chant as an orally transmitted tradition [9, 10], justifying an ethnomusicological perspective [11], although the extent of orality of the tradition has since been contested [12]. The formulaic structure of great responsories has been studied in detail [13], even in the pre-computer era [14].

Work on larger-scale computational analysis of chant melodies has recently been done in the area of melody segmentation [15], measurement of the melodic arch hypothesis [16] and of the relationship between antiphons and differentiae across modes [16]. Importantly, these works also provide the Cantus Corpus v0.2 database, which presents the contents of the Cantus Database in a manner ready

² The ecclesiastical environment of a manuscript, such as a monastery of a specific order, a city church, a cathedral.

for further processing.⁵ Cantus Index⁶ also provides the Cantus Analysis tool,⁷ which is however built solely for analyzing repertoire, not melodies.

In MIR, the potential for applying bioinformatic tools as string processing models has been previously noted in the context of music similarity search. Tune family identification using Multiple Sequence Alignment (MSA) has been tried [17, 18], and MSAs and BLAST search has been used for melody classification and fast melody retrieval [19], with mixed results.

More closely related to this work in terms of scientific goals, the field of cultural evolution has also been mapping patterns of musical diversity [20], with roots in the Cantometrics project [21]. Most notably, the evolution of folk melodies in English/US and Japanese traditions has been found to exhibit similar properties, using MSAs [22], and phylogeny of electronic music has been mapped using dynamic community detection rather than phylogenetic trees [23], citing limitations of the tree model in light of horizontal cultural transmission. Cultural and biological evolution was correlated in a study comparing populations in terms of genetics and their folk music [24].

Few works in MIR go beyond leveraging MSA as a tool for melodic similarity applications, and in one instance also on chant [25]. From the cultural evolution field have used some phylogenetic models to study music, but so far, not on chant.

3. METHOD

We model the relationships among melodies from a set of chant sources as a phylogenetic tree. The leaves of the chant sources, which carry (artificially ordered) melodies of the selected Cantus IDs in an analogy to how living species carry genes. Each instance of a chant with a certain Cantus ID in each source is a homologous sequence; the collection of melodies from one Cantus ID across sources is here termed a *locus*. The pipeline consists of the following steps:

1. Concatenate cleaned melodies per source (in an arbitrary but fixed order of Cantus IDs)
2. Compute a (partitioned) multiple sequence alignment (MSA) of the concatenated melodies
3. Infer a phylogenetic tree over the MSA

An overview of the pipeline is shown in Fig. 1.

In the Cantus network of databases, chant melodies are transcribed as strings using Volpiano [26]. Volpiano is both a standard for encoding chant melodies in a plain text format,⁸ and a font that renders these strings.⁹ The encoding uses several non-tone characters, such as hyphens to indicate boundaries between neumes, syllables, and words, or barline characters to indicate sections. For our experiments, we have removed non-note characters (retaining

syllable and word separators did not have an appreciable effect on alignment, and would thus unnecessarily complicate the state space).

Any string distance metric can then be used to model between two melodies, and between any two sources (by aggregating the distances between melodies). However, we specifically chose Bayesian phylogenetic trees as the model because (1) their inference procedure can distinguish between similarities that are substantial and those that are the product of chance, (2) the resulting trees, while perhaps not ideal as a model of transmission itself, are optimal results in terms of a clearly defined probabilistic model, and thus have a probabilistic interpretation that directly allows testing hypotheses about the dataset, rather than post-inference normalization of arbitrary similarity scores, (3) the software tools are readily available.¹⁰

3.1 MSA and Score Matrix

Multiple sequence alignment (MSA) was carried out with MAFFT v7.505 [27]. Mafft is used for the alignment of melodies because it is a state-of-the-art MSA tool that allows aligning arbitrary text using custom score matrices, thus allowing to process data which are not standard biological sequences such as DNA and aminoacids. (It has already been used in MIR, precisely for these advantages [28].) with our custom score matrix described below. We used a maximum of 1000 iterations and global pairing.

By default, Mafft aligns arbitrary text by checking whether a given symbol is equal or not to other entries in the alignment. This is not a good model for melodies, as substitutions are *not* equally likely. The default choice for melodic distance, Mongeau-Sankoff distance [29] addresses the unequal costs of substituting different steps of the scale, but it and others are designed for tonal music, which chant predates by several hundred years. We have not in fact found sufficient music-theoretical understanding of chant melodies (and mode) to design a similar scoring function. Therefore, we resort to a basic physical reality: the cost of a substitution is the number of steps between the two notes, thus crudely mimicking how physically different the position in the melody might feel for a singer familiar with the alternative (see Fig. 2). The application of B flats were assigned a low cost because they were commonly applied without modifying considerably the melody. Liquesces were treated as regular notes of the same pitch. We stress that this is by no means a definitive chant scoring matrix, but rather a starting point to search for one.

3.2 Bayesian Inference of Phylogenetic Trees

A *phylogenetic tree* (hereafter: tree) is a graph representing the evolutionary relationships between the objects of study. These trees have long been used in evolutionary biology as a means to depict evolutionary relationships

⁹ <http://www.fawe.de/volpiano/>

¹⁰ This article is not meant to inspire the impression that a large amount of technical work was performed: rather, we find it notable that already with a limited amount of technical work, this method already seems to obtain plausible results.

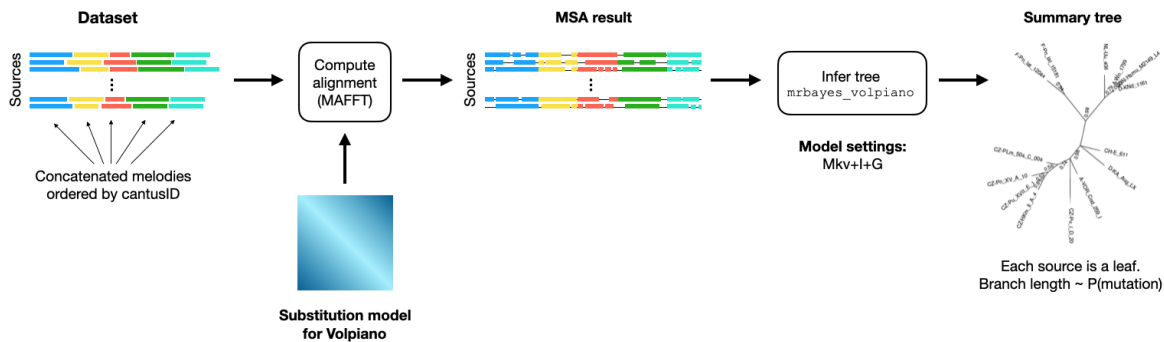

Figure 1. Outline of the pipeline for inference of phylogenetic trees of sources from melodies.

Figure 2. Instances of scores from a reference pitch D. Arrows represent the final pitch and numbers under note bodies represent the score in the matrix. For MAFFT, scores are positive: the furthest distance between pitches is from G3 to D6, which has a score of 1, and the unison has the largest score, which is 19.

among species, and we are here using it to represent the evolution of sources containing melodies in a similar way.

Trees are composed of s leaf nodes of degree 1, called *tips* or *terminals*, and up to $s - 1$ internal nodes of degree 3 which represent ancestors. Trees may have a root node: an internal node of degree 2. If a tree is unrooted, there are up to $s - 2$ internal nodes. Edges are called branches, and they have lengths that represent some amount of evolutionary change – usually (as in our case) the expected number of changes per site.

Bayesian inference has been applied to phylogenetic tree estimation since the 1990s [30] and consists of calculating the posterior probability of the tree parameters (topology and branch lengths) for a given tree τ [31]:

$$f(\tau_i, Q | \mathbf{X}) = \frac{f(\mathbf{X} | \tau_i, Q) f(\tau_i) f(Q)}{\sum_{j=1}^{B(s)} f(\mathbf{X} | \tau_j, Q) f(\tau_j) f(Q)} \quad (1)$$

In this model, $f(\mathbf{X} | \tau_i)$ is called the phylogenetic likelihood function, which gives the likelihood of observing the alignment data given the model of evolution parameters Q and a particular tree τ_i [32, 33]. Both $f(\tau_i)$ and $f(Q)$ are priors for the topology and model of evolution. The topology prior is usually set to be uninformative (uniform over all possible trees). The prior $f(Q)$ is derived from the Mkv+G model, which is the state of the art for morphology-based phylogeny.¹¹ As can be anticipated

¹¹ As opposed to phylogenies built from sequences of nucleotides (DNA/RNA) or amino-acids (proteins), morphology-based phylogeny models mostly model transition probabilities from one to a different character as equally likely.

by the fast-growing number of possible trees for a given set of s terminals $B(s) = \frac{(2s-3)!}{2^{s-2}(s-2)!$, this problem cannot be solved by visiting all possible topologies in order to calculate the normalising constant in the Bayes’ equation, which also, cannot be analytically solved even for a single topology. Therefore, MCMC sampling is used to construct the posterior densities for all the parameters of the model. The output of MCMC consists of inferred parameter values (mostly branch lengths), sampled trees, and the summary tree. The summary tree summarizes the posterior density of topologies in using a majority-rule consensus: it includes all bi-partitions which are at least in 50% of the sampled topologies. Node posterior probabilities are calculated from the relative frequency of bipartitions in the posterior tree density. Inferred trees are in principle unrooted.¹²

Unfortunately, all existing software for Bayesian phylogenetics restricts the input data to some sort of biological data, be it DNA, aminoacid, or morphological data; therefore, we had to adapt an existing tool to process Volpiano-encoded chants. We chose to modify MrBayes v3.2.7a [34]. We call our fork `mrbayes_volpiano`, in order to make clear that it is intended for use *only* with data in volpiano format.¹³ `mrbayes_volpiano` accepts Volpiano-encoded chant melodies as input and analyse them using a Markov model of evolution for an arbitrary number of the discrete character states [35]. It uses all the tools from MrBayes available for standard coding, which is the one applied to melody sequence data and can carry out inference of both single-partition or concatenated settings composed of multiple partitions. It processes alignments in nexus format and can be run both in interactive and scripting mode.

4. CHRISTMAS VESPERS DATASET

In order to test the ability of our pipeline to resolve substantial relationships between chant sources, we apply it on a dataset of Christmas divine office, specifically Vespers for Vigilia Nativitatis Domini. The dataset was originally collected in order to study relationships between

¹² They can be rooted for visualisation e.g. using FigTree (<https://github.com/rambaut/figtree>).

¹³ The source code is available at https://github.com/gaballench/mrbayes_volpiano

late medieval Bohemian sources with the data including transcribed melodies available in the Hymnologica database,¹⁴ and we combined this data with all further melodies available for Vig. Nat. Domini vespers from the Cantus Index interface, in order to cover a broader European context.

The combined dataset contained 14 sources, and a total of 78 chants falling under 6 distinct Cantus IDs. Because the repertoire in office sources is not entirely consistent across sources and our system aligns melodies directly, we had to select a subset of chants contained in as many sources as possible, and then reduce the set of sources to those that contained as many of these chants as possible. The resulting dataset contained **14 sources**, each of which had fully transcribed melodies for the following Cantus IDs: 001737, 002000, 003511, 004195, 007040a, and 605019.¹⁵

Some sources contained multiple instances of chants of one Cantus ID: In that case, we retained the version with the most complete version of the melody (as repeated instances of the same chant are sometimes only written as incipits in the sources), and if multiple full melodies were available, we selected the melody that was directly in the Vig. Nat. Dom. section (see Tab. 1).

Why use such a limited dataset, when the entirety of the Cantus Database is available? We originally intended to use the CantusCorpus dataset [15] of Office melodies. However, the authors of the Cantus Database preferred transcribing entire sources, so while there are more than 13000 fully transcribed antiphons in CantusCorpus v0.2, the vast majority comes from less than 20 sources. This is further compounded by the surprising diversity of office repertoire. Thus, in the entirety of CantusCorpus, it is only possible to find 10 different sources that have transcribed melodies for 5 antiphons. Hence, we decided to use the Christmas dataset, with its advantage of having been collected specifically in order to make the comparison between different sources possible.¹⁶

4.1 Sources and Evaluation

Our methodology differs from machine learning experiments in *when* data is used. The phylogenetic tree model is selected and parametrized *a priori*, and only then we use a dataset to *validate* the model: is the tree inferred on the dataset plausible according to musicological expectations? Given that chant transmission provides few hard predictions, these expectations are *not* expressed in terms of target values. The evaluation of a tree’s plausibility is qualitative.

Since we base the claim of valid results on comparing the inferred tree against known relationships between the sources, we must give an overview of the 14 sources in terms of their placement along the three major dimensions of chant culture: place, time, and liturgical context. This

section essentially describes our “evaluation data”.

A-Wn 1799.** A 13th century Cistercian antiphoner from the Rein monastery in Austria.

A-VOR Cod. 259/I. A 14th century antiphoner of the collegiate chapter church of Vyšehrad, Prague. In the early 15th century, it was moved to Voraú because of Hussite wars. In 1490-1500, it was adapted for Salzburg liturgy.¹⁷

CDN-Hsmu M2149.L4. Cistercian antiphoner from the Abbey of Salzinnes, Namur, in the Diocese of Liège, central Belgium, completed in 1554-1555.¹⁸

CH-E 611. A 14th-century antiphoner from the Benedictine monastery of Einsiedeln, central Switzerland.

CZ-HKm II A 4. An antiphoner from the 1470s, belonging to the municipal Church of the Holy Spirit in Hradec Králové, eastern Czechia.¹⁹

CZ-PLm 504 C 004. A late antiphony from the St. Bartholomew municipal church in Pilsen, western Czechia, from 1616.²⁰

CZ-Pu XVII E 1. A mixed Latin and Czech antiphony from the early 16th century, of Czech (but further unspecified) provenance.²¹

CZ-Pn XV A 10. Late 15th century notated breviary from the cathedral cursus in Prague, Czechia.²²

CZ-Pu I D 20. An antiphony from the Augustinian monastery in Třeboň, southern Czechia, created in the 2nd half of the 14th century.²³

D-KA Aug. LX. A complex 12th-century antiphoner, of which the musical notation was almost completely rewritten in the 13th or 14th centuries. From the Zwiefalten Benedictine monastery in southwestern Germany, moved to the abbey of Reichenau in the 15th century.²⁴

D-KNd 1161. A late 12th- and early 13th-century Cistercian antiphoner, possibly written for use by the female abbey of Saint Mechtern in Cologne, western Germany, renamed Saint Apern in 1477.²⁵

F-Pn lat. 12044. An early 12th-century antiphoner from the Benedictine abbey of St.-Maur-de-Fossés, close to Paris, France.²⁶

F-Pn lat. 15181. An early 14th-century notated breviary belonging to the Notre Dame cathedral in Paris, France.²⁷

NL-Uu 406. A 12th-century antiphony from St. Mary’s church in Utrecht, Netherlands. Later 13th-15th-century changes. Complex source that has multiple versions of some melodies.²⁸

What results should one expect from a phylogeny of these chant sources? The three major dimensions of “ex-

Table 1. Sources of the Christmas Vespers dataset with their provenance, approximate date, cursus, and presence of the chant in each source (1 or more instances per source). NA represents chants not present in a given source.

ternal” similarity between chant sources, in terms of how similar the segments of culture represented in these sources are expected to be, are geography, chronology, and cursus – space, time, and the liturgical context within which the books were used. It is not entirely clear in chant scholarship how strongly each of these factors should influence chant melodies (the exception where cursus is clearly expected to dominate other factors is that of the Cistercian order, which mandated that all monasteries must have identical liturgical books [36, p. 99]), but these organizing principles should be observed in the resulting tree.

5. EXPERIMENTS AND RESULTS

For all our experiments, we set up Bayesian inference using an MkV model of evolution with options +I+G. Metropolis-Hastings MCMC sampling was carried out with four independent runs, each with four chains (one cold and three hot), with 10.000.000 generations, sampling each 1000 generations. Parameter and tree summaries were generated combining the four trace files after a burn-in of 50 % was applied to each. Parameter convergence was assessed by examining the potential scale reduction factor (PSRF) [37] which should approach 1.0 as runs converge, and the average standard deviation of split frequencies (ASDPF) [38] which should be below 0.01 for topological convergence. Other parameters had effective sample size (ESS) values above 600. We do not root the summary trees, because there is no clear outgroup in our dataset.

5.1 Single-locus tree inference

We first computed a tree for sets of melodies under each of the six Cantus IDs separately. In this setting, we examine whether the model can resolve the structure of diversity of individual melodies.

For each cantus ID, we aligned the sets of melodies to obtain a nexus matrix that is then used as input for tree inference. This resulted in six different summary trees, one for each chant. We found varying but overall low degrees of resolution in topology. Some chants had nearly no variation and consequently the majority-rule consensus tree is almost a complete polytomy²⁹ (003511, 004195). Other

chants had several internal nodes resolved, therefore representing some degree of information contained in a single melodic line which shows changes across sources. However, at the scale of individual melodies, there was insufficient signal for the model to find meaningful differences.

5.2 Multi-locus tree inference

A concatenated experiment, in which the set of 14 sources was chosen to represent the terminals, was then conducted. We prepared individual alignments for each of the loci so that the boundaries for the same locus (Cantus ID) in the resulting nexus matrix were in fixed positions. Here, a tree was resolved (Fig. 3) that exhibits several properties that we believe make it a plausible model of how chant melodies in these sources are related.

First, cursus. All the Cistercian manuscripts (“white monks”) are grouped tightly together, with the lowest probability of differences – regardless of geographical area and century of origin. This is not entirely the case for the Benedictine manuscripts: the tree does keep together a S. German and a N. Swiss source, but the French Benedictine source is grouped with a French cathedral source. The probability of changes (expressed as branch length) is also much greater between the two closely related Benedictine manuscripts. Finally, there is an interesting case of the Augustinian CZ-Pu I D 20 manuscript and A-VOR Cod. 259/1. The latter is not from an Augustinian monastery, but belonged to a community of canon regulars – a type of clerical community from which the Augustinian order was organized in 1244. They are not particularly close – they do not have an extra internal node like e.g. the French manuscripts – but they are not separated by one, either, and they lie in between the rest of the Czech group and the rest of the tree.

Second, geography. If one briefly disregards the Cistercian branch, the topology of the rest of the manuscripts does roughly correspond to their geographical distribution, from the French group in the west to the Czech group in the east. Note also that while there is some resolution in the group of Czech secular manuscripts, it is barely there: the internal nodes occur at most in six out of ten MCMC samples.

Finally, chronology seems to exert a relatively weak influence, but the dataset is not well suited to study the development of chant melodies in time, as most of the Czech

²⁹ Star graph: a tree with only one internal node.

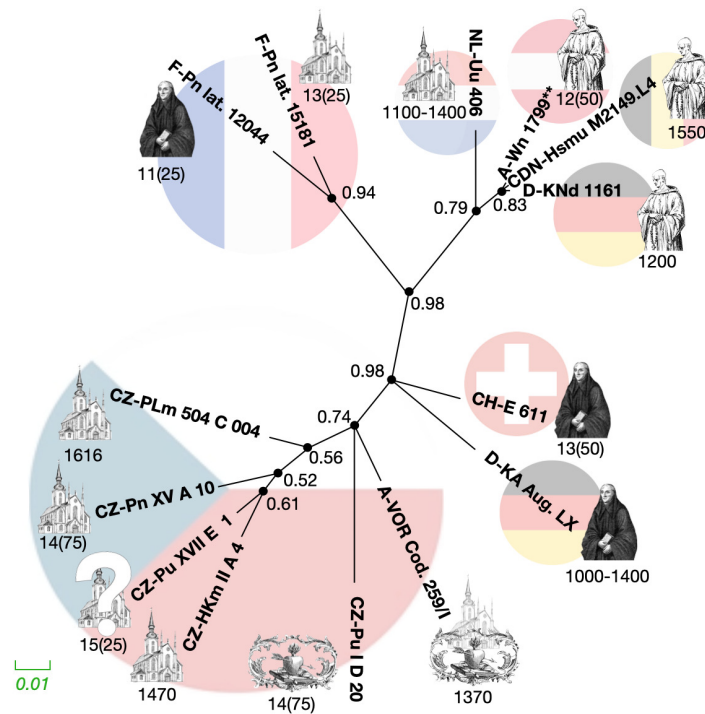

Figure 3. Main experimental result: summary of the posterior tree density as an unrooted majority-rule consensus tree for the concatenated dataset where each chant is a partition. All bipartitions present in at least 50% of the posterior trees are shown as internal nodes, with their nodal posterior probability. Terminals – tree leaves – are sources. Length of edges corresponds to probability of mutation; scale bar (bottom left) for 1 % expected mutation rate. Flags indicate geographical provenance, icons indicate cursus (black monks – Benedictines, white monks – Cistercians, heart – Augustinian, church building – secular cursus). Century (or half-century) indicated directly; some sources (D-KA Aug. LX, NL-Uu 406) have complex histories – see sec. 4.1.

sources are later than most other sources, so it is not clear how to distinguish geographical and chronological factors, and there is only one non-Cistercian clearly pre-1300 old source (F-Pn lat. 12044) that was not modified in the later centuries (which is the case both with D-KA Aug. LX and NL-Uu 406).

6. CONCLUSIONS AND FUTURE WORK

The proposed chant phylogeny pipeline produced a musicologically plausible model of the melodic diversity within the Christmas chant dataset. We do not claim that the resulting tree in Fig. 3 is the *only* or *best* possible way to model the relationships between the sources from our Christmas Vigil dataset; however, while further work should primarily focus on assembling a larger dataset and designing a more robust validation procedure, we believe that based on the current result, the proposed method can meaningfully enrich digital chant scholarship.

A major limitation is that the model requires homologous melodies (indicated by a shared Cantus ID). For the study of melodies to bypass this limitation, “morphological” features derived from melodies would be needed, so that we can process sources that do not share as many (transcribed) melodies. This is especially important for Office sources, where repertoire is strongly differentiated.

Provided one is not interested in the of melodic diver-

sity but only in repertoire structures of chant culture, one can build trees from binary features representing the presence/absence of Cantus IDs at given liturgical positions, using the same Bayesian model but with an alphabet of two rather than 19 characters.

Another limitation is that the current method does not model chronology: it is not yet a model of chant melody *evolution through time*. This complicates interpreting the tree: one potentially attractive idea is that the internal nodes correspond to likely manuscript copying events, but without a more explicit chronology, this remains speculative. Chronology can be incorporated by using Bayesian divergence time estimation (BDTE), an extension of topology inference that produces branch lengths in absolute time rather than the expected number of substitutions per site by using time priors for either nodes or terminals. Furthermore, BDTE could infer a posterior distribution for nodes without observed time values, and thus we could estimate e.g. the times of origin of different layers of a more complex source (such as D-KA Aug. LX or NL-Uu 406) by using time priors rather than precise time values.

Many methodological choices merit further exploration (such as the alignment scoring matrix, choice of tree model, or different ways of combining individual chants). However, based on the already plausible results of this pilot study, we are confident that chant phylogeny is a viable and exciting opportunity for digital chant scholarship.

AUDIO EMBEDDINGS AS TEACHERS FOR MUSIC CLASSIFICATION

alexander.lerch@gatech.edu

ABSTRACT

Music classification has been one of the most popular tasks in the field of music information retrieval. With the development of deep learning models, the last decade has seen impressive improvements in a wide range of classification tasks. However, the increasing model complexity makes both training and inference computationally expensive. In this paper, we integrate the ideas of transfer learning and feature-based knowledge distillation and systematically investigate using pre-trained audio embeddings as teachers to guide the training of low-complexity student networks. By regularizing the feature space of the student networks with the pre-trained embeddings, the knowledge in the teacher embeddings can be transferred to the students. We use various pre-trained audio embeddings and test the effectiveness of the method on the tasks of musical instrument classification and music auto-tagging. Results show that our method significantly improves the results in comparison to the identical model trained without the teacher’s knowledge. This technique can also be combined with classical knowledge distillation approaches to further improve the model’s performance.

1. INTRODUCTION

The classification of music has always been a widely popular task in the field of Music Information Retrieval (MIR). Music classification serves as an umbrella term for a variety of tasks, including music genre classification [1], musical instrument classification [2], and music auto-tagging [3]. The last decade has seen dramatic improvements in a wide range of such music classification tasks due to the increasing use of artificial neural networks [4–7].

One major contributing factor to these impressive accomplishments is the increased algorithmic complexity of the machine learning models which also means that the training process requires an increased amount of data. As not all tasks have this abundance of annotated data, transfer learning has been widely and successfully applied to various music classification tasks [8]. In transfer learning, a model is first pre-trained on a large-scale dataset for a

(source) task that is somewhat related to the (target) task and then fine-tuned with a comparably smaller dataset of the target task [9]. This enables knowledge to be transferred across datasets and tasks. Transfer learning has been repeatedly shown to result in state-of-the-art performance for a multitude of MIR tasks [10–12].

Another side effect of the increasing model complexity is the slow inference speed. One way to address this issue is model compression by means of knowledge distillation. Here, a low-complexity (student) model is trained while leveraging the knowledge in the high-complexity (teacher) model [13, 14]. The teacher-student paradigm has met with considerable success in reducing the model complexity while minimizing performance decay [15, 16].

In this study, we integrate ideas and approaches from both transfer learning and knowledge distillation and apply them to the training of low-complexity networks to show the effectiveness of knowledge transfer for music classification tasks. More specifically, we utilize pre-trained audio embeddings as teachers to regularize the feature space of low-complexity student networks during the training process. Thus, the main contributions of this paper are a systematic study of

- the effectiveness of various audio embeddings as teachers for knowledge transfer,
- different ways to apply the knowledge transfer from teachers to students, and
- the impact of data availability on the performance of the investigated systems.

The models and experiments are publicly available as open-source code.¹

2. RELATED WORK

This section first briefly introduces transfer learning and knowledge distillation, which are both often used to transfer knowledge between tasks and models, respectively, and then surveys the application of feature space regularization in the training of neural networks.

2.1 Transfer Learning

In transfer learning approaches, a model is pre-trained on a source task with a large dataset and subsequently fine-tuned on a (different but related) target task with a (typically

smaller) dataset [9]. By utilizing the knowledge learned from the source task, models trained following the transfer learning paradigm can often achieve significantly better results than the same models trained directly on the target task [17]; this is especially the case if these models have a large number of parameters and the training data for the target task is limited. In the case where fine-tuning the whole model might be too computationally expensive, another way to do transfer learning is to use the pre-trained embeddings and train only the classification head. This allows for a separation of the tasks of computing the embeddings and the classification itself.

Transfer learning has been successfully applied to a wide variety of areas ranging from computer vision [18, 19] to natural language processing [20]. In MIR, transfer learning has been used for a multitude of target tasks [8, 10, 11, 21]. Besides fine-tuning the whole model, pre-trained embeddings such as VGGish [22] and Jukebox [23] have also shown good performance on many tasks including auto-tagging [12, 24], instrument classification [4, 12], and music emotion recognition [12, 24–26].

One disadvantage of transfer learning is the slow inference speed. In most cases, the model has a large number of parameters, which means that both fine-tuning (if done on the whole model) and inference potentially lead to a high computational workload.

2.2 Knowledge Distillation

Approaches for knowledge distillation aim at model compression, i.e., reducing the complexity of the network. The knowledge of a (usually high-complexity) pre-trained network (the teacher) is transferred to a different (low-complexity) network (the student) during the training phase, in which the student not only learns from the ground truth labels but also from the teacher predictions. This is achieved by adding a “distillation loss” term to the student’s loss function to learn from the teacher’s prediction [13, 14].

The most popular distillation loss is the Kullback-Leibler divergence between the logits of the student and the teacher, with a hyperparameter called temperature to soften the probability distribution of the teacher’s prediction over classes [13]. The soft target provides more “dark” knowledge than the ground truth hard label [27, 28]. The Pearson correlation coefficient has also been proposed as a distance measure between the logits as an alternative to the Kullback-Leibler divergence [29].

Besides learning from logits, the student network can also try to learn from the feature map from the intermediate layers of the teacher network [30–32]. As the feature maps of the student and teacher do not necessarily share the same dimension and the same size, a variety of ways to match the feature space of the student and the teacher have been proposed [31, 33, 34]. Therefore, feature-based knowledge distillation has more flexibility than the logits-based traditional approach, which, at the same time, also makes it more challenging to find the best way of matching the feature space [35, 36].

2.3 Feature Space Regularization

Feature-based knowledge distillation is a technique of regularizing the feature space of the network during training. Besides knowledge distillation, there exists a wide variety of other ways to implement regularization. One example is contrastive learning, which aims at contrasting the features of instances with positive labels against negative labels [37, 38]. Contrastive learning has been shown to improve the performance of neural networks on music auto-tagging [39, 40] and music performance assessment [41].

Regularizing the feature space using pre-trained audio embeddings has also been reported to be effective in music classification [42] and music source separation [43], where Hung and Lerch proposed to use pre-trained embeddings to help structure the latent space during training. This technique is similar to but different from both transfer learning and knowledge distillation. In transfer learning, the same model is used on two different datasets, and a typical setting is that knowledge from the large dataset will be transferred to the small dataset. In knowledge distillation, only one dataset is used and the typical setting is that the knowledge will be transferred from a large model to a small model. In comparison, regularizing the feature space using embeddings requires neither the dataset nor the model to be the same, yet still allows to transfer knowledge learned by the teacher model from a large dataset to the low-complexity student network for a different (small) dataset.

3. METHODS

Inspired by the promising preliminary results of prior work [42], we integrate the idea of transfer learning and knowledge distillation by using pre-trained audio embeddings as teachers to regularize the feature space of the student network during training. The overall pipeline is illustrated in Figure 1.

3.1 Loss Function

Similar to knowledge distillation [13], we rewrite our loss function as

$$\mathcal{L} = (1 - \lambda)\mathcal{L}_{\text{pred}} + \lambda\mathcal{L}_{\text{reg}} \quad (1)$$

where $\mathcal{L}_{\text{pred}}$ is the loss function for conventional neural network training, \mathcal{L}_{reg} is the loss function that measures the distance between the student network’s feature map and the pre-trained embeddings, and $\lambda \in [0, 1]$ is a weighting hyper-parameter.

3.2 Regularization Location

Different stages in a neural network output different feature maps, and the optimal location to apply regularization continues to be controversially discussed in feature-based knowledge distillation [36]. In this study, we investigate either regularizing only the final feature map before the classification head as shown in Figure 1 or regularizing the feature maps at all stages of the student network.

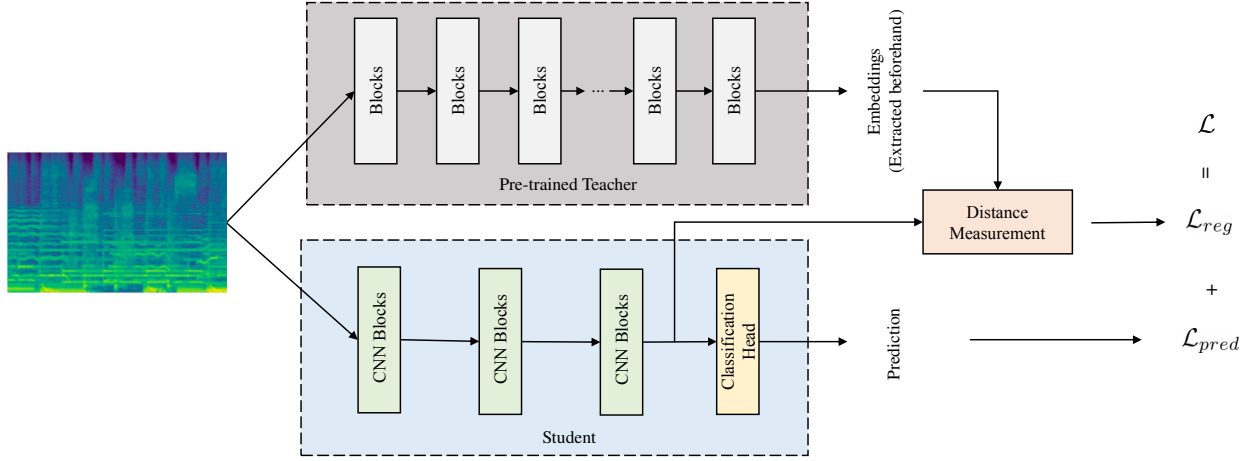

Figure 1: Overall pipeline of training a model by using pre-trained embeddings as teachers. The training loss is a weighted sum (weighting factor omitted in the figure) of prediction loss and regularization loss. The regularization loss measures the distance between pre-trained embedding and the output feature map after the feature alignment. During inference, only the bottom part with the blue background is used.

3.3 Feature Alignment

To measure the distance between the student feature map $l \in \mathbb{R}^{T_s \times C_s}$ and the pre-trained teacher embeddings $v \in \mathbb{R}^{T_t \times C_t}$ which might have different numbers of time frames (i.e., $T_s \neq T_t$), we first align the intermediate feature map with the pre-trained embeddings in time by repeating the one with fewer time frames, then compute the distance for each frame and finally average them along the time axis.

3.4 Distance Measure

Considering that pre-trained embeddings and feature maps have often different dimensionalities, the use of distance measures that are independent of dimensionality allows for easier application.

3.4.1 Cosine Distance Difference

Cosine distance difference² as proposed in previous work [42, 43] measures the difference in the cosine distance between pairs of samples. Given n pairs of samples of single-time-frame features l_1, l_2, \dots, l_n and pre-trained embeddings v_1, v_2, \dots, v_n , the cosine distance difference for one pair is

$$D_{ij} = |d_{\cos}(l_i, l_j) - d_{\cos}(v_i, v_j)|, \quad (2)$$

and the distance for this time frame is averaged among all pairs.

3.4.2 Distance Correlation

Distance correlation was proposed as a generalization of classical correlation to measure the independence between two random vectors in arbitrary dimensions [44]. It is capable of handling features of different dimensionality; furthermore, correlation-based distance measures have been

shown to be effective in knowledge distillation [29, 32]. Using the same notation as above, we define

$$a_{ij} = \|l_i - l_j\|, \quad (3)$$

$$\bar{a}_{i.} = \frac{1}{n} \sum_{j=1}^n a_{ij}, \quad \bar{a}_{.j} = \frac{1}{n} \sum_{i=1}^n a_{ij}, \quad \bar{a}_{..} = \frac{1}{n^2} \sum_{i,j=1}^n a_{ij} \quad (4)$$

$$A_{ij} = a_{ij} - \bar{a}_{i.} - \bar{a}_{.j} + \bar{a}_{..} \quad (5)$$

where $i, j \in \{1, 2, \dots, n\}$, and similarly, $b_{ij} = \|v_i - v_j\|$ and $B_{ij} = b_{ij} - \bar{b}_{i.} - \bar{b}_{.j} + \bar{b}_{..}$ ³. The distance for the time frame is then

$$\mathcal{L}_{\text{reg}} = 1 - \mathcal{R}_n^2(l, v) = 1 - \frac{\mathcal{V}_n^2(l, v)}{\sqrt{\mathcal{V}_n^2(l, l) \mathcal{V}_n^2(v, v)}} \quad (6)$$

where

$$\mathcal{V}_n^2(l, l) = \frac{1}{n^2} \sum_{i,j=1}^n A_{ij}^2, \quad \mathcal{V}_n^2(v, v) = \frac{1}{n^2} \sum_{i,j=1}^n B_{ij}^2,$$

$$\mathcal{V}_n^2(l, v) = \frac{1}{n^2} \sum_{i,j=1}^n A_{ij} B_{ij}.$$

Note that $\mathcal{V}_n^2(l, l)$ and $\mathcal{V}_n^2(v, v)$ will be 0 if and only if all the n samples of features (or embeddings) within one batch are identical [44], which we assume not to occur here.

To optimize both distance measures during training, block stochastic gradient iteration is used, which means that the distance is computed over mini-batches instead of the whole dataset [45, 46]. With stochastic approximation, the computational complexity of the distance measure for n samples is reduced from $\mathcal{O}(n^2)$ to $\mathcal{O}(mn)$ where m is the batch size.

It is worth mentioning that both distance measures ensure that if the distance is zero, the feature maps would

² has been referred to in previous work as Distance-based Regularization (Dis-Reg) [42, 43].

³ Eq. (3) uses 2-norm following the implementation in https://github.com/zhenxingjian/Partial_Distance_Correlation.

differ from the pre-trained embeddings by only an orthogonal linear transformation, which can be modeled in a single linear layer. Therefore, if the regularization loss is zero, the student would have the same performance as the teacher in classification.

4. EXPERIMENTAL SETUP

We test the effectiveness of using pre-trained embeddings as teachers on two different tasks, datasets, and models with four different pre-trained embeddings as follows.

4.1 Tasks, Datasets, Models, and Metrics

4.1.1 Musical Instrument Classification with OpenMIC

Musical instrument classification is a multi-label classification problem. We use the OpenMIC dataset [2], which provides weakly labeled audio snippets of length 10 s. Following prior work [4, 49], we use the suggested test set and randomly split 15% of the training data as the validation set, resulting in 12,692 training observations, 2,223 validation observations, and 5085 test observations. To ensure a consistent sample rate, the audio is resampled to 32 kHz [5, 49]. As the dataset is not completely labeled, i.e., parts of the labels are missing and not labeled as positive or negative, the missing labels are masked out when computing the loss function as suggested in previous work [5, 10, 49].

We use receptive field regularized ResNet (CP-ResNet) [5] for this task, as it reaches state-of-the-art performance when trained only on the OpenMIC dataset (i.e., neither trained with transfer learning nor trained with any knowledge distillation). CP-ResNet has a ResNet-like structure [19] with an added hyper-parameter ρ to control the maximum receptive field of the ResNet. We set $\rho = 7$ to match the setting which provides the best results in the original work [5].

The results are reported with the metrics mean Average Precision (mAP) and F1-score. The F1-score is calculated in a macro fashion, which means that for each instrument, the F1-score is computed for both the positive labels and the negative labels and then averaged, and the final F1-score is the mean of the F1-scores of all instruments. The detection threshold for the prediction is set to 0.4 following previous work [5].

4.1.2 Music Auto-Tagging with MagnaTagATune

Similar to musical instrument classification, music auto-tagging is also a multi-label classification problem. We use the MagnaTagATune dataset [3] for this task, which comes with audio clips of approximately 29.1 s. Following previous work, we use only the top 50 labels and exclude all the songs without any positive label from the dataset [7, 50]. For comparability, the data split is adopted from previous work, with audio files in the directories '0' to 'b' being the training set, 'c' being the validation set, and 'e' and 'f' being the test set [48, 51], resulting in 15,247 training clips, 1,529 validation clips, and 4,332 test clips.

We apply a modified fully convolutional neural network (FCN) [6] to this task. It is the simplest model among the

benchmark models for the MagnaTagATune dataset [48] and consists of several convolution and max-pooling layers. To further reduce the complexity of the model, we apply the MobileNet-like modification [52] to the network by breaking the 3×3 convolutions into depth-wise separable convolutions and 1×1 convolutions.

The results are evaluated with mAP and ROC-AUC.

4.2 Pre-trained Embeddings

4.2.1 VGGish

VGGish [22] is a widely used embedding in MIR, with a VGG network [53] being trained on a large number of Youtube videos. The open-source PyTorch implementation is used to extract VGGish features⁴ which by default extracts 128 principle components and then quantizes them to 8 bit. The time resolution is 960 ms.

4.2.2 OpenL3

The OpenL3 embedding [54,55] is trained on a music subset of AudioSet [56] in a self-supervised paradigm. The audio embeddings are extracted using the open-source Python package OpenL3⁵ with the dimensionality being 512. To keep consistent with VGGish, the time resolution is set to 960 ms.

4.2.3 PaSST

PaSST [10] is a 7-layer transformer trained on AudioSet for acoustic event detection. It applies the structure of a vision transformer [16, 57] and proposes the technique of Patchout to make the training efficient. We use the open-source code⁶ released by the authors to extract the 768-dimensional embeddings. The time resolution is also set to 960 ms.

4.2.4 PANNs

PANNs [11] include several convolutional neural networks and are also trained on AudioSet for acoustic event detection. We use the default CNN14 model from the official repository⁷. The embedding dimensionality is 2048. Different from other embeddings, PANNs provide only one global embedding for each clip of audio. Pilot experiments have shown that extracting the embeddings for short segments and concatenating them does not improve performance.

4.3 Systems Overview

The following systems are evaluated for comparison:

- Baseline: CP ResNet (on OpenMIC) and Mobile FCN (on MagnaTagATune) trained without any extra regularization loss.

Table 1: Results on OpenMIC (above) and MagnaTagATune (below) dataset for different models regularized with different pre-trained embeddings. Best performances are in bold, and best results excluding the teachers are underlined. *Reported results [5], SS means being trained with shake-shake regularization [47]. **When using KD, the missing labels in OpenMIC were masked to avoid potentially adding more training data. [†]Results from the open-source re-implementation [48].

- Teacher_{LR}: logistic regression on the pre-trained embeddings (averaged along the time axis), which can be seen as one way to do transfer learning by freezing the whole model except for the classification head.
- KD: classical knowledge distillation where the soft targets are generated by the logistic regression.
- EAsT_{Cos-Diff} (for Embeddings-As-Teachers): feature space regularization as proposed by Hung and Lerch that uses cosine distance difference and regularizes only the final feature map [42].
- EAsT_{Final} and EAsT_{All}: proposed systems based on distance correlation as the distance measure, either regularizing only at the final stage or at all stages, respectively.
- EAsT_{KD}: a combination of classical knowledge distillation and our method of using embeddings to regularize the feature space. The feature space regularization is done only at the final stage.

We perform a search of λ for each of the EasT systems and choose the best-performing value on the validation set.⁸

5. RESULTS

This section presents the results of different systems and their performance in the case of limited training data.

⁸ For all the hyperparameters, please refer to the config files in our GitHub.

5.1 Results on OpenMIC and MagnaTagATune

Table 1 shows the results on the OpenMIC and the MagnaTagATune datasets.

We can observe that the models trained with the extra regularization loss consistently outperform the non-regularized ones on both datasets, with all features, and all regularization methods. This means that the knowledge in the embeddings is successfully transferred to the student networks and consistently enhances the performance.

Although EAsT_{Final} appears to give better results on the OpenMIC dataset while EAsT_{All} seems to have slightly better performance on the MagnaTagATune dataset, the difference between them is very small, meaning that the model does not benefit significantly from being regularized by pre-trained embeddings at earlier stages where the feature maps are still relatively low-level.

The results for the teacher systems show that the older VGGish and OpenL3 embeddings are clearly outperformed by the more recently proposed embeddings PaSST and PANNs. In fact, the teacher systems for the newer embeddings perform so strongly that the students can rarely outperform them, while the student systems trained with VGGish and OpenL3 provide better results than the corresponding teachers. We can see that whether the teachers themselves have an excellent performance or not, students benefit from learning the additional knowledge from these embeddings, and the students’ upper limit is not bounded by the performance of teachers.

Comparing KD and the EAsT_{Final} or EAsT_{All} systems,

Model	Parameters (M)	Iteration / s
VGGish	72.1	172.2
OpenL3	4.69	117.9
PaSST	86.1	18.7
PANNs	79.7	70.6
Mobile FCN	0.34	319.3
CP ResNet	5.52	205.3

Table 2: Comparison of the model complexity.

we can see that with VGGish and OpenL3 embeddings, regularizing the feature space provides better results than simply using the teachers’ soft targets. On the other hand, for the PaSST and PANNs embeddings, classical knowledge distillation provides competitive results. The possible reason is that the soft targets given by “weak” teachers might have provided too much incorrect information to the students while the high-quality soft targets generated by the “strong” teachers provide good guidance for the students’ training.

The combination system EAS_{KD} gives us better results with PaSST and PANNs embeddings (with the exception of no noteworthy improvement with the PaSST embedding on the OpenMIC dataset) while for VGGish and OpenL3 embeddings, the performance is not as good as EAS_{Final} or EAS_{All} in most cases. This observation is in accordance with our speculation that traditional knowledge distillation performs best with a “strong” teacher. While learning from audio embeddings benefits a student network even more in the presence of a “strong” teacher, learning from “weak” embeddings can still improve the model’s performance.

5.2 Comparison of Model Complexity

Table 2 lists the number of parameters as well as rough inference speed measurements⁹ of the models.

The numbers of parameters only take the backbone structure (i.e., excluding the final classification head) into account so that it does not vary across datasets with different numbers of classes. Iterations per second are tested with 128×1000 input spectrograms.

We can see that Mobile FCN and CP ResNet are much faster in inference than pre-trained models.

5.3 Limited Training Data

To investigate the impact of limited training data on our methods, we present the system performances for reduced training data, i.e., for 25%, 50%, and 75% of the original training data. The results are shown in Figure 2. We use VGGish and PaSST as the pre-trained embeddings.

We can observe that limiting the training data has the greatest impact on the baseline systems, which show the biggest performance drop.

On the OpenMIC dataset, $EAS_{Cos-Diff}$ and EAS_{Final} have similar decreases in mAP, and the KD system is less

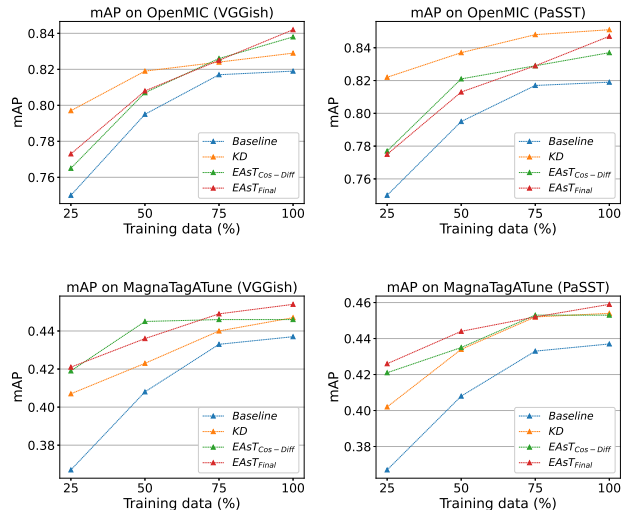

Figure 2: Results with limited training data on two datasets.

affected. An interesting finding is that when the VGGish embedding is used, KD shows better performance for limited data amounts while it is outperformed by $EAS_{Cos-Diff}$ and EAS_{Final} when the whole OpenMIC dataset is available. This means using embeddings as teachers might still require a sufficient amount of data to have good guidance on the student models.

On the MagnaTagATune dataset, however, the $EAS_{Cos-Diff}$ and EAS_{Final} systems show less performance decay than either KD or the baseline when the training data is limited. This suggests that in our training settings, there is no certain answer to which method is least affected by the lack of training data, and the answer might be dependent on specific tasks, models, and data.

6. CONCLUSION AND FUTURE WORK

In this paper, we explored the use of audio embeddings as teachers to regularize the feature space of low-complexity student networks during training. We investigated several different ways of implementing the regularization and tested its effectiveness on the OpenMIC and MagnaTagATune datasets. Results show that using embeddings as teachers enhances the performance of the low-complexity student models, and the results can be further improved by combining our method with a traditional knowledge distillation approach.

Future work will investigate the performance of our method on a wider variety of downstream tasks and embeddings. Moreover, as there have been a wide variety of models to extract audio and music embeddings, we speculate that using an ensemble of different pre-trained embeddings also has considerable potential. Finally, the flexibility of feature-based knowledge distillation offers a wide range of possible algorithmic modifications. Our focus will be on evaluating different distance measures and regularizing the network using features from different stages of the teacher network instead of using only the output embeddings.

ABSTRACT

We present ScorePerformer, an encoder-decoder transformer with hierarchical style encoding heads for controllable rendering of expressive piano music performances. We design a tokenized representation of symbolic score and performance music, the Score Performance Music tuple (SPMuple), and validate a novel way to encode the local performance tempo in a local note time window. Along with the encoding, we extend a transformer encoder with multi-level maximum mean discrepancy variational autoencoder style modeling heads that learn performance style at the global, bar, beat, and onset levels for fine-grained performance control. To offer an interpretation of the learned latent spaces, we introduce performance direction marking classifiers that associate vectors in the latent space with direction markings to guide performance rendering through the model. Evaluation results show the importance of the architectural design choices and demonstrate that ScorePerformer produces diverse and coherent piano performances that follow the control input.

1. INTRODUCTION

Musical expression is the human touch that transforms a written piece of music into an emotionally moving experience. In musical interpretation and performance, the musician interprets a musical score and translates the intended expression through the control of the musical instrument, the sound of which conveys affect and emotion to the listener [1, 2]. However, effective control of musical instruments often requires considerable expertise and training, making musical expression less accessible than it could be.

Deep learning music performance models reduce the need for musical expertise and open up new ways to create and perform music [3, 4]. To render expressive performances of written music [5, 6], the models mix recurrent neural networks to learn temporal dependencies in music with variational autoencoders to encode performance style and enable controllable generation [7–11]. The models are trained on real and categorical score and performance features for aligned score and performance notes.

The related task of symbolic music generation is approached differently. Transformer models [12] are primarily utilized due to their ability to effectively learn long-term dependencies in music sequences [13–17]. The symbolic music is encoded as sequences of musical tokens, either individual [15, 18, 19] or stacked into tuples [16, 20]. Similar approaches could be applied to the task of rendering expressive music performances for written compositions.

Aiming to advance the research and make musical expression more accessible, we develop ScorePerformer¹, a piano music performance rendering model with interactive fine-grained performance style control. The model combines encoder and decoder transformers [12] with hierarchical maximum mean discrepancy variational autoencoders [21, 22] that encode performance style representations at the global, bar, beat, and onset levels.

To interpret the learned style embedding spaces, we train embedding classifiers that associate local performance contexts with written musical score direction markings. For each marking, we use the classifier predictions to compute the average delta vectors in the style space from negatively to positively classified style embeddings. These vectors provide quantified model control inputs to move the performance rendering per given direction marking.

For data encoding, we design a tokenized representation of score and performance music, a Score-Performance Music tuple (SPMuple). It introduces a local window onset tempo function that produces smoother and more robust tempos than inset-bar, -beat, or -onset tempo functions.

The experiments and evaluation results show that the model trained on the designed encoding successfully captures different performance styles, can sample diverse and coherent piano performances, and can be used for expressive performance rendering with fine-grained style control.

Our main contributions are:

1. We extend transformers for expressive piano performance rendering with hierarchical style encoding and control at the global, bar, beat, and onset levels;
2. We design a tokenized encoding for aligned score and performance music that proposes an efficient local tempo computation function;
3. We introduce performance direction classifiers to provide musical language-driven performance control by modifying the learned style latent spaces.

2. RELATED WORK

Expressive Music Performance: Recent expressive music performance rendering models mainly utilize deep learning methods [3, 6]. Jeong et al. [8] and Maezawa et al. [9] use conditional variational autoencoders for performance style encoding and recurrent neural networks for expressive performance rendering. Rhyu et al. [11] allow performance style to be intuitively “sketched” by a set of learned latent representations. We propose to use transformers with self-attention mechanisms [12] to infer patterns in music performance and model its style through hierarchical style encoding heads.

Symbolic Music Generation: Symbolic music generation with deep learning [4] is dominated by transformers for learning long-term sequential musical patterns [13, 15–17, 23] and variational autoencoders for unsupervised style encoding and control [19, 23–26]. The models offer unconditional or priming melody-based music generation [14], global control of performance style [14, 25] or fine-grained control of music through learned high-level features [23, 26] and descriptions [19]. Our model is close to the melody-conditioned transformer autoencoder [14], but introduces modifications for the task of score-based performance rendering with style control.

Symbolic Music Encoding: The simplest way to encode symbolic music is a MIDI-like encoding with note-on, note-off, and time-shift events [13, 18]. REMI [15], REMI+ [19], and Compound Word [16] replace position shifts with absolute bar, position, and beat tempo tokens. OctupleMIDI [20] shortens sequence lengths by stacking note attributes into tuples of 8 tokens. For expressive music performance rendering, it is common to mix real, categorical and pianoroll-based score and performance features parsed from MusicXML and MIDI files [8, 9, 11, 27]. Transformers work well with tokenized data [12, 28, 29]. Inspired by OctupleMIDI, we design a tuple-like token encoding that naturally fits aligned score-performance data.

3. DATA ENCODING

3.1 Score and Performance Data Matching

Expressive music performance rendering models require datasets of aligned score and performance music [5, 30]. In this work, we consider piano music performances in MIDI format and use the following data preparation pipeline. First, we compute alignments using Nakamura’s alignment tool [31]. The alignments may contain errors, such as alignment holes or close performance notes aligned with distant and unrelated score notes. Following the literature [8, 32], we revise the alignments and filter out notes that deviate from the local performance tempo. After the cleanup, we omit performances with less than 80% aligned notes. Finally, to achieve a perfect match, we remove extra performed notes and interpolate missing notes using the local performance tempos and dynamics, since taking only matched notes and discarding score notes can result in the removal of important chord and bar information.

3.2 SPMuple Encoding

We introduce the Score-Performance Music tuple (SPMuple), a tokenized representation for aligned symbolic score and performance music. It encodes performed notes using tuples of 8 score and 4 performance tokens.

Score Tokens: a set of features extracted from the score MIDI. **Pitch** is a MIDI pitch number in the range 21 to 108. **Duration** is a score note value, encoded by 128 tokens with high and low resolution tokens for short and long durations, respectively [20, 33]. **Bar** is an index of the musical bar to which the note refers, ranging from 0 to the maximum bar in the data. **Position** is the position of the note in the bar, one of 128 tokens with 64th note resolution. **TimeSignature** is the time signature of the beat containing the note, a set of 22 tokens for 2nd, 4th, and 8th note beat lengths, with a maximum bar length of 2 whole notes for 2nd note, and 1.5 for 4th and 8th note. **OnsetShift** is the positional interval between the current and previous note onsets (chords). **NotesInOnset** and **PositionInOnset** are the number of notes and the index of the note in the onset, ranging from 1 to 12, notes are ordered by pitch.

Performance Tokens: a set of performance features extracted from the performance MIDI and processed using the aligned score note features. **Velocity** is a MIDI velocity from 1 to 127. **Tempo** is the performance tempo at the bar, beat or onset level, encoded by a geometric sequence of 121 tokens for beats per minute tempos from 15 to 480. **RelOnsetDeviation** models the exact timing of the note, encoded as the ratio of the absolute note-onset position deviation to the inter-onset interval scaled by the local onset tempo using 161 tokens for values in the range -2 to 2. **RelPerformedDuration** is an articulation of the performed note, computed as the ratio of the performed duration to the score duration, scaled by the local onset tempo, and encoded by 121 tokens for logarithmically distributed values between 0.1 and 3.

The score and performance token sequences are sorted by score note start position, pitch and duration.

3.3 Local Tempo

Inset-onset tempos are noisy and have very high variance, while beat and bar tempos are smoother but still fluctuate at beat/bar boundaries, which can lead to degraded musical experience [34–36]. We design a smooth alternative, local onset tempos, weighted with respect to previous onsets in the local onset time window.

Let $\{IOI_i^s\}$ and $\{IOI_i^p\}$ be the sets of score and performance inter-onset intervals between the onset o and N preceding onsets o_i in the time window W . The weights w_i^o for inter-onset tempos $\frac{IOI_i^s}{IOI_i^p}$ are computed as:

$$w_i^o = 1 - \frac{IOI_i^p}{\max_j \{IOI_j^p\} + 10^{-2}} \quad (1)$$

The weights give more attention to the closest preceding onsets, but still consider the more distant onsets to smooth the local tempo. Based on the decoding quality, we set the time window length W to 8s as the optimal one. In

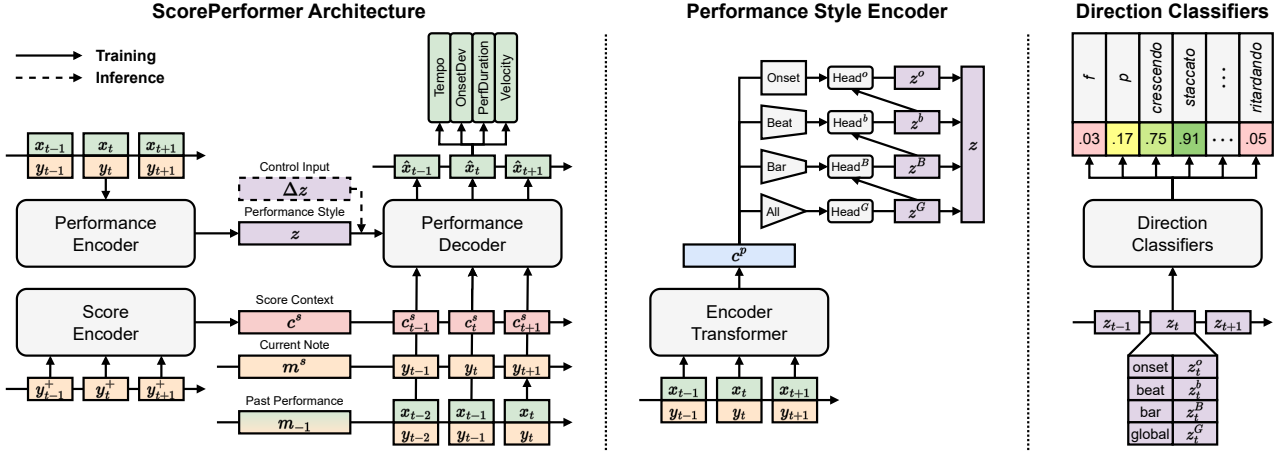

Figure 1. The overall architecture of ScorePerformer, hierarchical style encoding heads and direction classifiers.

addition to the window W , we filter out the nearest onsets with $\text{IOI}_i^p < 0.5$ to reduce the effect of immediate tempo changes, and take at least $N_{\min} = 8$ past onsets with any IOI^p to have enough points for smoothing ($N \geq N_{\min}$).

4. MODEL

With a focus on hierarchical performance style control and efficient training on tokenized sequences, we present **ScorePerformer**, an encoder-decoder model that combines transformers [12] and maximum mean discrepancy variational autoencoders (MMD-VAE) [21,22] for controllable expressive rendering of piano performances for written scores. The model is illustrated in Figure 1.

4.1 Model Architecture

Score Encoder is an encoder transformer that computes a contextual representation of the written music. It maps a score note sequence $y^+ \in \mathbb{N}^{N \times 10}$ (score tokens y + score tempos and velocities) to note embeddings $c^s \in \mathbb{R}^{L \times D}$.

Performance Encoder is an encoder transformer that computes performance style representations at different levels of the musical hierarchy. It takes a sequence of music tuples of score and performance tokens $m = [y, x]$, $y \in \mathbb{N}^{N \times 8}$, $x \in \mathbb{N}^{N \times 4}$, and outputs performance context embeddings $c^p \in \mathbb{R}^{N \times D}$. The embeddings are grouped and averaged over the entire sequence, bars, beats, and onsets, and iteratively passed through conditional linear layers to compute global, bar, beat, and onset latents z^G , z^B , z^b , and z^o . With the idea of learning missing lower-level details hierarchically, at each step t the latent z_t^* depends on the context c_t^p and all higher-level latents containing the note, e.g. $z_t^b = f_\phi^b(c_t^p, z_t^G, z_t^B)$. All note latents are stacked to produce note-level style embeddings $z \in \mathbb{R}^{N \times D_z}$.

The latent spaces are fit into the Gaussian distribution using a maximum mean discrepancy objective:

$$\mathcal{L}_{\text{MMD}}(p||q) = \mathbb{E}_{p(z),p(z')} [k(z, z')] + \mathbb{E}_{q(z),q(z')} [k(z, z')] - 2\mathbb{E}_{p(z),q(z')} [k(z, z')], \quad (2)$$

where $k(z, z') = e^{-\frac{\|z-z'\|^2}{2\sigma^2}}$ is a Gaussian kernel.

We use MMD-VAE [21,22] to solve issues with posterior collapse and latent space holes [37] common to conventional variational autoencoders [38], especially, when trained on sequential data [39].

Performance Decoder is a decoder transformer that renders performance by sequentially predicting performance tokens x_t for score note tokens y_t . The input token sequence combines two sequences: 1) a sequence $m^s = y$ with the current score notes to be rendered; 2) a sequence $m_{-1} = [y_{-1}, x_{-1}]$ shifted one step into the past score y_{-1} and rendered performance tokens x_{-1} describing the past performance history. To reuse the SPMuple token embedder, the first sequence is extended with the masked performance tokens. The two sequence embeddings are concatenated with the score context c^s and passed to the transformer layers together with the style embeddings z .

We use style-adaptive layer normalization (SALN) [40] and pass style embeddings z to the decoder’s layer normalization layers, rather than concatenating the style and input token embeddings, to increase the focus on the performance style at each transformer layer.

The performance decoder minimizes the negative log-likelihood for the sequence of performance tokens x :

$$\mathcal{L}_{\text{perf}} = - \sum_{t=1}^N \log p_\theta(x_t | x_{<t}, y_{\leq t}, c_{\leq t}, z_{\leq t}) \quad (3)$$

4.2 Transformer Modifications

Discrete+Continuous Tokens: Discrete musical tokens do not explicitly encode the absolute and relative information about note attributes, e.g. that pitches C2, C3, and C4 differ by an octave, or that velocity 80 is louder than 60. We mix discrete and continuous tokens by summing learned discrete token embeddings with delta embeddings provided by a learned nonlinear mapping of the real values associated with tokens to the token embedding dimensions.

Relative Attention: We use the learned ALiBi relative positional bias [41] in the decoder and the learned bidirectional symmetric bias [42] in the encoder for efficient interpolation to sequence lengths not seen during training.

Other: We use single key-value attention heads [43] to speed up decoding, SwiGLU activation [44,45] in feedforward layers, reuse token embedding weights between the encoders and decoder since they share token vocabularies, and tie input and output embeddings in the decoder [45].

4.3 Performance Direction Classifiers

We provide an intuitive interpretation of the learned style embedding space by training performance direction classifiers on the learned note style embeddings. We extract performance direction markings from MusicXML files and associate score notes with performance direction labels where they are present. We train classifiers for **dynamics** (degrees of *piano* and *forte*), **dynamic changes** (*crescendo* and *diminuendo*), **tempo** (*adagio*, *largo*, etc.), **tempo changes** (*accelerando*, *ritardando*, etc.) and **note articulation** binary classes (*staccato*, *fermata*, etc.).

Classifiers take as input the combined note-level performance style embeddings $z = [z^G, z^B, z^b, z^o]$ and output the probabilities of directions being performed in a given performance context. The module minimizes the sum of cross entropy losses for K classifiers with C_k classes each:

$$\mathcal{L}_{\text{clf}} = \sum_{k=1}^K \mathcal{L}_{\text{clf}}^k = -\frac{1}{N} \sum_{k=1}^K \sum_{t=1}^N \sum_{c=1}^{C_k} d_{t,c}^k \log(\hat{d}_{t,c}^k), \quad (4)$$

where $d_{t,c}^k$ and $\hat{d}_{t,c}^k$ are true and predicted labels for direction c of the classifier k at step t .

Given the smoothness of the learned latent space, the differences between embeddings with high and low classification scores for a given marking may provide a direction in the latent space to move the generation toward the marking. We compute and use mean per-marking delta embeddings to control performance rendering. Since markings are related to defined musical concepts, we can map natural language commands, such as “*play more piano here*” or “*switch to largo*”, to quantitative model control inputs.

4.4 Training and Inference

The total loss minimized by the model during training is:

$$\mathcal{L} = \mathcal{L}_{\text{perf}} + \mathcal{L}_{\text{MMD}} + \mathcal{L}_{\text{clf}} \quad (5)$$

To avoid overfitting of the decoder to lower-level performance embeddings during training, we drop bar, beat, and onset embeddings with probabilities of 0.1, 0.2, and 0.4, respectively. The embeddings are dropped inclusively, i.e. if the bar latent is dropped out, all beat and onset latents are also dropped. Additionally, the classifiers are trained on detached style embeddings z , as we found the model to overfit the unbalanced direction markings labels.

During inference, the sampled or modified reference performance embeddings can be used to control the rendering of the music performance. Based on the learned style spaces, the control can range from high-level global to low-level onset. The extracted performance direction delta embeddings can be used to provide intuitive, command-driven performance manipulation. The model supports real-time inference on the CPU for use in interactive applications.

5. EXPERIMENTS

Datasets: For all experiments, we use the ASAP dataset of matched piano scores and performances [46], preprocessed as described in Section 3.1. The prepared dataset represents 212 musical compositions by 15 composers with a total of 937 performances, 79 hours of performed music. The data is divided into training and evaluation sets with an approximate ratio of 9:1 for the number of performances in the entire dataset and for each composer.

Implementation: The SPMuple data encoding is implemented using `miditok`'s [33] MIDI tokenizer interface. The encoders and decoders in all experiments have a hidden dimension of 256, 4 layers, and 4 attention heads, except for the score encoder, which has 2 layers. The token embedding dimension is set to 128 for each token type, the projected embedding dimension for input embeddings is set to 256. The global, bar, beat, and onset latent dimensions are set to 32, 20, 8, and 4, respectively.

Training: The maximum sequence length during training is set to 256 tokens. To regularize the model and artificially increase the variety of data, we augment the data with sampled pitch shifts (up to ± 3 semitones) and velocity shifts (up to ± 12 MIDI values). In addition, we randomly replace real performances with deadpan performances with a probability of 25% to allow the model to learn the style of both expressive and inexpressive music. We use the ADAM optimizer [47] with an initial learning rate of $2 \cdot 10^{-4}$, decaying by 0.995 after each epoch. Models are trained for 70,000 iterations with batch size 128.

Evaluation: We conduct three sets of experiments: 1) evaluation of the designed data encoding and different local tempo calculation functions; 2) comparison of different latent style hierarchies and their impact on performance rendering; 3) an ablation study on the model architecture design. For the metrics, we use Pearson correlation [9, 11, 48] and mean absolute error for performance features: inter-onset intervals (IOI), absolute onset deviations (OD), performed note durations (PD), and velocity (Vel). We generate 3 samples for each performance in the evaluation set and compute and average the metrics between the ground truth and the generated performances, decoded to MIDI. The errors are measured in seconds, except for velocities, which are measured in MIDI velocity values. After the objective evaluation, we analyze the generation and control capabilities of the designed ScorePerformer model.

6. EVALUATION

6.1 Encoding and Local Tempos

The tokenized representation of performance is not lossless, since some information is lost during feature quantization. We evaluate the decoding quality and performance of ScorePerformer on sequences encoded using SPMuple with different local tempo functions.

Table 1 shows the evaluation results. The local window onset tempo function (Section 3.3) shows the least degradation in decoding quality for inter-onset intervals and onset deviations. It captures local tempo changes and note

Tempo	Decoded						Generated, $\Delta z = 0$							
	Error ↓			Correlation ↑			Error ↓				Correlation ↑			
	IOI	OD	PD	IOI	OD	PD	IOI	OD	PD	Vel	IOI	OD	PD	Vel

Table 2. Correlation with ground truth performances for samples generated by models trained with different combinations of latent hierarchies. G – global, B – bar, b – beat, o – onset, and z – total latent dimensions.

timing more efficiently than bar, beat and onset tempos. These findings are supported by the generation results. The model trained with local window tempo tokens renders samples with smaller errors and closer to the ground truth than the models trained with bar, beat, or onset tempo tokens. In particular, it shows more consistency in modeling local tempo changes and note timing. For future work, the encoding could be further improved by incorporating pedals, an essential element of piano performance [49].

6.2 Style Embedding Hierarchies

Table 2 shows the impact of different learned style embedding hierarchy combinations in ScorePerformer on the quality of performance rendering. Replacing lower-level latents with higher-level ones, using only a single level, or omitting any level of the hierarchy leads to a decrease in quality for all musical features. The lower-level onset latents account for most of the variation in performance features, while the higher-level latents provide the missing performance timing, articulation, and dynamics information at the beat, bar, and global levels. The results suggest that a hierarchical style representation is advantageous for modeling global and local changes in music performance. The search for an optimal configuration of latent dimensions is beyond the scope of this study.

	IOI	OD	PD	Vel
ScorePerformer	0.901	0.538	0.907	0.943
w/o Score Encoder	0.885	0.526	0.889	0.951
w/o input seq. m^s	0.844	0.422	0.895	0.925
w/o SALN	0.871	0.469	0.920	0.930
w/o in-out emb. tie	0.901	0.459	0.873	0.951
w/o Continuous Tokens	0.576	0.116	0.747	0.561

Table 3. Evaluation of model configurations using the correlation between ground truth and generated performances.

6.3 Ablation Study

The ablation study on the ScorePerformer model is summarized in Table 3. Removing any of the proposed design choices degrades the quality for all features in almost all cases. The score encoder adds a local future score context to the decoder and contributes to a slight quality improvement. The same is true for the additional decoder input sequence m^s , which explicitly highlights the currently rendered score notes. Without style-adaptive layer normalization or input-output embedding weight sharing, the correlation for timing features decreases. The most noticeable quality degradation occurs after using only discrete tokens without continuous input tokens, demonstrating the positive impact of value-aware inputs on model predictions.

6.4 Performance Embeddings Analysis

We explore the learned performance style spaces using the trained performance direction marking classifiers. We take the style embeddings z for note onsets in the dataset and project them into two dimensions using principal component analysis [50]. Figure 3 shows the projected embeddings labeled by the selected dynamics, tempo, and articulation markings classifiers and their ground truth labels. We can see the gradient moving from the light colors (high probabilities) to the darker colors (low probabilities). Despite the class imbalances and low representation of some labels in the dataset, the positive classifier predictions match the areas of the ground truth labels shown in the right plots for each marking. This suggests that the vectors for moving the performance toward the markings exist in the original latent style space and can be used to attempt to control the performance rendering through the model.

Figure 2. Pianorolls and performance features (inter-onset tempo, articulation, and velocity) for the first 12 musical bars of Bach’s “Prelude and Fugue No.19”, rendered by ScorePerformer with unconditional or conditional style control. The title of each plot indicates the form of the control input. Colored areas highlight the regions with the applied control.

Figure 3. Projected style embeddings classified by chosen direction marking classifiers. The left and right plots for each marking highlight predicted and ground truth labels.

The direction classifiers can also be used to analyze performance practices. For example, take all performance contexts with a given notated performance direction marking and sort them by the classification scores using the associated direction classifier. Further analysis of the score contexts can provide insight into the reasons why musicians follow or interpret differently certain markings.

6.5 Performance Rendering Control

For performance rendering control, we add control embeddings Δz to the encoded style embeddings and pass them to the decoder. We analyze both uncontrolled generation with sampled control embeddings and direction-based control using the computed delta latents for markings.

Figure 2 shows examples of music performance rendering for a composition from the evaluation set. The sample (a) shows the successful reconstruction of the performance variations from the encoded style embeddings. When generated using sampled delta latents (b), the added noise is transferred to higher variations in tempo than in articulation and dynamics. In our observations, small amounts of delta noise can result in both pleasant and diverse samples.

From the evaluation of the performance direction based control, we can see that in most cases the model follows the musical meaning of the marking. Example (c) shows

that *piano* and *forte* delta embeddings lead to the expected decrease and increase in dynamics. The *più mosso* (more movement, faster) and *largo* (slowly and broadly) in the example (d) lead to the expected changes in tempo, articulation and dynamics. An interesting behaviour can be found in example (e), where the model values one marking over the other. During the alternation of *crescendo* and *diminuendo*, the model follows *diminuendo* more and falls on the path of slow and quiet performance. The last example (f) shows that the control can also be applied effectively to individual notes. As the definitions suggest, the *staccato* on higher pitched notes makes them more abrupt, and the *fermata* on other notes holds the notes a bit longer.

Despite the positive examples of piano performance rendering control, the model has some limitations. The proposed marking delta embeddings encode the highest learned deviations between performance styles and lead to immediate changes in performance, which can sound unnatural. One solution is to scale or interpolate the control inputs for smoother performance changes. Another issue to be addressed is disentangling the learned latent space across direction classes for a more controllable generation. Finally, the study was limited by low performance variation for some markings and compositions in the dataset. We believe that the proposed approach has a high potential for both analytical and musical creativity applications that could be fulfilled with orders of magnitude larger datasets.

7. CONCLUSION

We presented ScorePerformer, an encoder-decoder transformer with hierarchical MMD-VAE style encoding heads for fine-grained controllable expressive rendering of piano music performances. We also introduced performance direction classifiers, trained on performance style embeddings, to map notated direction markings and natural language inputs to model control inputs. Evaluation showed that the model captures performance style variations and follows control intents. Future work will focus on improving the diversity of training data to enable large-scale analysis, and may include in-depth subjective evaluation of the proposed and existing performance rendering models.

8. ACKNOWLEDGEMENTS

We thank Dmitry Yarotsky for his valuable comments during the model development and experimentation. We thank the anonymous reviewers for their critical feedback, which allowed us to improve the paper. The experiments were performed on the Zhores computing cluster [51].

ABSTRACT

Roman Numeral analysis is the important task of identifying chords and their functional context in pieces of tonal music. This paper presents a new approach to automatic Roman Numeral analysis in symbolic music. While existing techniques rely on an intermediate lossy representation of the score, we propose a new method based on Graph Neural Networks (GNNs) that enable the direct description and processing of each individual note in the score. The proposed architecture can leverage notewise features and interdependencies between notes but yield onset-wise representation by virtue of our novel edge contraction algorithm. Our results demonstrate that *ChordGNN* outperforms existing state-of-the-art models, achieving higher accuracy in Roman Numeral analysis on the reference datasets. In addition, we investigate variants of our model using proposed techniques such as NADE, and post-processing of the chord predictions. The full source code for this work is available at <https://github.com/manoskary/chordgnn>

1. INTRODUCTION

Automatic Chord Recognition is one of the core problems in Music Information Retrieval. The task consists of identifying the harmonies or chords present in a musical piece. Various methods have been proposed to address this task using either an audio or symbolic representation of the music [1]. In the symbolic domain, most approaches focus on the related and arguably more complex problem of Automatic Roman Numeral Analysis, which is a functional harmony analysis problem that has its roots in musicological research of Western classical music.

Roman Numeral Analysis is a notational system used in music theory to analyze chord progressions and identify the relationship between chords in a given key. In this system, each chord in a piece of music is assigned a Roman numeral based on its position within the key's scale. For example, in the key of C major, the I chord is C major, the IV chord is F major, and the V chord is G major. Roman Numerals are

an important tool for understanding and analyzing the harmonic structure of music, and they are a valuable resource for musicians, composers, and arrangers alike.

In Music Information Retrieval, a lot of work has been done to automate Roman Numeral analysis. However, current approaches still face significant challenges. Some of these are related to the large chord symbol vocabulary. A common way to address this problem is to divide a Roman Numeral into several components (e.g., key, degree, inversion) and transform the analysis into a multitask learning scenario. However, multitask approaches themselves face challenges with interdependencies among tasks. Lastly, Roman Numeral analysis faces a score representation problem related to existing models such as CNNs whose inputs must be in fixed-sized chunks. Recent state-of-the-art approaches follow an audio-inspired strategy, dividing a musical score into fixed-length time frames ("windows") which are then processed by a Convolutional Recurrent Neural Network (CRNN). However, such a representation is unnatural for scores and has the added practical disadvantage of being time-limited (for example regarding notes extending beyond the current window) and, due to the fixed-length (in terms of score time) constraint, capturing varying amounts of musically relevant context.

In this paper, we propose a new method for automatic Roman Numeral analysis based on Graph Neural Networks that can leverage note-wise information to address the score representation issue. Our model, *ChordGNN*, builds on top of existing multitask approaches but introduces several novel aspects, including a graph convolutional architecture with an edge contraction pooling layer that combines convolution at the note level but yields the learned representation at the onset level.

Our proposed method, *ChordGNN*, is evaluated on a large dataset of Western classical music, and the experimental results demonstrate that it outperforms existing state-of-the-art methods, in terms of the commonly used Chord Symbol Recall measure. To address the interdependencies among tasks we investigate the effect of post-processing and other proposed techniques such as NADE and gradient normalization. Finally, we look at a qualitative musical example and compare our model's predictions with other state-of-the-art models.

Widmer, "Roman Numeral Analysis with Graph Neural Networks: Onset-wise Predictions from Note-wise Features", in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

Figure 1. A Roman Numeral analysis for two bars for four-part harmony in *C* major. Capital letters stand for major quality and lowercase for minor quality. The third chord has a dominant seven as its primary degree and the dominant of *C* major as its secondary degree. The V_5^6 indicates a major with a seven quality in second inversion. The bass (lowest chord note) of that chord is *F* sharp, the root is *D*, and the local key is *C* major.

2. RELATED WORK

There is a big body of literature covering the topic of Automatic Chord Recognition applied in the audio domain; however, in our work, we focus on the problem of automatic Roman Numeral Analysis in the symbolic domain. It consists of labeling the chords and harmonic progressions in a piece of music using Roman Numerals, where each numeral represents a chord built on a particular scale degree. Numerous approaches have tried to automate Roman Numeral analysis or infer harmonic relations between chords. Notable work includes statistical models such as *Melisma* [2], HMM-based models [3], and grammar-based approaches [4].

In recent years, research has shifted towards a deep learning and data-driven approach. Due to the large vocabulary of possible Roman Numerals, the problem has been divided into several component subtasks, thus resulting in a multi-task learning setting [5]. As a multitask problem, a Roman Numeral is characterized by the following components: the primary and secondary degree (as illustrated in Figure 1), the local key at the time point of prediction, the root of the chord, the inversion of the chord, and the quality (such as major, minor, 7, etc.). Although the root can be derived from the other components, it was pointed out by [6] that redundancy is assisting Roman Numeral analysis systems to learn. An example of Roman Numerals and their components can be viewed in Figure 1. Recent state-of-the-art approaches decompose the numeral prediction task to the simultaneous prediction of those 6 components [5–9].

Most deep learning approaches to Roman Numeral analysis are inspired by work in audio classification, cutting a score into fixed-size chunks (in terms of some constant score time unit; e.g., a 32nd note) and using these as input to deep models. Using this quantized time frame representation, [6] introduced a CRNN architecture to predict Roman Numerals. Other work has continued to build on the latter by introducing more tasks to improve performance such as the *AugmentedNet* model [7], or introducing intra-dependent layers to inform in an orderly fashion the prediction of one task with the previously predicted task, such as the model introduced by [8]. Other architectures, such as

Figure 2. Different representations of the score excerpt shown in the middle. Top: quantized time frame representation, bottom: graph representation.

the CSM-T model, have demonstrated good results by introducing modular networks which treat a score as a sequence of notes ordered first by onset and then by pitch [9].

Should a musicologist perform music analysis on a piece of music, they would consider the individual notes existing in the score. Thus, a time frame representation would come across as unnatural for symbolic music and in particular for such an analysis task. In this paper, we present a method that no longer treats the score as a series of quantized frames but rather as a partially ordered set of notes connected by the relations between them, i.e., a graph. A visual comparison of the two representations is shown in Figure 2. Recently, modeling scores as graphs has also been demonstrated to be beneficial for problems such as expressive performance generation [10], cadence detection [11], voice separation [12], or boundary detection [13].

Automatic Roman Numeral analysis, as a multitask problem, is mostly tackled with hard parameter-sharing models. These models share part of the model across all tasks as an encoder, and then the common embeddings are branched to a classification model per task [6–8]. However, some approaches separate tasks from this paradigm to a more modular or soft parameter sharing approach [9].

In the field of multitask learning, a lot of research has been done on the problem of conflicting gradients during backpropagation in hard parameter-sharing models. Issues with multi-objective optimization have been early addressed by Zhang et al. [14] and recent solutions have been proposed for the multitask setting in the form of dynamic task prioritization [15], gradient normalization [16], rotation matrices [17], or even game-theoretic approaches [18]. In our work, we experimentally evaluate some of these techniques in the multitask setting to investigate whether Roman Numeral analysis subtasks conflict with each other (see Section 5.2).

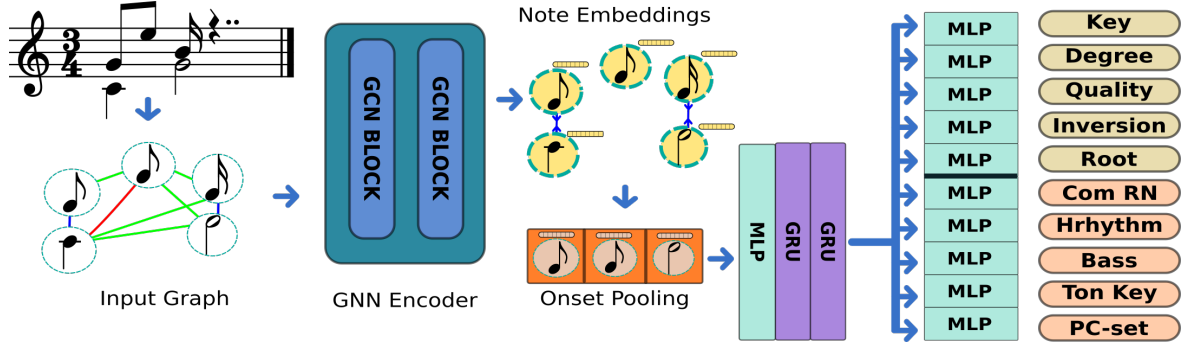

Figure 3. The proposed Architecture Chord-GNN

3. METHODOLOGY

3.1 Roman Numeral Analysis

We already discussed, in Section 2, how Roman Numeral analysis can be viewed as a multi-task problem. In this section, we describe in detail the additional tasks introduced by [7] that we also use for training and prediction. First, let us assume that the prediction can be broken down into specific time points, and each time point is attributed to a unique onset in the score.

The Roman Numeral prediction can be viewed as a simultaneous prediction of the local key, degree (primary and secondary), quality, inversion, and root. Each one of these tasks is a categorical, multiclass classification problem. However, [7] indicated that only three tasks would be sufficient for 98% of the Roman Numeral annotations in our dataset (detailed in Section 4.1). These three tasks comprise the prediction of a restricted vocabulary of common Roman Numeral symbols in combination with the local key and the inversion. We refer to Roman Numeral prediction involving the 5 tasks as *conventional RN*, and the combined prediction of key, inversion, and restricted RN vocabulary *alternative RN*, as RN_{alt} , in accordance with [7].

Several other tasks have been introduced that have been shown to improve the performance of related models [7]. These include the Harmonic Rhythm, which is used to infer the duration of a Roman Numeral at a given time point; the Tonicization task, a multiclass classification task that refers to a tonicized key implied by the Roman Numeral label and is complementary to the local key; the Pitch Class Sets task, which includes a vocabulary of different pitch class sets, and the Bass task, which aims to predict the lowest note in the Roman Numeral label.

3.2 Graph Representation of Scores

Our approach to automatic Roman Numeral analysis no longer treats the score as a sequence of quantized time frames but rather as a graph, which permits us to specify note-wise information such as pitch spelling, duration, and metrical position. We use graph convolution to model interdependencies between notes. We model our score generally following Karystinaios and Widmer [11], but we opt for a heterogeneous graph convolution approach, i.e., including different edge relations/types. Furthermore, we develop an

edge contraction pooling layer that learns onset-wise representations from the note-wise embeddings and therefore yields a sequence.

After the edge contraction, we follow [6–8] by adding to the graph convolution a sequence model for the hard-sharing part of our model, and simple shallow multi-layer perceptron heads for each task. In essence, we replace the CNN encoder that works on quantized frames of the score in previous approaches, with a graph convolutional encoder followed by an edge contraction layer. Our proposed architecture is shown in Figure 3.

The input to the GNN encoder is an attributed graph $G = (V, E, X)$ where V and E denote its node and edge sets and X represents the node feature matrix, which contains the features of the notes in the score. For our model, we used pitch spelling, note duration, and metrical position features.

Given a musical piece, the graph-building process creates a set of edges E , with different relation types \mathcal{R} . A labeled edge (u, r, v) of type r between two notes u, v belongs to E if the following conditions are met:

- notes starting at the same time:
 $on(u) = on(v) \rightarrow r = \text{onset}$
- note starting while the other is sounding: $on(u) > on(v) \wedge on(u) \leq on(v) + dur(v) \rightarrow r = \text{during}$
- note starting when the other ends:
 $on(u) + dur(u) = on(v) \rightarrow r = \text{follow}$
- note starting after a time frame when no note is sounding: $on(u) + dur(u) < on(v) \wedge \nexists v' \in V, on(v') < on(v) \wedge on(v') > on(u) + dur(u) \rightarrow r = \text{silence}$

3.3 Model

In this section, we introduce and describe *ChordGNN*, a Graph Convolutional and Recurrent Neural Network. The structure of the network is visually outlined in Figure 3. *ChordGNN* uses heterogeneous graphSAGE [19] convolutional blocks defined as:

$$\begin{aligned}
 \mathbf{h}_{\mathcal{N}_r(v)}^{(l+1)} &= \text{mean}(\{\mathbf{h}_u^l, \forall u \in \mathcal{N}_r(v)\}) \\
 \mathbf{h}_{v_r}^{(l+1)} &= \sigma(W \cdot \text{concat}(\mathbf{h}_v^l, \mathbf{h}_{\mathcal{N}_r(v)}^{l+1})) \\
 \mathbf{h}_v^{(l+1)} &= \frac{1}{|\mathcal{R}|} \sum_{r \in \mathcal{R}} \mathbf{h}_{v_r}^{(l+1)}
 \end{aligned} \tag{1}$$

where $\mathbf{h}_v^{(0)} = \mathbf{x}_v$ and \mathbf{x}_u is the input features for node u , $\mathcal{N}(u)$ are the neighbors of node u , and σ is a ReLU activation function. We name the output representations of all nodes after graphSAGE convolution $H = \{h_u^{(L)} \mid u \in V\}$ where L is the total number of convolutional layers.

Given the hidden representation H of all nodes, and onset edges $E_{\text{On}} = \{(u, v) \mid \text{on}(u) = \text{on}(v)\}$, the onset edge contraction pooling is described by the following equations: first, we update the hidden representation with a learned weight, $H' = HW^{(\text{cpool})}$. Subsequently we need to unify the representations for every node u , such that $\forall v \in \mathcal{N}_{\text{On}}(v)$, $h_u^{(\text{cp})} = h_v^{(\text{cp})}$:

$$h_u^{(\text{cp})} = h_u + \sum_{v \in \mathcal{N}_{\text{On}}(v)} h_v \quad (2)$$

where, h_u and h_v belong to H' . Subsequently, we filter the vertices:

$$V' = \{v \in V \mid \forall u \in V, (v, u) \in E_{\text{On}} \implies u \notin V'\} \quad (3)$$

Therefore, $H^{(\text{cp})} = \{h_u^{(\text{cp})} \mid \forall u \in V'\}$ are the representations obtained. Sorting the representations by the onset on which they are attributed we obtain a sequence $S = [h_{u_1}^{(\text{cp})}, h_{u_2}^{(\text{cp})}, \dots, h_{u_k}^{(\text{cp})}]$ such that $\text{on}(u_1) < \text{on}(u_2) < \dots < \text{on}(u_k)$.

The sequence S is then passed through an MLP layer and 2 GRU layers. This concludes the hard-sharing part of our model. Thereafter, an MLP head is attached per task, as shown in Figure 3.

For training, we use the dynamically weighted loss introduced by [20]. The total loss \mathcal{L}_{tot} of our network is calculated as a weighted sum of the individual losses for every task, where the weights are learned during training:

$$\mathcal{L}_{\text{tot}} = \sum_{t \in \mathcal{T}} \mathcal{L}_t * \frac{1}{2\gamma_t^2} + \log(1 + \gamma_t^2) \quad (4)$$

where \mathcal{T} is the set of tasks; \mathcal{L}_t is the cross-entropy loss relating to task t ; the γ_t are learned scalars that give the weight for each task t ; and the log expression is a regularization term [20].

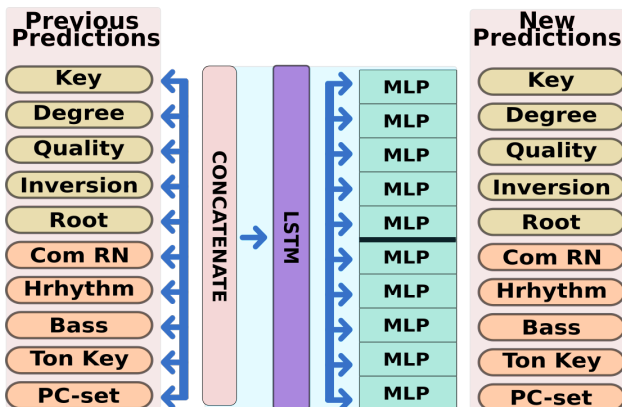

Figure 4. Post-processing of Roman Numeral predictions.

3.3.1 Post-processing

We enhance our model with a post-processing phase after the model has been trained. The post-processing phase combines the logits of all tasks' predictions by concatenating them and, then, feeds them to a single-layer bidirectional LSTM block. Then, again the embeddings of the sequential block are distributed to 11 one-layer MLPs, one for each task. The post-processing block is sketched in Figure 4.

4. EXPERIMENTS AND CORPORA

In the experiments, we compare our model, *ChordGNN*, with other recent models for automatic Roman Numeral analysis. We run experiments with our model in the exact same way as described in the paper [7], including the specific data splits, so that our results are directly comparable to the figures reported there. A detailed comparison of the results will be given in Table 1. Furthermore, we develop variants of our model using proposed techniques such as NADE [8], and post-processing of the chord predictions. We report a configuration study of our model on the use of gradient normalization techniques and NADE that should improve results on Multi-Task learning scenarios and avoid common Multi-Task Learning problems such as conflicting gradients. Lastly, we compare our model with the updated version *v1.9.1* of the state-of-the-art model Augmented-Net [21] and datasets.

4.1 Datasets

For training and evaluation, we combined six data sources into a single "Full" Dataset of Roman Numeral annotations in accordance with [7]: the Annotated Beethoven Corpus (ABC) [22]; the annotated Beethoven Piano Sonatas (BPS) dataset [5]; the Haydn String Quartets dataset (HaydnSun) [23]; the TAVERN dataset [24]; a part of the When-in-Rome (WiR) dataset [25, 26]; and the Well-Tempered-Clavier (WTC) dataset [25] which is also part of the WiR dataset.

Training and test splits for the full dataset were also provided by [7]. It is worth noting that the BPS subset splits were already predefined in [5]. In total, approximately 300 pieces were used for training, and 56 pieces were used for testing, proportionally taken from all the different data sources. We draw a distinction for the BPS test set, which includes 32 Sonata first movements and for which we ran an additional experiment. The full test set also includes the 7 Beethoven piano sonatas.

In addition to the above datasets, we include data augmentations identical to the ones described in [7]: texturization and transposition. The texturization is based on a dataset augmentation technique introduced by [27]. The transposition augmentation boils down to transposing a score to all the keys that lie within a range of key signatures that have up to 7 flats or sharps. It should be noted that the augmentations are only applied in the training split.

For our last experiment (to be reported on in Section 5.3 below), we add additional data that were recently introduced by [21]. The additional data include the annotated Mozart

	Model	Key	Degree	Quality	Inversion	Root	RN	RN (Onset)	RN _{alt}
BPS	Micchi (2020)	82.9	68.3	76.6	72.0	-	42.8	-	-
	CSM-T (2021)	69.4	-	-	-	75.4	45.9	-	-
	AugNet (2021)	85.0	73.4	79.0	73.4	84.4	45.4	-	49.3
	ChordGNN (Ours)	79.9	71.1	74.8	75.7	82.3	46.2	46.6	48.6
	ChordGNN+Post (Ours)	82.0	71.5	74.1	76.5	82.5	49.1	49.4	50.4
Full	AugNet (2021)	82.9	67.0	79.7	78.8	83.0	46.4	-	51.5
	ChordGNN (Ours)	80.9	70.1	78.4	78.8	84.8	48.9	48.4	50.4
	ChordGNN+Post (Ours)	81.3	71.4	78.4	80.3	84.9	51.8	51.2	52.9

Table 1. Model comparison on two different test sets, the Beethoven Piano Sonatas (BPS), and the full test set. RN stands for Roman Numeral, RN_{alt} for the alternative Roman Numeral computations discussed in Section 3.1. $RN(Onset)$ refers to onset-wise prediction accuracy, all other scores use the CSR score (see Section 5). Note that model *CSM-T* reports *Mode* instead of *Quality*.

Piano Sonatas (MPS) dataset [28] for which we also applied the aforementioned augmentations.

4.2 Configuration

For all our experiments, we train our network with the AdamW optimizer. We fix our architecture with a hidden size of 256, a learning rate of 0.0015, a weight decay of 0.005, and a dropout of 0.5 which is applied to each learning block of our architecture.

5. RESULTS

As an evaluation metric, we use Chord Symbol Recall (CSR) [29] where for each piece, the proportion of time is collected during which the estimated label matches the ground truth label. We apply the CSR at the 32nd note granularity level, in accordance with [6, 7, 9].

5.1 Quantitative Results

In the first experiment, which compares our *ChordGNN* to existing state-of-the-art approaches, we evaluate the full dataset, but also the annotated Beethoven Piano Sonatas (BPS) [5] subset, which many previous approaches had also used. The results are shown in Table 1. We present the CSR scores (where they are applicable) for Local Key, Degree, Quality, Inversion, Root, conventional Roman Numeral, and Alternative Roman Numeral (see Section 3). Furthermore, we include the onset-wise accuracy score for our models’ conventional Roman Numeral predictions.

On the BPS subset, we compare our model *ChordGNN* with the Micchi (2020) model [6], the *CSM-T* (2021) model [9] and the *AugmentedNet* 2021 model [7]. Our results on Roman Numeral prediction surpass all previous approaches. Note that the *AugmentedNet* model exhibits higher prediction scores on the individual Key, Degree, Quality, and Root tasks, which are used jointly for the prediction of the Roman numeral. These results indicate that our model obtains more meaningfully interrelated predictions, with respect to the Roman numeral prediction, resulting in a higher accuracy score.

Moreover, we compare *ChordGNN* to *AugmentedNet* on the full test dataset. Our model surpasses *AugmentedNet*

Variant	RN	RN _{alt}
ChordGNN (Baseline)	46.1 ± 0.003	47.8 ± 0.007
ChordGNN + WLoss	48.9 ± 0.001	50.4 ± 0.010
ChordGNN + Rotograd	45.5 ± 0.003	47.1 ± 0.005
ChordGNN + R-GradN	45.2 ± 0.006	46.7 ± 0.005
ChordGNN + NADE	48.2 ± 0.005	49.9 ± 0.005

Table 2. Configuration Study: Chord Symbol Recall on Roman Numeral analysis on the full test set. RN stands for Roman Numeral, RN_{alt} refers to the alternative Roman Numeral computations discussed in section 3.1. WLoss stands for the dynamically weighted loss described in Section 3, and R-GradN stands for Rotograd with Gradient Normalization. Every experiment is repeated 5 times with the same ChordGNN model as Table 1 without post-processing.

with and without post-processing in all fields apart from local key prediction and quality. Our model obtains up to 11.6% improvement in conventional Roman Numeral prediction.

In both experiments, post-processing has been shown to improve both RN and RN_{alt} . However, *ChordGNN* without post-processing already surpasses the other models.

5.2 Configuration Study

For a systematic study of multitask training, we investigated the effects of extension modules, gradient normalization techniques, and learnable weight loss. In detail, we test 5 configurations using as baseline the *ChordGNN* model (without post-processing) with standard CE loss and no weighing. Furthermore, we test our proposed architecture using the dynamically weighted loss described in Section 3.3 (same as the model in Table 1), Rotograd [17] and GradNorm [16] for Gradient Normalization, and NADE [8]. The models are run on the Full data set described above and averaged over five runs with random initialization. The results, summarized in Table 2, suggest that using the dynamically weighted loss yields better results compared to other methods such as the Baseline or Gradient Normalization techniques. Furthermore, the dynamically weighted loss is comparable to NADE but also more robust on Conventional Roman Numeral prediction on our datasets.

Figure 5. A comparison between the human annotation, AugmentedNet, and ChordGNN on a passage of Haydn’s string quartet op.20 No.3 movement 4. The red (wrong) markings on Human Analysis and AugNet (2022) are from [21]

5.3 Latest developments

Our last experiment focuses on specific developments that have very recently been published in Nápoles López’s Ph.D. thesis [21]. In the thesis, three additional tasks, related to predicting the components of a canonical representation of the current chord, as implied by the Roman Numeral, were proposed and the dataset was extended with the Annotated Mozart Piano Sonatas (MPS) corpus [28], as mentioned in Section 4.1 above.

To test the relevance of these updates, we trained an adapted version of our model, now with 11+3=14 individual tasks and including the Mozart data. It turns out that the updated model improves significantly in performance, achieving a 53.5 CSR score on conventional Roman Numeral (compare this to row "ChordGNN (Ours)" in Table 1). Furthermore, post-processing can improve the results by up to two additional percentage points.¹

5.4 A Musical Example

In Figure 5, we look at a comparison between the human annotations, *AugmentedNet* and *Chord-GNN* predictions (The musical excerpt is taken from Nápoles López’s thesis [21], and the predictions relate to the new models trained as described in the previous section.). Marked in red are false predictions, and marked in yellow are correct predictions of the model with wrong ground-truth annotations. Both models’ predictions are very similar to the human analysis. However, our model correctly predicts the initial pickup measure annotation. In measure 2, the ground truth annotation marks a tonic in first inversion; however, the viola at that point is lower than the cello and therefore the chord is actually in root position. Both models obtain a correct prediction at that point. Subsequently, our model predicts a harmonic rhythm of eighth notes, which disagrees with the annotator’s half-note marking. Analyzing the underlying harmony in that passage, we can justify our model’s choices.

¹ Unfortunately, we cannot directly compare these numbers to [21], as their results are not reported in comparable terms.

The human annotation suggests that the entire second half of the 2nd measure represents a *vii°* chord. However, it should not be in the first inversion, as the cello plays an F# as the lowest note (which is the root of *vii°*). The AugNet analysis faces the same issue, in contrast with the predictions of ChordGNN. However, there are two conflicting interpretations of the segment. First, the *vii°* on the third beat is seen as a passing chord between the surrounding tonic chords, leading to a dominant chord in the next measure. Alternatively, the *vii°* could already be part of a prolonged dominant harmony (with passing chords on the offbeats) leading to the *V⁷*. The ChordGNN solution accommodates both interpretations as it doesn’t attempt to group chords at a higher level, treating each eighth note as an individual chord rather than a passing event. The other two solutions prefer the second option.

6. CONCLUSION

In this paper, we presented *ChordGNN*, a model for automatic Roman Numeral analysis in symbolic music, based on a note-level, graph-based score representation. We showed that *ChordGNN* improves on other state-of-the-art models, and that post-processing can further improve the accuracy of the predictions. A configuration study suggests that gradient normalization techniques or techniques for carrying prediction information across tasks are not particularly beneficial or necessary for such a model.

Follow-up work will focus on strengthening the robustness of our models by pre-training with self-supervised methods on large corpora. We believe that such pre-training can be beneficial for learning helpful intrinsic musical information. Such a step is crucial since more data improves predictions but Roman Numeral annotations are hard to find or produce. Moreover, we aim to enrich the number of tasks for joint prediction by including higher-level analytical targets such as cadence detection and phrase boundary detection. Finally, we aim to extend our method to the audio domain.

7. ACKNOWLEDGEMENTS

We gratefully acknowledge the musical analysis of the *viiv* passage in Fig. 5 (Section 5.4) that was offered by an anonymous reviewer, and which we took the liberty of adopting for our text. This work is supported by the European Research Council (ERC) under the EU’s Horizon 2020 research & innovation programme, grant agreement No. 101019375 (“Whither Music?”), and the Federal State of Upper Austria (LIT AI Lab).

ABSTRACT

We present a system to assist Subject Matter Experts (SMEs) to curate large online music catalogs. The system detects releases that are incorrectly attributed to an artist discography (misattribution), when the discography of a single artist is incorrectly separated (duplication), and predicts suitable relocations of misattributed releases. We use historical discography corrections to train and evaluate our system’s component models. These models combine vector representations of audio with metadata-based features, which outperform models based on audio or metadata alone. We conduct three experiments with SMEs in which our system detects misattribution in artist discographies with precision greater than 77%, duplication with precision greater than 71%, and by combining the approaches, predicts a correct relocation for misattributed releases with precision up to 45%. These results demonstrate the potential of such proactive curation systems in saving valuable human time and effort by directing attention where it is most needed.

1. INTRODUCTION

Online music catalogs such as Spotify’s contain millions of releases, and new ones are added daily by providers ranging from professionally-staffed music labels to DIY artists via aggregators. In such large catalogs, it is common that multiple artists share the same or similar names, or that content by one artist comes from different providers. For example, there are 14 distinct metal bands with the name *Burial*¹. When a new release by a *Burial* makes it to the catalog, in the absence of a unique artist identifier, we must make a decision of where to place the content: Is it by the Italian doom metal band, the English death metal band, one of the other 12 bands named *Burial*, or an entirely new one? In general, *to which artist do we attribute a release when there are multiple artists with the same name?*

Music streaming services have multiple systems to ensure that releases are correctly placed on artist discogra-

phies. However, given the large volumes of content and the diversity of sources, it is inevitable that on rare occasions a release is incorrectly attributed (e.g. due to incomplete or incorrect metadata, extreme ambiguity, or human error). These errors can manifest in two different ways: 1) *Misattribution*: when a release is incorrectly attributed to an artist, so that their discography now contains releases from two separate real-world artists; 2) *Duplication*: when a release is not attributed to the correct existing discography but to a new one, so that a single artist’s work is split across the two discographies. These errors negatively impact the experience of both artists and users on the platform.

The problem of Named Entity Disambiguation (NED) has been extensively researched to attribute scientific papers to homonym authors using metadata such as the author’s fields of research, academic affiliations, and co-authors [1–3]. In Music Information Retrieval (MIR), NED is primarily tackled as artist identification or multi-class classification with known artist classes. Approaches to this problem rely primarily on audio feature representations [4–6]. These methods cannot be applied to catalogs with a large or unknown number of artists, and do not take advantage of all existing information.

Here we present a semi-automated proactive curation system to detect and correct attribution errors across large music catalogs. The system consists of two machine learning sub-systems: a system for detecting misattribution by splitting discographies with releases from multiple real-world artists into their constituent sub-discographies (Fig. 1a), and a deduplication system that takes pairs of discographies or sub-discographies and decides if they should be combined (Fig. 1b). Both sub-systems rely on metadata and the acoustic similarity between releases, using deep convolutional network embeddings of their mel-spectrograms [7]. We show that combining audio and metadata features improves average precision in misattribution and duplicate detection by 10% and 6% respectively.

“*In the wild*” experiments with music catalog curation Subject Matter Experts (SMEs) show that our system achieves over 77% precision on misattribution detection, over 71% precision on duplicate detection, and 45% precision on finding the correct relocation of misattributed releases. Together these results demonstrate the power of proactive catalog correction systems in assisting human-led curation efforts.

2. RELATED WORK

Recent advances in audio feature representation using deep learning [8] have applications to recommendations [7], audio classification [4] and artist identification [4, 6, 9, 10]. These works typically focus on the audio and do not include additional information (the method in [9] uses genre in its negative sampling method, but the model takes only audio). Work in other Named Entity Disambiguation (NED) applications shows that combining learned feature representations and manually crafted diverse features outperforms using either in isolation [11, 12]. This suggests that combining multiple data types (e.g. content and metadata) can improve the performance of music NED systems.

Duplicate entity detection (also known as entity matching or entity resolution) across or within databases typically has a *blocking* step [13] optimised for recall to reduce the set of pairwise comparisons, followed by an *entity matching* step optimised for precision. If labelled pairs of entities are available, supervised machine learning approaches can be used for matching. These are typically based on various string-based similarity features, such as entity name similarity [14].

Although state-of-the-art NED research focuses on automation [1], a human-in-the-loop (HITL) paradigm is commonly used in practice. A HITL approach is useful for resolving highly ambiguous cases and correcting automated decisions. In [3] the authors describe a machine learning approach that optimises human effort spent on labelling for author disambiguation. In the Microsoft Academic Graph [2], the author disambiguation system uses crowdsourced data as supervision signals.

Crowdsourced and authoritative sources such as MusicBrainz [15], VIAF [16], Wikidata [17], or ISNI [18] are useful for artist name disambiguation, but their benefit is limited for artists in the long tail or for brand new releases without unique artist identifiers.

3. METHODOLOGY

Our system operates on music releases (i.e. albums) denoted as a , and on artist credits in them. The set of releases credited to an artist forms the artist’s discography: $\mathcal{A} = \{a_1, a_2, \dots\}$. The objective of our system is twofold:

Correct discographies Every release within a discography should credit the same real-world artist; i.e. there is no misattribution in the discography.

Complete discographies A real-world artist’s releases should not be split across multiple discographies; i.e. there should be no more than one discography per artist.

Figure 1 illustrates our approach to achieve these goals; we achieve correctness and completeness by relocating misattributed releases and resolving (i.e. merging) duplicate discographies. Note that there are cases where a single real person performs under distinct artist identities (e.g. Dan Snaith performs as Caribou and Daphni). These

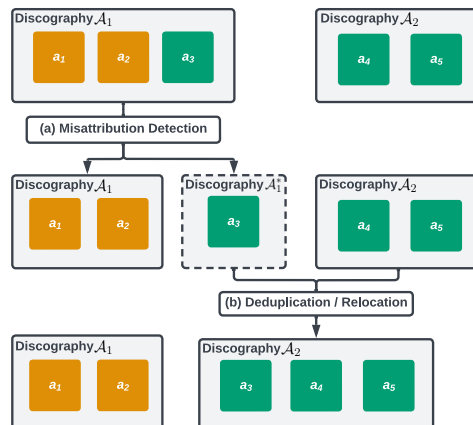

Figure 1: System Overview: (a) Misattribution detection is performed on each discography \mathcal{A} . The misattributed release a_3 is split out from \mathcal{A}_1 into *sub-discography* \mathcal{A}_1^* . (b) All (sub-)discographies are considered for deduplication; \mathcal{A}_1^* is merged into \mathcal{A}_2 , relocating the misattributed releases into the correct discography.

discographies should not be considered duplicates. In addition, some releases can belong to multiple discographies if they credit multiple distinct artists (e.g. collaborations and remixes); however, a discography should always contain releases under a common artist.

3.1 Misattribution Detection

The misattribution detection method, illustrated in Fig. 2, processes an artist’s attributed discography \mathcal{A} in two stages: First, we obtain a distance $\text{dist}(a_i, a_j)$ between all pairs of releases $a_i, a_j \in \mathcal{A}$ using the combination of audio and metadata signals in Table 1. Second, we partition \mathcal{A} using this distance by constructing a Minimum Spanning Tree (MST) [19] and imposing a threshold θ_{dist} . When we cut the MST edges where $\text{dist}(a_i, a_j) > \theta_{\text{dist}}$, the remaining connected components should contain releases from the same artist. These partitions are disjoint subsets: $\mathcal{A}_i \subseteq \mathcal{A}, i = 1 \dots m$, for which all releases belong to the same real-world artist. If the cardinality of the partition is $m > 1$, then there is at least one misattributed release in the discography (i.e. more than one artist’s content is detected) and the discography should be split.

3.1.1 Pairwise Model

To obtain the pairwise distance between releases in a discography, we train a Random Forest ensemble classifier [20] $\text{dist} : \mathcal{A} \times \mathcal{A} \rightarrow (0, 1]$, where high values indicate that the releases are likely to be from different artists.

Data. The training data consists of $\sim 45\text{K}$ release pairs from $\sim 28\text{K}$ artist discographies. This data, which we call the *Relocations* dataset, contains historical corrections of artist misattributions. The genres of the releases in this data are representative of Spotify’s catalog. Each relocation is a move of an incorrectly-placed release from an artist’s discography to the correct one. To construct the training

Figure 2: Misattribution detection: (a): An artist discography $\mathcal{A} = \{a_1, a_2, a_3\}$ in which release a_3 is misattributed. (b): The pairwise distance matrix D computed using our model. (c): A Minimum Spanning Tree (MST) is computed from the distances. (d): After applying a threshold θ_{dist} to the MST, the discography \mathcal{A} is split into two partitions, which correspond to the two distinct real world artists present in the discography.

data, consider a release a_1^i that was moved from discography \mathcal{A}_j to \mathcal{A}_i . We pair a_1^i with a release $a_1^j \in \mathcal{A}_j$ from the discography where it was incorrectly located: (a_1^i, a_1^j) , and give it the “mismatched” label. Then, we pair a_1^i with a release from the correct discography: (a_1^i, a_2^i) , $a_2^i \in \mathcal{A}_i$, and give it the “not mismatched” label.

Model Features. We use a combination of metadata and audio-based features, summarised in Table 1. Audio features include deep acoustic embeddings from a proprietary model trained in a fashion similar to [7], originally developed for music recommendations, and *speechiness* - a probability that a track contains spoken word as determined by another proprietary model [21]. An advantage of audio features is that they are available for every release. In general, we expect releases from the same artist to sound similar to each other. As mentioned in Sec. 2, previous works report good performance using audio-based methods alone [4, 9, 10]. However, releases from different artists can also sound similar (e.g. if they come from the same genre), and releases from the same artist can be musically different (e.g. an artist whose style evolved or spans many genres).

On the other hand, metadata features such as music labels, composers or lyricists can have high precision (e.g. releases from the same discography delivered by the same label are likely to be by the same artist), but in isolation metadata matches can be sparse, or have mistakes. Therefore, we supplement audio similarity with metadata based features to improve the performance of our classifier.

3.1.2 Grouping releases in a discography

Our distance allows comparisons between individual pairs of releases to decide whether they belong to distinct artists. For example, if $\text{dist}(a_i, a_j) > \theta_{\text{dist}}$ for a given $\theta_{\text{dist}} \in (0, 1]$, we could say that it is unlikely that the releases share an artist. However, this comparison ignores the context of the whole discography \mathcal{A} , and may fail when the sound of an artist has evolved in time, the artists changed collaborators or labels throughout their career. To mitigate these

² The Dice score is the average of the Dice coefficient [22] for n-gram values of 1,2,3 and 4.

³ Indicates whether the pair of releases have been identified by other systems as duplicates

⁴ Number of pairs of artists with Dice score > 0.7

Random permutations of underlined feature values decreased test-set performance $>95\%$ of the time.

issues, we consider each comparison in the context of all the releases in \mathcal{A} .

We construct the matrix $D \in \mathbb{R}^{m \times m}$ where $D_{ij} = \text{dist}(a_i, a_j)$, and use it to obtain a MST, which is a graph with node set \mathcal{A} , and edges with weight equal to the nodes’ pairwise distance (see Fig. 2c). The MST connects releases that are “close” to each other, and provides a global summary of how the releases are organised in a latent space, while capturing the continuity of the data arising from evolution in the style and career of an artist. We can attribute two dissimilar releases to the same artist if there is a path of short hops along the MST that connects them. Put another way, if we cut very long hops (i.e. long edges) in the MST, we get connected components in which we can only go between nodes by a series of short hops. Our hypothesis is that these components (partitions of \mathcal{A}) are releases that

are likely to be from the same artist. Specifically, we need to find a threshold θ_{dist} and cut all edges in the MST that are larger. The remaining connected components preserve transitive relations even when the distance is not transitive: if $\text{dist}(a_i, a_j)$ is low and $\text{dist}(a_j, a_k)$ is low, $\text{dist}(a_i, a_k)$ can still be high, but one can traverse from a_i to a_k with short hops via a_j . This approach preserves the diversity of releases over the careers of artists. If no edge is larger than θ_{dist} , then the MST connects all releases with paths of short hops, and we assume that they are all correctly attributed to the same artist.

3.2 Discography Deduplication

The goal of deduplication is to merge existing discographies, or sub-discographies split out from misattribution detection, that belong to the same artist (e.g. release a_3 in Fig. 1). Deduplication consists of two steps: (1) generating candidates for deduplication through a blocking strategy, and (2) a prediction step that determines whether the pair of discographies belong to the same real-world artist.

3.2.1 Blocking

To reduce the comparisons between pairs of discographies while maintaining high recall, we want to create small *blocks* of discographies that could belong to the same artist. One way is to simply take homonym artist discographies as a block; however, errors which lead to misattribution and duplication in music catalogs are often associated with varied spellings or aliases of the same real-world artist. Therefore, we need a more robust blocking strategy.

We build an Elasticsearch [23] index of all artist names in the catalog which we use to match and rank deduplication candidates. The matching strategy combines three conditions: (1) n -grams with $n = 2, 3, 4$; (2) fuzzy string matching with edit distance ≤ 2 ; and (3) normalised string matching without spaces and stop-words. If one or more of these conditions match a *seed* discography artist name, Elasticsearch returns a list of all matching candidates ranked by their *elastic score* [24]. We evaluate this strategy on a dataset of source and target artist name pairs from the *Merges* dataset (described below), and obtain a recall@10 of 97%.

3.2.2 Duplicate detection model

We train a Random Forest classifier to compute the similarity $\text{sim}(\mathcal{A}_i, \mathcal{A}_j) \in (0, 1]$ between pairs of artist discographies within each block. A high similarity score means that the two discographies are likely to come from the same real-world artist and should be merged, while a low score indicates that they are from different artists and should remain separate.

Data. The training data consists of $\sim 224\text{K}$ discography pairs. This data, which we call the *Merges* dataset, contains historical corrections of duplicate artist discographies. We assign a positive label to each merged pair and generate up to 10 negative examples for each positive one using the blocking strategy. During training we balance the

data by applying a weight to each sample to be inversely proportional to its class frequency.

Model Features. As in the misattribution model, we combine engineered metadata features with acoustic embeddings (see Table 2). Duplicate entity detection systems typically rely heavily on string similarity, but there are some challenges. For example, consider merging the discography referencing the artist *Prince*, with the one referencing his alias *Prince of Funk*, while remaining distinct from another artist called *Princess*. Relying solely on string similarity would suggest that the discographies from *Prince* and *Princess* are more likely to belong to the same artist than the ones from *Prince* and *Prince of Funk*. In this scenario, including audio representations in the model can improve performance in the absence of other distinctive features.

4. EVALUATION

We evaluate our system’s performance with a series of experiments: First, we examine the offline performance of each sub-system under different feature ablations, including audio and metadata signals alone, using the *Relocations* and *Merges* datasets. Second, we conduct three experiments with Subject Matter Experts (SMEs) showing the performance “in the wild” of the misattribution and deduplication models, and their unification for the relocation of misattributed releases, as described in Fig. 1.

4.1 Audio and Metadata Feature Ablations

We test the hypothesis that metadata and learned audio representations model catalog correction tasks (i.e. misattribution and duplicate detection) better together than separately. Figure 3 shows the performance of the two models in three configurations: audio features only, metadata features only and combined. The features for each model and the distinction between audio-based and metadata-based features can be found in Tables 1 and 2. For each set of features, we separately tuned the hyperparameters with 5-fold cross-validation.

Figure 3: (a) - (b): Precision-Recall curves in offline experiments with combinations of audio and metadata features for misattribution detection (a) and deduplication (b). Average precision (AP) is reported in the legend for each set of features. (c) - (d): Annotation experiment results for misattribution detection (c) and deduplication (d). Precision is calculated for each threshold bucket and reweighed by the distribution of predictions shown on the second y axis.

Figure 3a shows that the pairwise misattribution model using audio-based features alone has good performance, but combining both audio and metadata produces the best performance. The full model has an average precision (AP) increase of 10.69% over the metadata-only model, and 1.95% AP over the audio-based model. These improvements come from a reduction in false positives (e.g. when the sound is not similar, but metadata similarities exist between two releases). For example, the test data contains the releases *SHOOT MY SHOT* and *Hurts Like Hell (feat. Offset)* from the American rapper *Offset*. The audio-only model predicts these releases come from different artists (their distance is 0.77). The full model gives the pair a distance of 0.1 because “*Kiari Kendrell Cephus*” (which is Offset’s real name), appears in the credits of both releases as a writer and a composer/lyricist.

Figure 3b shows the performance of the duplicate detection task under the different ablations. Using metadata features alone outperforms audio features alone by 4% in AP. This is not surprising, as entity resolution tasks are usually heavily based on string similarity across aligned fields. Here too we can achieve good performance with metadata based features alone, but combining the features boosts AP by 6%. This boost is driven by cases where metadata features are insufficient. In the example of the *Prince* and *Prince of Funk* discographies, in the absence of shared collaborators or similarity on release titles we would get a false negative. However, the acoustic similarity between the two discographies is high, which allows us to correctly identify them as by the same real-world artist.

4.2 Experiments with SMEs

We conducted three experiments with SMEs to understand the performance of each task independently, and of the entire correction system (Fig. 1) in the context of its intended use, for a range of decision thresholds. We use precision as our evaluation metric since we want to reduce human effort spent reviewing and correcting the catalog.

4.2.1 Misattribution Detection

We ran the misattribution detection method from Sec. 3.1 using an early version of the pairwise model that was ready when the SMEs were available. The difference between the full model and this early version is that the latter uses only subset of the features of the full model (marked with * in Table 1). We selected a subset of artist discographies from the Spotify catalog, biased toward more popular artists, that reviewers are able to cross-reference externally. Then, we randomly sampled a pair of releases from each artist and calculated the value of the threshold θ_{dist} that would split the pair into two different partitions of the discography. This value is the largest edge weight along the path connecting the releases in the MST of the artist’s discography. In the example in Fig 2c, the threshold between releases a_1 and a_3 would be $\theta_{dist} = 0.85$. We stratified our sample by these bucketed threshold values in 10 equally sized bins between 0 and 1, with a maximum of 100 pairs per bucket. The sampling produces $\sim 1K$ pairs, each of which was reviewed by a SME who classified it as “by the same artist” or “by different artists”. Figure 3c shows the precision for each value of θ_{dist} (blue line, left y-axis). For example, at a $\theta_{dist} > 0.7$, we can achieve 77%

precision. When θ_{dist} is small, many single-artist discographies are split into more than one group. This lowers precision but increases the fraction of artists that would have their discography partitioned into more than one group at each threshold (grey bars, right y -axis).

4.2.2 Duplicate Detection

To evaluate the duplicate detection model from Sec. 3.2, we generated a list of 140K seed artist discographies of popular artists from the catalog. Then, we generated 10 candidates for each seed artist using our blocking strategy to form artist-candidate pairs. For each pair we compute $sim(a_i, a_j)$, and bucket the scores in the same way as for the misattribution detection task above, sampling up to 100 per bin. For this task, 3 SMEs reviewed each sample and answered the question: *Do the two discographies belong to the same real-world artist?* We aggregated the annotations per sample to reflect the majority vote (i.e. at least 2 out of 3 of the annotators agree) and got 94% agreement. The remaining 6% of cases are ambiguous, and were excluded from the analysis. These cases are interesting and give insight into edge cases for future iterations of the model. For example, when the discographies were related but not technically by the same artist, e.g. the *Thelonious Monk Quintet* and the *Thelonious Monk Quartet*.

As in the misattribution task, as the threshold θ_{sim} in Fig. 3d increases so does precision, but with fewer candidate pairs (shown as grey bars, right y -axis). At a $\theta_{sim} > 0.7$, we achieve 71% precision.

4.2.3 Predicted Relocation

Discography pairs that have been reviewed and determined to be duplicates can be merged in the catalog in a straightforward way. However, correcting misattributions is not so easy, and we still need to identify the correct discography in which they belong. Having validated both steps in our discography correction system, we can use the duplicate detection method to predict the correct discography (if any) for misattributed releases. To do this, we identify misattributions, using $\theta_{dist} > 0.7$ based on the previous experiments, and we treat the misattributed releases as a sub-discography. Then, we generate and score candidate duplicate discographies for these sub-discographies using the deduplication model.

We evaluate performance on $\sim 1K$ release-discography pairs. Since the model generates up to ten predictions per seed, we take the highest predicted placement as a candidate for annotation. We asked SMEs to review the release and its predicted relocation and answer the question: *Does the release belong with the discography?*

Figure 4 shows the precision as a function of the two steps in the correction system θ_{dist} and θ_{sim} . The highest precision is 45%, which is achieved when both the misattribution step and deduplication (relocation) step have a high θ (top right corner of Fig. 4, representing 17% of the sample). The relocation task is more difficult and less precise because it inherits the uncertainty and performance of misattribution and duplicate detection. Additionally, we expect that a large number of misattributed releases might not

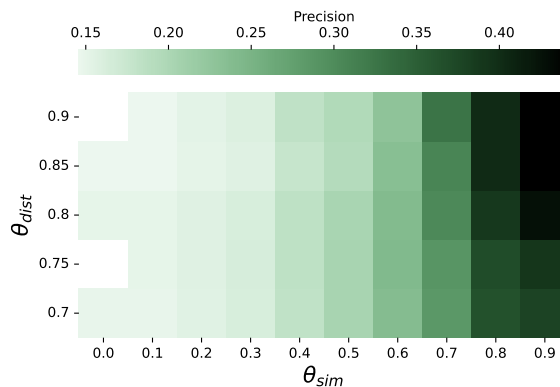

Figure 4: Precision of the combined system on the task of predicted relocation of misattributed releases for varying thresholds of the misattribution (θ_{dist}) and duplicate detection (θ_{sim}) methods.

belong anywhere, and will become standalone discographies. This means that even if the system considered this relocation to be the best out of ten candidates, a relocation might not be possible at all. Even in this scenario, the human effort to detect and correct misattributed content is significantly reduced.

5. DISCUSSION

We present a system designed for SMEs to maintain the correctness and completeness of artist discographies in a large online catalog. We demonstrate that leveraging both audio and metadata-based signals for misattribution detection and deduplication of discographies outperforms either in isolation. We validated each task separately, and the entire correction system across different thresholds, showing strong performance in three experiments with SMEs.

The power of this system is that it can scan a large catalog efficiently and direct the attention of human reviewers to where errors are most likely to be found, as well as suggest corrections for cases of misattribution and deduplication. This makes our system a key part of proactive catalog curation strategies. It is possible that some curation steps could be automated for high confidence predictions; however, due to the downstream impact of curation decisions (e.g. recommendations, search, user experience) the tolerance for incorrect relocations is low.

The current implementation of this system runs weekly, and the top-scoring candidates for misattribution, deduplication and predicted relocations are flagged for SMEs review. These reviews, in turn, become new labelled data on which the model can be re-trained and further improved.

Although discography errors are rare, it is important to minimise them as much as possible. Systems such as this are one tool among many that streaming platforms can use to ensure their catalog is correct, and to safeguard the experience of users and artists.

6. ACKNOWLEDGMENTS

We thank Nicola Montecchio and Glenn McDonald for discussions around the original idea for this work, Dimitrios Korkinof for valuable consultations throughout this project, Dana Puleo for assistance running experiments with SMEs, and Antonio Lima for comments on the manuscript.

ABSTRACT

Musical instrument recognition enables applications such as instrument-based music search and audio manipulation, which are highly sought-after processes in everyday music consumption and production. Despite continuous progresses, advances in automatic musical instrument recognition is hindered by the lack of large, diverse and publicly available annotated datasets. As studies have shown, there is potential to scale up music data annotation processes through crowdsourcing. However, it is still unclear the extent to which untrained crowdworkers can effectively detect when a musical instrument is active in an audio excerpt. In this study, we explore the performance of non-experts on online crowdsourcing platforms, to detect temporal activity of instruments on audio extracts of selected genres. We study the factors that can affect their performance, while we also analyse user characteristics that could predict their performance. Our results bring further insights into the general crowd’s capabilities to detect instruments.

1. INTRODUCTION

Studies of the last decade have shown the success of data-driven algorithms to tackle complex classification tasks. Such algorithms require large annotated datasets to train and capture the nuances of multi-faceted problems, with crowdsourcing being successfully utilized to scale annotation processes to meet the ever higher demands [1–3]. While works such as [4] and [5] show that crowdsourcing can be a viable and powerful tool to distinguish and annotate music audio, it still remains underutilised as a tool in the domain, primarily due to the complexity of the annotation tasks [6] which are believed to demand extensive domain knowledge and training – arguably, musical elements such as tempo, chords and timbre can be demanding for an untrained human annotator to detect.

With this study, we aim at providing more evidence that complex music audio annotation tasks can be performed on crowdsourcing platforms. We focus on the task of musical

instrument activity detection, and investigate non-experts’ capability to recognise their activity and annotate the times in which they perform. Our study builds upon the findings of [4] where users were able to detect if an instrument was present in an audio excerpt or not. We extend this detection task to also cover the exact time-frames of instrument activity. This is a type of task where experts are commonly employed [7] to annotate data, due to several challenges such as multiple instruments playing simultaneously [8,9], or instruments of the same family exhibiting similar timbre [10,11].

More specifically, we explore and analyse the capabilities of crowd workers to effectively detect temporal aspects of musical instrument activity in polyphonic audio (with focus on trio ensembles). We seek answer to the following questions:

- RQ1: To what extent non-experts can detect the onset and offset of a musical instrument’s activity on polyphonic audio?
- RQ2: How their self-assessed perceptual abilities and musical knowledge relate to their performance?

Our study takes place on Prolific¹. The audio excerpts were chosen from three different genres (namely *classical*, *jazz* and *rock*) to understand if different instruments and rhythms can affect the performance of crowd workers. We also utilize a set of pre-established and evaluated questionnaires to retrieve user attributes, that can potentially relate to their performance. We employ the “Musical Training” and “Perceptual Abilities” categories from Goldsmith’s Music Sophistication Index (GMSI) [12], a questionnaire specifically designed to capture an individual’s ability to engage with music. These specific categories were found previously to most significantly predict the workers’ musical perceptual abilities [13].

Our results show that non-experts can demonstrate good perception of musical instruments’ temporal activity for the chosen audio excerpts. Their self-assessed perceptual abilities reflect reasonably well their actual perception skill. These results open possibilities of further future studies on instrument activity annotation, and provide a positive outlook for systems relying on such annotations.

2. RELATED WORK

The work in OpenMic 2018 [4] is one of the first attempts to annotate instrument presence for instrument recognition at scale, employing 2,500 unique annotators from Crowd-Flower², using excerpts from Free Music Archive³ and the AudioSet [14]. The researchers followed specific task design approaches to assist the crowd workers in their task, which they adapted after an initial study. The annotation process was limited to binary annotations, indicating the presence or absence of a musical instrument in an audio excerpt. Showcasing that crowd workers are able to provide strongly-labeled data, e.g. with temporal annotation, as in our study, can enable new opportunities for instrument activity detection and source separation.

Even though the study in [15] is not based on music audio, it demonstrates the crowd’s ability to annotate temporal aspects of audio events. Our interface design is inspired by this study, as the crowd workers had to draw bounding boxes on spectrogram visualisations of audio excerpts. The sounds were synthesized using Scaper [16], for a greater control over *max-polyphony* and *gini-polyphony* (amount of sound overlap).

Our study is also motivated by recent findings regarding crowd workers music perception abilities [13]. Users of crowdsourcing platforms were shown to possess considerable skills to detect music aspects such as tempo and melody.

To the best of our knowledge, the current literature lacks works that study the performance of crowd workers on temporal activity detection of musical instruments in relationship with worker demographic or musical properties, which is the goal of this work.

3. EXPERIMENTAL DESIGN

We designed our experiment to study and understand if users on crowdsourcing platforms can perceive the temporal activity of a musical instrument in audio excerpts. We aim to focus on realistic use cases, thus testing the workers’ capacity to perceive instruments in audio excerpts that are performed, recorded, mixed and mastered professionally. Therefore, we used existing recordings instead of synthesized audio which would have been less representative of real-life scenarios, but could have given us higher control on the musical aspects of the audio and instrumentation. To that end, we carefully selected the audio excerpts to control, as much as possible, musical aspects such as timbre and performance.

We employed previously established and evaluated questionnaires, to learn about workers’ (a) “Perceptual Abilities” and “Music Training” through Goldsmith’s Musical Sophistication Questionnaire (GMSI); (b) cognitive load through NASA’s Task Load Index (NASA-TLX) survey⁴; (c) equipment quality [17] and (d) outside noise [18].

² https://visit.figure-eight.com/People-Powered-Data-Enrichment_T

³ <https://freemusicarchive.org>

⁴ <https://humansystems.arc.nasa.gov/groups/tlx/>

The task workflow started with simple demographic questions, followed by the GMSI questionnaire. The user was then introduced with the main task to annotate audio excerpts. The study concluded with a post-task survey regarding their cognitive load, equipment and a general feedback entry.

3.1 Selected Audio Excerpts

For the main annotation task, we made use of audio excerpts from trio ensembles of three major genres, *classical*, *jazz* and *rock*. We used audio excerpts of these particular three genres due to their wide discrepancy in instrumentation and rhythm. Even though in some occasions the instruments used in each genre can showcase timbre similarities (like double bass and bass guitar), in other cases the timbre can differ wildly (electric guitar compared to cello). To the best of our knowledge, there is no previous baseline of the crowd workers’ perception of polyphonic music, so we decided to control for the maximum number of instruments that would play simultaneously in an excerpt, by selecting recordings of trio ensembles for each genre. Each audio excerpt had a length of 10 seconds, as used also in similar studies [4, 15]. The authors annotated the instrument activity per audio excerpt, which was later used to evaluate the crowd’s annotations.

For the classical music excerpts, we made use of a specific type of a trio ensemble, namely *piano*, *clarinet* and *cello*. On the selected music clip, we selected an excerpt where both *clarinet* and *cello* have prominent parts, while *piano* is mostly following in the background. For our jazz excerpt, we used of the more standardized trio ensemble of *piano*, *double bass* and *drums*, where *double bass* and *drums* keep the rhythm and *piano* is performed in small melodic bursts. Lastly, for the category of rock, we made use of a music excerpt from “power trio” bands, which most frequently consist of *electric guitar*, *bass guitar* and *drums*. It follows the same performance pattern with the jazz excerpt on the *bass guitar* and *drums*, while the *electric guitar* enters near the middle of the excerpt with a sustained, distorted power chord.

We hypothesise that bass instruments will be more difficult to annotate in these genres, as bass-related sounds are more often “pushed back” during the mixing stage for such types of music. The different genres were selected to lessen the impact of possible enculturation bias. We believe that if only one genre was selected, participants who would be more familiar with it, would find it easier to spot the activity of instruments prominent in the genre. With the selected genres, we cover a variety of rhythms, instrumentations and performative aspects, which could impose a challenge to non-experts.

3.2 Task and Interface Design

To assess the music expertise of the crowd we employed parts of GMSI, namely: “Music Training” and “Perceptual Abilities”. The choice of the categories was based on a study on music perception skills of crowd workers [13],

Figure 1: Main audio annotation task

where results in these two categories were found to most significantly predict their auditory capabilities.

The questions of both GMSI categories were aggregated to one questionnaire, with one attention question placed in-between the questionnaire’s items. The users also had the ability to use a “Back” button to return to a previous question and alter their answer. We used the complete set of questions on both “Music Training” and “Perceptual Abilities”, after consulting the online GMSI “configurator”⁵.

The users were greeted with an “Instructions” message before the main annotation task, which described the steps to complete each microtask and a warning regarding the volume (as seen in Figure 2). The main audio annotation task (see Figure 1) consisted of four main parts: (a) audio waveform and controls (center-right), (b) instructions and instrument example (upper left), (c) description of controls and (d) submission button with a simple progress indication. The instrument to be identified, was indicated on both (a) and (b) in red, to draw the attention of the users.

Based on the findings during the OpenMic 2018 work [4], the crowd workers were found to struggle to detect multiple instruments at once. To that end, we followed their task design of annotating one instrument at a time; we presented the participants with the audio excerpt and requested to annotate the regions where a chosen single instrument, was active during the recording.

The worker would be presented with an audio excerpt and was instructed to detect the activity of one of the instruments present in the excerpt. The same procedure would follow for each of the instruments per audio excerpt, presented in a random order across genres (e.g. piano from classical music excerpt, followed by the electric guitar from rock music excerpt).

In the audio annotation interface, the users could play and pause the audio excerpt while also draw bounding boxes on the audio waveform. The regions drawn on the waveform were adjustable on both ends and the user could

Figure 2: Task instructions and warning

easily dismiss them with a double-click. A single-click on a region would play only the selected part of the audio excerpt. A crowd worker could only progress to the next excerpt if they had drew at least one bounding box on the waveform.

For the design of the interface, we utilized `wavesurfer.js`⁶ to draw the waveform and used the `regions` package to enable the bounding boxes interaction. Our choice of these tools was based on previous studies on audio annotation that utilized them successfully [15, 19].

Finally, as mentioned in [4], crowd workers could experience high cognitive load during instrument detection tasks, ultimately affecting their psyche. It was important for us to capture such a phenomenon, so we included the NASA-TLX questionnaire and a free text input to accommodate their feedback towards the study.

3.3 Evaluation methods

Our task design is based around one audio excerpt per genre (10 seconds), where maximum three instruments can play simultaneously. As described before, per task, a worker had to draw the regions where they detect the activity of the selected musical instrument.

⁵ <https://shiny.gold-msi.org/gmsiconfigurator/>

⁶ <https://wavesurfer-js.org>

To evaluate their performance, we followed the same methods established in [15, 20] and in the Detection and Classification of Acoustic Scenes and Events (DCASE) challenge [21]. We segmented each excerpt into 100ms-long frames which had binary values, depending on the presence or absence of the selected instrument. A frame is considered active when there is an overlap between the annotation region and any portion of the time interval of the frame. We believe that the frame’s resolution of 100ms can help us to adequately assess the extent of crowd workers’ precision when annotating the temporal activity of an instrument. Based on the ground truth values, we later calculated *Accuracy*, *Precision* and *Recall* of the workers’ annotations. To evaluate their performance, we followed the same methods established in [15, 20] and in the Detection and Classification of Acoustic Scenes and Events (DCASE) challenge [21]. We segmented each excerpt ($N = 3$) into 100ms-long frames which had binary values, depending on the presence or absence of the selected instrument. A frame is considered active when there is an overlap between the annotation region and any portion of the time interval of the frame. We believe that the frame’s resolution of 100ms can help us to adequately assess the extent of crowd workers’ capabilities to detect the temporal activity of an instrument. Based on the ground truth values, we later calculated *Accuracy*, *Precision* and *Recall* of the workers’ annotations.

4. RESULTS

The study took place on Prolific, employing 28 crowd workers. We used the built-in prescreening filters of Prolific, setting criteria for fluency in English – for instructions’ comprehension and higher chance of affinity to western music – and minimum task approval rate to 90% – to maximise the chances for good-quality work. The reward was set to 4.5 GBP (5.62 USD) which was classified as “Good” by the platform. We preserved the results of the 14 workers (see their demographics on Table 1) that successfully passed the attention question. Filtering the results based on the attention questions.

Variables		Statistics
Gender, n	Female	10
	Male	17
	Prefer not to say	1
Age (years)	Range	18-55
Occupation	Full-time	12
	Part-time	5
	Unemployed	11
Education	Associate degree	2
	Bachelor’s degree	12
	High school/HED	4
	Master’s degree	4
	Some college, no diploma	3
	Technical/trade/vocational training	3

Table 1: Participant demographics

4.1 Demographics and Equipment

The workers used mostly earphones, headphones and laptop speakers, while three reported using dedicated speakers. Most workers (15) reported the quality of their equipment as “Excellent”, with the majority (22) reporting “Imperceptible” impairment. Finally, the majority (15) reported that conducted the study in near silence conditions, while one reported performing the tasks in an environment with high noise levels.

4.2 Detecting Musical Instruments

The crowd workers showed high performance detecting most instrument activities on all three audio clips (RQ1). Studying the results per genre, we see on Table 2 that “Clarinet” was the most easily identifiable instrument. In the given audio excerpt, “Clarinet” had a prominent and distinct timbre, compared to the rest of the instruments. This might have helped annotators to detect its activity correctly. “Piano” on the other hand was more difficult to detect its temporal activity, as it accompanied the rest of the instruments with a softer tone.

	Accuracy	Precision	Recall
Piano	70.6%	91.5%	66.5%
Clarinet	84.5%	95.8%	82.9%
Cello	62.6%	95.5%	59.6%

Table 2: Accuracy, Precision, Recall and F-score on Classical audio excerpt (the highest scores per metric are in bold)

“Cello” though appears to be the hardest instrument to detect in the audio excerpt, as both accuracy and recall are near 60%. The high precision combined with low accuracy, could indicate that most workers mistook the activity of another instrument, with that of a cello. The results are surprising, as “Cello” was equally prominent as the “Clarinet”, playing at a lower register than the rest of the instruments.

In the case of “Jazz” we find the “Drums” to be the most recognizable instrument, while “Double Bass” yielded better results than “Cello” in the “Classical” excerpt (see Table 3. Recordings of “Double Bass” in jazz can vary from barely noticeable to accentuated, depending on the recording setting or the part of the song (being more prominent during solo performance). Despite being the prominent instrument alongside “Drums” for a large portion of the excerpt, the workers still had trouble identifying the regions where it was active.

	Accuracy	Precision	Recall
Piano	81.8%	70.9%	87.7%
Double Bass	64%	100%	64%
Drums	84.4%	100%	84.4%

Table 3: Accuracy, Precision, Recall and F-score on Jazz audio excerpt (the highest scores per metric are in bold)

It is very interesting to highlight how the performance on “Piano” which is present in both “Classical” and “Jazz” music clips, changes greatly between the two samples. A possible explanation could be on the rather more prominent role it plays in piano jazz trios, where in most cases carries the melodic part of a composition (which would explain also the high recall score). In this specific example, we see that on average the crowd workers accurately selected the small rhythmic bursts of piano play, although not as precisely. This shows that they could definitely detect its activity correctly, but could not indicate precisely its onset and offset regions.

	Accuracy	Precision	Recall
Electric Guitar	91.7%	96.5%	91.6%
Bass Guitar	82.4%	100%	82.4%
Drums	73%	100%	73%

Table 4: Accuracy, Precision, Recall and F-score on Rock audio excerpt (the highest scores per metric are in bold)

The participants performed better on average, in the “Rock” excerpt. We speculate that the sounds of “Electric Guitar” and “Bass Guitar” are more familiar to the demographics of the participating workers, who scored quite highly on accuracy and recall, on both instruments.

The sustained power chord of the “Electric Guitar” was easy to identify and correctly annotate its onset and offset. On the other hand, despite “Drums” and “Bass Guitar” being present during the entirety of the audio excerpt, crowd workers found “Drums” more difficult to recognize correctly, despite the results in the jazz excerpt. Difference in “Drums” between the two excerpts, show higher use of the snare drum in the jazz excerpt, while in the rock, the use of lower tone tom drums was more prominent.

4.3 Self-assessed Music Characteristics and Performance

On Table 5 we see the self-assessed “Perceptual Abilities” and self-reported “Musical Training” of the participants. The low “Musical Training” is consistent with the results of [13] but pretty low when compared to the participant pool of [12] (scoring near the bottom 30% of the population in the original study).

	Range	Median	Standard Deviation(1σ)
Perceptual Abilities	29-63	47.5	8.19
Musical Training	7-41	18.5	9.04

Table 5: Range, Median, Mean and Standard Deviation of Perceptual Abilities and Musical Training

The self-assessed “Perceptual Abilities” are also low compared to the sample of [12] but considerably higher than in [13]. The results in our study certainly showcase adequate perceptual skills, in regards with the task at hand.

We study the connection of their musical properties to their performance from a more qualitative perspective, due to the size of our participant pool. Their self-assessed “Perceptual Abilities” show that the users felt quite confident on the degree they can detect musical traits on sound, despite their lack of expertise as shown by their “Musical Training” average score (Table 5).

Comparing their assessment to their actual performance we further see that their “Musical Training” is not indicative of their capability to detect temporal activity of musical instruments. Their median score as shown on the table, is close to the low 25th percentile of the results in the original GMSI study [12], showing a general low formal musical training. While formal training could certainly be beneficial for such tasks, people are still exposed to different musical instruments through casually enjoying music, especially as it is widely and easily accessible through streaming services. We also believe that the task design with the inclusion of an audio example of a given instrument, assisted the workers in their task to identify instruments.

4.4 Cognitive Load and Feedback

The results on the NASA-TLX questionnaire, show that from the total of 14 crowd workers, 10 found the task’s difficulty average, while 9 were very confident on their performance. All of the participants reported average to low mental and physical demand, with mental load being higher than the physical. 10 workers experienced very low temporal demand, with most finishing the study in near 10 minutes. The results though show that the workers’ self-assessed performance varied greatly between individuals, with scores from “Very Low” to “Very High”.

Finally, crowd workers expressed their opinions on the study through a free form text area. Through their feedback we found that they greatly enjoyed the study through comments such as: “*Study was very well thought out. Nothing else to add.*”, “*It was fun, I would love to take part similar studies again*” and “*the study was interesting and I am finding the piano very interesting instrument after this study*”. Some even gave their insights for future improvements in comments such as: “*Put more instruments in there*” and “*it was ok but i propose next time the sounds be played slowly for us to easily identify. thank you*”.

5. DISCUSSION

Non-experts exhibited high precision with a rather high recall on most instruments, especially on the “Jazz” and “Rock” audio clips. Despite their low expertise as indicated through the “Musical Training” attribute, the results show that they were capable of perceiving the temporal activity of instruments. These abilities are in line with the findings from [13] but also people’s innate understanding of music, as shown in studies [22–24].

The high precision scores combined with lower accuracy and recall scores though, could indicate that the participants underestimated the activity of the instruments in

the excerpts. This means that the users although detected correctly segments of an instrument’s activity, they weren’t able to identify the totality of temporal activity for the given instrument. By selecting more, smaller and precise regions, one would select only the most prominent “True Positive” frames in an excerpt, but fail to select all of them, as is apparent on the cases of “Cello” and “Double Bass”. Additionally, in our evaluation, we used a quite short and strict frame resolution which could potentially affect their recall scores. However, further studies are needed with variable frame resolution to test its suitability for this type of annotation task.

While it is inevitable to experience issues of sampling bias when executing crowdsourcing studies (i.e. participants will always be a smaller set of the userbase, which by itself is highly specific and smaller than the general public), we justify the differences with [12] based on the form of incentive from the side of participants, to perform the study. In our case the incentive was strictly monetary, therefore we employed participants who could be less enthusiastic about music, compared to [12]. When comparing to [13] though, while the results are consistent regarding “Musical Training”, the results on “Perceptual Abilities” were higher in our case, despite the use of the same crowdsourcing platform. Of course, the landscape of crowdsourcing platforms is constantly changing, but it could be a nice indication of adequately, musically perceptive crowd workers.

Finally, we believe that our interface design with the inclusion of short examples of the musical instruments on each task, must have assisted the crowd workers during annotation. We encourage further experimentation on interface design, to explore effective ways to assist workers during their audio annotation task.

Limitations. Being an exploratory study, we acknowledge that the number of participating crowd workers is lower than in traditional crowdsourcing studies. Nonetheless, we believe that the rigorous set up and the in-depth qualitative analysis of the obtained results allow us to provide valuable and robust insights, which could be used to design and deploy larger-scale studies in the future.

The music excerpts we used in our study focus on popular genres of music. As such, despite the diverse demographics of Prolific, the participants in our study were expected to be familiar with the instruments in our excerpts. We strongly encourage future studies to experiment with instruments of different traditions, as we believe that similar techniques could yield equally promising results for those instruments.

6. CONCLUSION

Our study focuses on exploring the ability of non-experts to identify the temporal activity of musical instruments in audio excerpts of western music. This is an important task during dataset production for instrument recognition, as it can provide strongly-labeled annotations which enable event detection classification tasks. Results show that untrained crowd workers can successfully detect the ac-

tivity of instruments like *clarinet* and *electric guitar*, one at a time, given an example of the instrument. The overall cognitive load that workers experienced was average, while most of them expressed their enjoyment of the tasks through free-form feedback. The positive outcomes of this work encourage conducting further studies on the topic, with focus on a larger participant pool and a more extensive evaluation dataset that includes additional genres, instruments, and identification complexities.

MoisesDB: A DATASET FOR SOURCE SEPARATION BEYOND 4-STEMS

Igor Pereira

Felipe Araújo

Filip Korzeniowski

Richard Vogl

Moises Systems Inc., Salt Lake City, USA.

igor@moises.ai

ABSTRACT

In this paper, we introduce the MoisesDB dataset for musical source separation. It consists of 240 tracks from 45 artists, covering twelve musical genres. For each song, we provide its individual audio sources, organized in a two-level hierarchical taxonomy of stems. This will facilitate building and evaluating fine-grained source separation systems that go beyond the limitation of using four stems (drums, bass, other, and vocals) due to lack of data. To facilitate the adoption of this dataset, we publish an easy-to-use Python library to download, process and use MoisesDB. Alongside a thorough documentation and analysis of the dataset contents, this work provides baseline results for open-source separation models for varying separation granularities (four, five, and six stems), and discuss their results.

1. INTRODUCTION

Source separation is the task of splitting an audio signal into separate signals for each signal source. For music, the signal sources are the instruments that appear in the track, e.g.: guitar, bass, piano, drums, and vocals.

Music source separation is a relevant task within music information retrieval. While it can be used as a pre-processing step for other tasks (e.g. voice separation for f0 tracking), source separation enables diverse applications on arbitrary music tracks that would need manual creation of stems otherwise. For example, in the context of music education, the creation of play-along tracks for students, facilitating by-ear transcription of relevant instruments, or automatic creation of karaoke backing tracks. Such applications are relevant for industry, as demonstrated by initiatives like the demixing challenges¹.

State-of-the-art source separation systems are usually built using neural-network-based machine learning systems, trained in a supervised way [1–3]. In order to train these systems, a large amount of training data is required. For supervised approaches, the training data is represented

Dataset	Year	No. of Tracks	Stems / Multitracks
MedleyDB [4]	2014	122	Multitracks
MedleyDB-V2 [5]	2016	196	Multitracks
DSD100 [6]	2015	100	4 Stems
MUSDB18 [7]	2017	150	4 Stems
MUSDB18-HQ [8]	2019	150	4 Stems
MoisesDB	2023	240	Multitracks

Table 1. Overview of publicly released datasets for music source separation. The datasets are grouped according to the set of tracks they contain. For example, DSD100 is a subset of MUSDB18. Additionally, 46 songs from MedleyDB are also used in MUSDB18.

by pairs of *i.* a mixed audio track and *ii.* a set of so-called stems that, when combined, recreate the audio track. Stems are audio signals containing only one (or a group of related) sources, i.e. instruments. A pair of one mixed track and its corresponding stems constitutes one training example.

Besides the large amount of manual work involved in any large-scale dataset creation, this kind of data is especially hard to come by for several reasons. Whenever dealing with music audio data, legal issues may arise by collecting and sharing a dataset. The copy and distribution rights for most music are held by music publishers and record labels and are enforced rigorously. Obtaining the audio recordings for the individual instruments (stems) along with the final mix may expose recording, mixing, and mastering techniques of the recording studios, responsible for producing a track, which is why recording studios may oppose the publishing of stems in order to keep their trade secrets. Finally, processing, exporting, and organizing stems from recording projects (often from a digital audio workstation) is a considerable task. Usually, these recording projects are created without considering the requirement of exporting instrument stems. All these factors hinder the creation and release of multitrack and stem datasets.

While there exist source separation datasets aimed at a specific task, like vocal separation [9, 10], these are only of limited relevance for the more general task of splitting audio tracks up into stems. A majority of the existing stem datasets [6, 8] use a limited taxonomy of four stems, namely: vocals, drums, bass, and other. While this has become a de-facto standard for works on source separation [1–3] due to the availability of data and comparability of results, this is a strong limitation of the resulting mod-

Figure 1. Artist distribution of MoisesDB.

Figure 2. Genre distribution of MoisesDB.

els. For many practical applications, separation of other, widely used instruments may be relevant: e.g. guitars, keys, strings, etc.

Datasets featuring individually recorded tracks (multi-track, e.g. [5]), as well as other collections of multitrack recordings, like *Open Multitrack Testbed* [11], do exist. However, these are not prepared to be used for source separation, out of the box, and may come with license restrictions. Looking at recent source separation publications, we see that non-public data usually represents the bulk of training data (e.g. Bean dataset [12] in [1]; 800 tracks of undisclosed source in [3]). This hints that by only using publicly available data, it is not possible to train competitive source separation models. Thus, there is a need for more free data featuring a more detailed taxonomy, in order to be able to successfully train and test robust source separation models with the capability to separated more stems.

To improve the current situation, we introduce MoisesDB, a multitrack dataset featuring track annotations and a taxonomy to group individual tracks into stems. This dataset is offered free of charge for non-commercial research use only. It consists of 240 music tracks from different artists and genres with a total duration of over 14 hours. Along with the dataset, we provide baseline performance values for state-of-the-art source separation systems.

The remainder of this work is structured as follows: Section 2 covers related work and contrasts it with the dataset presented here. Section 3 discusses the details of MoisesDB. Section 4 introduces baseline performance evaluation statistics using freely available source separation models. Finally, Section 5 provides concluding remarks.

Stem	Track
Bass	Bass Guitar, Bass Synthesizer, Contrabass
Bowed Strings	Cello, Cello Section, Other Strings, String Section, Viola Section, Viola Solo
Drums	Cymbals, Drum Machine, Full Acoustic Drumkit, Hi-Hat, Kick Drum, Overheads, Snare Drum, Toms
Guitar	Acoustic Guitar, Clean Electric Guitar, Distorted Electric Guitar
Other	Fx
Other Keys	Organ, Electric Organ, Other Sounds, Synth Lead, Synth Pad
Other Plucked	Banjo/Mandolin/Ukulele/Harp
Percussion	A-Tonal Percussion, Pitched Percussion
Piano	Electric Piano, Grand Piano
Vocals	Background Vocals, Lead Female Singer, Lead Male Singer, Other
Wind	Brass, Flutes, Other Wind, Reeds

2. RELATED WORK

In the past, several multitrack and stem datasets have been published by the community (see Tab. 1). This section will discuss their properties and set the context for the dataset presented in this work. Since the main focus of this work is source separation into as many stems as possible, single stem focused datasets (e.g. voice separation datasets [9, 10]) will be mainly ignored.

In 2014, Bittner et al. released the *MedleyDB* dataset [4], which comprises 122 songs in multitrack format. It was extended by 74 songs (totalling 196 songs) in 2016, and published as *MedleyDB 2.0* [5]. The dataset provides audio files in a hierarchical structure, where the final mix is split into multiple stems, each containing numerous raw audio sources (multitracks). Besides the multitrack data, the MedleyDB dataset provides an extensive list of metadata, such as artist, track name, origin, genre, and producer, amongst others. Additionally it provides multiple annotations, such as instrument activation, melody, and pitch.

The annotations in MedleyDB make it useful for many MIR tasks, including the source separation of diverse instruments. However, the shortcoming of MedleyDB for

```

from moisesdb.dataset import MoisesDB

db = MoisesDB(data_path='./moises-db-data')
n_songs = len(db)
track = db[0]
# mix multitracks to stems
stems = track.stems
# stems = {
#   'vocals': np.ndarray (stem audio data),
#   'bass': np.ndarray (stem audio data),
#   ...}
mixture = track.audio # mixture: np.ndarray
track.save_stems('./stems/track_0') # save mixed stems
    
```

Listing 1: Usage of the MoisesDB Python package.

music source separation is the way it organizes tracks into stems. While it provides instrument information for each of them, and functional annotations for stems (such as “melody” or “bass”), stems are not meaningfully labelled, only numbered. As a result, stem 01 of one song may be the drum kit, while stem 01 of another mix is the bassoon. Furthermore, instruments—and thus tracks—are grouped according to how they physically produce their sound, rather than their role in the mix of a song. For example, the “drum machine” falls into the same category as “electric piano”, namely “electric→electronic”. These shortcomings make it cumbersome to use for music source separation out of the box and significant work has to be done in order to use it for this task.

In 2016, Liutkus et al. released the *DSD100* [6] dataset as part of the 2016 signal separation evaluation campaign to develop and benchmark source separation models. It contains 100 songs and uses the four-stems taxonomy (vocals, drums, bass, and other). Later, in 2017, Rafii et al. extended DSD100 to 150 songs by adding 46 pieces from MedleyDB, and including four previously unreleased recordings from commercial providers. This dataset became known as the *MUSDB18* [7] dataset, and was used for the 2018 signal separation evaluation campaign. In 2019, Z. Rafii et al. released an uncompressed version of the MUSDB18 dataset, MUSDB18-HQ [8]. As its predecessor DSD100, this dataset provides four stems—vocals, drums, bass, and other—as well as linear mixes. MUSDB18 is widely used to train and benchmark source separation models, but the limited number of stems prevents researchers from building more granular source separation systems.

Figure 5. Loudness and Dynamic Range distribution of tracks in MoisesDB. For a comparison with commercially mixed and mastered songs, we sampled 240 tracks from the HarmonixSet [13].

In summary, data for training granular source separation systems is scarce: the 150 tracks from MUSDB18 are ready to use, but offer only four stems to separate; the 140 remaining tracks from MedleyDB (46 of the originally 196 are already part of MUSDB18) are not organized in a way that easily supports source separation research. This issue is also reflected in the fact that state-of-the-art source separation models often use larger, non-public datasets for training [1, 3], or have to resort to synthetic training data (e.g. [14, 15]). Other works find that MUSDB18’s “source groupings remain overly coarse for many real-world remixing applications.” [16]. To address these issues and to foster more research in music source separation, we created the MoisesDB dataset.

MoisesDB comprises the largest publicly available set of multitrack audio recordings—240 previously unreleased songs—organized in a taxonomy that reflects the needs of source separation systems (as detailed in Sec. 3.1). The large number of songs, the diverse types of stems and tracks, and their organization in a source-separation-focused taxonomy will allow researchers to build their own stems according to their own requirements, and thus develop more granular source separation systems.

3. DATASET

MoisesDB consists of 240 songs by 47 artists that span twelve high-level genres. Both artists and genres follow a power-law-like distribution, where the majority of songs belong to few genres and are performed by few artists—see Fig. 1 and 2. The total duration of the dataset is 14 hours, 24 minutes and 46 seconds, where the average recording is 3:36 seconds, with a standard deviation of 66 seconds.

Figure 6. Distribution of tracks in MoisesDB.

3.1 Stem Taxonomy

Modern song recordings consist of multiple recorded *tracks*, which can be grouped and down-mixed into a smaller number of *stems*. For example, the “drums” stem might comprise tracks for the snare drum, the bass drum, hi-hat, cymbals, and so on. MoisesDB provides all individual tracks for each song, grouped into stems by the taxonomy shown in Table 2. This taxonomy reflects the recording & mixing process, and thus facilitates its reversal—music source separation—by grouping the raw tracks into semantically labeled stems. This also means that songs may consist of different numbers of stems, as shown in Fig. 3. MoisesDB thus facilitates many future research directions: source separation models for a larger number of stems, data augmentation through mixing stems on-the-fly from their tracks, or separation of individual tracks from a stem, to name a few.

Given the genres of the songs in MoisesDB, certain stems are more common in the dataset than others: “vocals”, “drums”, and “bass” appear on virtually every song, while “wind” is rare. Similarly, certain tracks appear much more frequently than others, both within stems (“bass guitar” vs. “contrabass”) and between stems (“snare drum” vs. “cello”). Figs. 4 and 6 show the distributions of stems and sources, respectively.

We anticipate that this imbalance will present a challenge in training source separation models for underrepresented stems, as it is likely that certain tracks, such as “other plucked” tracks, will still be difficult to distinguish from “guitar” tracks if trained solely on MoisesDB. However, the available data provides an opportunity for researchers to better identify and characterize errors made by their models. For instance, instead of simply observing that the separated “other” stem bleeds into “guitar,” MoisesDB enables researchers to pinpoint this issue to tracks where “other” includes plucked instruments.

3.2 Recording and Mastering

The songs in MoisesDB are professionally recorded in stereo. The individual tracks are combined additively to create stems, which are then mixed together to produce the final version of the song. Due to technical limitations during recording, minuscule bleeding from other stems may be present for some of the tracks. No compression, equalization, or other effects are used during the mixing process, and the songs are not subjected to mastering. As a result, the song mixes have a lower loudness and a higher dynamic range than professionally mastered commercial songs. This raises concerns about the distributional shift between un-mastered training data and commercial recordings. Indeed, Jeon and Lee [17] have found that training separation models using mastered mixes can improve separation quality. However, providing un-mastered mixes is common in existing datasets such as MUSDB18, and models such as HT-Demucs [3] generalize reasonably well to mastered recordings, even if trained on un-mastered data.

Figure 5 shows the loudness and dynamic range distributions for the dataset, where loudness is measured in LUFS (Loudness Units relative to Full Scale) [18], and Dynamic Range is computed based on the definitions of the “Pleasurize Music Foundation” as implemented in the “DR14 T.meter” software².

3.3 Python Library

With MoisesDB comes a Python library that facilitates working with the dataset by parsing metadata and automatically building stems and mixes. Listing 1 shows an example usage of the library. The code shown there initializes the library, retrieves the number of tracks, creates the stems and the full mix, and saves the individual stems to a directory. For a detailed and up-to-date documentation, we refer the reader to the GitHub repository³.

Table 3. Mean, standard deviation (Std), and median (Mdn) of the SDR in dB for each Model/Method and stem type. The varying number of available tracks is denoted by N. Overall indicates performance over all tracks regardless of stem group. Best results are marked in bold.

4. BENCHMARKING

In order to establish reference values for each track of the MoisesDB dataset, we computed the Source to Distortion Ratio (SDR) [19] scores for Ideal Binary Mask (IBM) [20], Ideal Ratio Mask (IRM) [21], and Multichannel Wiener Filter (MWF) [22] oracle separation methods. Additionally, we assessed SDR scores for two popular public available and open-source architectures: Hybrid Transformer Demucs (HT-DEMUCS) [3] and Spleeter [1]. The SDR scores were calculated for three different groups of sources: four, five, and six stems. Given the architecture of the open-source models, results for Spleeter are available for four and five stems, and for HT-DEMUCS for four and six stems.

The SDR measure [19] represents how much of the energy in a true source signal is preserved in an estimated source signal after applying a separation algorithm. The equation can be defined as

$$\text{SDR} = 10 \log_{10} \frac{\sum_n |s(n)|^2 + \epsilon}{\sum_n |s(n) - \hat{s}(n)|^2 + \epsilon}, \quad (1)$$

where $s(n)$ represents the true source signal at time n , $\hat{s}(n)$ represents the estimated source signal at time n , and the result is given in decibels (dB).

Table 3 shows the SDR values in dB for each group of stems (4, 5, and 6) evaluated in this benchmark. For a better comparison, we chose the stems available in the open-source models: vocals, bass, drums, other, guitar, and piano. We also pick tracks containing at least all the stems chosen for each group, which explains the distinct number of tracks in Table 3. Songs with more individual tracks than the ones specified for each group were merged into the “other” stem using a linear sum strategy.

Figure 7 depicts boxplots representing the distribution of the SDR metric for both oracle and separation methods, calculated for each group of tracks comprising 4, 5, and 6 stems. The groups of stems evaluated were vocal, bass, drums, other, piano, and guitar. Detailed results for every track and each stem are provided in the GitHub³ repository.

The first fact that calls our attention can be seen in Figure 7, where the SDR results of IRM and MWF oracle methods did not show a significant difference for all groups of stems. The striking fact is the performance of HT-DEMUCS architecture, which outperforms the oracle methods for bass and drums stems, for the groups of 4 and 6 stems tracks, as we can see in Figures 7 A and C, respectively. Those results contrast with the slightly worse performance of HT-DEMUCS for other, piano, and guitar stems, compared with oracle methods, as seen in Figure 7 C.

5. CONCLUSION

In this work, we introduced MoisesDB, a multitrack dataset with a hierarchical taxonomy aimed at more-than-four-stems source separation. We set the context by analysing the current landscape of source separation datasets and presented a comparison with other relevant datasets along with a detailed analysis of MoisesDB. Specifically, we discussed the organizational taxonomy focused on source separation, the distribution over track duration, the distribution over genres, and the number of songs for each stem and source available in the dataset.

Moreover, we include performance results for two publicly available source separation methods: HT-Demucs, which has the best overall SDR score evaluated on the MUSDB18 test set, and Spleeter, which was one of the first source separation models released and adopted by the general public. We also added results for a few masking-based oracle methods: IBM, IRM, and MWF, which indicate the theoretical performance limits for mask-based source separation models. Additionally, we provide an easy-to-use Python library to access the data which allows fast integration with machine learning libraries.

Overall, this paper represents a detailed report on the MoisesDB dataset, which will hopefully prove to be a great resource for the source separation community in the future. This work aims at facilitating the development of better and extended source separation models as well as providing opportunities to be applied for other use cases, such as automatic mixing and generative accompaniment systems, among others.

ABSTRACT

Modeling the temporal unfolding of musical events and its interpretation in terms of hierarchical relations is a common theme in music theory, cognition, and composition. To faithfully encode such relations, we need an elegant way to represent both the semantics of prolongation, where a single event is elaborated into multiple events, and process, where the connection from one event to another is elaborated into multiple connections. In existing works, trees are used to capture the former and graphs for the latter. Each such model has the potential to either encode relations between events (e.g., an event being a repetition of another), or relations between processes (e.g., two consecutive steps making up a larger skip), but not both together explicitly. To model meaningful relations between musical events and processes and combine the semantic expressiveness of trees and graphs, we propose a structured representation using algebraic datatype (ADT) with dependent type. We demonstrate its applications towards encoding functional interpretations of harmonic progressions, and large scale organizations of key regions. This paper offers two contributions. First, we provide a novel unifying hierarchical framework for musical processes and events. Second, we provide a structured data type encoding such interpretations, which could facilitate computational approaches in music theory and generation.

1. INTRODUCTION

When understanding music as a temporal art, there are at least two properties we need to model. The first is that musical events are ordered in a nontrivial way resembling goal-directedness; the essence of a piece is lost if we “re-compose” a piece by performing random temporal permutations. The second phenomenon is the temporal hierarchy, which is a central theme in the understanding of Western tonal music, where we hear multiple entities as the manifestation of a single musical entity. Regarding this hierarchy, there are at least two kinds of such entities. The first kind is a stationary process, such as key region, and har-

mony; we can say a phrase that enforces a key contains a tonic region (like some presentation in a non-modulating sentence) and we can also describe a time span as an arpeggiation of a harmony. The second kind is a transitory process, such as modulation region, passing, and neighboring motion; a descending third progression contains two step-wise downward motions.

There are multiple attempts to represent the hierarchical structure of such entities. For stationary entities, trees of musical events have been used to model tonal harmony [1, 2], extended tonal harmony [3], jazz harmony [4], rhythm and meter [2, 5]. One limitation of using trees of musical events is that semantics such as passing tones could not be elegantly expressed because one is forced to select either the left or the right parent event for the subordinate event whereas we would like to express an intermediate event subordinate to the melodic motion itself [2].

For the transitory process, trees on event transitions are also sometimes used [6]. They could model the semantics for a passing tone by describing how a melodic motion is split into two motions, one going to the passing note and one leaving the passing note. However, as the fundamental entities are transitions, it can not express the idea that a single event being elaborated in the temporal dimension, such as unfoldings, complete neighbor chords/tones, repetitions, and rearticulations [7].

There are attempts using graphical notations to capture both stationary and transitory processes [7–9]. There are also models [10] that extend such hierarchical organizations beyond the temporal dimension with inner structures of events resembling concurrent processes.

One could potentially encode the hierarchical organization between these two kinds of processes implicitly using networks and graphs, or more expressively using hypergraphs where higher-order relations can be encoded as hyper-edge. One could formulate a rewrite grammar on such networks and hypergraphs to describe the elaboration of nodes and edges. However, we believe there should be a more direct, elegant, and specialized solution (in a similar spirit as [11]) to not only implement but also characterize such generative principles of hierarchical processes.

In summary, there is a lack of formal representation as well as a specially designed data structure that explicitly captures the intricate hierarchical organizations of both the stationary and transitory processes, a fundamental idea in reductive theories of tonal music. This paper offers two contributions. First, we provide a novel unifying hierar-

chical framework for stationary and transitory processes. Second, we provide a structured data type encoding such interpretations, which could facilitate computational approaches in music theory, musicology, and algorithmic music composition.

2. THE HIERARCHICAL ORGANIZATIONS OF GENERAL PROCESSES

To demonstrate how these two kinds of processes could be hierarchically organized in the temporal dimension, perhaps it is helpful to consider a scenario in everyday life: “On his way back to home, John went to the supermarket, where he got his favorite yogurt from the fridge. Although he could take a bus directly to his house, he decided to get off one stop earlier by the lake to enjoy a short walk.” One hierarchical organization of this particular scenario is depicted in Fig.1. The overarching process is that John went back home from someplace. This transitory process (represented by the arrow connecting “someplace” denoted by X to “home”) contains three component processes: a transitory process from “someplace” to “supermarket”, a stationary process at “supermarket,” and a transitory process from “supermarket” to “home.” The stationary process at “supermarket” further contains a stationary process at the “entrance” of the supermarket, a transitory process from “entrance” to the “exit,” and a stationary process at the “exit”.

2.1 The syntactic constraint of the hierarchical organization of stationary and transitory processes

One pattern that we observe is the mutual recursive relationship between stationary and transitory processes. A stationary process can contain three components (stationary, transitory, stationary). Symmetrically, a transitory process can contain three components (transitory, stationary, transitory).

However, it is clear from the above example (Fig. 1) we can not arbitrarily subdivide a stationary process at X (denoted by \hat{X}), or a transitory process from X to Y (denoted by $\xrightarrow{X \rightarrow Y}$) into arbitrary triples of processes, even if they conform to the (stationary, transitory, stationary) or (transitory, stationary, transitory) patterns. We may allow a transitory process $\xrightarrow{A \rightarrow B}$ to be elaborated into three components of the form

$$\xrightarrow{A \rightarrow X} \hat{X} \xrightarrow{X \rightarrow B}$$

But we would not allow a decomposition like

$$\xrightarrow{C \rightarrow D} \hat{X} \xrightarrow{E \rightarrow F}$$

because their states are not compatible.

We can summarize the constraints as the following: a stationary process \hat{X} may contain $(\hat{X}, \xrightarrow{X \rightarrow X}, \hat{X})$; likewise, a transitory process $\xrightarrow{X \rightarrow Y}$ may contain $(\xrightarrow{X \rightarrow Z}, \hat{Z}, \xrightarrow{Z \rightarrow Y})$. The “entrance” and “exit” in the previous example, although being technically different, are equivalent to “supermarket” from abstract level.

3. LINEAR PROCESSES

We start with characterizing linear processes representing a single hierarchical stream.

3.1 An axiomatic system

We refer to a stationary process as *Joint*, and define it as a predicate J_x indexed by a state $x : A$. We refer to a transitory process as *Link* and define it as a predicate $L_{x,y}$ indexed by two states x, y of the same type. Then we propose the following four axioms to characterize the hierarchical interactions between of stationary and transitory processes.

$$\forall(x : A) \exists(j : J_x) \quad (1)$$

$$\forall(x, y : A) \exists(l : L_{x,y}) \quad (2)$$

$$\forall(j, j' : J_x) \forall(l : L_{x,x}) \exists(j^* : J_x) \quad (3)$$

$$\forall(l : L_{x,z}) \forall(j : J_z) \forall(l' : L_{z,y}) \exists(l^* : L_{x,y}) \quad (4)$$

Axiom 1 states that we may form a stationary process for a given state. Axiom 2 states that we may form a transitory process by for a pair of states of the same kind. Axiom 3 states that we may form a stationary process at x from any triple of processes (j, l, j') , where j and j' are both of stationary processes at x and l is a loop starting and ending at x . Axiom 4 states that we may form a transitory process from any triple of processes (l, j, l') , where l and l' are transitory and j is stationary, provided that their states are compatible.

3.2 A syntax based on dependent type theory

Using two mutually inductive algebraic datatypes, *Joint* and *Link*, we formalize the notion of hierarchical process in Backus–Naur form (Eq. 5,6,7,8). For a stationary process, the base case (Eq. 5) of a *Joint* is a *Point*, which means an atomic stationary process, whereas the inductive case (Eq. 6) resembles a stationary process (on the current level) containing two stationary process and a transitory process. The base case of a *Link* is a *Unit* (Eq. 7), representing a indivisible change of state, whereas the inductive case (Eq. 8) represents a composite motion that contains two changes and one stationary process. Eq. (5,6,7,8) corresponds to Axiom. (1,3,2,4) respectively.

$$Joint_{(x:a)} := \langle Point \rangle \quad (x : a) \quad (5)$$

$$| \langle Joint \rangle \quad Joint_x \quad Link_{x,x} \quad Joint_x \quad (6)$$

$$Link_{(x:a),(y:a)} := \langle Unit \rangle \quad (x : a) \quad (y : a) \quad (7)$$

$$| \langle Link \rangle \quad Link_{x,z} \quad Joint_z \quad Link_{z,y} \quad (8)$$

Dependent typing [12] allows us to define types depending on value. This algebraic data structure with dependent typing has an important application for a generative system. One can define a function using polymorphic recursion to sample a value of the given type. Do-

Figure 1: A hierarchical interpretation of John’s journey. Words on the transitions are abbreviated to save space. The symbol $s \sim en$ means the "entrance" is functionally equivalent to "supermarket" in the interpretation of this journey

ing so will guarantee the syntactic correctness of the output. For example, writing a harmonic transition between I and V means sampling a value of type $Link_{I,V}$; elaborating a melodic motion from $\hat{8}$ to $\hat{5}$ becomes sampling a value of type $Link_{\hat{8},\hat{5}}$. Note that between these two examples, the type of the state is different; the first is harmony(roman-numeral) while the second is scale degree. However, within each example, the types of the states are always the same by construction (Axiom 2, 3, 4).

3.3 A data structure in Haskell

Haskell is a functional programming language with an expressive type system [13]. Although the dependent type is not yet built into the language, there exists an encoding involving Algebraic Datatype and Singletons [14] to simulate the behavior of dependent type. The implementation of the linear process is shown below ¹.

```

data Joint (x::a)
  = Point (Sing x)
  | Joint (Joint x) (Link x x) (Joint x)

data Link (x::a) (y::a)
  = Unit (Sing x) (Sing y)
  | forall (z::a). Link (Link x z) (Joint z) (Link z y)
    
```

3.4 A graphical notation system

To visualize an interpretation of hierarchical processes, we use two types of slurs to connect states in a sequence. For a *Point*, the base case of *Joint*, no visual representation is needed as the state it expresses is sufficient. For a *Unit*, the base case of *Link*, a dashed slur is drawn connecting the starting state to the ending state. Nontrivial stationary processes (the inductive cases) are represented as continuous slurs whereas transitory processes are represented with dashed slur. For a non-trivial processes, the left/right anchor point of the slur is the same as the left/right anchor point of the slur of the process’s first/last component.

Five simple examples of such notation are provided in Fig. 2. The easiest to understand is Ex. D, which is a stationary process \hat{I} , decomposed into a $\hat{I} \xrightarrow{I \rightarrow I} \hat{I}$. This expresses not just repetition but also the loop from I to itself. This loop can be the parent for further elaborations

¹ Specifying the singleton arguments can be sometimes redundant and cumbersome. Instead, one could use the "implicit-passed" singleton by replacing the argument "Sing x" by a constraint "SingI x". In this way, the "Point" and "Unit" constructor takes no explicit argument and the state information is thus encoded as a phantom type that can be pattern matched using type application such as "Point @IV".

such as passing and neighbor chords. Note that the continuous slur covers a point, a dashed slur, and a point. This visual "covering" is intend to convey the hierarchical relation of processes where parent processes contains its component processes. Ex. C shows a more complex situation; although the top two level is the same as Ex. D (a *Joint* containing two base case *Joint* and a *Link*), there are richer structures within the *Link* in Ex. C. This dashed slur covers a dashed slur, a continuous slur, and a dashed slur, signaling a non-trivial transitory process that contains a transitory process $\frac{I}{V} \rightarrow V$, a stationary process at V , and a transitory process $\frac{V}{I} \rightarrow I$. This stationary process at V is also a non-trivial one, capturing the sense of prolongation within which passing notes can be generated connecting its chordal pitches, forming a harmonic the entity V_{5-4-3}^{7-6-5} . Ex. B expresses an overarching stationary process at I containing a nontrivial initial stationary process, a nontrivial transitory process and a trivial stationary process. The initial stationary process resembles a neighbor-passing chord with in the harmony of I . Note that there is a difference in semantic in drawing the continuous slur over the first two I s vs the last two I s. The former means that the overarching motion is stationary first and then moving to the target I chord, whereas the latter means the motion moves first and then performs a stationary rest. This kind of fine distinction could be used to further express embodied musical concepts such as "momentum," "potential energy," and "forces" [15]. Ex. A presents two interpretations of the same chord progression, where the top and bottom analysis reflects the melody and the bass respectively.

4. APPLICATIONS IN MUSIC ANALYSIS

We will demonstrate the potential usage of the proposed model in reductive analysis in three different levels of complexity.

4.1 The harmonic sequence of a hybrid theme type

For a harmonic sequence $I - V - V - I - IV - V - I$ in an 8-bar phrase, we may interpret the first four chords as a tonic prolongation and the rest as an incomplete cadential progression, as in an antecedent + cadential hybrid theme type [16]. Such an interpretation is captured by the derivation process in Fig. 3.

Figure 2: Examples of the graphic notation for Hierarchical processes where continuous slurs represent *Joint* and dashed slurs represent *Link*.

$$\begin{aligned}
 & \hat{I} \\
 & \hat{I} \xrightarrow{I \rightarrow I} \hat{I} \\
 & \hat{I} \xrightarrow{I \rightarrow I} \hat{I} \xrightarrow{I \rightarrow V} \hat{V} \xrightarrow{V \rightarrow I} \hat{I} \\
 & \hat{I} \xrightarrow{I \rightarrow V} \hat{V} \xrightarrow{V \rightarrow I} \hat{I} \xrightarrow{I \rightarrow IV} \hat{IV} \xrightarrow{IV \rightarrow V} \hat{V} \xrightarrow{V \rightarrow I} \hat{I}
 \end{aligned}$$

Figure 3: One derivation process for the harmonic sequence $I - V - V - I - IV - V - I$. The first three steps are elaboration of types whereas the last step is the instantiations of the types (in the framework of formal grammar, this corresponds to rules generating nonterminal and terminal symbols)

4.2 The key-level modulation analysis of a simple ternary form

Now we present an analysis of a section of Haydn, Piano Sonata in D, H.37, iii, using the proposed model (Fig. 4). The main focus of the analysis here is on key center and functional harmony. This overall section resembles a stationary process at the home key region. It contains a stationary process expressing the home key region, followed by a transitory process from a home key region to another home key region. Within this transitory process, there is a stationary process at the dominant key region, as well as the two transitory processes functioning as key transition. The first connects the tonic chord in the home key $I\{I\}$ to the tonic chord in the dominant key $V\{I^6\}$ as the pivot chord for modulation. The second connects $I\{V\}$ to $I\{I\}$ as to signal the return to the home key. In a prolongational framework of pitch reduction, this link at mm.12 is the interrupted motion in a typical interruption, implying the restart of the fundamental line [8]. In a functional harmony framework, this same link is the dominant to tonic preparation relation, also implying the arrival of the tonic in the home key. Within the dominant region the first stationary process corresponds to the complete cadential progression signaling the stabilization of the dominant key, whereas the following transitory pro-

cess $\frac{\hat{5} \rightarrow \hat{1}}{V\{I\} \rightarrow I\{V\}}$ corresponds to first attempted descent (interrupted) of the fundamental line accompanied by the ‘‘Ponte’’ modulation schema [17] that gradually change the underlying key of a chord.

4.3 A harmonic analysis of a Bach chorale

A more elaborated example of such harmonic organization can be found in Bach Chorale No 9 BWV 248 (Fig. 5). This analysis interprets the overarching structure of the piece as a stationary process in the home key tonic, containing an establishment of the home key, detour around the home key, and the re-stabilization of the home key. This transitory process $\frac{\hat{1} \rightarrow \hat{8}}{I\{I\} \rightarrow I\{I\}}$ enforces its unity with an ascending linear progression of an octave, within which the music modulates to the relative minor (*vi*) via its dominant minor key (V/vi). The first stationary process around the home key is elaborated into a $I - V - I$ ternary-like structure on the key level.

5. CONCURRENT PROCESSES

Besides providing a formalization for processes in the temporal dimension, we also offer an extension to model the processes that are simultaneous, which enables us to model polyphonic texture.

5.1 The Formalism

To model concurrent processes, we add two **non-commutative** binary² operations to construct *Joint* and *Link* respectively:

$$(\infty) : Joint_x \rightarrow Joint_y \rightarrow Joint_{(x,y)} \quad (9)$$

$$(\uparrow) : Link_{x,y} \rightarrow Link_{x',y'} \rightarrow Link_{(x,x'),(y,y')} \quad (10)$$

The first constructor ∞ , called ‘‘when’’, expresses the concurrency of two stationary processes. The second constructor \uparrow , called ‘‘while’’, expresses the concurrency of two transitory processes. Applying these operators using infix

² Although these operations are currently formulated as binary operations, they can be naturally extended to *n*-nary versions where the input is a vector of *Joint* and *Link* respectively.

notations, we have Eq. 11, 12:

$$\widehat{x \circ y} := \widehat{(x, y)} \quad (11)$$

$$\xrightarrow{x \rightarrow y} \uparrow \uparrow \xrightarrow{x' \rightarrow y'} := \xrightarrow{(x, x') \rightarrow (y, y')} \quad (12)$$

In addition we add an algebraic law (Eq. 13) on these two operations:

$$\begin{aligned} & (\widehat{x \circ y}) (\xrightarrow{x \rightarrow x} \uparrow \uparrow \xrightarrow{y \rightarrow y}) (\widehat{x \circ y}) \\ & = \\ & (\widehat{x} \xrightarrow{x \rightarrow x} \widehat{x}) \circ (\widehat{y} \xrightarrow{y \rightarrow y} \widehat{y}) \end{aligned} \quad (13)$$

To model temporal displacement of concurrent processes (like the suspension in fourth species counterpoint) we define a function $\uparrow \uparrow$ called “**leads**” that is derivable from the basic operations in terms of Eq. 9,10 :

$$(\uparrow \uparrow) : \text{Link}_{x,y} \rightarrow \text{Link}_{x',y'} \rightarrow \text{Link}_{(x,x'),(y,y')}$$

$$\xrightarrow{x \rightarrow y} \uparrow \uparrow \xrightarrow{x' \rightarrow y'} = \xrightarrow{(x,x') \rightarrow (y,x')} \widehat{(y, x')} \xrightarrow{(y,x') \rightarrow (y,y')} \quad (14)$$

$$= (\xrightarrow{x \rightarrow y} \uparrow \uparrow \xrightarrow{x' \rightarrow x'}) (\widehat{y \circ x'}) (\xrightarrow{y \rightarrow y} \uparrow \uparrow \xrightarrow{x' \rightarrow y'}) \quad (15)$$

With Eq. 14, we formalize the relation about two processes where that one process **leads** the other. For example, in a typical suspension, this allows us to capture the meaning that the bass motion leads the melody motion, causing a consonance-dissonance-consonance pattern.

5.2 Concurrent processes in contrapuntal textures

Now we demonstrate that using the proposed formalism, we can model many complex hierarchical coordination of processes in both temporal (horizontal) and spatial (vertical) dimensions.

5.2.1 First species counterpoint

For first species counterpoint, processes are always vertically aligned in a one-to-one fashion.

$$\begin{aligned} & 3 - 2 - 1 \\ & 1 - 7 - 1 \end{aligned}$$

can be modeled as:

$$\widehat{(3, 1)} \left(\left(\xrightarrow{3 \rightarrow 2} \uparrow \uparrow \xrightarrow{1 \rightarrow 7} \right) \widehat{(2, 7)} \left(\xrightarrow{2 \rightarrow 1} \uparrow \uparrow \xrightarrow{7 \rightarrow 1} \right) \right) \widehat{(1, 1)}$$

5.2.2 Second species counterpoint

For second species counterpoint, we encounter concurrent processes where one is more elaborated than the other. A segment of such texture

$$\begin{aligned} & 5 - 4 - 3 \\ & 7 - 1 \end{aligned}$$

can be modeled as

$$\widehat{(5, 7)} \left(\left(\xrightarrow{5 \rightarrow 4} \widehat{4} \xrightarrow{4 \rightarrow 3} \right) \uparrow \uparrow \left(\xrightarrow{7 \rightarrow 1} \right) \right) \widehat{(3, 1)}$$

Notice that the two-against-one coordination of the motion is reflected in the structure of the encoding and we do not need to “break” the $\widehat{7}$ into two copies of $\widehat{7}$ to convert it into first species texture.

5.2.3 Third species counterpoint

Third species counterpoint is a more elaborated version of the second species but the form of the representation is very similar.

5.2.4 Fourth species counterpoint

Fourth species counterpoint presents the opportunity of suspension. We can generalize such textures as overlaying transitory processes in an alternating manner, creating temporal displacement. Consider this 7-6 suspension (“=” represents “tied-over”)

$$\begin{aligned} & 3 = 3 - 2 = 2 - 1 \\ & 5 - 4 = 4 - 3 = 3 \end{aligned}$$

It can be modeled using Eq. 14 as the following:

$$\widehat{(3, 5)} \left(\left(\xrightarrow{5 \rightarrow 4} \uparrow \uparrow \xrightarrow{3 \rightarrow 2} \right) \widehat{(2, 4)} \left(\xrightarrow{4 \rightarrow 3} \uparrow \uparrow \xrightarrow{2 \rightarrow 1} \right) \right) \widehat{(1, 3)}$$

6. DISCUSSION

The contribution of this paper is to offer a characterization and representation on the hierarchical organization of both stationary and transitory musical processes as well as how they can be concurrently structured. Linear processes are modeled using two mutually inductive types *Joint* and *Link*. Concurrent processes are modeled on top of linear processes by adding two binary operations for *Joint* and *Link* respectively. In addition, an algebraic law is imposed on these two operators to express an isomorphism between the horizontal view and the vertical view. We introduced a graphical notation for linear processes and presented several harmonic analysis using the notation to demonstrate the music analytical application of the characterization of linear processes. To demonstrate the analytical application of the concurrent processes, we presented their corresponding encoding for contrapuntal textures in species counterpoint.

This general formalism can be flexible to adapt to specific music theoretical constraints. One might encode specialized elaboration rules by equipping the *Link* constructor with domain specific constraints on the type level and reuse the function itself. In Eq. 8, such constraint could be a predicate on the type variables $p_{x,z,y}$ ³.

³ Upper neighbor elaboration, for example, corresponds to the predicate $p_{x,z,y} = (x = y, z = \uparrow x)$. Likewise, downward passing elaboration corresponds to the predicate $p_{x,z,y} = (z = \downarrow x, y = \downarrow z)$.

7. ACKNOWLEDGEMENT

This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program under grant agreement No 760081 – PMSB. We thank Claude Latour for supporting this research through the Latour Chair in Digital Musicology.

We thank the team of the Digital and Cognitive Musicology Lab (DCML), particularly Gabriele Cecchetti and Xinyi Guan, for their helpful comments on earlier versions of this paper. Furthermore, we thank Yannis Rammos and Christoph Finkensiep for fruitful discussions on the music interpretations and implementation of the model in this paper.

ONLINE SYMBOLIC MUSIC ALIGNMENT WITH OFFLINE REINFORCEMENT LEARNING

Silvan David Peter

Institute of Computational Perception, Johannes Kepler University Linz, Austria

silvan.peter@jku.at

ABSTRACT

Symbolic Music Alignment is the process of matching performed MIDI notes to corresponding score notes. In this paper, we introduce a reinforcement learning (RL)-based *online* symbolic music alignment technique. The RL agent — an attention-based neural network — iteratively estimates the current score position from local score and performance contexts. For this symbolic alignment task, environment states can be sampled exhaustively and the reward is dense, rendering a formulation as a simplified offline RL problem straightforward. We evaluate the trained agent in three ways. First, in its capacity to identify correct score positions for sampled test contexts; second, as the core technique of a complete algorithm for symbolic online note-wise alignment; and finally, as a real-time symbolic score follower. We further investigate the pitch-based score and performance representations used as the agent’s inputs. To this end, we develop a second model, a two-step Dynamic Time Warping (DTW)-based *offline* alignment algorithm leveraging the same input representation. The proposed model outperforms a state-of-the-art reference model of offline symbolic music alignment.

1. INTRODUCTION

Music alignment refers to matching at least two different versions of the same musical material. In this paper, we address symbolic music alignment, for our purposes defined as models that match individual notes of a performance recorded as MIDI file to individual notes of a score encoded as MusicXML file.

Alignment procedures can be separated into online or offline classes. If the alignment procedure is carried out with access to the full versions of the musical material, we refer to it as offline alignment. Conversely, if one version is only known up to the point currently to be matched, we refer to it as online.

We introduce a reinforcement learning (RL)-based *online* symbolic music alignment technique. It aligns symbolically encoded music or, more specifically, MIDI performances to their corresponding MusicXML scores by

matching individual notes of each version. The RL agent — a small attention-based neural network — is trained to iteratively predict the current score position from limited score and past performance contexts. The current performance note and estimated score position are then processed to compute a symbolic note-wise matching.

RL terminology introduces another online versus offline differentiation. RL is termed online if the agent learns from data created by the agent’s interaction with its environment during training. In our case, we use offline RL, that is, the agent is trained using a dataset of exhaustively sampled environment states and associated rewards, effectively turning agent training into a supervised learning problem. Once trained in an offline fashion, the agent can be used in online alignment.

The agent processes a purely *pitch-based representation* and timing information is only incorporated in a post-processing step. Before addressing the online problem, we investigate the same separation of pitch and time processing in an offline setting: we develop a two-step (first pitch, then time) Dynamic Time Warping (DTW) offline model and evaluate it against the state of the art in note-wise alignment in Section 3. The subsequent Section 4 addresses the RL-based online model reusing the input setup.

The rest of this paper is thus structured as follows: Section 2 introduces related work. Section 3 discusses offline symbolic music alignment. We develop as well as evaluate an offline symbolic music alignment algorithm based on two different applications of DTW, first on pitch information, then on onset times. Starting from these results, section 4 introduces a formulation of online alignment as reinforcement learning problem. In particular, we train an agent’s value function in an offline setting. In section 5 we evaluate the trained agent in three ways: as a standalone score onset identification model, as an online symbolic alignment model (where the aim is the production of correct note-wise alignments), and in a score following scenario (where the aim is the precise temporal tracking the current score position). Finally, Section 6 concludes the paper with a critical appraisal of our models as well as recommendations for future research.

2. RELATED WORK

Symbolic music alignment has been a popular research area for many years. We begin our review of related work with online symbolic music alignment, then we progress

to offline symbolic music alignment, general music alignment, and finally applications of reinforcement learning.

Most often, online models have been presented in the context of score following, where the principal aim is to identify the current score position. Dannenberg [1] and Vercoe [2] pioneered this area of research in the mid 1980s. Recent works commonly use Dynamic Bayesian Networks to track the performance [3–6]. Recently, A. Anonymous compared both Hidden Markov Models (HMM) and On-Line Time Warping (OLTW) techniques. We use their OLTW model as comparison baseline for our online alignment technique. This model processes inputs represented as piano rolls, as is common for OLTW and DTW applications to symbolic music alignment in general.

The offline setting has seen more recent work [3, 5, 7–11]. Symbolic music alignment methods often perform very well, with error rates rarely exceeding 10%. Consequently, much recent work focused on the rare, indeterminate, or asynchronous events that make the errors difficult to identify and fix. Ornaments are one source of such events [9]. Another is left-right hand asynchrony in piano performance as discussed in Nakamura et al. [3]. Arbitrary skips and repeats further present a very difficult challenge for most algorithms, especially when runtime considerations are important [10]. This series of articles by Nakamura et al. [3, 9, 10] culminated in one of the most widely used automatic score-performance alignment tools and the current state of the art (SOTA) [11]. We use this model as reference for the evaluation of our offline algorithm.

Although beyond the scope of this article, no introduction of music alignment is complete without the mention of the large body of work concerning alignment of non-symbolic music formats, in particular audio. Wang [12], Arzt [13], and chapter three in Müller [14] present introductory discussions of audio alignment. As in our offline approach, applications of (non-standard) DTW are central to audio alignment [15–18]. Audio score following is commonly computed using On-Line Time Warping and variants of Hidden Markov Models [19–23].

To the best of our knowledge, Dorfer et al. [24] (later expanded upon by Henkel et al. [25]) are the only prior application of RL in a music alignment task, namely online audio to sheet music image alignment. For a general introduction to RL, we refer the reader to Sutton and Barto [26], for a discussion of the merits and disadvantages of offline RL to Levine et al. [27].

3. OFFLINE SYMBOLIC MUSIC ALIGNMENT

In this section, we introduce an offline symbolic music alignment based on two different DTW steps as well as an intermediate cleanup step. We close the section with an evaluation of our model against a state-of-the-art reference.

Symbolic music alignment produces *note alignments*, i.e., it matches individual notes of a performance recorded as MIDI file to individual notes of a score encoded as MusicXML file. Three types of note alignments exist: a match is tuple of a performance note and a score note, a deletion is a score note not played, and an insertion is a performed

Figure 1. First half measure of Chopin Op. 9 No. 2 (bottom score), encoded as pitch set sequence (left) and warped to its performance, encoded as sequence of pitches as played (top). The matrix shows the corresponding pairwise distance (shaded is distance of 1, see equation 1), red lines indicate equivalent optimal warping paths.

note not notated.

Our proposed offline algorithm consists of the following steps: First, the performance and score are aligned using DTW on a purely pitch-based representation (Section 3.1). Then, remaining gaps are filled by complete sequences of a single pitch. Finally, individual notes are aligned using an application of DTW on their onset times (Section 3.2).

3.1 Pitch Sequence Warping

In this approach, we align sequences of performance notes, encoded as integer pitches $p_t \in \mathbb{I} := \{1 \dots 88\}$, with sequences of score onset notes, encoded as sets of integer pitches $s_t \in \mathcal{P}(\mathbb{I}) \setminus \{\emptyset\}$, with $\mathcal{P}(\mathbb{I})$ denoting the power set of the set \mathbb{I} . Since these sequence elements are of different types — integers and sets of integers — no standard local distance metric can be used. Instead we opt for a non-symmetric inclusion metric, with some abuse of the term.

$$m(p_t, s_t) = \begin{cases} 0 & \text{if } p_t \in s_t \\ 1 & \text{else} \end{cases} \quad (1)$$

Having defined the metric in Equation 1, two standard DTW paths are computed, one forward and one backward, i.e., using inverted sequences. Figure 1 shows the encoding as well as exemplary DTW paths computed from cumulative pairwise distances. While the optimal DTW distance is unique, the DTW paths are not necessarily so. In our case, such ambiguity is often introduced by repeated pitches in neighboring score onsets, see e.g., the two adjacent (left, stacked vertically) notes of pitch D4/62 in Figure 1. To pinpoint non-robust path segments, we use the backward DTW path. Wherever the forward and backward paths disagree, they effectively bracket ambiguous parts from both sides, and we exclude all bracketed notes from the path.

These excluded segments are then processed using a simple heuristic: The notes in bracketed segments are sep-

arated by pitch. If two pitch-wise sequences with matching number of notes (in the performance and the score) are found, they are aligned and the result is added to the path. If no matching sequence is found, the path is linearly interpolated. We finally compute a mapping from score time to performance time from this merged and cleaned path.

3.2 Onset Sequence Warping

The next goal is to derive note-wise alignments from the approximate score to performance mapping computed in Section 3.1. To this end, the performance and score are split into pitch-wise sequences for each pitch occurring in the union of score and performance pitches. The approximate score-time-to-performance-time mapping computed in the previous step is used to project all score onsets (in beats) to performance time points (in seconds). The last step aligns the performance onset sequence with the score onset sequence, now mapped to the same space.

This alignment is computed by a DTW path between the onset sequences, this time using a simple L_1 metric, and for each non-unique alignment, keeping the tuple with the lowest distance. A threshold of maximal distance is further built-in (and set to 5 seconds) to avoid spurious alignment of unrelated deletions and insertions.

3.3 Offline Model Evaluation

To test the full offline model (first pitch DTW 3.1, then onset DTW 3.2), we compute alignments on four datasets of high-quality note-wise alignment piano music. The datasets are the Vienna 4x22 Dataset [28], four excerpts performed by 22 performers each; the Zeilinger Dataset [29], nine piano sonatas by Ludwig van Beethoven performed by Clemens Zeilinger; the Magaloff Dataset [30], the near complete solo piano works by Frederic Chopin performed by Nikita Magaloff; and the Batik Dataset [31], twelve piano sonatas by Wolfgang Amadeus Mozart performed by Roland Batik. We compare our model against the reference by Nakamura et al. [11], post-processed to produce the same output format we employ.

To compare produced alignments to ground truth ones, we have to define a metric. Recall that note alignments consist of three types: matches (tuples of performance and score notes), deletions (unplayed score notes), and insertions (unnotated performed notes). We use an F-score metric for matches: A predicted match is counted as a true positive (TP) only if the same notes are matched in the ground truth alignment. A false positive (FP) is a predicted note label that isn't in the ground truth, a false negative (FN) is a ground truth note label that isn't predicted. The F-score is defined as the harmonic mean of precision ($TP / (TP + FP)$) and recall ($TP / (TP + FN)$).

Table 3.3 shows dataset-wise and globally averaged F-scores for matches. Our proposed model outperforms the reference on each dataset. A two-sided sign test on performance-wise rankings shows significantly ($\alpha = 0.01$) higher performance for our proposed model on all datasets except the Vienna 4x22 Dataset. On the Vienna 4x22 dataset, the models reach the same F-score of 1.0 for 38

Dataset	DTW Offline	Nakamura
Magaloff	98.4 ± 0.9 %	97.8 ± 1.4 %
Zeilinger	99.3 ± 0.9 %	98.8 ± 1.2 %
Batik	99.4 ± 0.7 %	98.5 ± 2.1 %
Vienna 4x22	99.8 ± 0.4 %	99.5 ± 0.5 %
Combined	99.0 ± 1.0 %	98.5 ± 1.5 %

Table 1. Dataset-wise averaged F-scores and standard deviations of each model.

performances and our proposed model has higher F-scores for the remaining 50 performances.

4. ONLINE ALIGNMENT AGENT

Having established the effectiveness of the separation into pitch-based and time-based input representations in the offline setting, we now introduce a formulation of RL-based online alignment. We continue with the model and training setup used to approximate the agent's value function.

Reinforcement learning is formalized as Markov Decision Process (MDP). An MDP consists of the following components: a state space \mathcal{S} , an action space \mathcal{A} , an index set \mathcal{T} , a reward function \mathcal{R} , transition probabilities \mathcal{P} , and a discount factor γ .

An agent is placed in an environment and perceives this environment and itself as being in a possible state $S_t \in \mathcal{S}(t \in \mathcal{T})$. The agent now takes an action $A_t \in \mathcal{A}$ and receives a reward R_{t+1} as well as a new state $S_{t+1} \in \mathcal{S}$. Repeating this process iteratively yields a sequence of states, actions, and rewards, called an episode: $S_t, A_t, R_{t+1}, S_{t+1}, A_{t+1}, R_{t+2}, S_{t+2}, A_{t+2}, \dots$. It is now the agent's task to infer actions from states that maximize long-term reward. Before we look at our formulation of this optimization problem, we discuss the online alignment's state and action space in more detail.

4.1 Alignment as Reinforcement Learning

The state information S_t comprises both the current score context as well as the most recent past performance. Specifically, the score context is represented as a window of the pitch set sequence introduced in Section 3.1. The window centers the last predicted score onset position and spans seven score onsets to the past as well as eight score onsets to the future for a total windowed sequence of 16 pitch sets. The performance context is only derived from past performance notes to enable real-time application. It consists of the eight most recent notes in the performance pitch sequence. Whenever less score or performance context is available, e.g., at the very beginning or end of a piece, the windows are shortened accordingly.

At each state S_t the agent aims to match the most recent performance note to its most likely score onset. There are 16 actions at S_t ; select one score onset as matching onset position. Having decided on a next score onset, the agent receives a reward R_{t+1} which is set to one if the score onset is correctly aligned, zero otherwise. The environment transition probabilities \mathcal{P} determine a new state S_{t+1} : the

performance context of the new state is determined by an actual performance, i.e., the agent is presented a new state based on the estimated next position in the score and a new incoming performance note.

4.2 Simplified Deep Q-learning

The agent's behavior is captured by its policy $\pi(A|S)$, the distribution of actions taken by the agent in state S . Although it is possible to optimize the policy directly, we instead adapt a value-function-based formulation, or more specifically, deep Q-learning [32, 33]. Q-learning aims to optimize a state-action value function $Q : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$, an estimate of the expected cumulative discounted future reward, also called return, given a state and an action. In deep Q-learning the value function $Q(S, A, \theta)$ contains trainable parameters θ which are fitted to the experienced reward distribution. A typical optimization loss l looks like this:

$$l = (R_{t+1} + \gamma \max_{A_{t+1}} Q(S_{t+1}, A_{t+1}, \theta) - Q(S_t, A_t, \theta))^2 \quad (2)$$

where the discount factor $\gamma \in [0, 1]$ determines the weighting of future rewards. For the alignment case we can make several simplifications. We opt for a completely myopic agent, i.e., $\gamma = 0$. The argument for this is that the optimal action to take for each incoming performance note is determined by the correct score onset which can in turn be specified by the immediate reward. >For a discussion of the implications of this modeling choice see section 6. Setting $\gamma = 0$ removes the value function at subsequent states from the loss. Using that $\mathcal{R} = \{0, 1\}$, we make a second reformulation and replace this squared error loss by a binary classification: For each state-action tuple (S, A) the agent predicts the probabilities of the reward being 1 or 0, optimized with a cross-entropy loss. Note that this formulation still optimizes a state-action value function Q and not a policy $\pi(A|S)$, i.e., the probabilities of rewards are computed for each possible action (that is, per score onset) and do not sum to one over all actions. There are several ways of deriving a policy from a value function; two are discussed in section 4.5.

4.3 Value Function Model

To approximate $Q(S, A, \theta)$, we use an attention-based Transformer Neural Network. The input of the network consists of a sequence of tokens encoding the performance, a delimiter token, the score, and an ending token. We encode 88 pitches of the piano keyboard, adding extra tokens for "no_pitch", "delimiter", and "end" in a 64-dimensional embedding space. The performance pitches are straightforward to embed, however, the score onset pitch sets require more processing. For our data, more than 99% of score onsets can be represented with pitch sets with no more than seven different pitches, we thus limit our pitch sets to this length (with a subset of seven taken randomly at onsets with more pitches). Pitch sets with fewer than seven pitches are filled up with a pitch corresponding to the

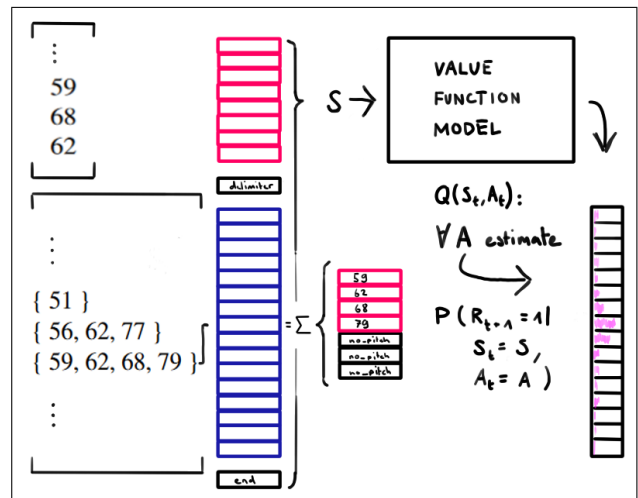

Figure 2. Setup of the value function model: states are encoded as contiguous token sequence of past performance (red) and current score (blue) contexts. Pitch set embeddings are summed over individual pitch embeddings. The model is set up as token classifier as each score onset in the context corresponds to a possible action (= "select this onset as next score onset") and is classified according to its expected reward class. The vector on the right shows the reward probability for each action (pink).

"no_pitch" token. To create score onset embedding with no more than 64 dimensions independent of the number of pitches at any onset, the pitch set tokens are summed up. Figure 2 shows the setup of the value function model. The model is set up with eight heads, and six layers, layer normalization, and a single feedforward head for binary classification, making for a total of 157250 parameters.

4.4 Training

The training is set up as token classification problem; i.e., for each token in the sequence, the probability of receiving a reward is estimated. The aligned piano datasets from Section 3.3 are used again. For our offline RL setting, a dataset of states is created before training. We extract local score and performance contexts from the aligned data, shifting the performance window such that true next score onsets fall from leftmost (current position minus seven) to rightmost (current position plus eight) to cover the possible states exhaustively. During training, batches of states are sampled randomly, not in sequence. To aid generalization, we further augment the data by random pitch shifting of all notes in the state within +/- one octave. We use an ADAM optimizer with a learning rate with warm-up followed by square root decay. The batch size is set to 8192, the models are trained for 50 epochs.

4.5 Online Models

Using a trained value function model, we derive two complete models. First, a simple score follower model ("Greedy Agent Model") that outputs only greedily estimated score onsets for incoming performance notes. Sec-

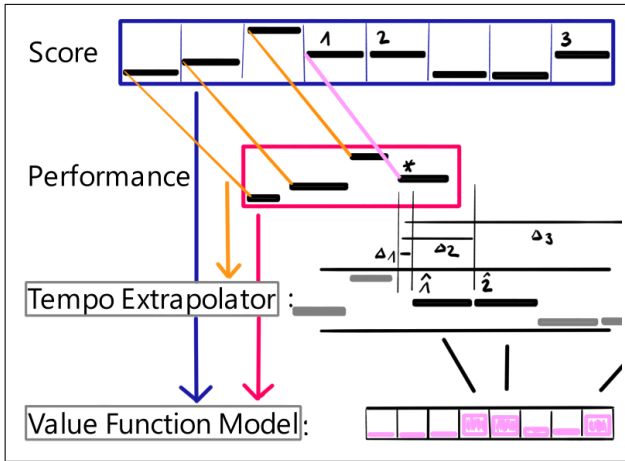

Figure 3. Schematic overview of the Online Alignment Model with a monophonic piece and 8 onset context. Score (blue, top) and performance (red) contexts are inputs to the Value Function Model which outputs value estimates (pink, bottom). The top three onsets (1,2,3) are passed to a tempo extrapolator, along with existing alignments (yellow). The tempo extrapolator predicts three onsets ($\hat{1}, \hat{2}$) for the the candidate onsets. The one with lowest distance (Δ_1) to the newest performance note (*) is aligned (pink).

ond, a note-level alignment model ("Online Alignment Model") that produces both note alignments as well as an estimate of the next score onset for the score following setting. The Greedy Agent Model consists of an agent following a greedy policy based on the trained value function model, i.e., an agent picking the action A with maximal estimated reward $Q(S, A)$.

For the Online Alignment Model a few additional steps are taken. See Figure 3 for an overview of the alignment loop. In this model, an action is selected from the top three value estimates for a given score and performance context. To pick one of these three actions, onset time information is incorporated. A simple local tempo estimator approximates an expected performed onset time for each of the three possible score onsets using linear extrapolation of beat periods computed from previously aligned notes. This process takes on the role of the second onset-wise DTW step in the offline model (see Section 3.2): to match notes that are closest together according to an approximate score-to-performance mapping.

There are two further heuristics worth mentioning. If the current performed pitch is not available at any of the three highest ranking score positions, the performed note is counted as an insertion, and the current score position is unchanged. Furthermore, we decrease the number of calls made to the agent in a real-time setting by directly aligning pitches that are trivially missing at the current score onset.

5. ONLINE EVALUATION

In the following, we evaluate the agent and the proposed online alignment model. In section 5.1, we address a greedy agent’s capacity to identify correct score positions for sampled test contexts. In section 5.2, the Online Align-

ment Model is evaluated with respect to correct note-wise alignment. Finally, we use both the Greedy Agent Model as well as the Online Alignment Model as real-time symbolic score followers in an experiment in section 5.3.

5.1 Agent Evaluation

Top0	Top1	Top2
94.5 ± 0.8 %	96.6 ± 0.5 %	97.6 ± 0.4 %

Table 2. Average topK score onset hit rate and standard deviation across the five test folds.

For direct value function evaluation, we assume a greedy policy for each testing state S . That is, the agent picks the action A with the highest estimated value $Q(S, A)$. We evaluate this action (= chosen score onset) via the distance from the ground truth score onset. Specifically, we compute three metrics: the number of states where this action corresponds exactly to the true score onset ("Top0"), the number of times this action picks a score onset in the neighborhood of ± one score onset of the true location ("Top1"), and the number of times this action picks a score onset in the neighborhood of ± two score onsets of the true location ("Top2"), each normalized by the total number of test states. We use five-fold cross-validation on the same combined datasets used in section 3.3, and report mean and standard deviation values across testing folds. The fold splitting is carried out piece-wise with roughly the same number of score onsets in each fold.

Table 2 shows the results. Greedy action selects the correct score onset with more than 94 % probability on unseen pieces. Furthermore, for more than half of the remaining errant actions, the greedy action is not further than two onsets from the correct one.

5.2 Online Note-wise Alignment

Piece	OAM	DTW Offline	Nakamura
B. Op. 53 3rd. m.	99.0 %	99.4 %	98.2 %
C. Op. 9 No. 1	97.6 %	98.4 %	98.8 %
C. Op. 9 No. 2	97.4 %	99.1 %	97.6 %
C. Op. 10 No. 11	90.3 %	96.3 %	94.3 %
C. Op. 60	95.1 %	97.9 %	94.7 %

Table 3. Piece-wise F-scores of each model. OAM = Online Alignment Model, DTW Offline = model of section 3.3, Nakamura = reference SOTA model [11].

To evaluate the Online Alignment Model’s performance, we perform alignments for five selected performances: Nocturnes Op. 9 No. 1 and 2, Etude Op. 10 No. 11, Nocturne Op. 15 No. 2, the Barcarole Op. 60 by F. Chopin, and the third movement of the Sonata Op. 53 (Waldstein) by L. v. Beethoven. The value function model used in this section was trained on all data except these five pieces for 100 epochs, the rest of the training and model setting remains the same. The same metrics of section 3.3

Model	Async	$\leq 25\text{ms}$	$\leq 50\text{ms}$	$\leq 100\text{ms}$
OLTW	60.6 ms	38.0 %	63.3 %	86.7 %
GAM	36.0 ms	89.0 %	91.4 %	94.6 %
OAM	15.7 ms	91.4 %	93.8 %	96.6 %

Table 4. Asynchrony of the models in score follower setting. Column "Async" presents the median asynchrony. Columns 3, 4, 5 present the percentage of onset estimates with lower asynchrony than 25ms, 50ms and 100ms, respectively.

apply, namely the F-score of retrieved matched note tuples. For comparison we also add piece-wise F-scores of our proposed offline model as well as the model by Nakamura et al. Table 3 shows the F-scores of note alignments. As expected, the proposed online alignment performs worse than offline methods, albeit with small difference. Notably, all models show the lowest performance on Chopin’s Op. 10 No. 11.

5.3 Score Following

In the score following setting, the core metric is the accurate prediction of the current position. We thus compute asynchrony values in milliseconds which give the absolute time between any onset in a performance and the onset in the same performance that corresponds to the estimated score onset. The data used for this experiment consists of the same five pieces used in the previous section 5.2 with the same value function model training. Three models are compared in this setting: The Online Alignment Model (OAM) previously evaluated in terms of note alignment F-scores in Table 3, the Greedy Agent Model (GAM), and an On-Line Time Warping (OLTW) Model. This latter OLTW model performed best in a recent music score following comparison by Cancino-Chacón et al. [34] and is added as a reference. However, this model does not predict note alignments, hence a comparison in terms of note alignment F-score as in Section 5.2 is not possible.

Both the GAM and the OAM outperform the reference model in all metrics in Table 4. Most of the lower performance of the GAM is due to the fact that for Chopin’s Op. 10 No. 11, this agent loses track of the performance close to the end when a full measure is deleted. All subsequent performance notes are estimated very wrongly. The online alignment model on the other hand follows all test performances robustly until the end.

6. DISCUSSION AND CONCLUSION

In this paper, we introduce two models, an offline alignment model based on dual DTW steps, and an online alignment model based on an RL agent trained in an offline fashion. Both models perform competitively; with the offline model surpassing the relevant state of the art.

In the setup of the RL training we made some simplifications that warrant further discussion. Specifically, we set the discount factor γ to zero and train using a dataset

of sampled states. In section 4.2, we claim that the optimal action for each step is determined by the correct score onset. While this is true for the states in the dataset and if optimality is defined by accuracy in note-wise alignment, it might not be for out-of-distribution states or if the focus of the agent is shifted to robustness, i.e., following the entire performance even at the cost of some misaligned notes.

For offline RL, a crucial issue is distributional drift [27]; i.e., the fact that the agent learns from states that follow a different distribution than the states it would encounter in an online setting. Even though we can sample the state space exhaustively for the training set, out-of-distribution states are expected in test sets consisting of previously unseen pieces and performances. Furthermore, the relative frequency of training samples does not necessarily correspond to the states an online agent is likely to see during training, where all target locations have the same frequency. Specifically, for an agent that already learned to predict the score onset with some accuracy, the targets at the limits of the context are going to be less frequent than the center ones. In other words, a non-myopic online agent is likely to behave more conservatively, avoiding large skips as they do not occur that frequently in actual performances.

On the other hand, the offline RL formulation successfully leverages prior knowledge about the task and — more importantly — stabilizes the gradient, rendering the training of a complex value function approximator feasible. Future work includes shifting this trade-off back towards online RL, for example with online RL training after initial offline training.

The RL agent learns to align purely on pitch information. Including onset or even duration information is likely to increase the accuracy of following at the cost of requiring a more expressive model which in turn affects inference speed — a hard bottleneck for real-time application. In fact, running the value estimation for every incoming performance note (such as the score follower "GAM" in Table 4) uses up to a minute of computation time for the 7273 notes in the performance of Beethoven’s Op. 53 Mvt. 3 (Roughly 10 ms per note). A further increase is liable to affect real-time score following in fast passages.

In terms of post-processing steps, both our offline and online models are comparatively crude, making little use of score information such as ornaments. As Nakamura et al. [11] correctly remark, their post-processing step is in principle able to improve upon any prior more error-prone alignment. Further research is needed to know whether the offline model can be improved in this way.

To conclude, we developed and evaluated two models of symbolic music alignment which both outperform relevant prior work. To the best of our knowledge, this RL-based online alignment model is one of the first applications of not only trainable but effectively *trained* models to symbolic music alignment.

ABSTRACT

Synthesizers are widely used electronic musical instruments. Given an input sound, inferring the underlying synthesizer’s parameters to reproduce it is a difficult task known as *sound-matching*. In this work, we tackle the problem of automatic sound matching, which is otherwise performed manually by professional audio experts. The novelty of our work stems from the introduction of a novel differentiable *synthesizer-proxy* that enables gradient-based optimization by comparing the input and reproduced audio signals. Additionally, we introduce a novel self-supervised finetuning mechanism that further refines the prediction at inference time. Both contributions lead to state-of-the-art results, outperforming previous methods across various metrics. Our code is available at: <https://github.com/inversynth/InverSynth2>.

1. INTRODUCTION AND RELATED WORK

Sound synthesis has been an active research field since the end of the previous century [1]. Given a query audio input, the task of crafting a specific sound is known as *sound matching*. Synthesizer sound matching, also known as *inverse synthesis*, involves carefully tuning parameters from an exponentially large number of possible configurations—a task mostly reserved for professional audio experts. This paper presents a novel algorithmic approach for *automated sound matching*.

Algorithmic approaches for inverse synthesis can be loosely categorized into *search-based* methods and *modeling-based* methods [2]. Search-based methods often utilize genetic algorithms (GA) which are based on principles of Darwinian evolution to determine the optimal synthesizer configurations. For instance [3] initiated a set of randomly sampled configurations and used GA optimization to reconstruct the original audio signal. Other search-based methods include Particle Swarm Optimization (PSO) [4] and Hill-Climbing [5]. Search-based methods can employ different objectives such as mel-frequency cepstral coefficients (MFCCs) or a combination of multiple objectives [6, 7]. However, optimizing configura-

tions through search-based methods can be both resource-intensive and time-consuming for every sound sample. Consequently, the rise of deep learning techniques has led to a shift from search-based methods to model-based ones, which avoid the previously mentioned drawbacks. However, search-based methods still possess a unique advantage: they can establish a loss term that directly contrasts the reconstructed audio signal with the input signal.

The aforementioned advantage is absent in most modeling-based methods, as they usually cannot propagate gradients through an external, commercial synthesizer. As a result, they depend on setting an optimization goal focused on reconstructing the parameters rather than the reproduced signal. In general, modeling-based methods employ deep learning in order to predict a synthesizer’s configuration based on the input audio signal. For example, [8] employed long short-term memory (LSTM) networks for predicting the parameters in FM synthesizers. InverSynth (IS) [9] employed strided convolution neural networks (CNNs) to estimate a synthesizer’s parameters as a multi-objective classification problem. When compared to the LSTMs approach of [8], IS provides improved accuracy with the ability to scale for longer audio sequences. Another direction involves employing variational inference [10] and normalizing flows [11, 12] to automatically tune an open-source replica of the Yamaha DX7 synthesizer [13]. Finally, [14–16] introduce different versions of audio synthesizer models for sound matching.

A completely different direction for sound matching and synthesis is through neural synthesizers [17–22]. For example, in [19] the authors train Generative Adversarial Networks to synthesize sounds that simulate natural audio samples. However, these directions are inherently different from the current line of work, as they do not deal with the problem of tuning existing musical synthesizers. Instead, these works suggest alternatives to familiar synthesizers, which may be useful for future applications but are less relevant to mainstream musicians that use existing commercial synthesizers.

In this paper, we present InverSynth II (IS2) - an innovative inverse-synthesis model that introduces a differentiable synthesizer-proxy capable of learning to “imitate” the behavior of any given synthesizer. This allows for a differentiable relationship between the synthesizer’s parameters and the produced audio signal. As a result, IS2 learns to focus on the synthesizer parameters that have more impact on the reproduced signal. Our evaluations indicate that this approach leads to a better reconstruction of the

original audio signal in terms of spectral loss and human perception.

Our contributions are as follows: (1) We introduce IS2 that effectively incorporates the synthesizer’s functionality into the computational graph. By learning a differentiable *synthesizer-proxy*, IS2 facilitates self-supervision based on the difference between the input and reproduced audio signals. This is in contrast to previous model-based works that optimized on the predicted synthesizer parameters alone [8, 9, 23]. (2) We introduce a novel self-supervised finetuning technique that utilizes the learned synthesizer-proxy to further refine predictions at inference time. (3) We compare IS2 against the state-of-the-art methods from [10] and [9] on the three datasets, including the datasets from both of these works. Our findings show that IS2 outperforms both methods on all datasets, across all metrics.

2. INVERSYNTH II

2.1 Problem Setup

Let $x \in \mathcal{X}$ be the audio signal i.e., raw waveform, Short-time Fourier transform (STFT) spectrogram, etc. Let $f : \mathcal{Y} \rightarrow \mathcal{X}$ be a synthesizer function that generates a signal $f(y) \in \mathcal{X}$ according to the parameters configuration $y \in \mathcal{Y}$, where y encodes the exact value for each of the configurable synthesizer parameters. For example, these parameters determine the oscillators’ waveform types, the amplitudes’ values, modulation indexes, ADSR envelopes, filter cutoff frequency, etc. The inverse-synthesis task is to learn an *encoder* function $e_\theta : \mathcal{X} \rightarrow \mathcal{Y}$, parameterized by θ , that receives an audio $x \in \mathcal{X}$ and predicts the parameters configuration $e_\theta(x) \in \mathcal{Y}$ s.t.

$$f(e_\theta(x)) = x' \approx x. \quad (1)$$

2.2 The IS Model

The IS model from [9] receives an input signal x and aims at inferring a parameters configuration \hat{y} which best matches the true yet unknown parameters configuration y that produced $x = f(y)$. To this end, a dataset $D = \{(x_i, y_i)\}_{i=1}^N$ is generated, where y_i is the synthesizer’s configuration used by f to generate the sound x_i , hence $f(y_i) = x_i$. IS trains an encoder network e_θ to predict y_i from x_i by minimizing the objective

$$\theta^* = \operatorname{argmin}_\theta \sum_{i=1}^N \mathcal{L}_p(e_\theta(x_i), y_i), \quad (2)$$

where $\mathcal{L}_p : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$ is the *parameters loss* that quantifies the difference between the predicted configuration $e_\theta(x_i)$ and the ground truth configuration y_i . In [9], each synthesizer parameter was treated as a categorical variable (continuous parameters were quantized), hence solving multiple classification problems simultaneously (one for each parameter). Accordingly, the loss \mathcal{L}_p was the sum of P cross-entropy (CE) losses, where P is the number of the synthesizer parameters.

2.3 The IS2 Model

IS does not optimize on the actual reproduced audio signal. Instead, it only optimizes on the parameters configuration according to Eq. 2. However, minimizing \mathcal{L}_p

is just a proxy to the original task from Eq. 1 that aims at minimizing the difference between the original signal x and the reproduced signal $f(e_\theta(x))$. This observation motivates an additional self-supervised loss term $\mathcal{L}_a : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$, namely the *audio loss*, that measures the discrepancy between the input signal x and the reproduced signal $f(e_\theta(x))$:

$$\theta^* = \operatorname{argmin}_\theta \sum_{i=1}^N \mathcal{L}_p(e_\theta(x_i), y_i) + \lambda \mathcal{L}_a(f(e_\theta(x_i)), x_i), \quad (3)$$

where λ is a hyperparameter. The audio loss term \mathcal{L}_a provides feedback on the quality of the reproduced signal $f(e_\theta(x_i))$ itself, hence better aligns with the ultimate task of Eq. 1.

Yet, a key challenge arises - how to backpropagate the error induced by \mathcal{L}_a via f ? A naive approach may propose implementing the synthesizer f as part of the computational graph. However, this approach suffers from several limitations: First, it requires a specific implementation per synthesizer and hence does not scale. Second, most commercial synthesizers are not open-source, and even if the source code was provided, it would still require rewriting of the entire codebase to support an auto-differentiation platform (e.g., PyTorch). Furthermore, some synthesizer functionalities are not differentiable and require workarounds that may incur discrepancies and hinder gradient-based optimization.

To this end, IS2 introduces a *synthesizer-proxy* decoder network $d_\phi : \mathcal{Y} \rightarrow \mathcal{X}$, parameterized by ϕ , that serves as a differential replacement to the true synthesizer function f . d_ϕ is trained to minimize \mathcal{L}_a w.r.t. ϕ over the dataset D , which leads to the IS2 training objective

$$\Theta^* = \operatorname{argmin}_\Theta \sum_{i=1}^N \mathcal{L}_p(e_\theta(x_i), y_i) + \lambda \mathcal{L}_a(d_\phi(e_\theta(x_i)), x_i), \quad (4)$$

with $\Theta = \{\theta, \phi\}$.

2.4 IS2 Training

IS2 employs stochastic gradient descent optimization [24] on the objective from Eq. 4 as depicted in Fig. 1(a) (the exact implementation and optimization details will follow in Secs. 2.6 and 3.2). We apply a K -fold cross-validation procedure over the dataset D , where each fold defines different training, validation, and test sets. For each fold, we train the IS2 model on the training set and monitor the following measure on the validation set $V \subset \{1..N\}$:

$$\mathcal{L}_V^f := \sum_{i \in V} \mathcal{L}_a(f(e_\theta(x_i)), x_i). \quad (5)$$

Finally, the best-performing model (in terms of \mathcal{L}_V^f across all epochs) is used for reporting results on the test set.

Note that the predicted parameters $e_\theta(x)$ in Eq. 5 are propagated to the *true* synthesizer f and not to the synthesizer-proxy d_ϕ (see Fig. 1(b)). This enables selecting the model that minimizes the discrepancy between x and $f(e_\theta(x))$, which aligns with the ultimate task of Eq. 1. Yet, f does not participate in the optimization objective (Eq. 4) since it is not necessarily differentiable. Instead,

Figure 1: (a)-(b) depict the IS2 training phase (Sec. 2.4) that utilizes the differentiable synthesizer-proxy d_ϕ , while monitoring for the best model via the true synthesizer f . (c)-(d) depict the IS2 inference phase (Sec. 2.5) that employs ITF, utilizing the optimized d_{ϕ^*} for improved parameters prediction on the specific test example. Again, f is used for monitoring.

the audio loss term \mathcal{L}_a in Eq. 4 utilizes d_ϕ as a differentiable proxy to f in order to propagate gradients as part of the optimization process.

2.5 IS2 Inference

A unique feature of IS2 is the ability to improve the predictions at inference time, by employing Inference-Time Finetuning (ITF). Given a test input x_t , we utilize the audio loss \mathcal{L}_a for leveraging self-supervision from x_t , and refine the prediction specifically for x_t . To this end, we freeze the trained decoder parameters ϕ^* (Eq. 4) and finetune the trained encoder parameters θ^* to obtain finetuned parameters θ^t :

$$\theta^t = \underset{\theta}{\operatorname{argmin}} \mathcal{L}_t + \lambda_B \mathcal{L}_B, \quad (6)$$

where

$$\begin{aligned} \mathcal{L}_t &= \mathcal{L}_a(d_{\phi^*}(e_\theta(x_t)), x_t), \\ \mathcal{L}_B &= \frac{1}{|B|} \sum_{i \in B} \mathcal{L}_p(e_\theta(x_i), y_i) + \lambda \mathcal{L}_a(d_{\phi^*}(e_\theta(x_i)), x_i), \end{aligned}$$

and $B \subset \{1..N\}$ is a subset of indexes from the training set (a training batch). While one could optimize only \mathcal{L}_t w.r.t. θ , we found that the inclusion of \mathcal{L}_B serves as a regularization (controlled by the hyperparameter λ_B) that leads to more accurate predictions. This can be explained by the fact that \mathcal{L}_B enforces the encoder to predict accurate configurations for the examples in B , effectively safeguarding the encoder from forgetting what it has learned during the training phase (Sec. 2.4) and avoid overfitting the test example x_t . In practice, the ITF procedure alternates between sampling a batch of examples from the training set $B \subset \{1..N\}$, and performing gradient descent update to θ according to the objective in Eq. 6, until either convergence w.r.t. $\mathcal{L}_t^f := \mathcal{L}_a(f(e_\theta(x_t)), x_t)$ is met or the number of alternations exceeds a prescribed threshold. ITF optimization and monitoring are depicted in Fig. 1(c)-(d).

It is important to clarify that ITF is applied per test example, i.e., for each test example x_t , we first initialize

$\theta \leftarrow \theta^*$, where θ^* are the optimal encoder parameters obtained from the IS2 training procedure (Eq. 4). Then, ITF alternations are employed according to Eq. 6 to obtain finetuned encoder parameters θ^t that might improve \mathcal{L}_t^f . However, improvement is not guaranteed due to an inherent discrepancy that may exist between the synthesizer-proxy decoder d_{ϕ^*} (used in \mathcal{L}_t) and the synthesizer f (used in \mathcal{L}_t^f). Therefore, if none of the ITF alternations yield improvement to \mathcal{L}_t^f , we fallback to the prediction obtained by the originally trained encoder $e_{\theta^*}(x_t)$ (that serves as a starting point for the ITF procedure).

2.6 IS2 Implementation

In [9], various encoder implementations were investigated and the spectrogram-based strided CNN encoder stood out as the best performer. Following this finding, we implement the encoder e_θ and decoder d_ϕ as strided CNNs. Accordingly, $x \in \mathcal{X}$ stands for the *processed* log-magnitude spectrogram or mel-spectrogram domain (where the spectrogram is obtained by the application of the STFT to the waveform), and \mathcal{L}_a is set to the Mean Absolute Error, hence measuring the spectral difference between the input and reproduced signals.

The synthesizer parameters configuration is encoded by a super-vector $y \in \mathcal{Y}$ that concatenates one-hot vectors and normalized scalars representing the categorical and continuous parameters, respectively. Accordingly, the parameters loss \mathcal{L}_p is set to the average of the cross-entropy and L2 losses for categorical and continuous parameters, respectively. The exact details of the data processing, data representation, and hyperparameters settings appear in Sec. 3.

3. EXPERIMENTAL SETUP AND RESULTS

3.1 Datasets, preprocessing, and data representation

In this study, we present findings from analyses conducted on three distinct datasets. As a consequence of space constraints, it is not feasible to detail all the numerous configurable parameters of every synthesizer utilized in our experiments. Nevertheless, a comprehensive account of

each synthesizer parameter can be found in the supplementary material accompanying this manuscript. The datasets which were used in this research are as follows: (1) **FM**: is based on the FM synthesizer implementation that is available in IS2 GitHub repository. The synthesizer is composed of a FM oscillator, AM modulation, and low-pass filter. It includes 9 configurable parameters, each represented by a categorical variable. Continuous parameters were discretized and binned to create a finite set of values. A dataset of 180K audio samples (1 second, 16KHz) was generated based on a random sampling of parameter configurations. Samples were transformed into 257x129 spectrograms using log-magnitude STFT (with window size 512 and hop size 128) followed by normalization to [-1,1]. (2) **DX7**: is the dataset from [10] which is based on the Dexed synthesizer¹ which is a virtual replica of the Yamaha DX7 synthesizer with 144 configurable parameters (represented by 54 categorical and 90 continuous variables). It contains 30K audio samples (3 seconds, 22.05KHz). Each sample was transformed into a 257x347 mel-spectrogram (257-bins) of the log-magnitude STFT (with window size 1024 and a hop size 256), followed by normalization to [-1,1]. (3) **TAL** is based on the commercial synthesizer: TAL-NoiseMaker². It consists of 180k audio samples generated using 9 configurable parameters controlling the oscillator, LFO1, LFO2, and cutoff parameters. Each sound has a duration of 1 second sampled at 16kHz and is converted into a 257x129 spectrogram. The spectrograms are normalized to the range [-1, 1] using the same method as the FM synthesizer dataset. The code for the generation of the datasets, including the parameter discretization process is available in our GitHub repository.

The above datasets encompass a broad spectrum of sounds that vary from basic sine waves to intricate waveforms with a wealth of harmonics. The TAL Noisemaker and FM synthesizer datasets comprise a range of sounds including bass, leads, pads, plucks, and percussion, while the DX7 dataset comprises percussive, bell-like, and metallic sounds, in addition to rich pads and complex bass sounds.

¹ <https://github.com/asb2m10/dexed>

² <https://tal-software.com/products/tal-noisemaker>

Our GitHub repository includes scripts that can reproduce these datasets.

3.2 Evaluated methods and hyperparameters setting

The following models were evaluated: (1) **IS2**: our model from Sec. 2. e_θ and d_ϕ are implemented by strided and transposed CNNs with 9 hidden LeakyReLU activated layers and Batch Normalization [25] (the exact hyperparameters which were chosen for each layer can be seen in our GitHub code). The IS2 objective (Eq. 4) was optimized with $\lambda = 1$ using the Adam optimizer [26] with $\beta_1 = 0.9$, $\beta_2 = 0.99$, batch size 64 and learning rate scheduling from 10^{-4} to 10^{-6} for 100 epochs. While training, we monitored \mathcal{L}_V^f (Eq. 5) on the validation set, and the best-performing model was selected eventually. For each test sample, we employed 30 ITF alternations according to the objective from Eq. 6, with $\lambda_B = 1$, and B is a stochastic sample of 64 examples drawn randomly from the training set at each alternation. Finally, L_t^f was monitored for selecting the best result as explained in Sec. 2.5. (2) **IS2xITF**: an ablated version of IS2, in which ITF is not employed and the predictions are performed by the trained encoder e_{θ^*} . (3) **IS**: the IS method from [9]. (4) **Flow**: the method from [10] which is based on variational inference with normalizing flows. We tuned hyperparameters for all models using the validation set.

3.3 Evaluation metrics

We report the average results obtained by a 5-fold cross-validation procedure with 80%-10%-10% (training, validation, test) splits, on the following metrics: (1) **Spec**: the Mean Absolute Error (MAE) between the log-magnitude STFTs of a - the signal reproduced by the application of f to the predicted parameters configuration, and b - the ground truth configuration signal. (2) **Melspec**: the MAE between the mel-spectrograms of a and b . (3) **MFCC**: the MAE between the 40-band MFCCs of a and b . (4) **SC**: the Spectral Convergence [27] between a and b . Note that SC was found less correlated with human perception [10], nevertheless we report this metric for the sake of completeness. (5) **ACC**: the accuracy of the predicted categorical synthesizer parameters. (6) **MAEparam**: MAE between the predicted and ground truth numerical synthesizer parameter values. This metric is reported for the DX7 dataset only, as all parameters in the FM and TAL dataset are modeled by categorical variables. Metrics (1)-(4) measure errors in the reproduced signal $f(e_\theta(x))$, while metrics (5)-(6) measure accuracy / error w.r.t. the ground truth parameter configurations.

To complete our evaluations, we also present the results of a MOS (Mean Opinion Score) test [28] with $N = 20$. The MOS test involves presenting a set of synthesized sounds to a panel of listeners, who are then asked to rate the sound quality of the reconstructed sound with respect to the original sound using a standardized rating scale: [1–5].

3.4 Quantitative Results

Table 1 displays the results obtained by all methods across all datasets and evaluation metrics. The ACC and MAEparam are averages across all categorical and continuous parameters, respectively. It is important to note that the Flow results reported in [10] were replicated, and our

Table 6: MOS test results. Scores on a scale of [1 – 5] represent the perceptual reconstruction quality w.r.t. the original audio.

results are consistent with the original findings. Table 1 demonstrates that our IS2 method outperforms the other baselines in all metrics and datasets, except for the MFCC score on the TAL datasets, where the ablated version of IS2, IS2xITF, outperforms it. Furthermore, the results indicate that the ablated version IS2xITF is highly effective in comparison to previous baselines which highlights the general utility of the IS2 architecture even without the ITF phase. In the following section, we aim to provide a more comprehensive analysis and interpretation of these results.

To provide additional perspective, we conducted the following analysis: We partitioned the 257 mel-spectrogram bins into ‘Low’, ‘Mid’, and ‘High’ equally sized mel-frequency bands. Then, for each sound in the test set, we computed the L2 loss between the reproduced version and the ground-truth of each mel-frequency band. The results for the different frequency bands, including the entire mel-spectrogram (‘All bands’) are presented in Table 2. First, We observe that IS2 outperforms the other models on the entire mel-spectrogram (‘All bands’), across all datasets, which is consistent with the results presented in Table 1 (note that Tables 1 and 2 report different metrics, i.e. MAE vs. L2). Specifically, IS2 performs particularly well on low frequency regime (‘Low’). Arguably, this finding might be explained later where we shall see that the IS2 model attains the best loss in 4 out of 6 low-frequency oscillator (LFO) parameters, which have a stronger impact on the low bands. This calls for further research into the relationship between parameter prediction accuracy and the mel-spectrogram error.

In terms of the ‘Mid’ band, the IS2 model demonstrated superior performance on the TAL and FM datasets,

whereas the IS model exhibited better results on the DX7 dataset. For the “High” band, different baselines achieved the best outcomes. This observation is not surprising since high frequencies typically undergo rapid changes and can be less perceptible even to experienced listeners. Overall, our findings indicate that the IS2 approach exhibits robust performance across various datasets and frequency bands, with exceptional accuracy in estimating low frequencies.

Next, we turn to evaluate the accuracy of predicting each parameter specifically. The DX7 synthesizer consists of two types of parameters: categorical, denoted as “cat”, and numerical, denoted as “num”. To evaluate performance, ACC was reported for categorical parameters, while MAEparam was calculated for numerical parameters, as previously mentioned. The DX7 parameters are further categorized into several groups, including Algorithm, Feedback, Operators, Pitch Envelope Generator, LFO, and Filter, with a comprehensive explanation of each parameter available in the supplementary material. Table 3 outlines the prediction results for the DX7 parameters. Note that parameters beginning with the prefix “OP” are an average aggregation of the six operators of the synthesizer, as explained in the supplementary material.

The results reveal that the IS2 method consistently outperformed other models in predicting all categorical parameters. Furthermore, the IS2 model also outperformed other models in 9 out of 25 numerical parameters. Notably, the IS2xITF model performed best among all models for the “OP_EGRATEI” ($i=1\dots4$) numerical parameters, demonstrating superior performance even without fine-tuning (ITF). Specifically, this model exhibited better performance in all numerical parameters and outperformed other models in 5 out of 25 numerical parameters. In contrast, the IS and Flow models demonstrated similarly robust performance, outperforming other models in fewer numerical parameters, namely 11 out of 25.

Overall, Table 3 displays a trend where all categorical parameters are more accurately estimated by the IS2 model. In terms of numerical parameters, the IS2 model performs better in predicting parameters with greater perceptual significance, such as LFO. However, parameters of lesser perceptual significance, such as the envelope level of pitch (PITCHEGLEVEL), exhibit lower estimation accuracy. These trends are consistent with the findings presented earlier in Table 2.

The trends observed in Table 3 repeat themselves in the TAL dataset (Table 4) and the FM Synth dataset (Table 5), with slightly improved accuracy for the alternative models. Nevertheless, the IS2 model maintains the highest mean accuracy. IS2 does not achieve the highest accuracy in certain parameters, such as filter cutoff, which are of lesser significance for perceived quality. For example, if the filter cutoff is estimated for class A instead of the correct class B, and A and B are neighboring classes, the impact on perception might be insignificant. Another set of parameters that demonstrate negligible differences in accuracy between models is Oscillator 2, LFO1 amount, and LFO2 values. In contrast, parameters such as LFO1 waveform and rate play a crucial role in controlling Oscillator 2 modulation and impacting the low frequencies of the sound, making them significant in terms of perception. Here, IS2 achieves significantly higher accuracies compared to other models. These findings are consistent with the low losses

of the IS2 model for low frequencies, as presented in Table 2.

In Table 5, Oscillator 1 waveform, LFO1, and filter cutoff frequency exhibit negligible differences in accuracy in favor of the alternative baselines. Higher differences are observed in AM modulation parameters. Nevertheless, these parameters primarily affect the Tremolo effect, which has a relatively no impact at all on the frequency composition, and for small changes, leading to less influence on human perception and less impact on the metrics presented in Table 1. Compared to the Flow model, the parameters with the most significant differences are Oscillator 1 frequency and modulation index, which have a significant impact on perception by affecting the carrier frequency of the signal.

Overall, the results in Tables 1-5 indicate that by leveraging information on the difference between the original and reproduced signal during training and inference (ITF), IS2 promotes accurate predictions for parameters that have the most significant impact on human perception, especially FM modulator parameters which very challenging to estimate. Consequently, IS2 produces reconstructions that more closely resemble the original signal, which is the ultimate goal of sound matching. In what follows, we further substantiate our findings via human subjective evaluation.

3.5 MOS Test and Qualitative Results

Table 6 presents MOS test results conducted using $N = 20$ individuals. Participants were asked to rate the reconstruction score of 80 random audio samples on a $[1 - 5]$ scale. The results are inline with those of Table 1, showing that the IS2 model outperforms the other models. Furthermore, the MOS test results indicate that the IS2 model has the highest perception quality of all the models evaluated. The samples from this test are available for listening on the GitHub repository.

Finally, in the supplementary materials, we provide extensive qualitative comparison between the ground-truth spectrograms and the reconstructions produced by each of the evaluated methods. Additionally, the audio signals for these examples are provided are available in our Google Drive folder³.

4. CONCLUSION

We presented IS2 - a novel model for automatic synthesizer sound matching. IS2 introduces two novel contributions: (1) a differentiable synthesizer-proxy decoder that enables gradient-based optimization of the reproduced audio signals, and (2) the ITF technique that enables improved model predictions at inference time. These contributions lead to state-of-the-art results compared to existing methods across multiple datasets and metrics.

ABSTRACT

Query-by-Humming (QbH) is a task that involves finding the most relevant song based on a hummed or sung fragment. Despite recent successful commercial solutions, implementing QbH systems remains challenging due to the lack of high-quality datasets for training machine learning models. In this paper, we propose a deep learning data collection technique and introduce Covers and Hummings Aligned Dataset (CHAD), a novel dataset that contains 18 hours of short music fragments, paired with time-aligned hummed versions. To expand our dataset, we employ a semi-supervised model training pipeline that leverages the QbH task as a specialized case of cover song identification (CSI) task. Starting with a model trained on the initial dataset, we iteratively collect groups of fragments of cover versions of the same song and retrain the model on the extended data. Using this pipeline, we collect over 308 hours of additional music fragments, paired with time-aligned cover versions. The final model is successfully applied to the QbH task and achieves competitive results on benchmark datasets. Our study shows that the proposed dataset and training pipeline can effectively facilitate the implementation of QbH systems.

1. INTRODUCTION

Query-by-Humming (QbH) is a well-known task in Music Information Retrieval. It aims to enable users to find a particular song within a retrieval system by providing a small audio segment of their voice or humming as a query. Such systems rely on a large database of songs and display the most similar matches to the user's query.

One significant benefit of the QbH system compared to other music search systems [1] is that users do not have to play a copy of the song or recall its lyrics. Instead, they can hum or sing the melody of the desired song, and the sys-

tem will use advanced audio processing and deep learning techniques to locate it.

A similar task to QbH is Cover Song Identification (CSI) task [2–4]. CSI aims to identify cover songs performed by different artists as versions of original songs within a music database. Although CSI systems often rely on neural networks, traditional QbH systems mainly utilize audio processing and music information retrieval techniques like pitch estimation, note extraction, and time series matching [5–7]. The main reason QbH lacks deep learning models is the absence of large datasets for training. This is primarily due to the high cost and limited availability of humming/singing data for QbH compared to CSI, where multiple versions of the same song are sufficient for training. Additionally, QbH requires the alignment of humming/singing fragments with the original versions of the song.

To overcome the challenges of limited data, we propose a novel dataset CHAD - Covers and Hummings Aligned Dataset. This dataset contains groups of time-aligned music fragments, primarily consisting of vocal segments from popular songs. *Time alignment* is the process of synchronizing a fragment from a humming or cover version of a song with its corresponding fragment from the original version to have the same temporal structure. The groups are separated into two categories: one with humming fragments collected via crowdsourcing and another with cover fragments collected using a semi-supervised training pipeline. We use this dataset to train our deep learning model for matching audio fragments with similar melodies using metric learning paradigm. We demonstrate that these techniques can also be successfully applied in the QbH task, achieving results comparable to the best performing scores on popular QbH benchmarks. Furthermore, we evaluate our model's performance on a large internal song database, showing its ability to generalize to a wider range of songs.

The paper is structured as follows. Section 2 briefly reviews existing approaches to the QbH task. Section 3 describes the proposed deep learning model and training method for the QbH task. Section 4 outlines the dataset and semi-supervised data collection pipeline. Section 5 describes the experiments conducted on public and private data. Finally, Section 6 concludes the paper.

2. RELATED WORK

QbH systems typically have two components: audio transcription and search modules. Many approaches in QbH research have focused on designing effective representations of hummings that can be easily matched with MIDI targets. Some standard methods include using Hidden Markov Models [5] to transcribe hummings into a sequence of symbols, discretizing fundamental frequency into semitones [6], and transcribing hummings into a note-like structure using pitch, interval, and duration features [7].

Once the humming has been transcribed into a format that can be compared to database entries, the search module is responsible for finding the most relevant songs. Dynamic Time Warping [6, 8] has been a popular algorithm for comparing the humming query to MIDI-audio entries in the database. This algorithm finds the minimum path between the discretized humming and the MIDI-audio database. Another approach, top-down melody matching [9], involves dynamically aligning the humming query with a song from the database. A third approach, progressive filtering [10], involves multiple stages of song recognition with increasingly complex recognition mechanisms. These algorithms serve to match humming queries with songs in a database effectively. In the approach [11], authors use melody extraction network to extract robust features from audios and match them with songs from database using an ensemble of melody matching algorithms.

In contrast to QbH, the latest research on the Cover Song Identification (CSI) task has been focused on deep learning-based techniques. A popular approach in CSI is to use deep neural networks for audio representation and metric learning for similarity search. In [12], the authors use Constant-Q Transform (CQT) of audio and train a modified version of ResNet with two losses - triplet loss for intra-class compactness and classification loss for inter-class discrimination. In the next study, [13], the authors improve results by integrating the PCA module into the fully-connected layer of ResNet. Metric learning is widely used in CSI. It is shown that different model and loss architectures like Siamese Network [3], triplet loss [12], and contrastive loss [4] can produce competitive results.

In [2], the authors use VGG on CQT features with variable length to tackle the problem of tempo changes of the cover songs. In [14], the authors use an audio signal’s Mel-Frequency Cepstrum Coefficients (MFCC) as the representation. They build cross-similarity matrices between songs and collect the nearest neighbors of each song based on these matrices.

Several datasets are available for CSI tasks [15–18]. These datasets contain audio features alongside music metadata and provide researchers with a way to evaluate and validate their models without collecting large amounts of audio data.

Figure 1: Audio encoder model. Vocal part is extracted from the input waveform. Then, either f_0 or CQT features are calculated on the vocal part. Finally, the features are processed by a convolutional encoder model and, then, the output embeddings are normalized.

3. MODEL

Our encoder model, M , is presented in Figure 1 and inspired by [4]. The whole fingerprints extraction pipeline can be described in the following steps:

1. The first step of the encoding process is to extract the vocal part of the audio waveform y using a pre-trained audio source separation model $V(\cdot)$. The model is applied only to cover fragments since humming fragments do not contain any accompaniments. We used Spleeter [19] as a model due to its high-speed performance.
2. The vocal part of the audio is then sent to the feature extractor model. In this study, two different extracted feature types are used: the first is the fundamental frequency (f_0) extracted using the CREPE model [20], which is considered a robust representation of the melody. The second is Constant-Q Transform (CQT) as its faster alternative. The melody is crucial for search as it contains essential song information while ignoring irrelevant singing person details.
3. The extracted feature matrix is then separated into overlapping segments, called analysis windows with length W and step H , which are fed separately to a convolutional encoder $F(\cdot)$ ResNet18 [21]. The final layer of the encoder is a \mathcal{L}_2 -normalization layer $G(\cdot)$, which normalizes the output of the encoder along the embedding dimension.

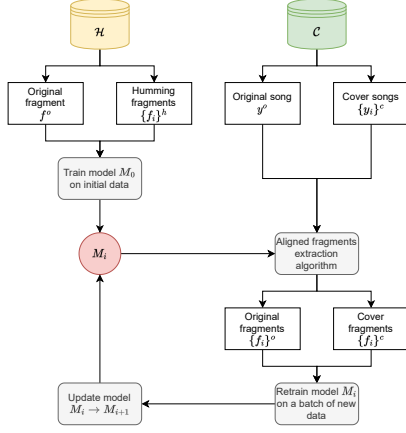

Figure 2: Semi-supervised training and data collection pipeline used to train the initial model, and iteratively gather new aligned audio fragments and retrain the model.

- The output fingerprints $Z = \{z_i\}_{i=1\dots T}$, where T is the total number of fingerprints for a waveform and 128 is its dimension size.

We use the metric learning method similar to [4] as a learning framework. To form a batch of audio fragments for training, we randomly sample K groups of time-aligned audio fragments. By *group*, we refer to a collection of original song and humming/singing fragments. Then, we select n random audio fragments from each group and extract a random analysis window of size W . Since our data is aligned, all windows from each group will represent the variations of the same data. Afterward, we apply our model and extract in total $N = K \cdot n$ fingerprints for n in each group.

Our loss is defined as follows:

$$\ell = - \sum_{k=1}^K \sum_{z_k^i, z_k^j \in Z_k} \log \frac{\exp(\frac{\text{sim}(z_k^i, z_k^j)}{\tau})}{\sum_{z_l \notin Z_k} \exp(\frac{\text{sim}(z_k^i, z_l)}{\tau})}, \quad (1)$$

where $Z_k = \{z_k^0, \dots, z_k^{n-1}\}$ is the group of fingerprints, z_k^i and z_k^j are different fingerprints from Z_k , $z_l \notin Z_k$ stands for all fingerprints not in a given group k , $\text{sim}(z_i, z_j) = z_i^T z_j$ is the similarity function, and τ is a temperature parameter. The final loss is computed across all possible positive pairs and averaged afterward.

4. DATASET

This section describes the process of collecting a dataset for the QbH task, its statistics, and its limitations.

4.1 Semi-supervised pipeline

Figure 2 presents our proposed semi-supervised pipeline. The dataset used in this study is structurally divided into two parts: \mathcal{H} and \mathcal{C} . The first part, \mathcal{H} , consists of original music fragments f^o paired with time-aligned humming/singing fragments f^h , making groups F^h . The f^o fragments are represented by various vocal and instrumental parts of music clips. The f^h fragments were collected

Algorithm 1: Aligned fragments extraction algorithm of data collection pipeline.

Input : y^o - original song;
 Y^c - set of cover songs;
 d_{min} - fragment's minimal length;
 d_{max} - fragment's maximal length;
 D_p - set of pause lengths;
 L_{db} - set of dB levels;
 α_{corr} - threshold value to exclude same fragments;

Output: \mathbb{F} - set of groups of aligned fragments from original and cover songs

```

23   end
24 end

```

using a crowdsourcing service Yandex.Toloka. The second part of the dataset, \mathcal{C} , was created by collecting the 100 most popular songs from the Billboard Charts for each year from 1960 to 2020. For each song, up to 10 cover versions were retrieved from YouTube top results using query "{song name} {artist name} cover".

Because \mathcal{H} already has groups of time-aligned fragments, we can train the initial encoder model M_0 with this data. However, \mathcal{C} only contains groups of full song versions instead of time-aligned fragments, so extracting fragments from these groups is necessary. We propose Algorithm 1 for this task. This algorithm is designed to extract the maximum amount of unique fragments from the original versions of the songs and find the corresponding aligned fragments from cover versions of the songs in \mathcal{C} . The algorithm can be described in three stages:

Initialization stage

- As input, the algorithm takes the vocal part of the original song y^o and a group of cover songs Y^c . Additionally, the algorithm takes the minimal and maximal length of the fragment d_{min} and d_{max} , respectively, the set of dB levels L_{db} by which to count the region in song as silent or non-silent, the set of maximal pause lengths D_p between adjacent fragments in a song separated by silence to be considered as one fragment, and threshold values α_{corr} , β_{rel} , and β_{irrel} to exclude unwanted fragments from the out-

put set.

2. Initialize empty sets of unique fragments \mathbb{F}^o and \mathbb{F}_{prev}^o , the encoder model M , and rms of the waveform y^o (lines 1-3).

Fragmentation stage

1. To find the best combination of D_p and L_{db} to yield \mathbb{F}^o of maximal size, start two loops by iterating over these sets (lines 4-5).
2. Compute the binary mask of non-silent regions $m_{silence}$ using rms and $l_{db} \in L_{db}$ and find a set of initial fragments by splitting the waveform y^o using this mask. Then, merge adjacent fragments, the pause between which is less than $d_p \in D_p$. Additionally, the length of such fragments should satisfy the condition $d_{min} < |f| < d_{max}, f \in \mathbb{F}^o$. (lines 6-8).
3. Apply model M_i to the found fragments and extract the fingerprints. Then, build the correlation matrix \mathcal{A}_{corr} based on the fragments' fingerprints \mathbb{F}_{emb}^o and exclude the ones with a correlation higher than the threshold α_{corr} . We used the maximum of cross-correlation function to measure the correlation of fingerprints with different lengths (lines 9-11).
4. Find the parameters of dB levels and pause lengths that yield the maximum amount of unique fragments (line 12).

Matching stage

1. Once the unique fragments from the original version of the song \mathbb{F}^o are extracted, initialize the empty set \mathbb{F} to be filled with groups of the time-aligned fragments from original and cover songs and iterate over each found original fragment $f^o \in \mathbb{F}^o$ and each cover song $y^c \in Y_c$ (lines 15-17).
2. Extract fingerprints from original fragment f_{emb}^o and cover song y_{emb}^c using M . Search for the same fragments in the cover song using a cross-correlation function and peak detection algorithm (lines 18-19).
3. Filter out noise cover fragments by establishing two thresholds:
 - (a) The cover fragments with correlation above β_{rel} are considered relevant, indicating a high level of certainty that the content of the cover fragment is similar to that of the original fragment.
 - (b) The cover fragments with correlation below β_{irrel} are considered irrelevant fragments and are excluded. Fragments with a correlation between these two thresholds are counted as uncertain and require double-checking via additional crowdsourcing.

Save the gathered groups of aligned fragments (lines 20-22).

We apply this pipeline to song batches of \mathcal{C} , which generates new groups of aligned data. These groups are then added to \mathcal{H} , and the model, M , is retrained on the newly gathered data. In such a way, we first train M_0 on initial humming data, then iteratively update our model from $M_i \rightarrow M_{i+1}$ and fill our dataset with new data.

For the unique fragments extraction algorithm, we set $d_{min} = 8, d_{max} = 20, D_p = \{0.5, 1, 1.5\}$ seconds, $L_{db} = \{52, 56, 60, 64, 68\}$ dB, $\alpha_{corr} = 0.8$. When searching for fragments in cover versions of songs, we set the optimal thresholds to $\beta_{rel} = 0.5$ and $\beta_{irrel} = 0.3$. All fragments from the same group have equal duration to retain the time-alignment consistency.

4.2 Statistics

We call the collected dataset Covers and Hummings Aligned Dataset (CHAD). Here are the dataset's statistics:

- CHAD contains 5494 original songs, 31630 cover songs, and 5164 hummings fragments.
- The total number of audio fragments is 81781, which amounts to over 270 hours of singing/humming audio fragments and 51 hours of original song fragments. The group size varies from 2 to 31, with an average size of 6 fragments.
- In \mathcal{H} , the duration of the fragments ranges from 4 to 20 seconds, with a mean of 11.06 ± 2.67 seconds, and a total for original fragments - 2.12 hours, and for humming fragments - 15.83 hours.
- In \mathcal{C} , the duration ranges from 8 to 20 seconds, with a mean of 14.66 ± 2.03 seconds, and a total for original fragments - 49.54 hours, and cover fragments - 259.03 hours, where 194.53 hours are for fragments with correlation above β_{rel} , and 64.50 hours are for fragments with correlation between β_{rel} and β_{irrel} .
- Additionally, the metadata is collected. It includes YouTube video ID, title, author, correlation value, and whether the fragment is double-checked. The dataset's audio IDs, metadata, start and end timestamps and data download script are available in our GitHub repository¹.

4.3 Limitations

However, our semi-supervised pipeline has some limitations. First, it can only extract vocal data, and the algorithm needs modification to extract instrumental segments. Second, the number of covers is limited, as there are usually fewer cover versions for non-popular songs. Lastly, there will still be some noisy unrelated fragments in the final set due to the automatic validation threshold. Future research could explore using generative networks [22] to overcome these limitations.

5. EXPERIMENTS

5.1 Experimental setup

Input features. We used CREPE [20] activations as f_0 features, yielding output features with a size of $(360, T)$. We further enhanced the robustness of the melody feature by trimming it to include only 3 octaves around its mean pitch, following the approach used in [25]. Additionally, we downsampled this representation to the size $(80, \frac{T}{4})$. However, we encountered issues with the slow speed of the melody extraction model during evaluation, rendering the overall approach unscalable. To address this, we incorporated CQT features into our model, extracted with the following parameters: 12 bins per octave with a total of 7 octaves, Hann window, hop length 512, and a sampling rate of 16 kHz.

Augmentations. We found an optimal set of augmentations to every batch of waveform fragments, which included continuous pitch shifting (with a shift range of -4.0 to 4.0 semitones and probability of 0.5), time stretching (with a stretch rate range of 0.8 to 1.25 and probability of 0.8), SpliceOut [26] (with 10 random intervals of 500 frames and probability of 0.8), mixing with other audio samples in the batch (with an SNR range of 5 to 10 dB and probability of 0.8), and adding background noises (with an SNR range of 3 to 30 dB and probability of 0.8).

Model. We discovered that as the length of a hummed or sung recording increases, the tempo/rhythm becomes more mismatched from the original song. So we trained two models with different analysis window lengths (W) and hop sizes (S): M_{short} for shorter recordings (up to 15 sec) with $W=3$ sec and $S=0.25$ sec, and M_{long} for longer recordings with $W=8$ sec and $S=0.64$ sec. Both models used a vanilla ResNet18 encoder model, with output embeddings of size $(128, T)$, where T is the number of fingerprints.

Training setup. We trained the encoder model using the ADAM optimizer, with a learning rate of $lr = 0.001$ and a batch size of 32 for 100 epochs. We used the NT-Xent Loss [27] with a temperature of $t = 0.05$. We employed the Multi-similarity miner [28] and an adaptive batch sampler to improve convergence speed. The batch sampler selects up to 4 fragments with a random starting point for each fragments group. We trained the model under two settings: only on the \mathcal{C} part and on both $\mathcal{C} + \mathcal{H}$ parts of CHAD. Models were trained on 1 NVIDIA GeForce RTX 2080 Ti 12 Gb.

To evaluate the performance of our model, we conducted a series of experiments, which involved:

- Experiments on the MIREX QbH datasets [29], specifically the Roger Jang and ThinkIt datasets, where MIDI recordings were used as references. The MIR-QBSH corpus of Roger Jang consists of 4431 query hummings and 48 original MIDI files, while the Thinkit corpus contains 355 queries and 106 original MIDI files. The song database was constructed according to MIREX QbH Challenge standards, with 2600 MIDI files. These experiments

aimed to find the ground-truth MIDI by a given query humming.

- Experiments on MIREX QbH datasets according to Subtask 2 testing protocol in MIREX evaluation system. In this protocol, queries are also considered as "versions" of ground truth, and the objective is to retrieve all variants related to a searched ground truth by given query humming.
- Experiments on a dataset of real recordings, which included MIREX Roger Jang Dataset with all MIDI files replaced with real recordings extracted from YouTube videos (Jang Real), and MTG-QbH [24] dataset with 118 queries and 118 original songs. The additional database comprises 1886 random songs from the internal dataset to serve as imposter songs.
- Experiments on a large-scale internal database (DB90K) containing more than 90k real song recordings. For this experiment, we used two types of queries: 126 humming fragments for 126 songs collected by our team as search-by-humming setup and 2000 singing fragments from karaoke recordings gathered from the DAMP-VPB dataset [30] as search-by-singing setup. In the latter case, we selected 5 of 16 original songs and their sung performances and manually split them into fragments.

For all real recordings, we extract the vocal part beforehand. Also, we ensure that CHAD does not contain any songs that are also present in the evaluation datasets. This was achieved by excluding such songs from the training set.

Retrieval. We use two variants of sequence matching methods at the retrieval phase: maximum Pearson correlation coefficient (Corr) or Dynamic Time Warping (DTW) [31]. For the large-scale experiment on DB90K, we use a two-step search procedure with a first step of fast retrieval of preliminary candidates using the FAISS Approximate Nearest Neighbors (ANN) algorithm with Euclidean distance followed by a second step of reranking. After further analysis, we discovered that Euclidean distance and Cosine distance yielded similar results. To maintain simplicity, we chose to use Euclidean distance. The ANN search returns the top 5000 candidates, which are reranked based on the Pearson correlation score.

Metrics. We follow the MIREX evaluation protocols [29] for the QbH task and compute the mean of the Top- n hit rate for every humming/singing fragment. There was only one related song in the database for every query fragment.

5.2 Results

We compare our model M_{short} trained on $\mathcal{C} + \mathcal{H}$ with 2 best performing methods according to the latest available result of MIREX QbH Challenge [32]. The first one [8] is based on f_0 -matching technique. The second one is a proprietary method for which only scores were reported in the leaderboard. We use only one of our models (M_{short} on CREPE and CQT features) in this experiment as most

Method		Top-10 hit rate \uparrow				
		Jang [23]	Thinkit	Subtask 2	Jang Real	MTG-QBH [24]
Ours	metric learning(CREPE)	0.921	0.966	0.959	0.868	0.883
	metric learning(CQT)	0.840	0.786	0.866	0.867	0.747
Stasiak [8]	$f0$ -matching	0.948	0.907	0.968	-	-
ACRCloud	proprietary	0.990	0.986	0.972	-	-

Table 1: Evaluation of model M_{short} trained on dataset $\mathcal{C} + \mathcal{H}$ with two types of features - CREPE and CQT . Evaluation is provided on MIREX datasets - Jang, Thinkit, and Subtask 2, and datasets - Jang Real, and MTG-QBH, which are more applicable to real-world scenarios.

query fragments are shorter than 16 seconds. We use DTW for matching feature sequences on MIDI-based datasets and Corr for non-MIDI datasets as we found that correlation coefficient gives performance improvement on real data.

The results are summarized in Table 1. Our model demonstrates competitive though slightly inferior performance on the given benchmarks. On real (non-MIDI) data our implementation of [8] produced near-random results which can be explained by the difficulty of tracking and matching $f0$ in real music recordings. Also, we see that while using CQT features led to a performance drop, it is not prohibitively large so CQT features can be used when computing $f0$ is infeasible.

Table 2 shows the scalability of our approach in the experiment with DB90k. We do not track the top-1 hit rate as the database contains several versions of the same song. Table 2a reports the results of the search-by-humming setup. We used M_{short} , M_{long} , and their combination model M_{fused} , which worked on a simple rule: M_{short} was used for hummings shorter than 15 seconds, while M_{long} was used otherwise. All presented models are trained with CQT features. We observed that M_{fused} worked better than M_{short} and M_{long} separately in all scenarios. Comparing models trained on \mathcal{C} and $\mathcal{C} + \mathcal{H}$, the accuracy gap suggests that training on real humming data is crucial for search-by-humming setup. In Table 2b, we report our results for search-by-singing setup with M_{fused} on DAMP-VPB. Our model, trained on both \mathcal{C} and $\mathcal{C} + \mathcal{H}$, retrieves the correct songs with high precision, with no performance drop observed for the model trained on \mathcal{C} alone, due to the dominance of sung fragments in our training dataset.

Additionally, we evaluate the retrieval speed of our models M_{short} and M_{long} on DB90k, as shown in Table 3. We find that M_{long} performs better than M_{short} in both search steps (ANN and Reranking) due to its ability to process longer humming recordings and thus require less processing of fragments. Our results demonstrate the scalability and efficiency of our search system in efficiently achieving high-precision results.

6. CONCLUSIONS

In this paper, we propose a novel dataset CHAD alongside a semi-supervised data collection and training pipeline for

Partition	Model	Top- n hit rate \uparrow			
		100	10	5	3
\mathcal{C}	M_{short}	0.643	0.548	0.524	0.476
	M_{long}	0.412	0.277	0.270	0.262
	M_{fused}	0.759	0.621	0.603	0.517
$\mathcal{C} + \mathcal{H}$	M_{short}	0.659	0.595	0.571	0.484
	M_{long}	0.595	0.508	0.413	0.389
	M_{fused}	0.776	0.707	0.691	0.586

(a) Results on humming queries.

Partition	Model	Top- n hit rate \uparrow			
		100	10	5	3
\mathcal{C}	M_{fused}	0.931	0.904	0.885	0.865
$\mathcal{C} + \mathcal{H}$		0.923	0.899	0.885	0.856

(b) Results on singing queries.

Table 2: Evaluation on DB90K with humming and singing fragments using models M_{short} , M_{long} , and their fusion model M_{fused} trained on \mathcal{C} and $\mathcal{C} + \mathcal{H}$ with CQT features.

Model	Search step, s	
	ANN	Reranking
M_{short}	1.41 \pm 0.57	5.37 \pm 0.87
M_{long}	0.52 \pm 0.11	2.39 \pm 0.43

Table 3: Query search speed on DB90K using models M_{short} and M_{long} trained on $\mathcal{C} + \mathcal{H}$ with CQT features using 32 CPU.

a Query-by-Humming system. We show that cover songs could be used to train query-by-humming models with competitive performance. Although the model trained on open data performs well on sung queries, the pure search-by-humming setup requires adding a portion of real humming data into the training set for acceptable performance. The main disadvantage of the proposed approach is that it cannot be used for searching instrumental tracks. One possible solution to this problem would lie in the field of dominant melody extraction and generative networks and is left for future research.

TOWARDS IMPROVING HARMONIC SENSITIVITY AND PREDICTION STABILITY FOR SINGING MELODY EXTRACTION

ABSTRACT

In deep learning research, many melody extraction models rely on redesigning neural network architectures to improve performance. In this paper, we propose an input feature modification and a training objective modification based on two assumptions. First, harmonics in the spectrograms of audio data decay rapidly along the frequency axis. To enhance the model’s sensitivity on the trailing harmonics, we modify the Combined Frequency and Periodicity (CFP) representation using discrete z -transform. Second, the vocal and non-vocal segments with extremely short duration are uncommon. To ensure a more stable melody contour, we design a differentiable loss function that prevents the model from predicting such segments. We apply these modifications to several models, including MSNet, FTANet, and a newly introduced model, PianoNet, modified from a piano transcription network. Our experimental results demonstrate that the proposed modifications are empirically effective for singing melody extraction.

1. INTRODUCTION

Singing melody extraction is a challenging task that aims to detect and identify the fundamental frequency (F0) of singing voice in polyphonic music recordings. This task is more complicated than the monophonic pitch detection task due to the presence of various instrumental accompaniments and background noises, making it more difficult to accurately extract the singing melody. Singing melody extraction is not only crucial for music analysis by itself, but also has many downstream applications, such as cover song identification [1], singing evaluation [2], and music recommendation [3].

Deep neural networks have been widely adopted in the singing melody extraction task to produce promising performance in terms of extraction accuracy. Early models [4–6] simply leveraged deep neural networks (DNN) and convolutional neural networks (CNN) [7]. In more recent

models, musical and structural priors were incorporated to improve performance. These include MSNet [8] with a vocal detection component at the encoder-decoder bottleneck, joint detection model [9] setting up an auxiliary network, and TONet [10] with tone-octave predictions. Additionally, models can capture frequency relationships better with multi-dilation [11], cross-attention networks [12], graph-based neural networks [13], or harmonic constant-Q transform (HCQT) [14].

One of our observations relates to the input representations of the models, which play an important role in affecting the extraction performance. Timbre, which is closely related to harmonics, is one of the key components that helps models distinguish the vocal from other instruments. When the CFP representation [15] is chosen as the input representation, its second feature, the generalized cepstrum, allows the model to learn the strength of harmonics of any given fundamental frequency in a localized manner. However, in music, the harmonics of a single sound usually decays rapidly along the frequency axis (detail in section 2.1), which can pose a challenge for the model to distinguish sounds that only differ significantly at the trailing harmonics.

The transformation from the spectrum to the generalized cepstrum in CFP is a Fourier transform, and hence mostly captures the first few peaks with large magnitudes. As a result, this representation is not helpful in sensing the trailing harmonics. This motivates us to apply a different transformation function that produces a generalized cepstrum with better harmonics sensitivity.

Another observation relates to the vocal detection component. Extremely short vocal segments surrounded by non-vocal regions, and vice versa, rarely occur since vocalists typically sing a melody for at least half a second or rest for at least a few hundred milliseconds. Threshold-based removal [16], mean or median filtering [17, 18] and Viterbi-based smoothing [19, 20] are frequently used to address the problem. When they are implemented alongside a network-based algorithm, however, the network remains unaware of our smoothing intention and configuration. To investigate whether such awareness can increase the prediction performance, we derive a differentiable loss component that specifically penalizes spurious short-term predictions of these kinds during training, thus potentially guiding the model to produce consistently stable predictions.

In this paper, we propose two techniques that attempt

*The first two authors have equal contribution.

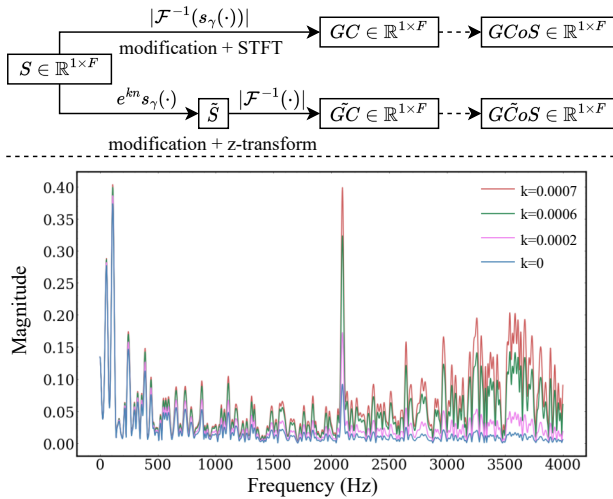

Figure 1. Top: the transformation pipeline of the original CFP representation, and our proposed z -CFP representation. Bottom: modified Spectrum \tilde{S} with different growing rates k applied. Note that the original CFP corresponds to the case of $k = 0$.

to improve the two concerns mentioned above, namely the harmonic sensitivity and the prediction stability of singing melody extraction models. Our contributions are as follows:

- We propose to use exponentially growing sinusoids along the frequency axis to transform the spectrum into the generalized cepstrum of the CFP representation. This approach is equivalent to taking a z -transform instead of Fourier transform, which increases the harmonic sensitivity of the input.
- We design a differentiable loss function as part of the training objective to teach the network to avoid predicting unrealistically short sequences of vocal and non-vocal at the voice detection bin.
- We evaluate our techniques by applying them on several melody extraction models. Additionally, we adapt PianoNet [21], originally developed for piano transcription, into the melody extraction task. Experimental results demonstrate state-of-the-art performance of our improved models.

2. METHODOLOGY

In this section, we introduce three main parts of our methodology. First, we propose a modified CFP representation, z -CFP, to enhance the harmonic sensitivity of the network input. Second, we introduce extraction models used for evaluating our techniques, namely MSNet, FTANet, and PianoNet. Third, we propose a new loss function as part of training objective to improve the prediction stability of models.

2.1 z -CFP Representation for Harmonic Sensitivity

Our input representation of audio data is a modified version of the CFP representation. A CFP representation

$X \in \mathbb{R}^{3 \times T \times F}$ contains three features, with T the length of time frames and F the number of frequency bins. **At each time slice**, it contains: (1) a power spectrum $S \in \mathbb{R}^{1 \times F}$; (2) a generalized cepstrum $GC \in \mathbb{R}^{1 \times F}$; and (3) a generalized cepstrum of spectrum $GCoS \in \mathbb{R}^{1 \times F}$,

As illustrated in the upper part of Figure 1, the standard CFP generation process begins by computing the frame-wise spectrum of an input audio waveform using short-time Fourier transform (STFT). We then obtain the magnitude of each spectrum, which serves as the first feature of CFP, denoted as S . To derive the second feature, we compute the generalized cepstrum using the following equation:

$$GC = |\mathcal{F}^{-1}(s_\gamma(S))| = |\mathcal{F}(s_\gamma(S))| \quad (1)$$

where \mathcal{F} and \mathcal{F}^{-1} denotes the Fourier transform and its inverse, $s_\gamma : \mathbb{R} \rightarrow \mathbb{R}$ is an element-wise applied, logarithm-like modification function as described in [15], and the absolute value sign represents an element-wise complex norm operation. The second equality comes directly from the fact that norm of a complex number equals to that of its conjugate.

As mentioned in the introduction, GC is not sensitive to the trailing harmonic dynamics, as it mostly captures the first few peaks with large magnitudes. Since the harmonics decay rapidly along with the frequency axis, we shall revert the decay to better preserve such dynamics. In other words, instead of applying complex sinusoids $\sum_n s_\gamma(S[n])e^{-iwn}$ as in Fourier transform (n is the entry of frequency bins in S), we apply growing complex sinusoids $\sum_n s_\gamma(S[n])e^{(k-iw)n}$, where $k \in \mathbb{R}$ and $k > 0$. This is equivalent to taking a discrete z -transform $\sum_n s_\gamma(S[n])z^{-n}$, where $z = e^{iw-k}$.

In the actual implementation, k is manually assigned and fixed across different w . Therefore, as illustrated in Figure 1, we can separate the computation of k part and w part as follows:

$$\tilde{S}[n] = e^{kn} s_\gamma(S[n]) \text{ for } \forall n \quad (2)$$

$$\tilde{GC} = |\mathcal{F}^{-1}(\tilde{S})| = |\mathcal{F}(\tilde{S})| \quad (3)$$

In the lower part of Figure 1, we present \tilde{S} of an audio waveform with different values of k . We can observe that the harmonics of \tilde{S} at the tail gets amplified so that the subsequent Fourier transform can better capture their dynamics. While we observe some amplifications of harmonics at frequencies other than the fundamental frequencies, their magnitudes are always smaller than those of nearby fundamental frequencies. Therefore, they pose no sufficient distraction for the extraction model, as long as the chosen k is not too large. In our experiments, we set $k = 0.0006$.

We then generate the generalized cepstrum of spectrum \tilde{GCoS} from cepstrum \tilde{GC} the same way as in the original CFP. Finally, **each time slice** of our modified CFP representation $\tilde{X} \in \mathbb{R}^{3 \times T \times F}$ consists of $\{S, \tilde{GC}, \tilde{GCoS}\}$ with log-scaled frequency axis. For the rest of the paper, we denote it z -CFP.

Figure 2. The model architecture. Note that we choose only one of the three extraction models at a time.

2.2 Model Architecture

Our extraction models are referred from three state-of-the-art (SoTA) models, MSNet [8], FTANet [12], and PianoNet [21]. Different from MSNet and FTANet, PianoNet is the SoTA model of piano transcription. Given its superior performance on piano transcription, we incorporate a sub-network of PianoNet into singing melody extraction, as we hypothesize that it may also yield good results for melody extraction.

MSNet contains a 3-layer encoder, a 3-layer decoder, and a bottleneck module. The channel size is shifted as $3 \rightarrow 32 \rightarrow 64 \rightarrow 128 \rightarrow 64 \rightarrow 32 \rightarrow 1$. The bottleneck module maps the encoder output to a 1-channel featuremap for voice detection. All 2D-convolutional layers come with (5×5) kernel size. FTANet contains a 4-layer encoder, a 3-layer decoder, and a 4-layer bottleneck module. Both encoder and decoder contain FTA-modules and SF-modules to process the audio latent features. The channel size is shifted from 3 to 128, then back to 1. More specifications of MSNet and FTANet can be found in their papers [8, 12].

The PianoNet we use for this task is modified from a sub-network of [21]. It starts with four convolutional blocks, each block containing two 2D-convolutional layers with kernel sizes (3, 5) and (3, 3) respectively, a batch normalization layer and a ReLU activation. Then it is followed by bidirectional-GRU and softmax layers, with dense layers as transitions. The layer bias is turned off for all layers before the Bi-GRU.

Figure 2 illustrates a more detailed structure of the three extraction models. Following the pipeline, we first process

Figure 3. The illustration of how we perform the loss functions \mathbb{L}_v and \mathbb{L}_{nv} on the subsequences of the voice detection prediction. Each loss components L are used to give large penalties (i.e., \times) to certain types of subsequences.

the audio waveform into z -CFP representations. Then we feed them into the extraction model, which produces output feature maps $\tilde{Y} \in \mathbb{R}^{T \times (F+1)}$. The additional one feature along the frequency axis denotes the voice detection bin output. It is then compared against the ground truth label $Y \in \mathbb{R}^{T \times (F+1)}$, through the loss function introduced in the following section.

2.3 Loss Function for Prediction Stability

We add two differentiable training objectives, \mathbb{L}_v and \mathbb{L}_{nv} , to the conventional binary cross entropy loss \mathbb{L}_{BCE} to teach the extraction model to avoid unrealistically short vocal and non-vocal sequences at the **vocal detection bin**. Since the design for these two cases are symmetric, we first introduce the loss object \mathbb{L}_v , for the vocal case.

As shown on the top of Figure 3, the predictions at the vocal detection bin is a time series $\{a_1, a_2, \dots, a_T\}$. First, since our training objectives are dealing with certain types of short burst segments of vocal and non-vocal, we extract all possible subsequences, with stride 1. For example, for 3-length subsequences we have $\{a_{1:3}, a_{2:4}, \dots, a_{T-2:T}\}$, and similarly $\{a_{1:4}, a_{2:5}, \dots, a_{T-3:T}\}$ for subsequences of length 4, etc.

Second, to simplify the problem a bit at the beginning, we assume that the voice detection output is binary valued $a \in \{0, 1\}$. Formally, we do not want “sharp-burst” sequences inside the following set:

$$B_v = \bigcup_{m=3}^{M_v} \{a_1 \dots a_m \mid a_1 = a_m = 0, a_i = 1 \text{ for } \forall i \neq 1, m\} \quad (4)$$

where M_v is a hyperparameter threshold, above which the duration of vocal segments becomes reasonable. Figure 3 illustrates examples of “sharp-burst” sequences in B_v (and B_{nv}) as red segments inside black-border boxes.

Suppose $m = 3$, all possible binary sequences are $\{000, 001, 010, 011, 100, 101, 110, 111\}$ and $010 \in B_v$. To make the model avoid predicting the short burst vocal

segment, i.e., 010, we construct a polynomial objective that can fulfill the goal by satisfying the following:

$$L_v^3(a_1a_2a_3) = \begin{cases} 1 & \text{where } a_1a_2a_3 = 010 \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

A decent choice will then be

$$L_v^3(a_1a_2a_3) = (1 - a_1)a_2(1 - a_3) \quad (6)$$

which can be easily extended to sequences with longer length m .

$$\begin{aligned} L_v^4(a_1a_2a_3a_4) &= (1 - a_1)a_2a_3(1 - a_4) \\ &\vdots \\ L_v^m(a_1\dots a_m) &= (1 - a_1)(1 - a_m) \prod_{i=2}^{m-1} a_i \end{aligned} \quad (7)$$

However, there is a small caveat in this extension when we move back from binary values to probability values $a \in [0, 1]$. For example, our loss component will be having trouble capturing sequences like $\{0.1, 0.4, 0.6, 0.1\}$ and $\{0.1, 0.6, 0.4, 0.1\}$ as both L_v^3 and L_v^4 result in relatively small values. However, we observe that polynomials $(1 - a_1)(1 - a_2)a_3(1 - a_4)$ and $(1 - a_1)a_2(1 - a_3)(1 - a_4)$ respectively works better than our original L_v^4 , but still insufficient to work standalone.

Since none of the polynomials above gives high values to sequences outside of B_v in 4-length, a simple solution would be to redefine L_v^4 to be the sum of all such polynomials:

$$\begin{aligned} L_v^4 &= (1 - a_1)(1 - a_4)(a_2a_3 + a_2(1 - a_3) + (1 - a_2)a_3) \\ &\vdots \\ L_v^m &= (1 - a_1)(1 - a_m) \sum_{\substack{c_1 \dots c_m \in \{0,1\}^m \\ \text{at least one } c_i \neq 0}} \prod_{i=2}^{m-1} a_i^{c_i} (1 - a_i)^{1-c_i} \\ &= (1 - a_1)(1 - a_m) \left(1 - \prod_{i=2}^{m-1} (1 - a_i)\right) \end{aligned} \quad (8)$$

This redefined loss L_v allows better recognition of the bad sequences mentioned above while not falsely flagging sequences outside of B_v . Furthermore, when dealing with longer sequences, for example $\{0.1, 0.9, \dots, 0.9, 0.1\}$ with increasingly many 0.9s in the middle, the original L_v 's output quickly diminishes while the redefined L_v does not.

This redefined objective does come with a small side effect, as it over-counts the shorter bad sequences. For example, $(0.1, 0.9, 0.1, 0.1)$ now gets a high loss value not only in L_v^3 , but also in L_v^4 . However, we believe this side effect does not have significant impact as it does not matter whether neural network decides to stop producing shorter bad sequences or longer bad sequences first.

A further improvement is to pass the value of L_v^m into the S-curve function:

$$L_v^m \leftarrow \frac{(L_v^m)^r}{(L_v^m)^r + (1 - L_v^m)^r} \quad (9)$$

where $r \in \mathbb{R}$ and $r > 1$. It will amplify those sequences that receive loss values closer to 1 and suppress those sequences with loss values closer to 0.

Finally, for each $m \in [3, M_v]$, we compute L_v^m across all m -length subsequences in the model's output. The aggregated loss function \mathbb{L}_v is then computed by concatenating all these L_v^m arrays and taking the average.

Now analogously, assuming non-vocal sequences beyond length M_{nv} become reasonable, we can perform the same analysis on the following set of sequences:

$$B_{nv} = \bigcup_{m=3}^{M_{nv}} \{a_1 \dots a_m \mid a_1 = a_m = 1, a_i = 0 \text{ for } \forall i \neq 1, m\} \quad (10)$$

and consequently obtain \mathbb{L}_{nv} . Practically, L_{nv}^m of any sequence $a_1 \dots a_m$ can be computed as L_v^m of the flipped sequence $b_1 \dots b_m$, where $b_i = 1 - a_i$ for all $i \in \{1..m\}$. Our final loss function will then be:

$$\mathbb{L} = \mathbb{L}_{BCE} + \mathbb{L}_v + \mathbb{L}_{nv} \quad (11)$$

3. EXPERIMENTS

3.1 Datasets and Experiment Setup

For the training data, we complied with the setting of [10, 12] and chose all 1000 Chinese pop songs from MIR-1K¹ and 35 vocal tracks from MedleyDB [22]. For the testing data, we chose 12 tracks in ADC2004 and 9 tracks in MIREX05². We also selected 12 tracks from MedleyDB that are disjoint from those already used for training.

For the signal processing part, we used 8000 Hz sampling rate to process audio tracks. We use a window size of 768, a hop size of 80 to compute the STFT of audio tracks. Note that the time resolution of our labels is 0.01 seconds, and this hop size was chosen to match that. Then, when creating z -CFP representations, we set the time dimension of the representation to be $T = 128$, or 1.28 seconds, and the number of frequency bins $F = 360$, or 60 bins per octave across 6 octaves. The start and stop frequencies are 32.5 Hz and 2050 Hz. Hence, the input shape becomes $X \in \mathbb{R}^{3 \times 128 \times 360}$ and the output/label shape becomes $Y \in \mathbb{R}^{128 \times 361}$.

Within the extra loss component, we set the duration threshold of vocal segments $M_v = 30$ (0.3 seconds), the duration threshold of non-vocal segments $M_{nv} = 7$ (0.07 seconds), and the S-curve exponent parameter $r = 5$.

For the training hyperparameters, we use a batch size of 10, the Adam optimizer [23] with a fixed learning rate of 1×10^{-4} . The maximum training epoch is 500. During the evaluation, we use the standard metrics of the singing melody extraction task, namely, voice recall (VR), voicing false alarm (VFA), raw pitch accuracy (RPA), raw chroma accuracy (RCA), and overall accuracy (OA) from the `mir_eval` library [24]. Following the convention of this task, overall accuracy (OA) is regarded as the most important metric. All models are trained and tested in NVIDIA RTX 2080Ti GPUs and implemented in PyTorch³.

Table 1. Ablation studies on ADC2004, MIREX05 and MedleyDB testsets. Baselines use CFP as the input representation and \mathbb{L}_{BCE} as the loss function. $\{\mathbb{L}_v, \mathbb{L}_{nv}\}$ denotes the use of our proposed loss function in section 2.3. Among median filter sizes in the range $[3, 100] \subset \mathbb{Z}$, 3 point works best for MedleyDB, 7 point works best for MIREX 05, and 15 point works best for ADC 2004. But they neither significantly outperform our proposed loss component in any single dataset, nor uniformly outperform in all three datasets.

3.2 Ablation Study

We choose three extraction models, namely MSNet [8], FTANet [12], and PianoNet [21], to evaluate our z -transform and loss functions. We conducted ablation studies and presented the results in Table 1. We re-trained these models from scratch, and the results are largely consistent with the original reports of [8, 10, 12]. The option z -transform denotes the use of z -CFP representations. Note that $\{\mathbb{L}_v, \mathbb{L}_{nv}\}$ in the table denote the use of loss functions to address short burst segments of vocal and non-vocal. Due to the page limitation, we present a detailed ablation study on PianoNet while ablating MSNet and FTANet in an all-or-nothing fashion.

From Table 1 we can clearly observe decent performance of both z -CFP and $\{\mathbb{L}_v, \mathbb{L}_{nv}\}$ when added to the PianoNet, MSNet, and FTANet. Among these results, the addition of loss functions $\{\mathbb{L}_v, \mathbb{L}_{nv}\}$ increases the overall accuracy while improving the VR, RPA, and RCA. The median filter postprocessing [18] is used as a comparison. Since our loss component focuses on the vocal detection, we took the pitches predicted by median filters only when the original predictions are non-vocal. Further, to ensure fairness, we optimized the filter size against each single dataset within the range $[3, 100] \subset \mathbb{Z}$ and listed the evaluation results of those optimal ones. As we can see in Table 1, none of these median filters outperforms our loss component in a consistent manner, nor do they obtain considerable margins in any single dataset.

The z -CFP also increases several metrics, especially either VR or VFA, on each dataset. This indicates that by preserving more dynamics in the high frequency bins, the model can distinguish different sounds better and consequently improve the extraction performance. Also, note that unlike TONet [10] and JDC [9], which achieved this through model design or music inductive bias, this technique relies solely on the inherent characteristics of the data.

When we incorporate both techniques into the extraction models, we observe a promising increase in each metric compared to the original models. However, we notice that some models with both techniques carried do not yield better performance than the models carrying only one of the techniques. These models appear to be an averaging weighting or an ensemble of models improved with either technique, implying better generalization.

3.3 Comprehensive Performance Comparison

Table 2 presents the results as we compare our best model, i.e., PianoNet with z -transform and $\{\mathbb{L}_v, \mathbb{L}_{nv}\}$, with other SoTA models. Among these SoTAs, there are two models with “*”, indicating that these are only partial comparisons. For SpecTNT [25], since there is no official open-source implementation, we report its results based on our own re-implementation. For H-GNN [13], we directly copied its reported performance from the original paper.

From Table 2, our improved PianoNet with z -transform and $\{\mathbb{L}_v, \mathbb{L}_{nv}\}$ yield the best OA performance over all datasets, the best RPA and RCA on ADC 2004 and MIREX 05 datasets. We do note, despite the use of the extra loss component, that our model’s VFA is not necessarily the smallest. This is because the extra loss component only targets a particular type of false positive, and is not meant to minimize the false positive rate in general. For example, sometimes the network’s vocal to non-vocal transition happens later than the reference labels. In this case, since the vocal sequence itself lasts long enough, the extra loss component will not mark this type of false positives. Addressing this type of errors is potentially a future work.

Another thing we found is that the PianoNet, as one of SoTAs in the piano transcription task and ported by us to the melody extraction task in this paper, has already yields very high performance on MIREX 05 dataset. This indicates that there may exist more powerful network architectures for this task yet to be explored. Additionally, it is

Table 2. The comprehensive performance comparison among our improved models and current baselines.

noteworthy that our proposed PianoNet architecture has a small number of parameters (5.5 million), which is comparable with MCDNN (5.6 million), FTANet (3.4 million) and far less than TONet (152 million). This demonstrates its potential in practical applications where computational resources are limited. Again, as demonstrated in Table 1, our techniques could help models other than PianoNet achieve higher performance than their original versions.

3.4 Loss Value and Extraction Visualization

To empirically verify if applying the polynomial loss functions \mathbb{L}_v and \mathbb{L}_{nv} could reduce the voice detection errors, i.e., short burst segments of vocal and non-vocal, we visualize two types of plots in Figure 4. The top three plots demonstrate the loss values of L_v^{30} between the original extraction models and the improved models with \mathbb{L}_v and \mathbb{L}_{nv} , across the entire MIREX05 dataset (i.e., we concatenate all tracks in the dataset). We see that cases in which the improved models’ prediction receive loss values close to 1 diminishes comparing to those of the original models. This phenomenon implies that after applying \mathbb{L}_v and \mathbb{L}_{nv} , the chance of models to predict short burst segments

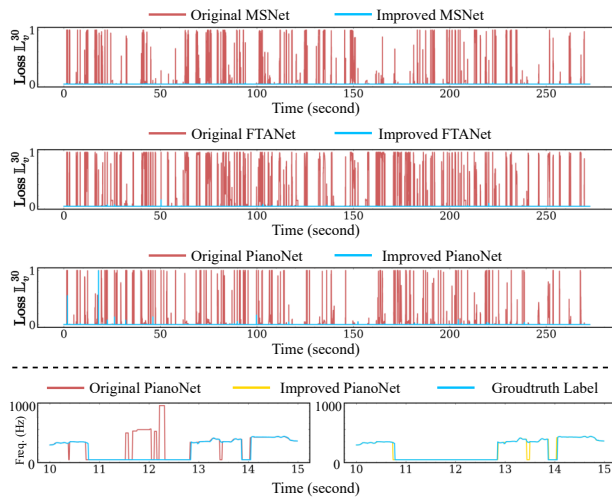

Figure 4. The effect of applying the loss \mathbb{L}_v and \mathbb{L}_{nv} . The top three plots are values of L_v^{30} across the entire MIREX05 dataset. The bottom two plots are one 5-sec MIREX05 predictions.

significantly reduces.

The pair of plots in the last row compares the prediction performance of PianoNets, trained without and with the extra loss components, on a zoomed-in section of MIREX05. Note that the original PianoNet has a short burst non-vocal segment in between the 10th second and 11th second. Further, it has a considerable number of short burst vocal segments around the 12th second. Once trained with the extra loss components, these issues are resolved. Also note that both the original version and the improved version make a mistake in between the 13th and the 14th second. This is because the length of that non-vocal transition is greater than our threshold M_{nv} , which ends up not triggering \mathbb{L}_{nv} . All these observations further verify the effectiveness of our proposed loss components.

4. CONCLUSION

In this paper, we propose two techniques to respectively utilize the two assumptions we made for improving the performance of singing melody extraction models. First, comparing to Fourier transform, the use of z -transform in generating cepstrum allows the network to better recognize the strength of harmonics of any fundamental frequencies. Empirically, while the trailing harmonics of those frequencies that do not actually appear in the audio also get elevated, the benefit of the technique is greater than its setback. Second, our extra loss components make the network less prone to predict vocal and non-vocal sequences are unreasonably short, while not affecting the network’s overall accuracy due to its differentiability. Along with different extraction models, we achieve better performance when compared to their original version and other state-of-the-art models. We regard these two techniques as decent improvements on singing melody extraction models.

Papers – Session VI

SINGING VOICE SYNTHESIS USING DIFFERENTIABLE LPC AND GLOTTAL-FLOW-INSPIRED WAVETABLES

Chin-Yun Yu György Fazekas

Centre for Digital Music, Queen Mary University of London, UK

chin-yun.yu@qmul.ac.uk, george.fazekas@qmul.ac.uk

ABSTRACT

This paper introduces GIottal-flow LPC Filter (GOLF), a novel method for singing voice synthesis (SVS) that exploits the physical characteristics of the human voice using differentiable digital signal processing. GOLF employs a glottal model as the harmonic source and IIR filters to simulate the vocal tract, resulting in an interpretable and efficient approach. We show it is competitive with state-of-the-art singing voice vocoders, requiring fewer synthesis parameters and less memory to train, and runs an order of magnitude faster for inference. Additionally, we demonstrate that GOLF can model the phase components of the human voice, which has immense potential for rendering and analysing singing voice in a differentiable manner. Our results highlight the effectiveness of incorporating the physical properties of the human voice mechanism into SVS and underscore the advantages of signal-processing-based approaches, which offer greater interpretability and efficiency in synthesis.

1. INTRODUCTION

Singing voice synthesis (SVS) has attracted substantial interest as a research topic over the last decades, and a variety of techniques have been developed. Early successful SVS systems were usually based on sample concatenation [1–4], while parametric systems have become much more prevalent. The actual synthesis process in parametric systems is carried out by a *vocoder* controlled by synthesis parameters generated from a separate acoustic model given some musical context factors (i.e. note number, duration, phoneme, etc.). Early systems of this kind use a linear source-filter model as vocoder [5, 6]. Deep Neural Networks (DNNs) have subsequently become the dominant approach for state-of-the-art vocoders [7–13]. However, mel-spectrograms are often chosen as input features to these models, which are less interpretable than traditional vocoder parameters (e.g. f_0 , aperiodicity ratios). Also, a significant amount of data is needed to cover various vocal expressions to achieve generalisation.

In contrast, Differentiable Digital Signal Processing (DDSP) models [14–16] incorporate existing signal processing operations into neural networks as an inductive bias, making them more interpretable and generalisable. DDSP additive synthesis has been proposed for SVS by Alonso et al. [17]. Wu et al. [18] improved this further by using subtractive synthesis and sawtooth as the harmonic source. Nercessian et al. [19] proposed a differentiable version of the WORLD vocoder [20] for doing end-to-end singing voice conversion. Yoshimura et al. [21] used Taylor expansion to approximate the mel-log spectrum approximation filter’s (MLSA) exponential function and embedded it into an SVS system. However, most of their architectures only assume the target signal is a monophonic instrument, which can potentially lead to solutions that do not reflect some properties of voice. In their design, the harmonic sources are fixed to a specific shape (e.g. sawtooth, pulse train), and the filters are symmetric in the time domain, except Yoshimura et al. [21] which use a minimum-phase MLSA filter. Incorporating constraints specific to the human voice on the harmonic source and the filters could lead to a more interpretable and compact SVS vocoder.

In this work, we propose GIottal-flow LPC Filter (GOLF), an SVS module informed by the physical properties of the human voice. We build upon the Harmonic-plus-Noise architecture of DDSP [14] and the subtractive synthesis of SawSing [18], but replace the harmonic source with a glottal model and use IIR filters. We developed a differentiable IIR implementation in PyTorch [22] for training efficiency. We then used this module as a neural vocoder and compared its performance with other DDSP-based vocoders. Specifically, a simple and lightweight NN encoder converts the mel-spectrogram into synthesis parameters, and the synthesiser decodes the signal from it. We paired different synthesisers with the same encoder and trained them jointly.

Our contributions are twofold. First, GOLF has significantly fewer synthesis parameters but is still competitive with state-of-the-art SVS vocoders. Second, GOLF requires less than 40% of memory to train and runs ten times faster than its alternatives for inference. Moreover, we indirectly show that GOLF could model the phase components of the human voice by aligning the synthesised waveforms to the ground truth and calculating the differences. This characteristic has excellent potential for analysing singing voice in a differentiable manner. Decomposing the

human voice into the glottal source and vocal tract could also enable us to adjust the singing style in different ways, such as altering the amount of vocal effort with varying shapes of the glottal pulse.

2. BACKGROUND

We first introduce the relevant notation. \mathbf{x}_i denotes the i^{th} column vector and $x_{i,j}$ denotes the entry at the i^{th} row and the j^{th} column of the matrix \mathbf{X} . Concatenating two matrices along the column dimension is denoted by $[\cdot; \cdot]$. x_i denotes the i^{th} entry of the vector \mathbf{x} or a time sequence x indexed by i . $X(z)$ denotes the response of x_n in the z -domain. Unless stated otherwise, we use n as the time index and k as the frame index. Angular frequencies and periods are normalised to the interval $[0, 1]$. We use one-based indexing for elements with finite dimensions.

2.1 Glottal Source-Filter Model

In the source-filter model, we have the following simplified voice production model:

$$S(z) = (G(z) + N(z))H(z)L(z), \quad (1)$$

where $G(z)$ represents the periodic vibration from the vocal folds, $N(z)$ represents random components of the glottal source, $H(z)$ represents the vocal-tract filter, and $L(z)$ represents the radiation at the lips [23]. Since this formulation is linear, the radiation filter $L(z)$ and the glottal pulse $G(z)$ can be merged into a single source $G'(z)$ called *the radiated glottal pulse*. If we assume $L(z)$ is a first-order differentiator $1 + z^{-1}$ [24], then $G'(z)$ is the derivative of the glottal pulse, which can be described by the LF model [25], a four-parameter model of glottal flow. $H(z)$ is usually a Linear Predictive Coding (LPC) filter.

2.2 Linear Predictive Coding

LPC assumes that the current speech sample s_n can be predicted from a finite number of previous M samples s_{n-1} to s_{n-M} by a linear combination with residual errors e_n :

$$s_n = e_n - \sum_{i=1}^M a_i s_{n-i}, \quad (2)$$

where a_i are the linear prediction coefficients. This is the same as filtering the residuals, equivalent to the glottal source in our case, with an M^{th} -order all-pole filter, a filter that has an infinite impulse response (IIR). We can use the LPC filter to represent the response of the vocal tract if the vocal tract is approximated by a series of cylindrical tubes with varying diameters [26], providing a physical interpretation.

Using LPC for neural audio synthesis is not new [8, 27, 28], and works have been conducted to incorporate IIR filters and train them jointly with deep learning models [29–35]. The difficulty of training IIR in deep learning framework (e.g. PyTorch) using Eqn (2) is that its computation is recursive, i.e. the output at each step depends on

the previous results, and to make the calculation differentiable, separated tensors are allocated in each step. This generates a significant number of memory allocations and overheads for creating tensors, thus leading to performance issues, especially for long sequences. One way to mitigate this is to allocate shared continuous memory before computation. However, in-place modification is not differentiable in these frameworks. Some studies sidestep the recursion by approximating IIR in the frequency domain using Discrete Fourier Transform (DFT) [27, 30, 32–35], but the accuracy of this approximation depends on the DFT resolution. Moreover, the IIRs used in practice are usually low-order; in this case, it is faster to compute them directly, especially on long sequences.

3. PROPOSED MODEL

Usually, $N(z)$ in Eqn (1) is treated as amplitude-modulated Gaussian noise [23, 24]. Our early experiments found this formulation to be challenging to optimise. As an alternative, we move the noise components $N(z)$ outside the glottal source and filter it with time-varying filter $C(z)$, resulting in

$$S(z) = G'(z)H(z) + N(z)C(z). \quad (3)$$

This resembles the classic *Harmonic-plus-Noise* model [36] and was used in previous DDSP-based SVS [17, 18]. Alonso et al. [17] modelled $G'(z)H(z)$ jointly using additive harmonic oscillators and time-varying Finite Impulse Responses (FIRs) as $C(z)$; Wu et al. [18] introduced a sawtooth oscillator as $G'(z)$ and zero-phase time-varying FIRs as $H(z)$. In this work, we use a glottal flow model to synthesise harmonic sources and time-varying IIRs as filters.

3.1 Glottal Flow Wavetables

We adopted the transformed-LF model [37] for generating glottal pulses. This model re-parameterises the LF model [25] using just one parameter R_d , which has been found to correspond to the perceived vocal effort well and covers a wide range of different glottal flow shapes. We sampled K values of $\log(R_d)$ with equal spacing inside $[\log(0.3), \log(2.7)]$ according to the value range suggested by [23]. We calculate the flow derivative function $g'(t; R_d)$ in continuous time t for each sampled R_d and then sampled L points in one period to get its discrete version. The details for calculating $g'(t; R_d)$ were given in [38]. By stacking these sampled glottal flows, we built wavetables $\mathbf{D} \in \mathbb{R}^{K \times L}$, with each row containing one period of a sampled glottal pulse (see Fig. 1). The rows are sorted based on R_d .

The model generates glottal pulses g'_n by linearly interpolating the two \mathbf{D} axes. The encoder network first predicts instantaneous frequency $f_n \in [0, 0.5]$ and the fractional index $\tau_n \in [0, 1]$ for R_d . We then use the instantaneous phase $\phi_n = \sum_{i=1}^n f_i$ to interpolate the waveform

Figure 1. An example of the wavetables we used, corresponding to matrix \mathbf{D} with $K = 31$.

as:

$$g'_n = (1 - p) \left((1 - q) \hat{d}_{[k], [l]} + q \hat{d}_{[k], [l]} \right) + p \left((1 - q) \hat{d}_{[k], [l]} + q \hat{d}_{[k], [l]} \right), \quad (4)$$

where $l = (\phi_n \bmod 1)L + 1$, $k = \tau_n(K - 1) + 1$, $p = k - [k]$, $q = l - [l]$, and $\hat{\mathbf{D}} = [\mathbf{D}; \mathbf{d}_1] \in \mathbb{R}^{K \times (L+1)}$. The wavetables \mathbf{D} are fixed in our case, contrary to [16], and we only pick one wavetable at a time, not a weighted sum.

3.2 Frame-Wise LPC Synthesis

Time-varying LPC synthesis is usually done by linearly interpolating the LPC coefficients to the audio resolution and filtering sample by sample. This is not parallelisable and slows down the training process. As an alternative, we approximate LPC synthesis by treating each frame independently and using overlap-add:

$$s_n = \sum_k LPC(g'_n \gamma_n u_{n-kT}; \mathbf{a}_k) w_{n-kT}, \quad (5)$$

where $LPC(e_n; \mathbf{a})$ represents Eqn (2), $\mathbf{a}_k \in \mathbb{R}^M$ are the filter coefficients at the k^{th} frame, u_n and w_n are the windowing functions, $\gamma_n \in \mathbb{R}^+$ is the gain, and T is the hop size. u_n is fixed to the square window. In this way, the computation can be parallelised. We found that the voice quality differences between overlap-add LPC and sample-by-sample LPC are barely noticeable if we use a sufficiently small hop size. We empirically found that a 200 Hz frame rate is sufficient.

3.3 LPC Coefficients Parameterisation

For the LPC filter to be stable, all of its poles must lie inside the unit circle on the complex plane. Stability can be guaranteed using robust representations, such as reflection coefficients [28]. The representation we chose in this work is cascaded 2nd-order IIR filters, and we solve the stability issue by ensuring all the 2nd-order filters are stable. We use the *coefficient representation* from [33] to parameterise

the i^{th} IIR filter's coefficients $1 + \eta_{i,1}z^{-1} + \eta_{i,2}z^{-2}$ from the encoder's outputs and cascade them together to form an M^{th} -order LPC filter:

$$\begin{aligned} & (1 + \eta_{1,1}z^{-1} + \eta_{1,2}z^{-2})(1 + \eta_{2,1}z^{-1} + \eta_{2,2}z^{-2}) \\ & \cdots (1 + \eta_{\frac{M}{2},1}z^{-1} + \eta_{\frac{M}{2},2}z^{-2}) \\ & = 1 + a_1z^{-1} + a_2z^{-2} + \cdots + a_Mz^{-M} = A(z). \end{aligned} \quad (6)$$

3.4 Unvoiced Gating

The instantaneous frequency f_n predicted by the encoder is always non-zero and keeps the oscillator working. Without constraint, the model would utilise these harmonics in the unvoiced region creating buzzing artefacts [18]. We propose to mitigate this problem by jointly training the model to predict the voiced/unvoiced probabilities as $v_n \in [0, 1]$ and feeding the gated frequency $\hat{f}_n = v_n f_n$ to the oscillator instead.

4. OPTIMISATION

Training deep learning models is usually accomplished by backpropagating the gradients evaluated at a chosen loss function \mathcal{L} throughout the whole computational graph back to the parameters. Partially inspired by Bhattacharya et al. [29], we derived the closed form of *backpropagation through time* to utilise efficient IIR implementation to solve the problems we mentioned in Section 2.2 while keeping the filter differentiable. Here, $\mathbf{e} \in \mathbb{R}^N$ is the input, $\mathbf{a} \in \mathbb{R}^M$ is the filter coefficients, and $\mathbf{s} \in \mathbb{R}^N$ is the output. Assuming we know $\frac{\partial \mathcal{L}}{\partial \mathbf{s}}$, we can get the derivatives $\frac{\partial \mathcal{L}}{\partial \mathbf{e}}$ and $\frac{\partial \mathcal{L}}{\partial \mathbf{a}}$, using chain rules $\frac{\partial \mathcal{L}}{\partial \mathbf{s}} \frac{\partial \mathbf{s}}{\partial \mathbf{e}}$ and $\frac{\partial \mathcal{L}}{\partial \mathbf{s}} \frac{\partial \mathbf{s}}{\partial \mathbf{a}}$.

4.1 Backpropagation Through the Coefficients

Taking the derivatives of Eqn (2) with respect to a_i we get:

$$\frac{\partial s_n}{\partial a_i} = -s_{n-i} - \sum_{k=1}^M a_k \frac{\partial s_{n-k}}{\partial a_i}, \quad (7)$$

which equals $LPC(-s_{n-i}; \mathbf{a})$. $s_n|_{n \leq 0}$ does not depend on a_i so the initial conditions $\frac{\partial s_n}{\partial a_i}|_{n \leq 0}$ are zeros. We can get $\frac{\partial s_n}{\partial a_j}$ with one pass of filtering because $\frac{\partial s_n}{\partial a_j}$ is $\frac{\partial s_n}{\partial a_i}$ shifted by an offset $j - i$. Lastly, we calculate $\frac{\partial \mathcal{L}}{\partial a_i}$ as $\sum_{n=1}^N \frac{\partial \mathcal{L}}{\partial s_n} \frac{\partial s_n}{\partial a_i}$.

4.2 Backpropagation Through the Input

To get the derivatives for input e_n , we first re-write Eqn (2) as the following convolutional form:

$$s_n = \sum_{m=1}^n e_m h_{n-m}, \quad (8)$$

where $h_n = \mathcal{Z}^{-1}\{H(z)\}$, $H(z) = \frac{1}{A(z)}$. From Eqn (8) we see that $\frac{\partial s_n}{\partial e_m} = h_{n-m}$. The derivative of loss \mathcal{L} with respect to e_m depends on all future samples s_n , which is:

$$\frac{\partial \mathcal{L}}{\partial e_m} = \sum_{n=m}^N \frac{\partial \mathcal{L}}{\partial s_n} \frac{\partial s_n}{\partial e_m} = \sum_{n=m}^N \frac{\partial \mathcal{L}}{\partial s_n} h_{n-m}. \quad (9)$$

By swapping the variables n, m and considering the equivalence of Eqn (2) and Eqn (8), Eqn (9) can be simplified to

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial e_n} &= \sum_{m=n}^N \frac{\partial \mathcal{L}}{\partial s_m} h_{m-n} \\ &= \frac{\partial \mathcal{L}}{\partial s_n} - \sum_{i=1}^M a_i \frac{\partial \mathcal{L}}{\partial e_{n+i}}. \end{aligned} \tag{10}$$

Eqn (10) shows that we can get the derivatives $\frac{\partial \mathcal{L}}{\partial e_n}$ by just filtering $\frac{\partial \mathcal{L}}{\partial s_n}$ with the same filter, but running in backwards. The initial conditions $\frac{\partial \mathcal{L}}{\partial e_n}|_{n>N}$ are naturally zeros.

In conclusion, backpropagation through an IIR filter consists of two passes of the same filter and one matrix multiplication¹. We implemented the IIR in C++ and CUDA with multi-threading to filter multiple sequences simultaneously². The differentiable IIR is done by registering the above backward computation in PyTorch, and we submitted the implementation to TorchAudio [39] as part of the `torchaudio.functional.lfilter`.

5. EXPERIMENTAL SETUP

5.1 Dataset

We test GOLF as a neural vocoder on the MPop600 dataset [40], a high-quality Mandarin singing voice dataset featuring nearly 600 singing recordings with aligned lyrics sung by four singers. We used the audio recordings from the `f1` (female) and `m1` (male) singers. For each singer, we selected the first three recordings as the test set, the following 27 recordings as the validation set, and used the rest as training data (around three hours in total). All the recordings were downsampled to 24 kHz. The vocoder feature we choose is the log mel-spectrogram. We computed the feature with a window size of 1024 and 80 mel-frequency bins and set the hop size T to 120. We normalised the feature to between zero and one and sliced the training data into two seconds excerpts with 1.5 seconds overlap.

5.2 Model Details

We adopted the encoder from SawSing but replaced the transformer layers with three layers of Bi-LSTM for favourable implementation, resulting in around 0.7M parameters in total. A final linear layer predicts the synthesis parameters $\{f_k, v_k, \gamma_k, \beta_k, \mathbf{a}_k, \mathbf{b}_k\}$. The first four parameters are linearly upsampled to $\{f_n, v_n, \gamma_n, \beta_n\}$. β_n and \mathbf{b}_k are the Gaussian noise’s gain and filter coefficients. We added an average pooling layer with a size of 10 and two convolution layers after the encoder to predict the R_d fractional index τ_o at a lower rate and then linearly upsampled to τ_n . This step avoids possible modulation effects caused by switching the wavetables too quickly. A

¹ The computation of the IIR does not need to fulfil the implementation requirements set by the automatic differentiation framework, thus can be highly optimised.

² Although the single-core performance of a GPU is usually inferior to a CPU, and we can only use at most one thread for each IIR, the GPU has a much higher number of cores, which is beneficial for training on a large number of sequences at once.

system diagram of GOLF is shown in Fig. 2. We set $K = 100, L = 2048$, Hanning window for w_n , and $M = 22$ for both LPC filters. We used the same hop size T and a window size of 480 for frame-wise LPC. We normalised all wavetables to have equal energy and aligned them with the negative peak.

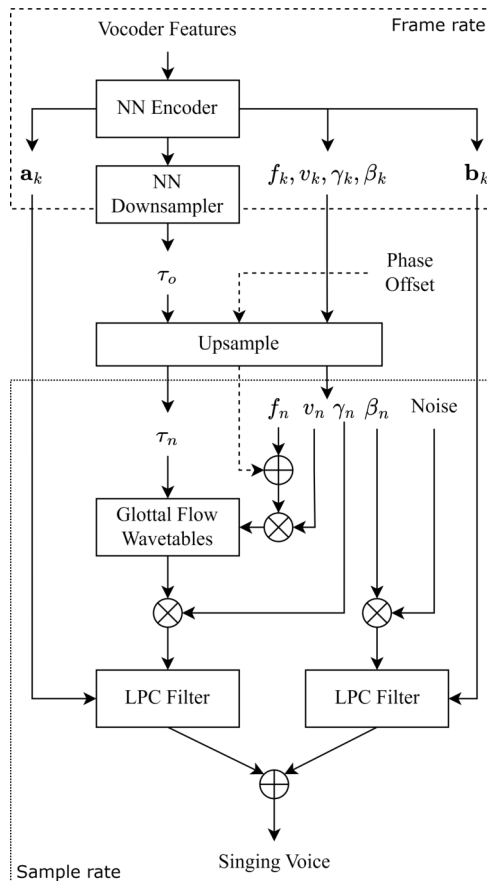

Figure 2. Overview of the GOLF synthesis process. *phase offset* is only introduced at test time, where the details are given in Section 6.1.

We compare GOLF with three DDSP-based baselines using the same NN encoder to predict their synthesis parameters. The first two are the original DDSP [14] and SawSing [18]. We set their noise filter length to 80 and harmonic filter length to 256 for SawSing. The third model is PULF, which is similar to GOLF but replaces the glottal flow wavetables with a band-limited pulse train [19] using additive synthesis, while the LPC order for the harmonic source is increased to 26 to accommodate the glottal pulse response. The number of oscillating sinusoids was set to over 150 for all the baselines. We did not compare GOLF with Nercessian et al. [19] and Yoshimura et al. [21] because these architectures are based closely on the source-filter model, and use additional post-nets to enhance the voice, which makes it harder to compare directly with GOLF.

5.3 Training Configurations

We trained separate models for each singer, resulting in 8 models. The loss function is the summation of the

multi-resolution STFT loss (MSSTFT) and f0 loss from SawSing with FFT sizes set to $\{512, 1024, 2048\}$, plus a binary cross entropy loss on voiced/unvoiced prediction. We stopped the gradients from the harmonic source to the f0s and voiced decisions to stabilise the training. We used Adam [41] for running all optimisations. For DDSF and SawSing, the batch size and learning rate were set to 32 and 0.0005; for GOLF and PULF, the numbers were 64 and 0.0001. We used the ground truth f0s (extracted by WORLD [20]) for the harmonic oscillator of PULF during training due to stability issues. We trained all the models for 800k steps to reach sufficient convergence and picked the checkpoint with the lowest validation loss as the final model³.

6. EVALUATIONS

6.1 Objective Evaluation

The objective metrics we choose are the MSSTFT, the mean absolute error (MAE) in f0, and the Fréchet audio distance (FAD) [42] on the predicted singing of the test set. Table 1 shows that DDSF has the lowest MSSTFT and f0 errors, while SawSing reaches the lowest FAD. GOLF and PULF show comparable results in f0 errors to other baselines. We report the memory usage when training these models and their real-time factor (RTF), both on GPU and CPU, in Table 2. The amount of memory required to train GOLF is around 35% of others, and it runs extremely fast, especially on the CPU.

Singers	Models	MSSTFT	MAE-f0 (cent)	FAD
f1	DDSP	3.09	74.47 ±1.19	0.50±0.02
	SawSing	3.12	78.91±1.18	0.38 ±0.02
	GOLF	3.21	77.06±0.88	0.62±0.02
	PULF	3.27	76.90±1.11	0.75±0.04
m1	DDSP	3.12	52.95 ±1.03	0.57±0.02
	SawSing	3.13	56.46±1.04	0.48 ±0.02
	GOLF	3.26	54.09±0.30	0.67±0.01
	PULF	3.35	54.60±0.73	1.11±0.04

Table 1. Evaluation results on the test set. We omit the standard deviation if it is smaller than 0.01.

As an additional metric we use the L2 loss between the predicted and the ground truth waveform. The intuition behind this is that GOLF and PULF are the only two models introducing non-linear phase response because of IIR filtering. The filters in DDSF and SawSing are all zero-phase, and the initial phases of the sinusoidal oscillators are fixed to zeros. We emphasise that this test is not targeting human perception but the phase reconstruction ability of the models. Humans cannot perceive the absolute frequency phase, but accurate reconstruction could be important in sound matching and mixing use cases. We evaluate the loss on one of the test samples from m1 we used in the subjective evaluation. We created a new parameter

³ The trained checkpoints, source codes, and audio samples are available at <https://github.com/yoyololicon/golf>.

called *phase offset* sampled at 20 Hz. We linearly upsampled *phase offset* and added it to the instantaneous phase ϕ_n , introducing a slowly varying phase shift. We optimised this parameter by minimising the predicted waveform’s L2 loss to the ground truth using Adam with a learning rate of 0.001 and 1000 steps. We wrapped the differences between the points of *phase offset* during optimisation to $[-0.5, 0.5]$. We ran this optimisation five times for each model. Each time the *phase offset* was initialised randomly. We report the minimum and maximum final losses from these trials. Table 2 shows the lowest losses GOLF and PULF can reach are significantly smaller than the others, with GOLF having the smallest among all.

Models	Memory	RTF		Waveform L2	
		GPU	CPU	Min	Max
DDSP	7.3	0.015	0.237	71.83	88.77
SawSing	7.3	0.015	0.240	75.72	93.16
GOLF	2.6	0.009	0.023	21.98	64.82
PULF	7.5	0.015	0.248	44.08	70.59

Table 2. The required number of VRAM (GB) for training with a batch size of 32, real-time factor (RTF), and the minimum/maximum L2 loss on waveform using one of the test samples. The benchmark was conducted on an Ubuntu 20.04 LTS machine with an i5-4790k processor and an NVIDIA GeForce RTX 3070 GPU.

6.2 Subjective Evaluation

We conducted an online listening test using Go Listen [43]. We picked one short clip from each test set recording, resulting in 6 clips with duration ranging from 6 to 11 seconds. The test is thus divided into six examples, each consisting of one ground truth clip and four synthesised results from different models, and their loudness was normalised to -16 dB LUFS. The order of the examples and the stimulus were randomised for each subject. Each subject was requested to rate the quality of these stimuli on a score from 0 to 100. We collected responses from 33 anonymous participants. We dropped one of the participants who did not indicate using headphones. We normalise scores to fall between 1 to 5 and report the Mean Opinion Score (MOS) in Fig. 4. DDSF has the highest opinion scores overall, and a Wilcoxon signed-rank test shows that it is not statistically significantly different from the f1 ground truth ($p = 0.168$). We applied the one-side Wilcoxon test on GOLF and PULF to compare them with SawSing, and the results show that GOLF significantly outperforms SawSing ($p < 0.0001$), and PULF performs better than SawSing on m1 ($p < 0.022$).

7. DISCUSSIONS

Given the evaluation results and the number of synthesis parameters in GOLF is roughly six times smaller than DDSF and SawSing, it is clear that GOLF’s synthesis parameters are a more compact representation. Comparing

Figure 3. The predicted waveforms of a short segment from one of the *m1* test samples. The differences were computed by subtracting the predicted signal from the reference.

Figure 4. The MOS results of the vocoders trained on different singers with 95% confidence interval.

the differences between GOLF and PULF in Table 2, we can see that the performance gain is due to the use of wavetables. Other baselines synthesise band-limited harmonic sources with many sinusoids oscillating simultaneously, thus increasing the computational cost. PULF’s MOS score is much worse on *f1*, with noticeable artefacts in the unvoiced region and random components of the voice. After investigation, we found the noise gains β_n predicted by PULF fluctuating at high speed, producing a modulation effect. This behaviour is also found in PULF trained on *m1* and GOLF, even on the harmonic gains γ_n . Still, the amount of fluctuation is small and barely noticeable in the test samples. Given the available results, we could only conclude that this effect relates to the type of harmonic source and the range of f_0 , i.e., female singers have higher f_0 . This amplitude modulation effect cannot be observed in spectrograms and thus is not captured by the training loss we used. It could be an intrinsic drawback of using frame-wise LPC approximation, but more experiments and comparisons with sample-wise LPC are needed. In addition, SawSing produced low scores for both singers because of the buzzing artefacts in the unvoiced region. Although unvoiced gating (Sec. 3.4) reduces this problem to a large degree, human ears are susceptible to this effect. This could be an inherent problem in using a sawtooth as the harmonic source.

The L2 loss shown in Table 2 demonstrates that GOLF matches phase-related characteristics more accurately than

other models. Fig. 3 shows GOLF produces the most similar waveform to the ground truth. Other baselines’ waveforms are similar because they use the same additive synthesiser. It is possible to reduce their L2 loss by optimising the initial phases of the oscillators, but this cannot account for time-varying source shapes. Low L2 loss is a positive effect of the deterministic phase responses embedded in GOLF. This opens up many possibilities, such as decomposing and analysing the voice in a differentiable manner and training the vocoder using the time domain loss function. The latter could be a possible way to reduce the fluctuation problem discussed in the previous paragraph. The waveform matching of GOLF can be improved further by using a more flexible glottal source model, adding FIR and all-pass filters to account for the voice’s mixed-phase components and the recording environment’s acoustic response.

Lastly, we note that cascaded IIR filters provide an orderless representation (i.e. the cascading order does not affect the outputs). This results in the *responsibility problem* [44, 45] for the last layer of the encoder, which might be one of the reasons why GOLF and PULF are less stable to train than other baselines. Developing architectures that can handle orderless representation or switch to other robust representations are possible ways to address this.

8. CONCLUSIONS

We present a lightweight singing voice vocoder called GOLF, which uses wavetables with different glottal flows as entries to model the time-varying harmonic components and differentiable LPC filters for filtering both the harmonics and random elements. We show that GOLF requires less memory to train and runs an order of magnitude faster on the CPU than other DDS-based vocoders, but still attains competitive voice quality in subjective and objective evaluations. Furthermore, we empirically show that the predicted waveforms from GOLF represent the voice’s phase response more faithfully, which could allow us to use GOLF to decompose and analyse human voice.

9. ACKNOWLEDGEMENTS

The authors want to thank Moto Hira (mthrok), Christian Puhrsch (cpuhrsch), and Alban Desmaison (alband) for reviewing our pull requests to TorchAudio. We are incredibly grateful to Parmeet Singh Bhatia (parmeet) for implementing the first version of efficient IIR in the TorchAudio codebase as `lfilter.cpp`. We thank Ben Hayes for giving feedback on the equations of backpropagation through an IIR. The first author wants to exclusively thank Ikuyo Kita for giving positive, energetic support during the writing process. The first author is a research student at the UKRI Centre for Doctoral Training in Artificial Intelligence and Music, supported jointly by UK Research and Innovation [grant number EP/S022694/1] and Queen Mary University of London.

HARMONIC ANALYSIS WITH NEURAL SEMI-CRF

ABSTRACT

Automatic harmonic analysis of symbolic music is an important and useful task for both composers and listeners. The task consists of two components: recognizing harmony labels and finding their time boundaries. Most of the previous attempts focused on the first component, while time boundaries were rarely modeled explicitly. Lack of boundary modeling in the objective function could lead to segmentation errors. In this paper, we introduce a novel approach named *Harana*, to jointly detect the labels and boundaries of harmonic regions using neural semi-CRF (conditional random field). In contrast to rule-based scores used in traditional semi-CRF, a neural score function is proposed to incorporate features with more representational power. To improve the robustness of the model to imperfect harmony profiles, we design an additional score component to penalize the match between the candidate harmony label and the absent notes in the music. Quantitative results from our experiments demonstrate that the proposed approach improves segmentation quality as well as frame-level accuracy compared to previous methods. The source code used in this paper is available on GitHub¹.

1. INTRODUCTION

In music, harmony is the sound resulted from two or more pitches being performed together. It is the vertical aspect of music [1], and is essential for both music creation and perception. During music analysis, a harmony label is often assigned to a music segment that is harmonically coherent. Many composers use harmonic progressions to set up a musical template in which texture could then be filled [2]. For listeners, harmonic structure is a crucial mid-level representation of music that can influence the perception of other music elements such as melody and rhythm [3].

The task of harmonic analysis aims to find the correct segmentation of a music piece and to identify the corresponding label for each segmented region. These two goals are closely related. Regions with strong confidence of a candidate harmony label tend to possess the boundaries of

a true segmentation [4]. On the other hand, the oracle segmentation could help the prediction of the true underlying harmony for the notes in each region [4]. Therefore, to achieve successful analysis of harmony, both of the two goals as well as their relationship should be considered.

Targeting the two indispensable components of harmonic analysis simultaneously, we propose an approach to jointly predict the boundaries and labels of harmonic regions using neural semi-Markov conditional random field (semi-CRF). It is well-known that the harmonic regions in music do not always share the same length [5]. Compared to conventional sequence labeling models, semi-CRF is more suitable for the task because it allows for various lengths among the labeled regions [6].

In the original setting of semi-CRF, a score is computed in each segmented region using the weighted sum of rule-based features [6]. However, rule-based features are bounded by pre-defined rules and might not exploit the interaction between notes and other intermediate music representations deeply enough. To solve this problem, we design a neural scoring function that first estimates the frame-level harmony distributions using a neural network and then adapts them to candidate harmony labels with an attention mechanism. The attention mechanism could make the scoring module more efficient by concentrating on sub-regions that are more harmonically related to the candidate label. In addition, an absence score is added to the scoring function to improve the robustness of the model to imperfect harmony profiles of the music. Through experiments we find that the proposed architectural components collectively yield improvement on both segmentation quality and harmony labels accuracy. We focus on MIDI-like symbolic music input in our experiments but the method could be easily adapted to audio.

In summary, our contributions include:

- Proposing the first neural semi-CRF model to jointly estimate harmony labels and their time boundaries;
- Proposing an attention-based score function to alleviate the influence of extra non-chordal notes and missing chordal notes; and
- Proposing a novel absence score to improve the robustness to imperfect harmony profiles.

2. RELATED WORKS

Due to the importance of harmony in music, a substantial amount of automatic systems have been designed for har-

¹ <https://github.com/QiaoyuYang/harana>

monic analysis. Early systems tended to focus on using music audio as input and apply domain knowledge from music theory. To encode the audio waveform, a time-frequency representation, or spectrogram, is usually extracted using the short-time Fourier Transform. Then, with the observation that it is the pitch class of notes rather than the absolute pitch height that affects the harmonic content, a common practice is to reduce the spectrogram to a chromagram with 12 bins corresponding to the 12 pitch classes. In the decoding stage, the chromagram can be matched to predefined chord profiles [7, 8] or made to emit explicit labels using probabilistic models such as hidden Markov model (HMM) [9–11] or CRF [11].

With the increasing popularity of deep learning in the past decade, end-to-end models based on deep neural networks have received extensive attention [12–16]. To model the temporal evolution of music context, Boulanger-Lewandowski et al. extracted audio features using a recurrent neural network (RNN) [17]. To better aggregate context information and learn intermediate representations with a temporal hierarchy, Zhou and Lerch used a convolutional neural network (CNN) with low-pass filters [12]. McFee and Bello further combined CNN and RNN in the feature encoder for chord recognition [13]. As a powerful attention-based architecture designed for long-term sequence modeling, transformers have also been incorporated in some recent approaches to harmonic analysis [14, 15].

While the harmonic progression or context information can be modeled with various techniques, the majority of existing methods do not directly optimize for region-level output. Some methods adopt a two-stage approach, where the first stage outputs frame-level chord labels and the second stage smooths frame-level labels with post-processing [9–11, 18–20]. However, different from other simple sequence labeling tasks such as part-of-speech tagging, a harmonic label could correspond to a region spanning multiple frames. Although temporal smoothing by HMM or CRF regresses some sporadically outliers back to the harmonic streams, these models could still suffer from segmentation errors. Masada and Bunescu relaxed the constraint on fixed-size time-span of the output prediction [21]. They used a generalized variant of CRF, semi-CRF, to jointly detect chord labels and their boundaries. However, the features to the semi-CRF are entirely rule-based, which means they are not necessarily optimal for the end task. In this work, we build on the semi-CRF framework and explore neural features and scoring techniques that are jointly optimized for the end task - harmony labeling and boundary prediction.

3. METHODS

In our proposed model, Harana, we first estimate the harmony (including root, quality, and pitch activation in this work) at the frame-level; then we aggregate the frame-level estimation into region-level segment scores based on candidate segments; finally, we use semi-CRF to find the best

segmentation candidate and its corresponding labels. We focus on symbolic music input in our experiments. The following subsections describe the model in detail.

3.1 Data Representation

3.1.1 Symbolic Music Input

Given a symbolic music piece, we slice it into short frames of one eighth of a beat long. We use beat instead of note duration in order to represent the basic time unit because music with different meters may have different distributions on the note length. The pitch information in each frame is summarized with a 12-d pitch class distribution vector, which describes the normalized distribution of the duration of each pitch class in the frame. To help distinguish between harmonies with the same pitch class vector, we also include the bass note (the lowest note) in the input to the model; it is represented as a 12-d one-hot vector indicating the bass pitch class in each frame. Combining the pitch class distribution and the bass note, the input to the model is a sequence of 24-d vectors.

3.1.2 Harmony

A popular representation of music harmony in symbolic music is the Roman numeral encoding, where the full harmonic context of a label, including tonic and degree, is considered [22]. However, the combination of all the components produces 47k different harmony labels, which are intractable for a classification model with limited training data. A possible solution is to classify each harmony component independently, but this is incompatible with semi-CRF because the boundary of each component must be the same. As a compromise, we use a subset of the harmony components, root and quality, and model them jointly.

The root is represented as a 12-d one-hot vector corresponding to the 12 pitch classes. The quality is represented as a 10-d one-hot vector corresponding to 10 commonly used classes. In addition to root and quality, we use another harmony representation, the pitch class activation vector, in the neural score function. Previous works have shown its effectiveness as a label encoding for harmonic analysis [13]. These vectors are 12-d multi-hot and are circularly shifted from the pitch-class activation vectors rooted at C.

3.2 Semi-CRF

Semi-CRF is a probabilistic model for sequence labeling with a variable label-span. Given a sequence of input frames $X = \langle X_1, X_2, \dots, X_N \rangle$, semi-CRF provides the conditional probability of the sequence of contiguous non-overlapping labeled segments $Y = \langle Y_1, Y_2, \dots, Y_K \rangle$, where N is the number of frames and K is the number of segments. Since the labeled segments could span multiple frames, they are represented as three-dimensional tuples $Y_i = (u_i, v_i, l_i)$, where u_i , v_i and l_i respectively denote the onset, offset and label of the segment. In the context of harmonic analysis, X represents the input music frames and Y represents the harmonic regions.

Figure 1: The semi-CRF architecture in the context of harmonic analysis. The total score is computed from music input and a set of candidate harmony segments. Numbers in the blue squares are the frame indices. Numbers in the green rectangles are the indices of candidate harmony segments.

The conditional probability given by semi-CRF takes the form of

$$P(Y|X) = \frac{e^{WF(Y,X)}}{Z(X)}, \quad (1)$$

where F is a feature vector computed from X and Y , W is a learnable weight matrix, and $Z = \sum_Y e^{WF(Y,X)}$ is a normalization factor summarizing all possible segmentation and labeling of the input sequence. In this work, we propose to generalize the weighted feature score to a neural score function $S(Y, X)$ so that

$$P(Y|X) = \frac{e^{S(Y,X)}}{Z(X)}. \quad (2)$$

With the assumption that the harmony labels are Markovian given the music input, the score function could be decomposed into the sum of segment-level scores that are dependent only on the current and the previous segments.

$$S(Y, X) = \sum_{i=1}^K S_i(Y_i, X; Y_{i-1}). \quad (3)$$

To simplify the notation, we treat Y_{i-1} as a parameter for the i -th segment's score function and omit it in the following sections. Figure 1 demonstrates the structure of semi-CRF in the context of music harmonic analysis.

3.3 Frame-Level Estimation

Following Micci et al. [23], the frame-level estimation of harmony information is achieved with a DenseNet-GRU architecture. The DenseNet-GRU module is followed by fully connected layers and finally the vectors corresponding to different types of harmony information are estimated using separate linear heads. The softmax function is used to produce the class distributions of the root and the quality, whereas sigmoid is used to find the activation of each pitch class. Mathematically, the computation of frame-level harmony estimation can be formulated as

$$\begin{aligned} E(n) &= MLP(GRU(DenseNet(X_n))), \\ \hat{D}_R(n) &= \text{Softmax}(FC_R(E(n))), \\ \hat{D}_Q(n) &= \text{Softmax}(FC_Q(E(n))), \\ \hat{P}C(n) &= \text{Sigmoid}(FC_{PC}(E(n))), \end{aligned} \quad (4)$$

where X_n is the n^{th} frame of the input music. $\hat{D}_R(n)$, $\hat{D}_Q(n)$ and $\hat{P}C(n)$ represent the root distribution, quality distribution and the pitch class activations of the estimated harmony for a frame.

3.4 Attention-Based Score Function

As described in Eq. (3), the CRF model evaluates possible sequences of harmony labels and their segmentation. For each segment, i.e., a candidate harmony region, we need to aggregate the frame-level harmony information (root, quality and pitch activation) computed from Eq. (4). A simple method would be taking the average or the mode, but we note that a harmonic region is not likely to contain homogeneous harmonic content. In order to dynamically weigh the harmonic importance of each frame within a region, an attention module is proposed to focus on the frames that are most similar to the candidate harmony label. In particular, the scaled dot-product attention [24] is used:

$$A(Q, K, V) = \frac{\sum_{i=1}^N Q^T K_i V_i}{\sqrt{d}}, \quad (5)$$

where Q is the query vector, K is the key sequence, V is the value sequence and d is the vector size.

In the context of our model, the estimated frame-level harmony sequence of a candidate harmony region serves as both the key and value while the candidate region-level harmony itself is the query. Then, the candidate-informed (CI) estimation can be computed as

$$\hat{H}_{CI}(Y_i) = A(H(l_i), \hat{H}(u_i : v_i), \hat{H}(u_i : v_i)), \quad (6)$$

where l_i is the i -th candidate harmony label, and $H(l_i)$ is its harmony representation, which can be root D_R , quality D_Q or pitch class activation PC as defined in Eq. (4). Variables u_i and v_i are the first and last frames of the i^{th} harmonic region Y_i , and $\hat{H}(u_i : v_i)$ is the vector sequence of estimated frame-level harmony representations from the music input.

Now that we have a single embedding vector to summarize the harmonic content in the i -th candidate region, the score of assigning the candidate harmony label l_i to this region can be described by the similarity between the candidate harmony label embedding $H(l_i)$ and the candidate-informed music embedding $\hat{H}_{CI}(Y_i)$. Dot product is used

Figure 2: The proposed pipeline of the neural encoder and scoring function.

to calculate the similarity:

$$S_i^H(Y_i, X) = H(l_i)^T \hat{H}_{CI}(Y_i). \quad (7)$$

To further model the transition probability between adjacent harmony labels and enforce more inductive bias in decoding, a transition score between segments is computed:

$$S_i^T(Y_i) = T[l_{i-1}, l_i] + (v_i - u_i)T[l_i, l_i], \quad (8)$$

where T is the transition matrix containing log-probabilities of harmony transitions at the frame level. It is pre-computed from the ground-truth labels in the training data.

Combining the similarity score and the transition score, the score function of a candidate harmony region is

$$S_i(Y_i, X) = \sum_H S_i^H(Y_i, X) + \lambda S_i^T(Y_i), \quad (9)$$

where λ is a hyperparameter to balance the two score components. Figure 2 illustrates the overall structure of the neural front end and the scoring function.

3.5 Absence Score

In Eq. (7), the comparison between the candidate-informed music embedding \hat{H}_{CI} with the candidate harmony representation H indicates the likelihood of the candidate harmony. However, this comparison may not be robust when there are many non-chordal notes or missing chordal notes in the estimation. In this case, the estimated class distributions \hat{D}_R and \hat{D}_Q in Eq. (4) would be relatively flat and the pitch class activation vector $\hat{P}C$ would not align well with a chord template. In other words, the neural front-end may not sufficiently suppress non-chordal notes and recognize missing chordal notes to produce class distributions discriminative enough for the semi-CRF to decode the harmony. To improve the robustness of the model to such issues, we introduce an *absence score* to allow the model to filter out pitch activations that are not active within the input music, the majority of which represent non-chordal notes that should not intersect with chordal notes of the underlying harmony. To compute the absence score, the complement of the input pitch class vector is sent to the neural

front-end. That means the input to Eq. (4) is transformed by

$$X_n[1:12] = 1 - X_n[1:12]. \quad (10)$$

The harmony information estimated from the inactive music \hat{H}^{inact} are then compared with the candidate harmony vectors $H(l_i)$. The similarity between them should be minimized. In summary, the absence score of a candidate harmony region is

$$AS_i^H(Y_i, X) = -H(l_i)^T \hat{H}_{CI}^{inact}(Y_i). \quad (11)$$

When the absence score is used, the complete score function becomes

$$S_i(Y_i, X) = \sum_H S_i^H(Y_i, X) + AS_i^H(Y_i, X) + \lambda S_i^T(Y_i), \quad (12)$$

3.6 Optimization

For training, both the input music frames and the ground-truth harmony label segments are provided. The goal is to update the model parameters such that the probability computed in Eq. (2) is maximized. This is equivalent to minimizing the negative log likelihood (NLL) loss:

$$\begin{aligned} NLL(\theta) &= -\log P_\theta(Y|X) \\ &= \log(Z_\theta(X)) - S_\theta(Y, X), \end{aligned} \quad (13)$$

where θ are the model parameters. We then compute the gradient of the loss with respect to the parameters to train our model using gradient descent.

During inference, where only the input music frames are provided, the goal becomes finding the correct segmentation and the corresponding labels that maximize the probability $P(Y|X)$. Since the normalization factor as a sum of exponential scores stays positive, maximizing the score function $S(Y, X)$ suffices to decode the segments and labels.

In both training and inference, we used the algorithms based on dynamic programming proposed in the original semi-CRF paper to expedite the optimization process [6].

4. EXPERIMENTS

4.1 Data

A collection of datasets from various sources [22, 25–27] organized by Micchi et al. [28] is used to train and evaluate the proposed architecture. Table 1 summarizes the statistics of the data included in our experiments. MusPy [29] is used to read the compressed MusicXML files and a parser adapted from [28] is employed to handle the proposed data representations. To increase the size of the dataset and help alleviate possible data imbalance, each piece is transposed to 12 different keys. The dataset is split into disjoint subsets for training and testing with a 2:1 split.

4.2 Implementation Details

Following the original paper for faster training [30], DenseNet is implemented in three separate blocks. 1-D convolution along the time frame dimension is used in each convolutional layer. Guided by the observation that harmony changes usually occur on average at a lower frequency than the frame rate, pooling layers are added between blocks to reduce the temporal resolution of the harmony output.

To ensure continuity and completeness of harmony regions in the training samples, we force the sample boundaries to be aligned with measure boundaries. A sample is chosen as 96 frames because it is divisible by all the common measure lengths existed in the dataset. Additionally, to avoid over-sampling from music pieces with longer length, the piece index is sampled uniformly first before a music sample is selected from the piece.

The entire pipeline is implemented using PyTorch. Adam optimizer is applied with learning rate of 10^{-4} and weight decay of 10^{-2} . Dropout with rate 0.2 is added between GRU layers and after each hidden fully-connected layer to avoid over-fitting. The λ in Eq. (12) is chosen empirically to be 0.001.

4.3 Evaluation Metrics

The task of music harmony analysis is two fold: recognizing the correct labels and finding the correct segmentation corresponding to the labels. To obtain a full picture of the model performance, we used two types of evaluation metrics to assess both aspects of the task.

First, the frame-level accuracy is computed for both root and quality. The accuracy on a reduced dictionary of quality including only major and minor is also reported due to

	Pieces	Crotchet	Chord Annotations
BPSFH	32	23554	8615
Roman Text	82	18208	7935
Tavern	27	20673	10723
Lopez	180	31367	16666

Table 1: Summary of statistics of the datasets.

its prevalence in the literature and adequacy in many practical uses. During training, the accuracy is computed at the sample level. During inference, the result is averaged across all frames in a song.

The other evaluation metric focuses on the segmentation quality of the output. We use the standard segmentation scores from the mir_eval package [31, 32]. The scores are based on directional Hamming distance and consider the overlap between the estimated harmony intervals and the ground-truth intervals. The directional Hamming distance between the set of estimated intervals $\hat{\mathcal{I}} = \{\hat{I}_i\} = \{\hat{u}_i, \hat{v}_i\}$ and the set of ground-truth intervals $\mathcal{I} = \{I_i\}$ is computed as the following:

$$DHD(\hat{\mathcal{I}}, \mathcal{I}) = \frac{\sum_{\hat{I}_i \in \hat{\mathcal{I}}} (|\hat{I}_i| - \max_{I_j \in \mathcal{I}} |\hat{I}_i \cap I_j|)}{\sum_{\hat{I}_i \in \hat{\mathcal{I}}} |\hat{I}_i|} \tag{14}$$

When a harmony boundary is missing from the estimation, an estimated harmony interval overlaps with multiple ground-truth intervals, but the maximum overlap is bounded by the length of the ground-truth intervals, leaving a large portion of the estimated interval not subtracted hence a large distance value. Therefore, a large $DHD(\hat{\mathcal{I}}, \mathcal{I})$ often indicates under-segmentation, while a large $DHD(\mathcal{I}, \hat{\mathcal{I}})$ often indicates over-segmentation. To summarize the two directional distances in a single metric, the overall segmentation quality score is computed as

$$SQ = 1 - \max(DHD(\mathcal{I}, \hat{\mathcal{I}}), DHD(\hat{\mathcal{I}}, \mathcal{I})) \tag{15}$$

4.4 Baseline Models

Three baseline models are included in our experiments to demonstrate the performance improvement of our proposed method. The chosen baselines are all relevant to our model by sharing parts of the architecture. Since the neural front-end of Harana is CRNN, we first test if a plain CRNN model [23] could achieve comparable results. A second baseline model, frog [28], also relies on CRNN to extract music features. In contrast to our model, it uses a neural autoregressive distribution estimator (NADE) to decode the harmony label. At the decoding stage, it defines an order of the harmony components and iteratively predict the next component conditioned on the current component. The same output harmony categories of root and quality output are considered in the NADE decoder. A third baseline worth comparing to is the rule-based semi-CRF proposed by Masada and Bunesco [21]. It uses handcrafted rules as features to compute the segment scores in semi-CRF. For simplicity, we implemented the two most important features, chord coverage and segment purity, in our experiment. Chord coverage measures what percentage of chordal notes are covered by the music segment while segment purity describes what proportion of notes in the music segment are indeed chordal notes.

Model	Root Acc	Quality Acc	Overall Acc	Under Seg	Over Seg	Overall Seg
Harana	0.744	0.743	0.651	0.722	0.747	0.649
Harana - no semi-CRF	0.732	0.715	0.634	0.678	0.740	0.639
Harana - no Attention Fusing	0.741	0.738	0.650	0.716	0.749	0.645
Harana - no Absence Score	0.743	0.746	0.643	0.719	0.748	0.650

Table 2: The result of ablation studies summarizing the effect of removing each proposed component of the model on both frame-level accuracy and segmentation quality.

Model	Root	Quality	Majmin	Overall
CRNN	0.735	0.714	0.865	0.634
frog	0.733	0.542	0.815	0.459
RuleSCRF	0.684	0.645	0.847	0.600
Harana	0.744	0.743	0.886	0.651

Table 3: The frame-level accuracy for different models.

Model	Under Seg	Over Seg	Overall
CRNN	0.681	0.738	0.639
frog	0.681	0.724	0.624
RuleSCRF	0.666	0.741	0.625
Harana	0.722	0.747	0.649

Table 4: The segmentation quality for different models.

5. RESULTS

5.1 Frame-Level Accuracy

Table 3 shows the result on frame-level accuracy. It can be seen that Harana outperforms the baseline models on all the measures. The large gap between Harana and the rule-based semi-CRF model demonstrates the value of a neural score function. Without a neural front-end, the rule-based model even has weaker performance than the plain CRNN. We also notice that frog has lower accuracy than the plain CRNN model. While the autoregressive decoding in frog could help enforce coherence between harmony components, it may require the full spectrum of the harmony components including key and degree. However, only root and quality were used in our experiments. Complete harmony information is difficult to collect so we believe Harana has a greater potential to leverage larger datasets in the future.

5.2 Segmentation Quality

As shown in Table 4, Harana provides improvement on segmentation quality compared to other models. Higher under-segmentation score of Harana means there are fewer missing boundaries in the estimation. Higher over-segmentation score shows that most detected boundaries are indeed true boundaries. An interesting observation is that the rule-based semi-CRF yields the most severe under-segmentation even though it is optimized on the segmentation boundaries. The reason for this might be that rule based-features are unable to clean noises such as the non-chordal notes and missing chordal notes in the input music but directly compute features from them. The noise in the features of short regions may be confused with the intrinsic noise of longer regions.

5.3 Ablation Studies

To show the effectiveness of each component of the architecture, we conduct additional ablation studies by removing each component. Table 2 summarizes the results.

We can see that the full architecture achieves the best result overall. Among the missing components, semi-CRF leads to the largest performance drop. That confirms semi-CRF is an indispensable component to capture boundary information in harmony analysis. The attention module, although also helpful, produces relatively smaller performance gain. It is expected because after the neural front-end, the frame-level estimations to be aggregated may be already harmonically coherent; The attention module only helps to focus on the most representative frames. The effect of removing the absence score is less significant. Without it, the quality accuracy and overall segmentation quality even slightly improved. The phenomenon could result from the more difficult training objective. Inactive pitch class activations of the input music are an extreme scenario of noisy harmonic information. More data and a larger neural front-end might be needed to fully leverage the advantage of the absence score [33].

6. CONCLUSIONS

In this paper, we proposed an automated approach for harmonic analysis based on neural semi-CRF to jointly segment the harmonic regions and predict the labels. We developed a neural encoder and an attention mechanism to replace the conventional rule-based score function. We further proposed an absence score to improve the model robustness to imperfect harmony profiles. Experiments showed that our proposed architecture improves the performance on both frame-level accuracy and segmentation quality. Although our experiments focused on music input of symbolic format, the architecture could be adapted to audio input by simple modifications on the neural front-end. One limitation of the semi-CRF architecture is that it has quadratic time complexity with respect to sequence length so it is difficult to train the model on very long sequences. To capture the long-term dependency of harmony progression, more efficient sequence modeling methods could be explored in the future.

ABSTRACT

Music Performance Analysis is based on the evaluation of performance parameters such as pitch, dynamics, timbre, tempo and timing. While timbre is the least specific parameter among these and is often only implicitly understood, prominent brass pedagogues have reported that the presence of excessive muscle tension and inefficiency in playing by a musician is reflected in the timbre quality of the sound produced. In this work, we explore the application of machine learning to automatically assess timbre quality in trumpet playing, given both its educational value and connection to performance quality. An extensive dataset consisting of more than 19,000 tones played by 110 trumpet players of different expertise has been collected. A subset of 1,481 tones from this dataset was labeled by eight professional graders on a scale of 1 to 4 based on the perceived efficiency of sound production. Statistical analysis is performed to identify the correlation among the assigned ratings by the expert graders. A Random Forest classifier is trained using the mode of the ratings and its accuracy and variability is assessed with respect to the variability in human graders as a reference. An analysis of the important discriminatory features identifies stability of spectral peaks as a critical factor in trumpet timbre quality.

1. INTRODUCTION

The significance of tone quality in brass musical instruments has attracted considerable attention due to its relevance in areas such as pedagogy and musical performance. Teaching aural discrimination skills of tone quality is indeed a major component of music training [1]. The emphasis placed on the development of good tone quality can be attributed to its close relationship with sound production efficiency. In brass instrument pedagogy, there is a

widely held belief that the most efficient sounds are perceived as rich and round, while less efficiently produced tones tend to sound strained and shrill [2–4]. This implies that a method that can accurately and consistently distinguish the perceived tone quality in a brass instrument may hold significant potential in pedagogical applications, providing guidance to beginning students on how to achieve greater efficiency in sound production. However, understanding factors that contribute to the timbral quality of trumpet sound remains an unsolved challenge thus far.

Playing a trumpet tone involves a complex interplay between the musician’s embouchure, oral cavity, and airflow [5]. It is a delicate balance in which even the slightest alteration in any component contributing to the creation of a tone can result in changes to the overall timbre [6]. The multi-variable interaction that contributes to the characterization of timbre makes defining its quality a challenging task [7].

Helmoltz was among the first to attempt providing insight into the audio properties related to the quality of a musical tone by proposing a direct relationship to the quantity and to the relative intensity of its constituent partials [8]. In an exploratory study using the trumpet as a case study, Madsen and Geringer identified the amplitude of the first overtone as a discriminatory feature between tones of differing sound quality [9]. Building on this finding, a subsequent perceptual study by Geringer and Worthy analyzed the tonal quality of the trumpet by altering the content of partials in the sound [10].

In recent years, the investigation of trumpet tone quality has emerged as an area of inquiry within the field of Music Information Retrieval. A pioneering study conducted by Knight et al. examined the potential of a model classifier to categorize trumpet tones into two, three, and seven classes [11]. This research assessed 56 single- and multi-dimensional audio features, as well as their correlations with human judgments, utilizing a dataset comprised of 239 individual sounds. Despite the relatively low accuracy of the resultant model, this foundational work has paved the way for subsequent advancements in the automatic assessment of brass tone quality, highlighting its potential in pedagogical applications.

A subsequent collaborative research project between

* Equal contribution

the Music Technology Group of Pompeu Fabra University (MTG-UPF) and KORG Inc. employed machine learning algorithms to evaluate various musical parameters of trumpet sounds, including timbre quality [12, 13]. To the best of our knowledge, this represents the most recent investigation in this domain. The researchers collected and analyzed a publicly accessible dataset containing 738 trumpet sounds. However, the findings revealed a weak correlation between the scores generated by the trained model and the rankings assigned by human evaluators, indicating significant room for improvement in the model’s performance. Limitations were also identified in relation to the reference dataset, which lacked diversity by utilizing sounds from only two graduated trumpet players, and in the proposed interface for implementation in pedagogical contexts [14].

The current study aims to provide a comprehensive exploration of this subject, incorporating a complete dataset of sampled sounds and expert-generated labels.¹ Section 2 describes dataset collection and preprocessing, while Section 3 presents the machine learning training, results and visualization based on the most important feature.

2. MATERIALS

The dataset employed for training the proposed model comprises auditory samples gathered by the first author at various music institutions and master classes throughout Europe before the start of his academic program at the host institution. In total, 110 distinct trumpet performers were recorded under varying acoustic conditions. To encompass the complete spectrum of sound production efficiency levels, individuals from diverse backgrounds were recorded, including students and instructors from amateur music schools, arts universities, orchestral musicians, and international jazz and classical soloists.

The same recording system was utilized across all data acquisition sessions, specifically the IM69D130 Shield2Go evaluation board developed by Infineon Technologies, which is equipped with two Infineon IM69D130 Micro-Electro-Mechanical Systems microphones. Such a microphone exhibits an Acoustic Overload Point of 130 dB, allowing it to capture loud audio signals such as those produced by a trumpet without distortion or saturation. Moreover, the microphone offers a sufficiently flat and extensive frequency response ranging from 20 Hz to 20 kHz, thereby covering the entire audible spectrum.

The selected evaluation board was connected to a Raspberry Pi 4 Model B and a Raspberry Pi Model 3B+ for recording. A sampling rate of 48 kHz and 32-bit depth were used for the acquisition of audio data. The subsequent section provides a detailed account of the recording methodology employed for audio data collection.

2.1 Dataset acquisition methodology

The data acquisition process involved inviting each musician into a room with a fairly low ambient noise level. A

microphone was positioned approximately 50 cm in front of the trumpet bell and 10 cm from its longitudinal axis. In most instances, a set of two microphones was employed concurrently to ensure data redundancy, mitigating the risk of data loss should a device malfunction occur during the recording session.

Participants were instructed to play isolated tones of approximately one-second duration over a chromatic scale ranging from E3 to B♭5 at three distinct dynamic levels: *piano*, *mezzoforte*, and *forte*, in their preferred sequence. Musicians utilized their personal instruments and mouthpieces and were not required to adhere to a reference pitch (e.g., A4 at 440 Hz) as timbral quality concerning sound production efficiency is anticipated to be independent of a reference pitch.

The inclusion of various dynamic levels aimed to enhance the dataset’s variability, as the timbre of brass instruments is significantly influenced by loudness [15]. A digital sound level meter was positioned adjacent to the microphone, providing real-time decibel level readings during the recording. Trumpet players were given indicative reference levels of 85 dB, 105 dB, and 115 dB, corresponding to the *piano*, *mezzoforte*, and *forte* dynamic levels, respectively.

Despite the specified guidelines, the dataset exhibits several inherent variabilities:

- The sustain duration of the tones ranged from 0.7 to 4 seconds.
- The chromatic scale’s range was contingent upon the performer’s skill level. Generally, less proficient musicians struggled to produce tones in the high register, in which case they were instructed to play up to their highest achievable note.
- For beginner musicians, playing a chromatic scale in front of a microphone proved challenging at times. Some participants opted to perform legato notes rather than separate tones.
- Less skilled musicians often experience difficulty in controlling the instrument’s dynamic range, resulting in the recommended dynamic levels being primarily adhered to by more proficient players.

During the recording sessions, the first author, who holds a degree in trumpet performance and has professional experience as a musician and instructor, assigned a preliminary grade of the overall sound production efficiency on a scale of 1 to 100 to each player. Figure 1 illustrates the distribution of assigned grades divided into four ranges (i.e., 0–25, 26–50, 51–75, and 75–100), demonstrating that a substantial number of players are represented in each category.

The dataset under examination was partitioned into discrete trumpet tones utilizing the *pyin vamp* plugin developed by Mauch and Dixon [16], yielding a collection of over 19,000 tones. Although the segmentation process demonstrated a degree of inaccuracy, with certain audio

¹The dataset can be accessed at: <https://github.com/PNinad/ISMIR2023>

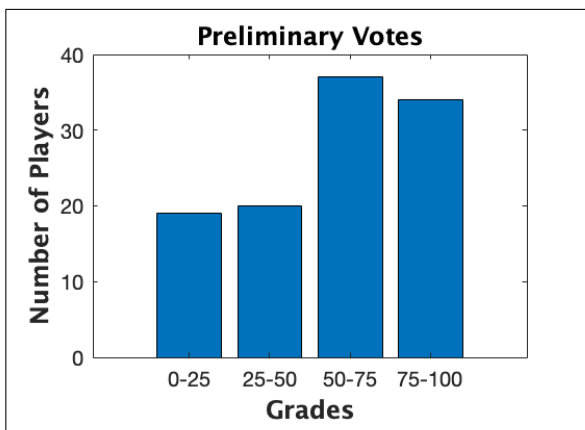

Figure 1. Distribution of recorded players according to the level of tone quality noted at the time of recording.

segments containing noise rather than trumpet tones, it nevertheless provided a satisfactory initial categorization of the data.

The following section outlines the methodology employed to prepare the dataset for label assignment by chosen evaluators.

2.2 Dataset preparation

Considering the approximate accuracy of the segmentation algorithm and the extensive nature of the overall dataset, it was decided to select a representative subset of the dataset for the manual examination of audio samples. To ensure that the whole range of tone quality is sufficiently represented, the subset was constructed of seventeen trumpet players such that five individuals had received a preliminary vote between 0–25 and four individuals with a grade between the other 3 ranges 26–50, 51–75, and 76–100 respectively. The first category was assigned one player more as the less experienced participants only partially cover the required chromatic scale, thus compensating for the lower representation of tones within this class. The selected subset encompassed 1,712 distinct trumpet tones.

It was decided to classify each tone into four categories based on their sound production efficiency, resulting in four classification levels: 1:poor, 2:fair, 3:good, and 4:excellent. This classification into four levels was employed with the intention of simplifying the label assignment process while retaining sufficient variability, as suggested by Wesolowski [17] and employed by Köktürk-Güzel et al. in a related research study [18].

The web interface shown in Figure 2 was subsequently developed to facilitate blind listening (i.e., without revealing the player’s identity) and label assignment for each tone. The first author listened to all 1,712 sounds in the subset under analysis through the interface and assigned a label to each tone. The "Not a note" button enabled tagging of erroneously segmented sound samples which were filtered out to yield a dataset 1,481 clean samples.

The assignment of sound production efficiency class through anonymous listening to the audio samples in random order facilitated the allocation of a grade on a note-

by-note basis, as opposed to providing an overall grade to the performance. This allowed for different grades to be assigned depending on the note if the level of sound efficiency varied along the chromatic scale. Additionally, the reliability of unbiased judgment could be assessed through a comparison with the preliminary grades assigned during the recording. The Spearman correlation coefficient between the two sets of grades was found to be 0.873 (P value<0.001), indicating the consistency of the author in assigning grades over time. This further indicates that players in general exhibit a consistent level of sound production efficiency along the chromatic scale.

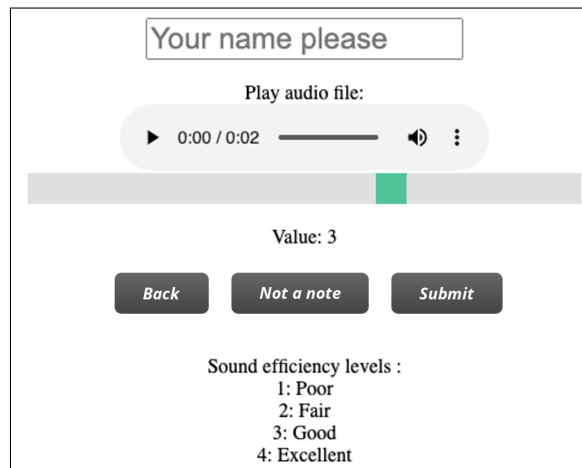

Figure 2. Interface for blind grading the trumpet tones.

2.3 Assessment labels

The cleaned dataset with 1,481 samples was subsequently presented to a panel of expert raters for evaluation via the described interface. A total of seven experts from different schools across Europe, North America and South America were chosen for the task. Among the raters, six were trumpet players, and one was a bass trombone player. All raters have professional experience as performers and/or teachers. This exploratory perceptual study was conducted online, with raters instructed to complete the task in a low-noise environment using professional headphones.

The rating sessions started with an introduction to the concept expressed by renowned brass instrument pedagogues, which asserts that rigidities in a trumpet player’s body result in inefficiencies in playing, manifesting as a forced and strained sound. In contrast, a high-quality sound indicates efficiency of the embouchure and breathing muscles. Audio samples demonstrating extreme cases of this idea were presented and each rater confirmed their understanding of the concept and their ability to discern sound production efficiency in trumpet sounds based solely on audio information.

The dataset of 1,481 samples was split into two parts with 100 and 1,381 tones respectively. The raters first graded each of the 100 samples in approximately 15 minutes. After a 5 minute break, additional samples, randomly selected from the remaining 1,381 samples were presented

for evaluation. The raters continued to assess the trumpet tones until they experienced fatigue or until 90 minutes had elapsed from the beginning of the experiment. Table 1 displays the number of audio samples rated by each grader. Grader 1 corresponds to the first author who assigned the ratings manually by listening to all 1,481 samples in the subdataset, as described in the previous section. The set of 100 sounds were chosen such that they were equally distributed across the four classes, as determined from the labels by the author, and were used to ascertain the level of inter-rater reliability.

The next section describes the statistical analysis implemented on the data thus collected.

Grader ID	Graded tones
Grader 1	100 + 1381
Grader 2	100 + 401
Grader 3	100 + 206
Grader 4	100 + 312
Grader 5	100 + 383
Grader 6	100 + 366
Grader 7	100 + 564
Grader 8	100 + 491

Table 1. Number of individual tones evaluated by each grader.

2.4 Data analysis

The inter-rater reliability was assessed using the subdataset containing 100 tones graded by all the experts. Table 2 presents the Spearman ρ correlation coefficients with the corresponding P values for each pair of evaluators. As depicted in the table, all P values, representing the likelihood of obtaining the same results by chance, are less than 0.05.

The reported Spearman correlation coefficients range from 0.237 to 0.701. Notably, pairs including Grader 8 (the sole non-trumpet-playing expert) exhibited significantly lower correlation coefficients than all other pairs, potentially suggesting the significance of employing experts whose primary instrument aligns with the instrument under analysis for tasks of this nature. Due to the substantial differences in the ratings relative to the other raters, Grader 8 was deemed an outlier, and their results were excluded from further consideration. This adjustment increased Spearman ρ coefficients from 0.496 to 0.701, indicating fairly strong agreement among the judges [19].

Subsequently, a confusion matrix was computed for each evaluator, comparing the ratings assigned by that specific grader to the most frequently occurring (i.e., statistical mode) value in the ratings assigned by the seven evaluators for that specific tone. Cases where the mode was uncertain on one value were eliminated, resulting in 87 overall tones. The first seven subplots of Figure 3 display the resulting confusion matrices for each grader and their respective accuracy values (average f1 scores).

The next section describes the description of a model trained on the data obtained with reference to the variability of human assessment.

3. METHODOLOGY AND RESULTS

3.1 Audio Preprocessing and Model Training

The dataset preparation process described in Section 2.2 yielded a clean dataset with the audio samples of 1,481 tones. As a preprocessing step, the sound samples were first normalized to have a maximum signal amplitude equal to one. White noise at -60 dB was then added to the normalized audio to overcome the numerical errors (division by zero) encountered during feature extraction, without significantly altering the original signal. The audio features for each tone were then extracted using the Extractor algorithm from the Essentia library [20]. To reduce the computational complexity, only the statistical aggregates of the audio features (e.g., mean, variance, and mean of derivative) were utilized. Rhythm-based features were excluded since they were not deemed suitable for a timbre classification task. A total of 1,230 features were thus extracted to represent each audio sample.

As a first step, a Random Forest (RF) Classifier [21] was trained using the extracted audio features and labels provided by Grader 1, since Grader 1 had annotated each of 1,481 samples in the dataset. When the model was trained using the full set of audio features, a mean accuracy score of 78% was obtained in the 10-fold cross-validation. Using the model based feature selection in scikit-learn, the top 256 features were identified from an RF-classifier model trained using a 75%-25% train-test split of the dataset. Using just the top 256 features for training, the mean accuracy for the 10-fold cross-validation improved to 81.37%. The model thus obtained was implemented in a pedagogical application in a concurrent publication by the authors [22].

To eliminate the bias introduced by using a single grader, it was assumed that the most frequent label given by the expert graders is the true label. Only samples with at least two votes were used and samples which had equal number of votes for two labels by the expert graders were assumed to be ambiguous and were discarded from the dataset. With this approach, out of the 1,381 samples, 871 samples were deemed unambiguous. Similarly, 87 out of the 100 samples were unambiguous. An accuracy score of 59% was obtained on the test set of 87 samples for the RF model trained using the 871 samples as training set. The confusion matrices on the test-set for the different graders and the RF classifier can be seen in the bottom right subplot of Figure 3. It can be observed that most of the confusion is between the adjacent classes. Since the audio samples in the adjacent classes are in fact more similar to each other than the other classes, the errors seem to be reasonable, for both the graders and the model. While an accuracy score of 59% appears low, it is within the range of accuracy scores (53%–72%) of the human expert graders and it demonstrates that the extracted audio features could be used to classify the audio samples based on timbre quality.

The trained model was tested in real time by trumpet players and on labeled datasets different from the one in this study [12] showing promising generalisability.

Grader Pair	Grader

3.2 Feature importance

Due to a slightly subjective nature of the problem, there is considerable variability in the labels by human experts. Hence, very high classification accuracy scores cannot be achieved even with sophisticated machine learning models. However, even with a moderately accurate classifier, analysis of the most important features could help to develop an intuitive understanding of good quality timbre in trumpet sounds.

One of the main reasons to choose the Random Forest Classifier algorithm was that it gives access to the importance of each feature in the classification task. The feature importance scores for the classification are available as a model property in the scikit-learn implementation of the Random Forest algorithm [23]. The top 20 observed features are listed in Table 3.

Many of the top features are based on the mean of the derivative ‘dmean’ and the mean of the double derivative ‘dmean2’, suggesting that the change in the

spectrum across time is a crucial factor in the perception of the timbre quality. Notably three of the top features namely `lowLevel.spectral_complexity.dmean`, `lowLevel.spectral_complexity.dmean2` and `lowLevel.spectral_complexity.dvar` are related to the time varying properties of the same underlying feature of spectral complexity.

A scatter plot of the `lowLevel.spectral_complexity.dmean` and `lowLevel.spectral_complexity.dmean2` features considering only the best and worst class samples is shown in Figure 4. It is apparent that just this pair of features is quite successful in discriminating between the best and worst samples. Since both features are statistical aggregates of the spectral complexity feature, the raw feature was explored to develop a visualization of the sound production efficiency as described in the following subsection.

3.3 Visualization based on Spectral Complexity

Spectral complexity is based on the number of peaks in the spectrum of a time window [24]. The Essentia implementation of this feature considers the spectral peaks only up

Audio feature	Score (%)
lowLevel.spectral_complexity.dmean	1.381
lowLevel.scvalleys.mean_5	1.182
lowLevel.spectral_complexity.dmean2	1.049

Figure 4. Scatter plot depicting the spectral complexity based features for best (blue) and worst (orange) class samples.

to 5 kHz. From the spectra of the collected dataset, the presence of harmonic peaks at frequencies higher than 5 kHz was evident. It was therefore decided to implement the spectral complexity considering the entire audible frequency range. To enhance peak detection accuracy, prior knowledge of the fundamental frequency ‘f0’ of the tone was utilized to search for spectral peaks exclusively in the vicinity of the integer multiples of the f0 frequency. For a normalized audio, peaks with signal energy less than -40dB were discarded to reduce noise. An FFT-bin mask was generated by assigning the value of one to the FFT bin if a peak was detected in it while all other bins were assigned a value of zero, thus generating a visualization to track the peaks across the analysis time windows.

Figure 5 shows the visualization for two representative sounds. It is evident that for sounds rated as excellent quality, the spectral peaks consistently lie in the same FFT-bin across time, leading to flat horizontal lines in the visualiza-

Figure 5. Visualization of the temporal evolution of spectral peaks for trumpet sounds rated as low-quality (top) and high-quality (bottom) timbre.

tion. Whereas for sounds rated as poor quality, the spectral peaks show unsteadiness, particularly at the higher harmonics, which leads to broken and wavy lines in the visualization. The total number of peaks could be more or less depending on the f0 frequency of the note and the loudness. However, it appears that the perception of timbre quality is correlated to the steadiness of the peaks rather than their total number. A real-time implementation of this visualization could offer invaluable feedback on the efficiency of sound production, greatly benefiting new trumpet students who are still developing their auditory skills.

4. CONCLUSIONS

In this paper, we introduced the importance of timbre quality in trumpet performance and pedagogy. With an aim to develop an automated tool for the assessment and visualization of trumpet tone quality, an extensive dataset of trumpet tones was collected and manually graded with the help of experts. Through the inter-grader analysis presented, it was shown that while there are some differences in timbre preferences, most experts generally concur in differentiating the different levels of trumpet tone quality.

Random Forest Classifier models trained using extracted audio features were found to have accuracy scores comparable to the accuracy scores of human experts. Features based on spectral complexity were observed to have very high importance in the models trained for the task of trumpet timbre discrimination.

A representation based on the harmonic peaks in the spectrum was developed to visualize the timbre quality. The proposed visualization suggests that the stability over time of spectral partials plays an important role in discriminating the timbre quality of trumpet sounds.

Future research aims to incorporate the developed model and visualization in a pedagogical application and assess its efficacy in music classrooms.

5. ETHICS STATEMENT

Ethical approval for the study, including consenting procedures, was granted by the Research Ethics Board Office of McGill University following the guidelines of the Canadian Tri-Council Policy Statement.

VISUAL OVERVIEWS FOR SHEET MUSIC STRUCTURE

ABSTRACT

We propose different methods for alternative representation and visual augmentation of sheet music that help users gain an overview of general structure, repeating patterns, and the similarity of segments. To this end, we explored mapping the overall similarity between sections or bars to colors. For these mappings, we use dimensionality reduction or clustering to assign similar segments to similar colors and vice versa. To provide a better overview, we further designed simplified music notation representations, including hierarchical and compressed encodings. These overviews allow users to display whole pieces more compactly on a single screen without clutter and to find and navigate to distant segments more quickly. Our preliminary evaluation with guitarists and tablature shows that our design supports users in tasks such as analyzing structure, finding repetitions, and determining the similarity of specific segments to others.

1. INTRODUCTION

Common music notation can be considered as a special visual encoding to convey music, including instructions on how to perform it. Despite its compactness and detailed information, a music sheet is hard to analyze for novice musicians [1]. Moreover, it contains lots of information that is hard to display at once without visual clutter or getting too small – getting an overview is tricky. When pieces contain repeating sections such as a chorus, much information is redundant. Even with abbreviations that denote repetitions, such as a double bar with colon, da capo, or al segno, a complex structure can lead to tedious navigation.

Recent work [1–3] strove to enrich notation to better convey music-theoretical information and patterns. In this paper, we instead focus on quickly gaining an overview of structures such as similarities and repetitions. This overview is meant to support learning, or teaching a music piece, as musicians often have to remember which segment of a piece they have to play when and how often, information that can be obscured in classical sheet music notation. According to the visualization principle “eyes beat mem-

ory” [4], we argue that the current notation leaves room for further optimization.

Toward this goal, we propose to visually enrich sheet music by mapping calculated similarities among segments of the sheet music, such as sections or bars (measures), to colors. To fit the notes of a whole piece onto a screen while remaining legible, we propose compact alternative encodings to common music notation that allow for overview and easier navigation without having to scroll or change pages. This work focuses on guitar tablature of Western music, which is easier to represent compactly and often features more repeating parts than other kinds of sheet music. However, we argue that our general method of mapping similarities to color can also help with other kinds of music. We conducted a preliminary qualitative evaluation through pair analytics with four guitarists. The results indicate that our design supports tasks such as summarizing structure, finding repetitions, and analyzing similarity.

In summary, we contribute 1) the exploration of novel representations of sheet music for easier overviews, specifically a method for mapping similarity among components of a music sheet to color, and 2) a preliminary pair analytics study with four guitarists. We further provide source code and a web app where users can try their own sheet music in MusicXML [5] at visvar.github.io/sheetmusic-overviews.

2. RELATED WORK

Similarity in music concerns many dimensions such as cognition, perception, tempo, pitch, and more. Therefore, existing metrics use different approaches, including a continuous representation of notes [6], a geometrical metric [7], shapes of curves [8], and a graph-based metric for harmony [9]. Janssen et al. [10] evaluated melodic similarity metrics using human annotators and a survey [11] defined eight criteria for symbolic melodic similarity. The overall aim of the above work is to query pieces in a database. In contrast, our work focuses on supporting the structural analysis of a single piece, by visualizing similarities within it. While our design allows integrating any metric, its main purpose is demonstrating how visualization can support sheet music analysis. We thus use a simpler symbolic metric to instantiate our design.

There is a broad range of music-related visualization [12, 13], including structure [14–22]. However, some visual encodings, such as one based on Tonnetz [21], re-

quire knowledge of music theory. Similar to our approach, *MoshViz* [17] focuses on visual analysis in an overview-detail fashion, but without considering perceptual or cognitive aspects. Our design allows encoding any similarity metric (mathematical or perceptual) with colors, to make sheet music easier to understand. Closest to our work is a structure visualization that uses dimensionality reduction (DR) to map audio features to color [18], which inspired us to design a similar mapping for sheet music.

Augmented sheet music adds visual components to common music notation to increase expressiveness. Related work augments a music piece with radial note histograms, to facilitate analyzing harmonic patterns [2], or visualizes rhythm through color-coded sunbursts [1]. Miller et al. [3] combined both approaches, but do not address supporting performance preparation tasks. Only little research supports instrument learning and composition. Bunks et al. [23] use color for reference keys on a tabular layout to support jazz improvisation. Others augment sheet music with lines and ellipses to support error detection in composition [24] or pianists in identifying mistakes while practicing [25, 26]. In this work, we also support learning by aiding music reading before and during practice.

3. DESIGN

We first introduce the tasks we want to support with our approach. Then, we describe how we compute similarities and map them to colors and how we represent sheet music visually (Figure 1).

3.1 User Tasks

Our overall goal is to improve the efficiency of reading sheet music, by sparing users the need to search for certain segments or memorize patterns. We want to reveal potentially interesting patterns that are hard to infer from the bare sheet music itself but could be helpful for better understanding or practicing a piece. More specifically, we want to support the following tasks: (T_1) understand the *overall structure* of a piece, (T_2) detect repetitions, which means to spot *where* something repeats *how often*, and detect *repetitions nested within* repetitions, (T_3) *compare* multiple segments regarding their similarity.

3.2 Color Mappings

Similarity metrics. Our approach works with any metric that takes notes and returns a scalar similarity score. We compare non-overlapping segments of the piece, which can be bars, pre-defined sections read from the MusicXML file, or the result of an automatic segmentation (the latter is not implemented).

In our related work section, we discussed existing similarity metrics for symbolic music. Some of these metrics do not support polyphony or require complete scores or additional annotations (such as chords) or assumptions on musical meaning. Metrics that are based on western tonal harmony [27, 28] would also not generalize to various cultures and genres. Therefore, we designed the following simple but robust algorithm: First, the notes of a segment

are sorted by their start time and those with equal start time by pitch ascending. Mapping each note to its pitch then results in one sequence of integers for each segment. We then compute a similarity matrix by calculating the *Levenshtein distance* [29] for all possible pairs of segments, equals the minimum number of pitches one would have to insert, delete, or replace, to transform the first sequence into the second.

We further compute similarities between all sets of notes that have the same start time, which we refer to as harmonies. For these sets, we only use the notes' pitch class (disregarding octaves) and compute the *Jaccard index* [30], which equals the ratio of intersection over union.

Mapping. Once we have a similarity matrix, we can create a color mapping that respects these similarities. We explored three alternative methods that use either a one-to-many comparison, dimensionality reduction, or hierarchical clustering. Figure 2 shows an example for our similarity-based color mapping, Figure 3 summarizes our different mapping strategies.

The first method colors bars by their similarity to a selected bar. This selection is made by the user or automatically when playing the piece, where the currently played bar is selected. To obtain colors, we linearly map the similarities to a color scale. Another mode only colors bars that the metric considers identical to the selected one, allowing users to quickly spot where and how often it repeats.

Our second method uses dimensionality reduction (DR), a method commonly used to transform data from a high-dimensional space to a lower-dimensional one. Usually, the target space is two- or three-dimensional, such that data points can be shown on a screen. We instead project onto a one-dimensional space that we can then linearly map to a color scale. As we do not have concrete positions in a space, but only the similarities between them, we chose *multi-dimensional scaling* (MDS) [31] that accepts a similarity matrix as input. Furthermore, MDS optimizes the computed projection to preserve these similarities, leading to a coloring optimized for these.

As an alternative to MDS, we designed a method that clusters similar segments together and then assigns each cluster one color such that similar clusters have similar colors. Using our similarity matrix, we compute *hierarchical agglomerative clustering*, which gives us a binary tree. We then sort the tree's leaves from left to right, as leaves that are closer together are more similar, and map them in this order to a color scale. Compared to the above method using MDS, the resulting colors are easier to distinguish but represent similarities less accurately. Using a similarity threshold, users can steer the number of clusters and therefore colors, to choose a trade-off between detail and overview.

Color scales. Research on perception proposed a range of color scales specifically designed for visualization. Since there are different irreconcilable goals, no scale is appropriate for all tasks. While multi-hue scales such as rainbows have been criticized [32], they have been shown to work well for some circumstances [33–35]. For users

Figure 2: Example of similarity-based color mappings. *Top:* rectangles represent all bars of a piece, from left to right in the order they occur. *Bottom:* a color scale. Curves connect each bar to its color. In this figure, the curves of a single color are highlighted through a stronger opacity to show how they connect to identical bars.

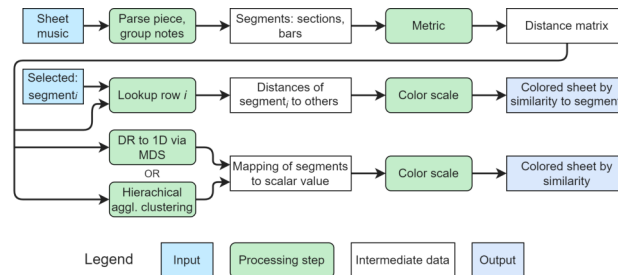

Figure 3: We compute similarity-based colors for extracted segments via direct comparison, dimensionality reduction, or clustering. A *segment* can be any sequence of notes in the piece, such as a bar or a pre-defined section. The *selected segment* is chosen by the user to compare it to all others.

with a color vision deficiency, scales with fewer hues and, therefore, less discernible colors can be used, such as *cividis* [36]. When color is used to compare different values or intervals, a color scale needs to accurately represent similarities between values. For this task, single-hue scales or interpolations between two hues are appropriate but further reduce the number of discernible colors. Although the number of distinguishable colors is small, there are enough for our use case, as the number of different segments in a piece is limited. Since colors are distributed by similarity, indistinguishable colors should only be assigned to very similar segments. To accommodate different user needs, we choose a broad multi-hue scale (spectral) as default but also provide more accessible ones; for direct comparison, we choose a single hue scale (blues) (Figure 4).

Figure 4: Some of the included color scales, taken from D^3 [37]. The choice depends on the current task and individual limitations of the user's color vision.

Figure 5: A pattern of repetitions with different endings. Bar 16 is colored blue, 24 and 40 are the same yellow, and bar 32 is green.

3.3 Visual Encodings

Layout enrichment for common music notation. We designed several visual encodings to address different tasks and reveal different kinds of patterns. The most straightforward encoding is to display the full sheet music as the common notation that is familiar to musicians and represents the complete information. We enrich this display by adding colored, semi-transparent rectangles on top of the segments, for example, one for each bar (Figure 5). The reduced opacity makes colors brighter than in other views but improves the readability of the notation. This coloring helps more quickly see where a bar repeats (T_2), as the user only has to compare bars with similar colors (T_3). Even when two different bars were assigned similar colors, this process allows for ruling out many others. This encoding suffers from the same limitations as non-colored sheet music. Due to its highly detailed nature, fitting the complete piece on the screen at once would lead to small and illegible visuals. Therefore, we designed simplified, filtered, and compressed alternatives, which we explain in the following paragraphs.

Note display. In most views, we represent notes by blocks that are positioned horizontally by start time and have a width proportional to the note’s duration, to visually indicate timing and rhythm (Figure 6). The first mode displays the notes as triangles in a piano roll, allowing it to represent music for any instrument, but less readable than other encodings. A second mode displays guitar tablature, where each row stands for one string, and the third adds fret numbers for more detail. We focus primarily on guitar tablature in this work, but new encodings resembling other instruments’ common notations could extend our approach. Depending on their size, our encodings become hard to read but still reveal coarse patterns more clearly than detailed notation. In order to show the whole piece at once (T_1), without filtering or compression, we display the full score with the above encodings (Figure 1g).

Hierarchy. Most music pieces have a hierarchical structure in the form of sections such as verse and chorus, spanning multiple bars, each with none to a few notes, which might be grouped in harmonies (notes played at the same time). We visualize this structure as a tree, where users can select a node to show only its children in the level below (Figure 1e). This representation supports gaining an

Figure 6: Note display: a) Piano rolls can represent any music but lack additional information. b, c) Tablature either simplified or with fret numbers. Notes are drawn in black or white depending on the background’s luminosity.

overview (T_1) and allows navigating the sheet music more conveniently. The colors are level-specific, such that they only represent similarities within, not between, the levels. Notes have their own color map that is not based on similarity but still allows to spot repetitions or patterns such as sequences of increasing pitch (T_2).

Compressed multi-level repetitions. Music pieces might have another hierarchical structure regarding *repetitions* when a repeating segment contains repeating sub-segments ($T_{1,2}$). Similar to data compression, this allows us to create a more compact representation, by only displaying a repeating segment once and annotating it with its number of repetitions. Doing this recursively results in a tree where each leaf is a bar of the music piece, and each inner node contains the following information: A pre-fix child, a repeated child with its repetition count, and a post-fix child, where pre- and post-fix can be empty. The visual encoding we chose for this data structure uses our compact note encoding (Figure 6) for the leaves and brackets for the inner nodes (Figure 7). Numbers above the bars denote the index of their first occurrence, allowing to spot recurring ones that are farther apart.

Figure 7: Our compressed view shows repetitions as nested blocks (cut). Note, that bar 51 appears two times, as it equals bar 53.

Workflow and interaction. We envision musicians using our interface primarily while learning a new piece, where they first get an overview and then take a closer look at the detailed sheet music. During navigation, reading, and playing, they could use overviews as ‘minimaps’ that provide context for what they are currently focusing on. As all views are linked, clicking on a bar in any view allows users to highlight or jump to a certain bar in all other views.

4. EVALUATION

We chose a pair analytics setup over a comparative user study, as most related work focuses on different tasks or data, which does not allow fair comparison. Furthermore,

instead of quantitative usability ratings and time measurements, we were more interested in qualitative feedback on *how* guitarists would use our design and *what limitations* they encounter. In pair analytics [38], designers and participants collaboratively analyze the participants' data, allowing designers to evaluate a design without needing to teach participants how to use it, saving them time and ensuring they use all features appropriately.

Our participants (P1–P4) have experience with reading guitar tablature. P1 has played guitar for 15 years and regularly teaches it and P2 has played drums for 5 years and guitar occasionally. P3 and P4 have played guitar for 16 and 12 years. P1 and P3 have full color vision, P2 and P4 have a slight red-green deficiency. All but P3 were familiar with visualization. We met with each participant for roughly 1.5 hours. After an introduction to our interface, we looked at guitar tablature of their choice together, encouraging them to use different features and think aloud.

Our participants found the coloring generally helpful: *"I have played classical pieces with 8 or 12 pages ... you searched, with your teacher, made annotations with a pen ... 'here it's that part again' ... if it's only black-on-white, you're blind at some point"* (P3). They were able to detect various patterns: *"the color indicates a new segment"* (P1) (T₁), *"always two bars one note, two bars the other note, ..."* (P1) (Figure 8). One interesting example was a pattern where the same segment was repeated four times, with a different ending each time, except for the fourth that equals the second (Figure 5, T_{2,3}).

Figure 8: A simple alternating pattern with bars that repeat as AABB multiple times.

In some cases, our current similarity metric did not work well: *"here, I'm sure it's different, but the color is not quite different ... if you check the color carefully, I think you can see it"* (P1). We proposed coloring annotated sections of the sheet music by their similarity: *"That is already very useful, because ... when I'm [teaching] and want to show segments, then I always have to mark them by hand. This is doing it for me"* (P1). While we currently colorize either by section or bar, P3 suggested alternatively coloring by sequences of bars that occur together multiple times, such as riffs or motifs. Interestingly, our coloring allows users to quickly guess the effort needed to learn a piece: *"The colors show what you already learned"* (P3), *"For me it looks like I practice this purple bar ... and then I practice these yellow and green bars and then I can play 90 percent of the song"* (P1) (T_{1,2}). P4 suggested ignoring bars with only a single note or chord when coloring, as these are less interesting. Instead, they proposed coloring differently transposed versions of the same pattern more similarly and allowing users to manually adjust the color of a set of identical bars.

We also compared coloring via DR versus via cluster-

ing. When trying clustering, P3 first pondered *"I think [coloring via clustering] is easier to understand ... as you can really see that it's different"* but then concluded that *"it's difficult, both have pros and cons ... now if I would search [by color], it would be more difficult to spot"* (T_{2,3}). P4 suggested to additionally vary the color's brightness for different segments in the same cluster, to also reveal similarity within clusters (T₃).

Most patterns were visible with all color scales, although less clearly with those using fewer hues, so users with color vision deficiencies can also benefit from our design. Even though P4 has a slight red-green deficiency, they wanted to use the default *spectral* scale for most of the study. When trying out other scales, they told us that it indeed makes a good default, as it has fewer hues than rainbow scales. P4 further preferred *viridis* over *cividis*: *"here I see better"*. When turning of colors, P3 was astonished: *"here you see how white it is! When looking at colors for so long, you see for the first time how ugly white it is"*.

The simplified and full tablature encodings still reveal characteristics: *"These are power chords, right?"* (P2), *"This is a power chord on the second fret ... and that should be A minor"* (P3). For our hierarchy view, P4 found that *"the tab encoding doesn't help much, the simplified tab and piano roll work much better"*. Especially, since with the piano roll *"you can see well which bars have similar notes"* (P4) (T₃).

In our hierarchy view, clicking on different sections allows users to quickly compare them: *"Main riff and verse is almost the same, it's labeled as 'main riff' because it is ... without singing"* (P1) (T₃). This also shows a drawback of sheet music, where repetition signs often apply for all instruments at once, so if one repeats and another does not, the first instrument's notes will show up redundant. During the comparison, we found that P1 labeled the sections incorrectly, as one had a few more bars that actually belonged to the following section: *"we found that we labeled it wrong, that's good!"* (P1) (T₃). Switching between different sections allows comparing them: *"here's again a verse, but a little different ... back there, this bar is repeated ... this chorus is much longer"* (P3) (T_{2,3}). During our study with P4, we saw that a whole bar consisted of almost only the note E, as indicated by identical color, except for a single note with different color – *"I also wouldn't have noticed that [without color]"* (P4). As we only support highlighting sections and bars for now, P3 missed being able to click on single harmonies and notes to highlight them in other views.

The compressed encoding (Figure 7) was P1's favorite: *"This is the feature I'm most excited about for showing people the song structure because this is something I just can't do with a [music notation software]"* (T₁). For playing a song with students where each plays a different instrument of the piece, it *"would be great if everyone would have something like this"* to have a compact summary of the part they should play. Our participants proposed features we could add to this view, such as reducing or disabling nested repetitions: P1 found *"it would*

Figure 9: Our algorithm might not create the same structure as a musician: The sequence 2, 3, 2, 5 appears twice in a row, but since the following bars of the second appearance form a longer repetition, the sequence was included there instead.

be great if you had the option to simplify it” and P2 suggested adding a slider for the compression level. They also told us that this view could be extended to support annotation: “That would be great, to be able to go here and annotate some things” (P1). Our compression sometimes leads to unexpected results as it tries to find the longest repetitions, which might not be how musicians would compress a piece: “I would expect that this is in here two times, but somehow it’s here – it makes sense, it’s just two different ways of describing it” (P1) (Figure 9). P3 and P4 did not consider the compressed view useful (“I would not use compressed much, maybe once when first looking at a new song” (P3)) and P4 proposed merging it with the compact view by optionally drawing repeated segments only once with the brackets used in this view.

As our compact sheet music view shows the whole piece at once, it allows users to spot global patterns, such as how often a bar appears ($T_{1,2}$): “The compact view shows how things repeat” (P4), “If you go here and go for [the color mode] ‘Identical’, you can see that there is a lot of this” (P1). P4 wished for an alignment, to have repeating patterns exactly below each other: “it could auto-align it for me”. We then asked what they think about manually inserting line breaks, whereto P4 responded: “this would be the most important to me – if this should help me learn or read or play, I have to be able to customize and save it”.

When asked for general feedback, P1 told us they “like it a lot, because it’s always hard to see what is similar to something else ... I think it’s very important that you [know] not just what is played, but also if there is a connection to other segments” ($T_{1,2,3}$). P1 wished to be able to directly compare bars or sections (T_3): “That would be great if you could select two and then see the difference because I always click [back and forth]”.

When asked for use cases, our participants told us they would use our interface for learning, for example by playing along. Both P3 and P4 further imagined using our compact view as a cheat sheet during a performance: “[For songs with chords and simpler rhythm] you could print this and give it to someone ... and they could play the song ... or you use a tablet” (P3). P4 hid all views but tracks and compact, thereby maximizing the latter: “like this, I see the whole song at once ... convenient as a memory aid. Assuming I know the song already ... I see how often I have to

play everything” ($T_{1,2}$). As another use case, P4 wished to be able to see multiple instruments at once to be able to compare them visually.

5. LIMITATIONS AND DISCUSSION

We mainly focus on guitar tablature, which is easier to represent compactly and often features more repeating segments than other kinds of sheet music. However, we argue that our general method of mapping similarities to color can also help with other kinds of music. With new, specialized similarity metrics and note encodings, our approach could support non-western kinds and even music without discrete notes, as long as a piece can be segmented. Our example design for guitar tablature and with a simple similarity metric allowed us to stay within a reasonable scope and matched our own musical expertise.

Human color vision is limited, even more with color vision deficiencies. Our approach can add value compared to non-colored sheet music for everyone, although accessible color scales reveal less detail. In our study, some patterns were clearly visible while some were harder to spot – still, they were easier to spot than without any color. Coloring by similarity works well for pieces with a few different segments that are repeated, as fewer colors are necessary, but will not work as well for others.

As our current approach depends on dimensionality reduction and clustering, it inherits the limitation of these techniques, such as distortion and artifacts. We chose MDS and hierarchical agglomerative clustering to preserve similarities as well as possible, but other algorithms or approaches might further reduce these limitations.

In our current interface, the participants missed being able to directly compare two selections of bars, align bars automatically or through line breaks, and assign custom colors and labels. Our evaluation only included four participants. While such a number is typical for pair analytics, real-world acceptance can only be evaluated through longitudinal field studies, where a larger number of users regularly use a product in their daily life.

6. CONCLUSION

We designed multiple methods to ease the detection of repeating structures in sheet music. Our evaluation provided a first qualitative indication of the effectiveness of our approach. Therefore, we are confident that extensions to our design can turn our work into a helpful tool for musicians.

Future work includes further similarity metrics and visual encodings better suited for different tasks, sheet music characteristics, instruments, and music genres. Adding labels and exporting them would allow musicians and teachers to save and share their results. Showing multiple instruments of a piece at once would allow comparing them, for example, to quickly see where two guitars play similar notes. We plan to let more musicians actively use our design during learning, playing, and teaching over months to test real-world usage and acceptance longitudinally.

PASSAGE SUMMARIZATION WITH RECURRENT MODELS FOR AUDIO – SHEET MUSIC RETRIEVAL

ABSTRACT

Many applications of cross-modal music retrieval are related to connecting sheet music images to audio recordings. A typical and recent approach to this is to learn, via deep neural networks, a joint embedding space that correlates short fixed-size snippets of audio and sheet music by means of an appropriate similarity structure. However, two challenges that arise out of this strategy are the requirement of strongly aligned data to train the networks, and the inherent discrepancies of musical content between audio and sheet music snippets caused by local and global tempo differences. In this paper, we address these two shortcomings by designing a cross-modal recurrent network that learns joint embeddings that can summarize longer passages of corresponding audio and sheet music. The benefits of our method are that it only requires weakly aligned audio – sheet music pairs, as well as that the recurrent network handles the non-linearities caused by tempo variations between audio and sheet music. We conduct a number of experiments on synthetic and real piano data and scores, showing that our proposed recurrent method leads to more accurate retrieval in all possible configurations.

1. INTRODUCTION

The abundance of music-related content in various digital formats, including studio and live audio recordings, scanned sheet music, and metadata, among others, calls for efficient technologies for cross-linking between documents of different modalities. In this work, we explore a cross-modal task referred to as audio – sheet music passage retrieval. We define it as follows: given an audio fragment as a query, search within an image database and retrieve the corresponding sheet music passage; or vice versa, find the appropriate recording fragment given a query in the form of some snippet of (scanned) sheet music.

A fundamental step in audio–sheet music retrieval concerns defining a suitable shared representation that permits the comparison between items of different modalities

Figure 1: Distribution of system durations in around 40,000 examples from the MSMD. More than 25% of the passages are longer than ten seconds.

in a convenient and effective way. The conventional approaches for linking audio recordings to their respective printed scores are based on handcrafted mid-level representations [1, 2]. These are usually pitch-class profiles, like chroma-based features [3,4], symbolic fingerprints [5], or the bootleg score [6, 7], which is a coarse mid-level codification of the main note-heads in a sheet music image. However extracting such representations requires a series of pre-processing stages that are prone to errors, for example optical music recognition on the sheet music side [8–10], and automatic music transcription on the audio part [11–13].

A promising approach [14, 15] has been proposed to eliminate these problematic pre-processing steps by learning a shared low-dimensional embedding space directly from audio recordings and printed scores. This is achieved by optimizing a cross-modal convolutional network (CNN) to project short snippets of audio and sheet music onto a latent space, in which the cosine distances between semantically related snippets are minimized, whereas non-related items of either modality are projected far from each other. Then the retrieval procedure is reduced to simple nearest-neighbour search in the shared embedding space, which is a simple and fast algorithm.

A first limitation of this strategy relates to its supervised nature: it requires strongly-aligned data in order to generate matching audio–sheet snippet pairs for training, which means fine-grained mappings between note onsets and corresponding note positions in the score. Obtaining such annotations is tedious and time-consuming, and also

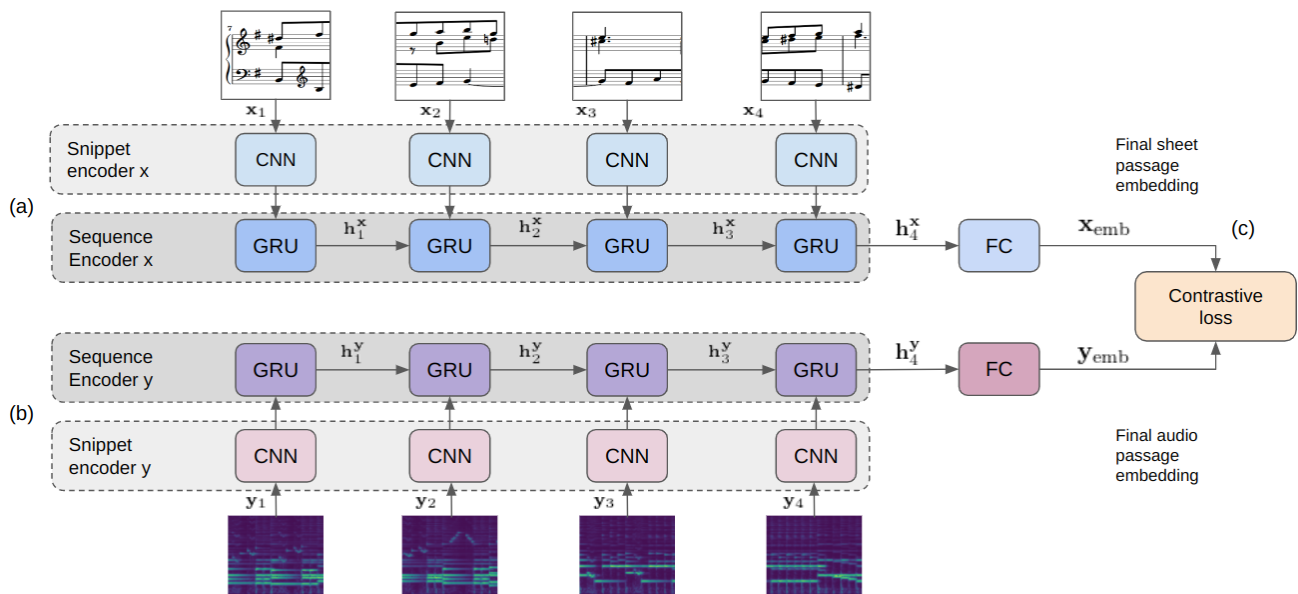

Figure 2: Diagram of the proposed network. Two independent pathways are trained to encode sheet music (a) and audio (b) passages by minimizing a contrastive loss function (c).

requires specialized annotators with musical training. As a result, embedding learning approaches have been trained with synthetic data, in which recordings, sheet music images, and their respective alignments are rendered from symbolic scores. This leads to poor generalization in scenarios with real music data, as shown in [16].

Moreover, the snippets in both modalities have to be fixed in size, meaning that the amount of actual musical content in the fragments can vary considerably depending on note durations and the tempo in which the piece is played. For example, a sheet excerpt with longer notes played slowly would correspond to a considerably larger duration in audio than one with short notes and a faster tempo. This leads to generalization problems caused by differences between what the model sees during training and test time; [17] attempted to address this limitation by introducing a soft-attention mechanism to the network.

In this paper we address the two aforementioned limitations by proposing a recurrent cross-modal network that learns compact, fixed-size representations from longer variable-length fragments of audio and sheet music. By removing the fixed-size fragment constraint, we can adjust the lengths of fragments during training so that cross-modal pairs can span the same music content, leading to a more robust representation. Moreover, by operating with longer music passages, it is possible to rely solely on weakly-annotated data for training, since we now require only the starting and ending positions of longer-context music fragments within music documents, in order to extract audio-sheet passages to prepare a train set. This is a remarkable advantage compared for example to other approaches based on [14], where fine-detailed alignments are indispensable to generate short audio-sheet snippet pairs.

The rest of the paper is structured as follows. In Section 2 we describe the model proposed to learn joint repre-

sentations from cross-modal passages. Section 3 presents a series of experiments on artificial and real data and Section 4 summarizes and concludes the work.

2. AUDIO-SHEET PASSAGE RETRIEVAL

For the purposes of this paper, and in order to be able to use our annotated corpora for the experiments, we define a "passage" as the musical content corresponding to one line of sheet music (also known as a "system"). System-level annotation of scores are much easier to come by than note-precise score-recording alignments, making it relatively easy to compile large collections of training data for our approach. Our definition of passages resembles that of "musical themes", which has been used under a cross-modal retrieval scenario with symbolic queries in a number of previous works [18, 19]. To illustrate the temporal discrepancies between passages, we show in Figure 1 the distribution of time duration of the systems from all pieces of the MSMD dataset [14] (later we will elaborate more on this database). In this dataset, we observe that systems can cover from less than five to more than 25 seconds of musical audio.

This important temporal aspect motivates us to propose the network depicted in Figure 2 to learn a common latent representation from pairs of audio-sheet passages. The architecture has two independent recurrent-convolutional pathways, which are responsible for encoding sheet music (Figure 2a) and audio (Figure 2b) passages. The key component of this approach is the introduction of two recurrent layers that, inspired by traditional sequence-to-sequence models [22], are trained to summarize a variable-length sequences into context vectors, that we conveniently refer to as embedding vectors.

Defining a pair of corresponding passages in the form of image (sheet music) and log-magnitude spectro-

Audio CNN encoder input: 92×20	Sheet-Image CNN encoder input: 160×180

Table 1: Overview of the two convolutinal encoders. Each side is responsible for their respective modality. Conv(3, pad-1)-24: 3×3 convolution, 24 feature maps and zero-padding of 1. BN: Batch normalization [20]. We use ELU activation functions [21] after all convolutional and fully-connected layers.

gram (audio) as \mathbf{X} and \mathbf{Y} , respectively, two sequences $(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N)$ and $(\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_M)$ are generated by sequentially cutting out short snippets from \mathbf{X} and \mathbf{Y} . The shapes of the short sheet and audio snippets are respectively 160×180 (pixels)¹ and 92×20 (frequency bins \times frames), which corresponds to one second of audio. After that, each individual snippet is encoded by a VGG-style CNN [23] into a 32-dimensional vector, as shown in Figure 2, generating two sequences of encoded snippets, one for the audio passage, and the other for the sheet passage (note that each modality has its own dedicated CNN encoder). The architecture of the CNN encoders are detailed in Table 1.

Then each sequence is fed to a recurrent layer in order to learn the spatial and temporal relations between subsequent snippets, which are inherent in music. After experimenting with two typical simple recurrent layers, namely long short-term memory cells (LSTM) [24] and gated recurrent units (GRU) [25], we observed on average better results with GRUs, and we decided for the latter for our architecture. Each of the two GRUs is designed with 128 hidden units, where the hidden state of each GRU after the last step is the context vector that summarizes the passages. Finally a fully connected layer (FC) is applied over each context vector, in order to encode the final passage embeddings $(\mathbf{x}_{\text{emb}}, \mathbf{y}_{\text{emb}})$ with the desired dimension.

During training, a triplet (contrastive) loss function [26] is used to minimize the distances between embeddings from corresponding passages of audio and sheet music and maximize the distance between non-corresponding ones. Defining $d(\cdot)$ as the cosine distance, the loss function is given by:

$$\mathcal{L} = \sum_{k=1}^K \max \left\{ 0, \alpha + d(\mathbf{x}_{\text{emb}}, \mathbf{y}_{\text{emb}}) - d(\mathbf{x}_{\text{emb}}, \mathbf{y}_{\text{emb}}^k) \right\}, \quad (1)$$

where $\mathbf{y}_{\text{emb}}^k$ for $k \in 1, 2, \dots, K$ are contrastive (negative) examples from K non-matching passages in the same

training mini-batch. This contrastive loss is applied to all $(\mathbf{x}_{\text{emb}}, \mathbf{y}_{\text{emb}})$ pairs within each mini-batch iteration. The margin parameter $\alpha \in \mathbb{R}_+$, in combination with the $\max\{\cdot\}$ function, penalizes matching snippets that were poorly embedded.

For the sake of simplicity, we leave the remaining details concerning the design of the networks, such as learning hyper-parameters, to our repository where our method will be made publicly available,² as well as the trained models derived in this work.

3. EXPERIMENTS

In this section we conduct experiments on different audio-sheet music scenarios. We first elaborate on the main dataset used for training and evaluation and define the steps of the passage retrieval task. Then we select four experiment setups and present the results.

We train our models with the Multi-Modal Sheet Music Dataset (MSMD) [14], which is a collection of classical piano pieces with multifaceted data, including score sheets (PDF) engraved via Lilypond³ and corresponding audio recordings rendered from MIDI with several types of piano soundfonts. With over 400 pieces from over 50 composers, including Bach, Beethoven and Schubert, and covering more than 15 hours of audio, the MSMD has audio-sheet music alignments which allow us to obtain corresponding cross-modal pairs of musical passages. From the MSMD we were able to derive roughly 5,000 audio-sheet passages for training, which is scaled up to around 40,000 different pairs after data augmentation: audios are re-rendered with different soundfonts and have their tempo changed between 90% and 110%. Then we generate a test set of 534 pairs from a separate set of music pieces, that were rendered with a soundfont that was not seen during training. Later, in 3.2, we will also consider real scanned scores and real audio recordings.

To perform cross-modal passage retrieval, we first embed all audio-sheet pairs in the shared space using our trained model depicted in Figure 2. Then the retrieval is conducted by using the cosine distance and nearest-neighbor search within the space. For example, in case of using an audio passage as a query to find the appropriate sheet music fragment, the pairwise cosine distances between the query embedding and all the sheet music passage embeddings are computed. Finally, the retrieval results are obtained by means of a ranked list through sorting the distances in ascending order.

As for evaluation metrics, we look at the *Recall@k* ($R@k$), *Mean Reciprocal Rank* (MRR) and the *Median Rank* (MR). The $R@k$ measures the ratio of queries which were correctly retrieved within the top k results. The MRR is defined as the average value of the reciprocal rank over all queries. MR is the median position of the correct match in the ranked list.

¹In our approach, all sheet music pages are initially re-scaled to a 1181×835 resolution

³<http://www.lilypond.org>

Figure 3: Mean Reciprocal Rank (MRR) for different embedding dimensions, evaluated in both search directions.

3.1 Experiment 1: Embedding dimension

In the first round of experiments, we investigate the effect of the final embedding dimension in the retrieval task. We consider the values in $\{16, 32, 64, 128, 256, 512, 1024\}$ and train the model of Figure 2 with the same hyperparameters. Then we perform the retrieval task in both search directions: audio-to-sheet music (A2S) and sheet music-to-audio (S2A).

Figure 3 presents the MRR of the snippet retrieval results evaluated on the 534 audio-sheet music passage pairs of the MSMD testset. A first and straightforward observation is that in all cases the S2A direction indicates better retrieval quality. We observe the performance increasing together with the embedding dimensionality until it stagnates at 64-D, and the MRR does not improve on average for higher-dimensional embeddings. For this reason, we select the model that generates 64-dimensional embeddings as the best one, which will be evaluated more thoroughly in the next experiments.

3.2 Experiment 2: Real data and improved models

In this section, we conduct an extensive series of experiments comparing our proposed recurrent network and some improved models thereof with baseline methods, and extend the evaluation to real-world piano data.

Given that our training data are entirely synthetic, we wish to investigate the generalization of our models from synthetic to real data. To this end, we evaluate on three datasets: on a (1) fully artificial one, and on datasets consisting (2) partially and (3) entirely of real data. For (1) we use the test split of MSMD and for (2) and (3) we combine the Zeilinger and Magaloff Corpora [27] with a collection of commercial recordings and scanned scores that we have access to. These data account for more than a thousand pages of sheet music scans with mappings to both MIDI files and over 20 hours of classical piano recordings. Then, besides the MSMD (I), we define two additional evaluation sets: (II) *RealScores_Synth*: a partially real set, with *scanned* (real) scores of around 300 pieces aligned to *synthesized* MIDI recordings. And (III) *RealScores_Rec*: an entirely real set, with *scanned* (real) scores of around 200

pieces and their corresponding *real audio* recordings.

As a baseline (BL), we implement the method from [14] and adapt their short-snippet-voting strategy to identify and retrieve entire music recordings and printed scores so it can operate with passages.⁴ In essence, short snippets are sequentially cut out from a passage query and embedded, and are compared to all embedded snippets which were selected from passages in a search dataset of the counterpart modality, resulting in a ranked list based on the cosine distance for each passage snippet. Then the individual ranked lists are combined into a single ranking, in which the passage with most similar snippets is retrieved as the best match.

Additionally, we investigate whether our models can benefit from pre-trained cross-modal embeddings. Since both CNN encoders of our proposed network architecture (see Figure 2) are the same as in [14], we re-designed the baseline cross-modal network to accommodate our snippet dimensions (160×180 and 92×20 , for sheet and audio, respectively) and trained a short-snippet embedding model also with the MSMD, as a pre-training step, and then loaded the two CNN encoders of our recurrent network with their respective pre-trained weights before training. Our hypothesis is that, by initializing the CNN encoders with parameters that were optimized to project short pairs of matching audio-sheet snippets close together onto a common latent space, models with better embedding capacity can be obtained. After loading the two CNNs with pre-trained weights, we can either freeze (FZ) them during training or just fine-tune (FT) on them. Therefore, in our experiments, we refer to these modifications of our proposed vanilla recurrent network (RNN) as RNN-FZ and RNN-FT, respectively.

Moreover, an additional CCA (canonical correlation analysis) layer [28] is used in [14] to increase the correlation of corresponding pairs in the embedding space. This CCA layer is refined in a post-training step, and we investigate whether this refinement process is beneficial to our network. In our experiments we refer to models that were initialized with pre-trained parameters from networks that had their CCA layer refined as RNN-FZ-CCA and RNN-FT-CCA.

Table 2 presents the results for all data configurations and models defined previously. To keep our experiments consistent and the comparison fair, we randomly select 534 passage pairs from sets (II) and (III) to create the retrieval scenario for their respective experiments.

An evident observation from the table is the considerable performance drop as we transition from synthetic to real music data. For all the models, the MRR drops at least

⁴ The reasons we did not use the attention-based method from [17] as a baseline comparison are twofold. First we intend to compare the exact original snippet embedding architecture with and without a recurrent encoder, and adding the attention mechanism to a baseline model would introduce a significant number of additional trainable parameters, making the comparison unfair. Second, the purpose of the attention model is to compensate the musical content discrepancy between audio and sheet snippets, which is not the case for musical passages as defined here: pairs of audio-sheet music passages comprise the exact musical content (that is the reason why fragments are not fixed in time).

Table 2: Results of audio–sheet music passage retrieval, performed in both search directions, and evaluated in three types of data: (I) fully synthetic, (II) partially real and (III) entirely real. Boldfaced rows represent the best performing model per dataset.

	Audio-to-Score (A2S)					Score-to-Audio (S2A)

0.2 points to a partially real test set, and drops more than 0.3 points when moving to the entirely real data. Moreover, as mentioned in Subsection 3.1, the passage retrieval metrics of the S2A direction are better than those of A2S for all models and scenarios.

Our recurrent model RNN and its variants outperform the baseline approach in all retrieval scenarios for all evaluation metrics. In our findings, we did not see noticeable improvements when the pre-loaded encoders were frozen during training. In fact, for some configurations (scenarios I and III) the evaluation metrics were slightly worse than those from the vanilla RNN model. When the CNN encoders are pre-loaded and enabled for fine-tuning, we observe the largest improvements over RNN and subsequently over BL. Moreover, the models initialized with pre-trained weights from CCA-refined networks (RNN-FT-CCA) achieved the best overall results, for all test datasets and search directions.

In addition to the overall absolute improvements, we observe that the performance drop between synthetic and real datasets shrinks with our proposed models, specially with RNN-FT-CCA. In comparison with the baseline, the I-to-III MRR gap is reduced by 0.036 and 0.06 points in the directions A2S and S2A, respectively.

The results we obtained and summarized in Table 2 indicate that introducing a recurrent layer to learn longer contexts of musical content is beneficial in our cross-modal

retrieval problem. However the real-data generalization problem is still evident, and in Section 4 we discuss potential solutions to address such issues.

3.3 Experiment 3: Global tempo variations

In this experiment, we investigate the robustness of our system to global tempo changes. To this end, the pieces of the MSMD test dataset are re-rendered with different tempo ratios $\rho \in \{0.5, 0.66, 1, 1.33, 2\}$ ($\rho = 0.5$ means the tempo was halved and $\rho = 2$ stands for doubling the original tempo). A similar study was conducted in [17] for retrieval of short audio–sheet snippets.

Table 3 summarizes the MRR values obtained for each tempo re-rendering, where the baseline method is compared with our proposed recurrent model. We notice the general trend that the MRR gets worse as the tempo ratio is farther from $\rho = 1$ (original tempo). This behavior is somehow expected because the new tempo renditions are more extreme than the tempo changes the model has seen during training.

Besides the better MRR values of the proposed network, an important improvement concerns the performance drop when changing from $\rho = 1$ to $\rho = 0.5$ (slower renditions). The MRR gap between these tempo ratios drops from 0.12 to 0.1 and from 0.09 to 0.07 points for the A2S and S2A directions, respectively, when comparing our net-

Model	$\rho = 0.5$	$\rho = 0.66$	$\rho = 1$	$\rho = 1.33$	$\rho = 2$

RNN	0.60	0.64	0.67	0.61	0.50

(b) S2A search direction.

Table 3: MRR for different tempo renderings of the test pieces of MSMD in both (a) audio-to-sheet and (b) sheet-to-audio retrieval directions. We evaluate both baseline and RNN models.

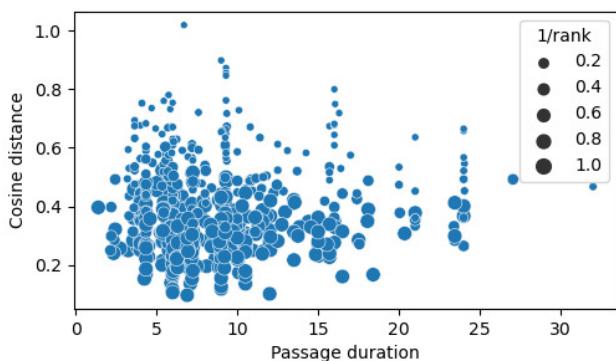

Figure 4: Cosine distance in the embedding space in relation to the respective audio passage duration of 534 pairs from the MSMD test set. The cosine distances were computed with the RNN model.

work with the baseline. This indicates that the recurrent model is more robust to global tempo variations and can operate well with longer audio passages.

3.4 Experiment 4: Qualitative analysis

To get a better understanding of the behavior of our proposed network, in this last experiment we take a closer look at the shared embedding space properties. Figure 4 shows the distribution of the pairwise cosine distances between the passage pairs from the MSMD test set, in relation to the duration (in seconds) of their respective audio passages. Moreover, we scale the point sizes in the plot so they are proportional to their individual precision values (inverse of the rank values), when considering the S2A experimental setup.

An interesting behavior in this visualization is the size of the points increasing as the cosine distance decreases. It is expected that passage pairs with smaller distances between them, meaning that they are closer together in the embedding space, would lead to better retrieval ranks.

Another interesting aspect of this distribution concerns the proportion of larger cosine distances as the audio duration of the passages increases. For example, between five and ten seconds, there are more large points observed than smaller ones, while between 20 and 25 seconds, the pro-

portion is roughly equal. This indicates that, in our test set, embeddings from shorter passages of audio are still located closer to their sheet counterparts in comparison with longer audio passages, despite our efforts to design a recurrent networks that learns from longer temporal contexts.

4. CONCLUSION AND FUTURE WORK

We have presented a novel cross-modal recurrent network for learning correspondences between audio and sheet music passages. Besides requiring only weakly-aligned music data for training, this approach overcomes the problems of intrinsic global and local tempo mismatches of previous works that operate on short and fixed-size fragments. Our proposed models were validated in a series of experiments under different retrieval scenarios and generated better results when comparing with baseline methods, for all possible configurations.

On the other hand, a serious generalization gap to real music data was observed, which points us to the next stages of our research. A natural step towards making deep-learning-based cross-modal audio-sheet music retrieval more robust would be to include real and diverse data that can be used for training models. However such data with suitable annotations are scarce, and recent advances in end-to-end full-page optical music recognition [29] can be a possible solution to learn correspondences on the score page level. Moreover, the powerful transformers [30] are potential architectures to learn correspondences from even longer audio recordings, accommodating typical structural differences between audio and sheet music, such as jumps and repetitions.

ABSTRACT

Estimating the performance difficulty of a musical score is crucial in music education for adequately designing the learning curriculum of the students. Although the Music Information Retrieval community has recently shown interest in this task, existing approaches mainly use machine-readable scores, leaving the broader case of sheet music images unaddressed. Based on previous works involving sheet music images, we use a mid-level representation, bootleg score, describing notehead positions relative to staff lines coupled with a transformer model. This architecture is adapted to our task by introducing an encoding scheme that reduces the encoded sequence length to one-eighth of the original size. In terms of evaluation, we consider five datasets—more than 7500 scores with up to 9 difficulty levels—, two of them particularly compiled for this work. The results obtained when pretraining the scheme on the IMSLP corpus and fine-tuning it on the considered datasets prove the proposal’s validity, achieving the best-performing model with a balanced accuracy of 40.34% and a mean square error of 1.33. Finally, we provide access to our code, data, and models for transparency and reproducibility.

1. INTRODUCTION

Estimating the difficulty of a piece is crucial for music education, as it enables the effective structuring of music collections to attend to the student’s needs. This has led to a growing research interest [1–4], as well as the development of automatic systems for exploring difficulties by major industry players such as Muse Group [5,6] and Yousician [7].

Previous research on predicting piano difficulty has primarily focused on symbolic machine-readable scores [1, 2, 4, 8–10]. Early studies explored feature engineering descriptors [1,2] and the relationship between piano fingering

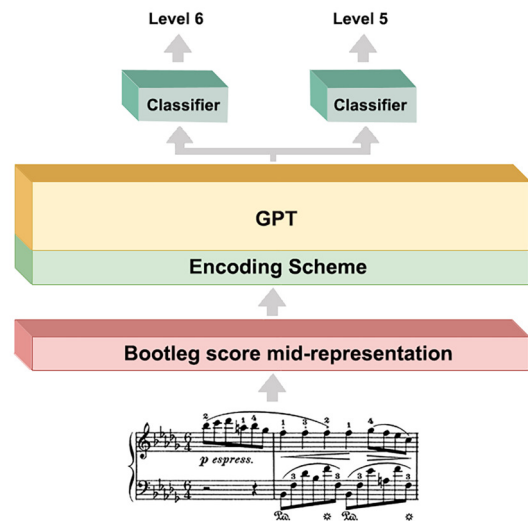

Figure 1. We consider the bootleg score mid-representation with a multi-task GPT-based recognition framework to predict the performance difficulty associated to a piano score directly from sheet images from multiple annotated collections with varied difficulty levels.

and difficulty [8–10]. A recent study [4] used stacked recurrent neural networks and context attention for difficulty classification on machine-readable scores, employing embeddings from automatic piano fingering, piano expressive generation [11], and score information. This study found that modeling the score difficulty classification task as an ordinal regression problem [12] was advantageous, and using entire pieces for training, rather than fragments, was essential to avoid degraded performance.

Although symbolic machine-readable scores offer more interpretability [10], with all the music information completely accessible, their limited availability compared to sheet music images restricts the practical use of difficulty prediction tools for librarians, teachers, and students. Focusing on sheet music image analysis expands the range of available music, has the potential to preserve the cultural heritage of symbolic-untranscribed scores, and addresses the lack of diversity in Western classical piano curricula. By analyzing image-based sheet music, we aim

to create technology for highlighting historically under-represented communities like female composers [13, 14] and promoting diversity in piano education. This promotion is crucial since the piano teaching repertoire has remained mostly unchanged for decades [15], containing around 3,300 pieces [16], while projects such as IMSLP house remarkably larger databases.

One of the main challenges in working with sheet music is attaining a symbolic music-based representation for direct analysis. Although Optical Music Recognition (OMR) literature has considerably improved in creating such representations over the past 30 years, it remains an unsolved task [17]. Bootleg score [18] is an alternative to symbolic scores obtained with OMR. This mid-level symbolic representation keeps the most relevant primitives of the music content in a music sheet, which has shown remarkable success in several tasks [19–22], especially in classification, such as piano composer classification [19, 23, 24] or instrument recognition [25].

We build on this literature, employing the GPT model [26] and bootleg score in our analysis. More precisely, we consider the approach by Tsai et al. [18], in which a GPT model pretrained on the IMSLP piano collection is finetuned for specific recognition tasks. With adequate adaptations, we hypothesize that this framework may also succeed in estimating performance difficulty on music sheet images.

As aforementioned, difficulty estimation benefits from the use of entire music pieces rather than excerpts to obtain adequate success rates. However, processing large sequence stands as a remarkable challenge in music processing, especially when addressing bootleg representations due its considerable verbosity. While some recent mechanisms address this issue in general learning frameworks (e.g., Flash Attention [27]), we extend the original proposal by Tsai et al. [18] with a multi-hot optimization target for GPT pretraining, and replace the categorical encoding with causal convolutional or feedforward projection layers to enhance performance and reduce costs.

Moreover, addressing data scarcity is crucial for promoting and establishing this task within the Music Information Retrieval community. As of now, the *Mikrokosmos-difficulty* (MK) [10] and *Can I Play It?* (CIPI) [4] symbolic datasets stand for the only available annotated collections, out of which music sheet images can be obtained by engraving mechanisms. To enhance data availability and encourage further research, we have collected additional datasets from existing collections, namely *Pianostreet-difficulty* (PS), *Freescore-difficulty* (FS), and black female composers collection Hidden Voices (HV). This results in more than 7500 music pieces, spanning up to 9 difficulty levels and each annotated with a difficulty classification system. Although difficulty prediction contains a subjective element, global trends may emerge when examining multiple difficulty classification systems simultaneously. To our knowledge, no previous research has explored this aspect. Consequently, we propose a multitask approach to training simultaneously on CIPI, PS, and FS datasets. Fi-

nally, we also analyze the generalization of our proposed methodologies with the MK and HV benchmark datasets.

Considering all above, our precise contributions are: (i) we adopt the previous bootleg-representation literature [23, 24], pretraining a GPT model on IMSLP and finetuning it for our task, adapting the encoding scheme accordingly, as presented in Figure 1; (ii) we evaluate our proposal using a novel sheet music image collection of five datasets with more than 7,500 pieces with difficulty levels ranging up to 9; (iii) we propose a multi-task strategy for combining multiple difficulty classification systems from the datasets; (iv) we conduct extensive experiments to assess the proposed methodologies, including a zero-shot scenario for testing generalization and comparisons with previous proposals on the CIPI dataset; and (v) to promote the task, code, and models ¹, and datasets ² are publicly available.

2. MUSIC SHEET IMAGE DATASETS

Due to the relative recentness of the field, the lack of annotated corpora has severely constrained the performance difficulty assessment. The earliest data assortments may be found in the works by Sebastian et al. [1] and Chiu et al. [2], which respectively collected 50 and 300 MIDI scores from different score repositories. However, these datasets were never publicly released.

To our best knowledge, the *Mikrokosmos difficulty* (MK) set by Ramoneda et al. [10], which comprises 147 piano pieces by Béla Bartók in a symbolic format graded by the actual composer, represents the first publicly available collection for the task at hand. More recently, the authors introduced the *Can I Play It?* (CIPI) dataset [4], a collection of 652 piano works in different symbolic formats annotated after 9 different difficulty levels. Note that, while sheet music scores can be obtained by resorting to engraving mechanisms, the insights obtained may not apply to real-world scenarios.

Dataset	Pieces	Classes	AIR	Noteheads	Composers
MK [10]	147	147	.78	49.2k	1
CIPI [4]	652	9	.33	1.1M	29
PS	2816	9	.24	7.2M	92
FS	4193	5	.37	5.8M	747
HV	17	4	1	21.5k	10

Table 1. Description of existing collections for performance difficulty estimation based on the number of pieces, classes, average imbalance ratio (AIR), noteheads, and composers. The dashed line differentiates the datasets based on symbolic (above) and image (below) sheet music.

To address this limitation, we compiled a set of real sheet music images of piano works together with their performance difficulty annotations from different music education and score-sharing platforms on the Internet. More

¹<https://github.com/PRamoneda/pdf-difficulty>

²<https://zenodo.com/record/8126801>

precisely, we arranged three different collections attending to the source: (i) the *Pianostreet-difficulty* (PS) set retrieved from [28] that depicts 2,816 works with 9 difficulty levels annotated by the Pianostreet team; (ii) the *Freescores-difficulty* (FS) assortment from [29] that contains 4,193 pieces with 5 difficulty levels comprising a variety of compositions and annotations by the users of the platform; and (iii) the *Hidden Voices* (HV) collection [30,31], a set of 17 pieces by black female composers annotated with 4-level difficulty labels by musicologists of the Colorado Boulder Music Department.

Table 1 summarizes the main characteristics of commented publicly-available collections. The *average imbalance ratio* (AIR), measured as the mean of the individual ratios between each difficulty class and the majority label in each collection, is also provided for reference purposes.

3. METHODOLOGY

Based on its success when addressing classification tasks from sheet music images [23, 25], our proposal considers the use of the so-called bootleg score representation coupled with a GPT-based recognition model to estimate the performance difficulty of a piece.

Introduced by [18], bootleg scores stand as a simple—yet effective—representation to encode the content of a sheet music image for certain recognition tasks. Formally, a bootleg score is a binary matrix of length w and $h = 62$ vertical positions—i.e., $\mathcal{X} \in \{0, 1\}^{w \times 62}$ —that respectively denote the temporal and pitch dimensions. Note that the w value represents the number of note heads detected by the bootleg extraction process. Our work resorts to this representation, being the use of alternative codifications posed as a future line to address.

The GPT recognition framework undergoes an unsupervised pretraining step on the IMSLP piano collection, which was originally used by [18]. Eventually, considering a set of labeled data $\mathcal{T} \subset \mathcal{X} \times \mathcal{C}$ where $\mathcal{C} = \{c_1, \dots, c_{|\mathcal{C}|}\}$ denotes the possible difficulty levels, the model is finetuned to retrieve the recognition function $\hat{f} : \mathcal{X} \rightarrow \mathcal{C}$ that relates a bootleg representation to a particular difficulty level. Based on previous work addressing this task [4], we consider an ordinal classification framework [12] as the difficulty grading scales naturally fit this formulation.

Despite being capable of addressing the task, the framework was noticeably affected by two factors: (i) the excessive length of the input sequences when pretraining the model; and (ii) the inconsistent definition of difficulty levels among corpora. Consequently, we introduce two mechanisms specifically devised to address these limitations.

3.1 Sequence length in pretraining

One of the main drawbacks related to bootleg representations is their verbosity, as it depicts $h = 62$ elements per frame. To address this issue, Tsai et al. [23] proposed subdividing each column into groups of 8 elements and encoding each according to a vocabulary of $|\sigma| = 2^8$ elements. In this regard, the initial bootleg score $x \in \{0, 1\}^{w \times 62}$ is

mapped to a novel space defined as $\Sigma^{w \times 8}$. This representation is then flattened to undergo a categorical embedding process that maps it to a feature-based space denoted as $\mathbb{R}^{8w \times 768}$, which is eventually used for pretraining the GPT model with 768-dim hidden states. Note that this process reduces the vocabulary size and remarkably increases the sequence length.

To address this issue, we propose substituting this tokenization process with an embedding layer that directly maps the bootleg score into a suitable representation, avoiding the extension of the initial length of the sequence. In this sense, the initial bootleg representation $x \in \{0, 1\}^{w \times 62}$ is mapped to a space defined as $\mathbb{R}^{w \times 768}$ that serves as input to the GPT model with a fraction of the length of the encoding used by Tsai et al. [23]. Besides reducing the length of the sequences to process, we hypothesize that such an embedding may benefit the recognition model as a suitable representation is inferred for the task. In this regard, our experiments will compare two types of embedding approaches—more precisely, a fully-connected layer and a convolutional one, respectively denoted as FC and CNN—to quantitatively assess this claim.

Figure 2 graphically describes the approach by Tsai et al. [23] and the presented proposal. In opposition to the reference work, the proposal considers multi-hot encoding instead of discrete categorical index as the output of the GPT recognition framework, by using binary cross-entropy loss instead of negative log-likelihood loss.

Figure 2. Comparison between the proposal by Tsai et al. [23]—denoted as (a)—and the presented proposal—highlighted as (b)—for a case of toy example with a duration of $w = 4$.

3.2 Multi-task learning of multiple difficulty classification systems

The pretrained GPT model can be simply finetuned for a performance difficulty classification task by adding a projection layer and a learnable classification token, as de-

picted in Figure 3. However, the actual definition of the performance difficulty of a piece is a highly subjective problem that may bias—and, hence, remarkably hinder—the goodness of a recognition model. In this regard, we hypothesize that using a multi-task approach that attends different definitions of difficulty—*i.e.*, a labeled assortment of data from multiple annotators—may benefit the generalization capabilities of the approach.

In this regard, we modify the reference architecture for the downstream task to include an additional classification layer for each training collection. While simple, such a proposal is expected to improve the overall recognition performance given the wider variety of data provided during the training process. Figure 3 graphically describes this proposal.

Finally, no pre-processing is done in relation to the label distribution of the corpora to avoid inducing any type of bias. In this regard, the sampling protocol of the model has been forced to maintain its original distributions.

Figure 3. Graphical description of the downstream architecture depicting the classification heads for the multi-task proposals as well as the single-head case of the reference work.

4. EXPERIMENTAL SETUP

4.1 Data collections and assessment metrics

To validate the proposal, we have considered the five publicly-available data collections presented in Section 2, *i.e.*, *Mikrokosmos difficulty* (MK) [10], *Can I Play It?* (CIPI) [4], *Pianostreet-difficulty* (PS) [28], *Freescores-difficulty* (FS) [29], and *Hidden Voices* (HV) [30, 31]. While MK and CIPI exclusively comprise symbolic scores, we engraved them into music sheets and included them due to the commented scarcity of annotated data.

We considered a 5-fold cross-validation scheme with a data partitioning of 60% for the finetuning phase after the pretraining stage with IMSLP together with two equal-size splits of the remaining data for validation and testing. Note that, since MK and HV are exclusively used for benchmark purposes, no partitioning is applied to them.

In terms of performance evaluation, we resort to two assessment criteria typically used in ordinal classification [32]: *accuracy within n* (Acc_n) and *mean squared error* (MSE). To adequately describe them, let $\mathcal{S} \subset \mathcal{X} \times \mathcal{C}$ denote a set of test data and let $\mathcal{S}_c = \{(x_i, y_i) \in \mathcal{S} : y_i = c\}$ with $1 \leq i \leq |\mathcal{S}|$ be the subset of elements in \mathcal{S} with class c .

Based on this, Acc_n is defined as:

$$\text{Acc}_n = \frac{1}{|\mathcal{C}|} \sum_{\forall c \in \mathcal{C}} \frac{|\{y \in \mathcal{S}_c : |\hat{f}(x) - c| \leq n\}|}{|\mathcal{S}_c|} \quad (1)$$

where $\hat{f}(\cdot)$ represents the trained recognition model and $n \in \mathbb{N}_0$ denotes the tolerance or class-boundary relaxation that allows for errors in adjacent labels. In our experiments we consider the values of $n = 0$ (no tolerance) and $n = 1$ (smallest adjacency tolerance), respectively denoted as Acc_0 and Acc_1 in the rest of the work.

Regarding MSE, this figure of merit is defined as:

$$\text{MSE} = \frac{1}{|\mathcal{C}|} \sum_{\forall c \in \mathcal{C}} \frac{\sum_{\forall x \in \mathcal{S}_c} (\hat{f}(x) - c)^2}{|\mathcal{S}_c|} \quad (2)$$

Finally, note that all these metrics are macro-averaged to account for the unbalanced nature of the data collections used in the work.

4.2 Training procedure

As commented, the recognition model undergoes an initial pretraining stage considering the IMSLP corpus. During this stage, the model considers sequences of 256 tokens, each with a binary cross-entropy as a loss function. To speed up this process, the Flash Attention framework by [27] is also considered. For comparative purposes, all other parameters remain unaltered from the reference works [23].

After that, the model is finetuned on the downstream difficulty estimation task, considering an Adam optimizer [33] with a learning rate of 10^{-5} and early stopping based on the Acc_0 and MSE metrics on the validation set. Moreover, a balanced sampler is considered to tackle the issue of unbalanced data collections. Ordinal Loss [12] is applied to train the difficulty prediction as an ordinal classification problem, while no loss weighting is considered in the multi-task framework. For regularization and stable training, gradient clipping is set to 10^{-4} , with a batch size of 64 and L2 regularization. This optimization process is carried out exclusively on the last layer of the model, resorting to the remaining parts to the weights obtained during the pretraining phase of the procedure.

Note that while these processes may be further studied to account for the optimal solution that retrieves the best-performing results, such a study is out of the scope of the work and is left as future work to address.

5. EXPERIMENTS AND RESULTS

This section presents the results obtained with the introduced experimental scheme. To adequately provide insights about the task, the section provides a series of individual experiments devoted to analyzing one aspect of the proposal: Section 5.1 analyzes the influence of the encoding scheme; Section 5.2 evaluates the influence of the multitask architecture; Section 5.3 delves on the ranking generalization in a zero-shot scenario; finally, Section 5.4 compares the attainable results when addressing the task from the symbolic versus the sheet-image domains.

5.1 Encoding schemes experiment

This first experiment compares the performance of the two encoding schemes presented in Section 3.1, *i.e.*, GPT_{FC}^{multi} and GPT_{CNN}^{multi} . Table 2 presents the results obtained for the CIPI, FS, and PS collections for the three figures of merit considered.

Encoding	Acc ₀ (%)	Acc ₁ (%)	MSE
<i>Can I Play it?</i>			
GPT_{FC}^{multi}	34.3(6.1)	78.1(4.6)	1.6(0.3)
GPT_{CNN}^{multi}	36.2(8.2)	81.7(1.5)	1.4(0.1)
<i>PianoStreet</i>			
GPT_{FC}^{multi}	30.9(3.8)	71.1(9.6)	2.1(0.4)
GPT_{CNN}^{multi}	31.8(1.6)	78.8(1.8)	1.9(0.1)
<i>FreeScores</i>			
GPT_{FC}^{multi}	46.6(1.9)	92.5(1.0)	0.8(0.1)
GPT_{CNN}^{multi}	47.3(3.4)	92.4(0.6)	0.8(0.1)

Table 2. Results of comparing the encoding schemes GPT_{FC}^{multi} and GPT_{CNN}^{multi} . Bold values highlight the best results per collection and metric.

As it may be observed, the GPT_{CNN}^{multi} experiment outperformed the GPT_{FC}^{multi} experiment in most evaluation metrics across the three datasets. More precisely, the GPT_{CNN}^{multi} consistently achieved the best performance in the Acc₀ metric for all data collections, showing an average improvement of 1% concerning the GPT_{FC}^{multi} case. This trend remains for the rest of the figures of merit except for the case in the FS assortment, in which the results of the FC-based model outperform those of the CNN case.

Nevertheless, attending to the high standard deviations, the performance results of the two models show a remarkable overlap in performance, hence suggesting that both schemes are equally capable of performing the posed task of score difficulty analysis from sheet music images. In this regard, further work should explore other encoding alternatives to assess whether this performance stagnation is due to the representation capabilities of the considered embedding layers or due to the recognition framework.

5.2 Multi-task learning experiment

In this second study, we assess the capabilities of the multi-task framework proposed in Section 3.2 trained simultaneously on the CIPI, PS, and FS datasets for the two GPT_{FC}^{multi} and GPT_{CNN}^{multi} encoding schemes. Table 3 provides the results obtained.

Encoding	Acc ₀ (%)	Acc ₁ (%)	MSE
GPT_{FC}^{multi}			
CIPI	40.3(4.3)	82.0(1.4)	1.3(0.1)
PS	35.9(3.1)	78.2(3.4)	1.9(0.2)
FS	45.8(2.5)	92.0(1.4)	0.8(0.1)
GPT_{CNN}^{multi}			
CIPI	34.9(5.0)	81.4(1.3)	1.4(0.1)
PS	35.9(2.8)	74.5(3.4)	2.7(0.2)
FS	45.9(1.2)	92.4(2.1)	0.8(0.1)

Table 3. Results of multi-task learning experiment when evaluated on different test collections for the two encoding schemes. Bold values highlight the best results per collection and metric.

Overall, the GPT_{FC}^{multi} method had higher results than the GPT_{CNN}^{multi} method on the CIPI and PS datasets, especially on Acc₀ and Acc₁. For CIPI, GPT_{FC}^{multi} surpassed GPT_{CNN}^{multi} with gains of 5.4% in Acc₀, 0.6% in Acc₁, and 0.1 in MSE. For PS, GPT_{FC}^{multi} slightly exceeded GPT_{CNN}^{multi} with a 3.7% improvement in Acc₁ and a 0.6-point reduction in MSE, while Acc₀ was nearly equal for both methods, although GPT_{CNN}^{multi} had a smaller standard deviation. Both methods displayed similar performance on the FS dataset, with less than a 1% difference across all metrics. As a result, subsequent experiments will reference the GPT_{FC}^{multi} model.

The comparison between Tables 2 and 3 shows a trend change with better results performed with the FC version of the models. The other major difference is the relative improvement between the GPT_{FC}^{multi} method and the best previous model GPT_{CNN}^{multi} in the CIPI and slightly in the PS dataset. In contrast, the FS dataset results remain comparable. In CIPI, Acc₀ is 11.3% higher in GPT_{FC}^{multi} , and in PS, there is a relative improvement of 12.8%. For CIPI, Acc₁ sees a minor increase of 0.4%. MSE exhibits a small improvement of 3.6% for CIPI and 0.5% for PS. Possible reasons include label quality differences—CIPI annotated by a musicology team, PS labels provided by the platform, and FS crowdsourced by users—or the impact of dataset sizes—CIPI being the smallest and FS the largest.

5.3 Ranking generalization experiment

In this experiment, we assess the ranking capabilities of the proposal in a zero-shot setting by utilizing the embeddings of the projection layer of the model (check Figure 3). We reduce the 768-dimensional embeddings to a single dimension using Principal Component Analysis (PCA) and employ the resulting values to rank the target pieces.

Table 4 shows the results obtained resorting to the

Kendall rank correlation coefficient, τ_c , for all data collections discussed in the experiment, considering both the single-task and multi-task frameworks posed. Note that MK and HV are only used for benchmarking purposes.

Train	Evaluation				
	CIPI	PS	FS	MK	HV
CIPI	.67 (.01)	.56 (.02)	.56 (.01)	.67 (.05)	.50 (.05)
PS	.67 (.01)	.58 (.02)	.56 (.01)	.68 (.01)	.43 (.04)
FS	.64 (.04)	.55 (.01)	.56 (.02)	.71 (.02)	.56 (.07)
MULTI	.68 (.02)	.59 (.02)	.56 (.01)	.63 (.02)	.51 (.07)

Table 4. Zero-shot ranking results. Bold values denote the best-performing result on each evaluation dataset.

In the three training datasets, the multi-task architecture $\text{GPT}_{\text{FC}}^{\text{multi}}$ achieves the best performance with CIPI ($\tau_c = 0.68$), PS ($\tau_c = 0.59$), and FS ($\tau_c = 0.56$). Unexpectedly, the FS method outperforms others in the datasets of the MK ($\tau_c = 0.61$) and HV ($\tau_c = 0.56$). This outcome may suggest that simultaneous training on all three datasets could limit generalizability. Alternatively, the presence of license-free pieces composed after 1900 in the FS dataset, which users have uploaded, might explain the difference.

The HV dataset displays notably lower generalizability, possibly due to the smaller number of pieces, resulting in higher standard deviations. Potential bias similar to MK could also arise from the predominance of pre-20th-century data in CIPI and PS. These factors might affect the zero-shot experiment’s performance. However, we must also acknowledge that most composers used for training are white males, and the HV results are significantly worse than the rest of the datasets. Therefore, future research should investigate and minimize the potential gender gap in difficulty prediction tasks.

5.4 Comparison with previous approaches

This last experiment compares the goodness of the proposed methodology in sheet music scores against other image-based approaches and with the symbolic-oriented methods domain. Regarding sheet image methods, we consider the reference method by Tsai et al. [23] based on bootleg mid-representation, denoted as GPT_{EMB} . Concerning the symbolic baseline, we reproduce the approach in [4] that proposes to describe the symbolic score in terms of piano fingering information, expressive annotations, and pitch descriptors to feed a recurrent model based on Gated Recurrent Units with attention layers (referred to as GRU+Att). Table 5 provides the results obtained. For comparative purposes, we only consider the CIPI dataset as the reference symbolic work accounted for that collection.

Examining the experiments, the $\text{GPT}_{\text{FC}}^{\text{multi}}$ model may be observed to outperform the other cases in the Acc_0 figure of merit. However, for the rest of the metrics, the reference symbolic case—denoted as GRU+Att—outperforms all image-oriented recognition models. Such a fact suggests that, while a bootleg score somehow suits this dif-

ficulty estimation task, a performance gap between this representation and pure symbolic notation needs to be addressed.

Case	Acc_0 (%)	Acc_1 (%)	MSE
<i>Symbolic</i> [4]			
GRU+Att	39.5(3.4)	87.3(2.2)	1.1(0.2)
<i>Tsai et al.</i> [23]			
GPT_{EMB}	19.7(4.0)	58.1(7.2)	3.3(0.8)
<i>Proposal</i>			
GPT_{FC}	34.3(6.1)	78.1(4.6)	1.6(0.3)
GPT_{CNN}	36.2(8.2)	81.7(1.5)	1.4(0.1)
$\text{GPT}_{\text{FC}}^{\text{multi}}$	40.3(4.3)	82.0(1.4)	1.3(0.1)

Table 5. Performance results for the symbolic [4] and Tsai et al. [23] methods as well as the proposed approach for the CIPI dataset. Bold values highlight the best result per figure of merit.

Finally, the GPT_{EMB} model achieves the lowest performance of all alternatives, with remarkably lower accuracy rates than our proposal. Note that such a fact emphasizes the relevance of our work as a more suitable approach for performing difficulty estimation in sheet music images.

6. CONCLUSIONS

Estimating the performance difficulty of a music piece is a crucial need in music education to structure the learning curriculum of the students adequately. This task has recently gathered attention in the Music Information Retrieval field, given the scarce existing research works devoted to symbolic machine-readable scores. However, due to the limited availability of this type of data, there is a need to devise methods capable of addressing this task with image-based sheet music.

Attending to its success in related classification tasks, this work considers the use of a mid-level representation—namely, bootleg score—that encodes the content of a sheet music image with a GPT-based recognition framework for predicting the difficulty of the piece. Instead of directly applying this methodology, we propose using specific embedding mechanisms and multi-task learning to reduce the task complexity and improve its recognition capabilities. The results obtained with five different data collections—three of them specifically compiled for this work—prove the validity of the proposal as it yields recognition rates comparable to those attained in symbolic machine-readable scores.

Further work comprises assessing and proposing alternative representations to the bootleg scores (*e.g.*, solutions based on Optical Music Recognition). Also, we consider that using smaller training sequences using hierarchical attention models or weak labels for varying-length piece fragments may report benefits in the process. Finally, the practical deployment of this proposal in real-world scenarios involving real users may report some additional insights about the validity of the proposal.

7. ACKNOWLEDGMENT

We want to thank T.J. Tsai and all his students, especially Daniel Yang, for having conducted the prior research on the bootleg score and, above all, for sharing all their work in the interest of Open Science. We are also grateful to Pedro D’Avila for bringing to our attention the work of Alejandro Cremaschi related to the Hidden Voices project. Lastly, we thank Alejandro Cremaschi and the University of Colorado Boulder Libraries team, David M. Hays and Jessica Quah, for providing us with the scores.

This work is funded by the Spanish Ministerio de Ciencia, Innovación y Universidades (MCIU) and the Agencia Estatal de Investigación (AEI) within the Musical AI Project – PID2019-111403GB-I00/AEI/10.13039/501100011033 and the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Korea Government (MSIT) (NRF-2022R1F1A1074566).

ABSTRACT

Music source separation (MSS) faces challenges due to the limited availability of correctly-labeled individual instrument tracks. With the push to acquire larger datasets to improve MSS performance, the inevitability of encountering mislabeled individual instrument tracks becomes a significant challenge to address. This paper introduces an automated technique for refining the labels in a partially mislabeled dataset. Our proposed self-refining technique, employed with a noisy-labeled dataset, results in only a 1% accuracy degradation in multi-label instrument recognition compared to a classifier trained on a clean-labeled dataset. The study demonstrates the importance of refining noisy-labeled data in MSS model training and shows that utilizing the refined dataset leads to comparable results derived from a clean-labeled dataset. Notably, upon only access to a noisy dataset, MSS models trained on a self-refined dataset even outperform those trained on a dataset refined with a classifier trained on clean labels.

1. INTRODUCTION

Music source separation (MSS) is a critical task in the field of music information retrieval (MIR), with applications ranging from remixing [1–3] to transcription [4–6] and music education [7, 8]. To train high-performing MSS models, it is essential to have clean single-stem music recordings for guidance, which serve as the ground truth for model training. However, obtaining clean, large-scale datasets of single instrument tracks remains a challenging task.

With the increasing availability of music data on the internet, platforms such as YouTube provide a vast pool of potential single-instrument tracks. Although these sources offer an opportunity for performance gains through larger training datasets, collecting single instrument tracks from such platforms inevitably leads to encountering tracks with

*Equal contribution

Figure 1. Overview of self-refining procedure on a noisy-labeled dataset for music source separation.

incorrect labels. For example, a query aimed at obtaining drum recordings might yield results that contain other types of instruments or noise, causing discrepancies between the expected and actual content of the collected recordings.

Label noise in datasets can arise from various factors, such as bleeding between instrument tracks, mislabeling due to human error, or the ambiguous timbre of instruments that resemble other instrument categories [9]. These factors make it challenging to assign a single definitive instrument label to a given recording. Such label noise is detrimental to the performance of MSS models, and there is a pressing need for an approach that can effectively train MSS models using partially corrupted datasets.

In response to this challenge, we propose an automated approach for refining mislabeled instrument tracks in a partially noisy-labeled dataset. Our *self-refining* technique, which leverages noisy-labeled data, results in only a 1% accuracy degradation for multi-label instrument recognition compared to a classifier trained with a clean-labeled dataset. The study highlights the importance of refining noisy-labeled data for training MSS models and demonstrates that utilizing the refined dataset for MSS yields results comparable to those obtained using a clean-labeled dataset. Notably, when only a noisy dataset is available, MSS models trained on self-refined datasets even outperform those trained on datasets refined with a classifier trained on clean labels. This paper presents a comprehensive analysis of our proposed method and its impact on the performance of MSS models.

Figure 2. Overall training procedure of the Instrument Classifier Ψ . The classifier is trained to perform instrument recognition with mixtures that are synthesized by randomly selecting each stem from the noisy labeled dataset. After this training procedure, we refine the original noisy dataset and then use this new dataset to train the final Ψ .

2. RELATED WORKS

Self-training of machine learning models has been studied in various literatures, where a teacher model is first trained with clean labeled data and is used as a label predictor of unlabeled data, then a student model is trained with clean and pseudo-labeled data [10, 11]. Recently, Xie et al. proposed a noisy student method for self-training [12], which uses an iterative training of teacher-student models and noise injection methods for training student models. Thanks to their usefulness, these self-training methods have been used in diverse MIR tasks, such as singing voice detection [13, 14] and vocal melody extraction [15].

Instrument recognition or classification has been researched in various literatures, both in single-instrument [16–19] or multi-source settings [20–27]. Although such research has been focused on single or predominant-label prediction, Zhong, et al. [28] recently proposed the hierarchical approach for multi-label music instrument classification.

Our self-refining method for training of instrument classifier shares similar attributes with noisy student training [12] and the previous multi-label instrument classification [28] but differs from some perspectives. *i)* We train all our models only with partially noisy-labeled data, without access to clean-labeled data. *ii)* We train the classifiers for direct prediction of labels used in standard music source separation, e.g., vocals, bass, drums, and others, instead of the hierarchical approach. *iii)* We train multi-label classifiers with mixtures of randomly selected instruments, which are based on the characteristic of musical audio. If there exist two different instruments in one audio signal, that can be classified into two instruments. This random mixing of different instrumental tracks has been used in music source separation as well [29]. Note that the mixup method [30], which is also a mixing method of two different images, also shares a similar attribute with our method but is used for regularization of training single-label classifiers, not like our multi-label classifiers.

3. METHODOLOGY

Given a real-world scenario where the available multi-track dataset for MSS is partially incorrect with its instrument labels, a possible naive approach is first to rectify mislabeled tracks and then train an MSS model using stems with the revised labels. In this section, we introduce an effective training technique that first performs instrument recognition by only utilizing data with noisy labels and then leverages the refined dataset inferred with the trained multi-label instrument classifier to train the MSS model. With this two-stage approach, we explore the impact of the refined noisy datasets on the performance of MSS models.

3.1 Multi-label Instrument Recognition

Figure 2 summarizes the proposed training procedure of the Instrument Classifier Ψ . Similar yet different from self-training, our approach learns directly from noisy labeled data and re-labels the training data to train the final Ψ using this refined dataset. We call this training procedure *self-refining*, and this is possible by *random mixing*, a method to synthesize a mixture of multiple instruments with pseudo labels. The *random mixing* technique takes advantage of the acoustic music domain in that mixing sources of different instrument tracks still leads to natural output mixture, whereas naively combining different images in the image domain is likely to produce unrealistic results. We further discuss about the benefits and the detailed process of *random mixing* at 3.1.1.

The network architecture of Ψ is that of the ConvNeXt model [31], where it has shown great performance on a multi-instrument retrieval in [27]. The input of the network is a stereo-channeled magnitude linear spectrogram. Followed by a sigmoid layer, the model outputs four labels indicating the presence of each stem. The objective function for instrument recognition \mathcal{L}_{Ψ} is a mean absolute loss between the estimated and synthesized pseudo labels. Preliminary experiments showed no significant difference in performance when employing mean absolute loss as compared to binary cross-entropy loss. This is likely due to

Figure 3. Music source separation training. Similar to the training procedure of the instrument classifier, we randomly mix each stem from the refined dataset to synthesize a mixture and use it as a network input. When a multi-labeled segment is selected for synthesis, the corresponding estimated stems are summed for loss computation.

the random mixing sampling that ensures similar occurrences of positive and negative labels of each instrument class during the training procedure.

3.1.1 Random Mixing

Randomly mixing stems with label noise not only creates various combinations of multi-labeled mixtures for training the instrument classifier but also brings the chance to generate a correct pseudo label from mislabeled stems. For instance, if we randomly select one correctly labeled drum track and a track that contains both sources of drums and vocals but is mislabeled as vocals, the mixing process synthesizes a correctly labeled mixture. Thanks to these fortunate chances, the random mixing technique assists the instrument classifier’s accuracy in refining the label noise dataset by utilizing mislabeled stems.

To synthesize a random mixture and its pseudo label, each stem is first selected with a chance rate from the noisy dataset. The audio effects manipulation is then applied to each chosen track by simulating the music mixing process for data augmentation [3]. The order of applying audio effects with random parameters is 1. *dynamic range compression*, 2. *algorithmic reverberation*, 3. *stereo imaging*, and 4. *loudness manipulation*. Labels corresponding to randomly selected stems are used as a multi-label objective for the instrument classifier.

3.2 Music Source Separation

In this section, we describe the training procedure of MSS model employing a multi-labeled refined dataset curated by the classifier trained in Section 3.1. The majority of MSS research has focused on estimating each of the four instrument groups (*vocals*, *bass*, *drums*, and *other*) [32–35]. However, our refined dataset contains sources labeled with multiple stems, which are unsuitable for use as distinct target instruments. To utilize multi-labeled sources, we propose an appropriate MSS training framework tailored to our refined dataset.

First, we determine whether to include the multi-stem source for each input mixture sample by considering the probability p . If we decide not to include the multi-labeled source, we can train the MSS model in a conventional manner, computing the losses for each stem. Otherwise, we select a multi-labeled source from the refined dataset. Sub-

sequently, we choose the remaining stems that do not correspond to the selected multi-labeled source from a pool of single-labeled sources and combine them to simulate a mixture. For example, when selecting a multi-labeled source *bass+drums*, we opt for single sources labeled as *vocals* and *others* to synthesize the mixture. After conducting inference with the MSS model, we add the estimated stems corresponding to the multi-stem source of the input mixture and assess the loss between them. Figure 3 illustrates our training procedure when a multi-labeled source is selected. We compute the losses for each stem, treating the multi-labeled source as an individual stem, and subsequently sum these losses to derive the final loss value.

4. EXPERIMENTS

4.1 Dataset

We use the label noise dataset provided by the Music Demixing Challenge 2023 (MDX2023) [36], which consists of 203 songs, licensed by *Moises.AI*¹. Similar to MUSDB18 [37], the provided dataset contains mixtures of music recordings segregated into four different instrumental stems: *vocals*, *bass*, *drums*, and *other*. Each stem and its corresponding label are intentionally altered to produce a corrupted dataset to simulate mislabeling such as bleeding or human mistakes. That is, for instance, *drums.wav* may contain drum sounds and singing voices simultaneously, which is likely to be caused by bleeding. For another example, a kick-drum sound might be mislabeled as *bass.wav* when the pitch of the kick drum is melodic enough to trick a human labeler. Due to the nature of the MDX2023 challenge, the dataset does not contain the actual ground truth labels. Hence, we use all 203 songs of the MDX2023 dataset only as training data.

To validate our system trained with noisy labeled data, we employed the MUSDB18 [37] as the clean dataset for comparison and evaluation. MUSDB18 comprises 150 songs, with 100 songs for the training and 50 songs for the test set. We adopt the test subset for evaluating all systems, while the training subset is used to train the upper bound system for observation.

Data preprocessing. To prevent models from mislabels caused by silence, we remove all silent sections through-

Table 1. Instrument recognition performance on single and multi-label instrument classifiers trained with different datasets. The training data of *clean*, *noisy*, and *refined* each represents the training subset of MUSDB18, MDX2023, and MDX2023 refined with the instrument classifier trained with MDX2023 Ψ_{noisy} , respectively.

out both datasets. The preprocessing procedure for silence removal is as follows:

1. For each song, detect silent areas that are below 30 dB relative to the maximum peak amplitude.
2. Remove all detected areas then merge them into one single long audio track.
3. Repeat 1. (with the threshold of 60 dB) and 2. based on the merged audio track, in case of stems that are almost silent.

After trimming silent regions, the total durations for each stem in the respective order of *vocals*, *bass*, *drums*, and *other* are [7.2, 7.8, 9.2, 10.3] hours for the MDX2023 dataset, and [2.2, 2.7, 2.9, 3.3] hours for the test subset of MUSDB18. Note that for evaluating MSS performance, we instead follow the original convention of processing entire songs from the test subset without any silence removal. We use the original audio specifications of both datasets where all audio tracks are stereo-channeled and have a sampling rate of 44.1 KHz.

4.2 Experimental Setups

For multi-label instrument recognition, the network architecture of Ψ is ConvNeXt’s tiny version [31], which consists of 27.8M parameters. We feed the network with stereo-channeled mixtures of instruments that are of 2.97 seconds, which are transformed into a time-frequency domain linear magnitude spectrogram with an FFT size of 2048 and a hop size of 512. We train all Ψ for 100 epochs. During inference, Ψ performs classification by processing the entire input audio in windows of a size equivalent to the network input size, with a hop size of one-fourth of this window size. The output labels from these windows are then averaged to yield the final decision, based on a threshold value of 0.9. We utilized this inference procedure to refine the noisy dataset, which was then used to train our MSS models. Our final version of the instrument

classifier trained on the refined dataset $\Psi_{refined}$ only uses stems inferred as a single-labeled for better performance based on our preliminary experiments.

We employed two MSS models, Hybrid Demucs (Demucs v3) [38] and CrossNet-Open-Unmix (X-UMX) [39], to evaluate their performance when trained on the processed datasets. Multi-labeled sources were selected with a probability of 0.4, and input loudness normalization (-14 LUFS) was applied for both training and inference in accordance with [40]. `pyloudnorm` [41] was used for loudness calculation [42].

For Demucs, the input duration was set to 3 seconds, and optimization was performed using Adam optimizer [43] and L1 loss on the time domain. The model was trained for 21,000 iterations with a batch size of 160.

For X-UMX, the input duration was set to 6 seconds, and optimization was performed using AdamW optimizer [44] and mean squared error loss on the time-frequency domain. For the sake of simplicity, we omit the multi-domain and combination loss proposed in [39]. The model was trained for 56,400 iterations with a batch size of 32. For the + *finetune w/ multi-labeled* model in Table 3, we first train the model with only single-labeled data for 20,680 iterations, then finetune it with multi-labeled data for another 35,720 iterations.

5. RESULTS

5.1 Instrument Recognition

Table 1 presents the instrument recognition performance of the multi-instrument classifier on single-labeled and multi-labeled data. As ground-truth labels are not available for the MDX2023 dataset, we validate the classification performance according to single and multi-labeled data with the MUSDB18 test set for evaluation. For the multi-label evaluation, we synthesized 3,941 mixtures from the test set with the random mixing technique described in 3.1.1. We observe the performance of Ψ trained with MUSDB18 (*clean*), MDX2023 (*noisy*), and MDX2023 once refined

Network	Training Data	SDR [dB]				
		vocals	bass	drums	other	avg
Demucs [38]	<i>clean</i>	5.92	6.16	5.58	4.43	5.52
	<i>noisy</i>	3.37	1.92	0.70	0.86	1.71
	w/ Ψ_{clean}	5.31	5.12	1.32	2.16	3.48
	w/ Ψ_{noisy}	4.15	4.58	1.62	2.85	3.30
	w/ $\Psi_{refined}$	5.36	5.04	3.09	3.13	4.16
X-UMX [39]	<i>clean</i>	5.76	4.44	5.47	3.65	4.83
	<i>noisy</i>	3.39	1.78	1.52	0.96	1.91
	w/ Ψ_{clean}	4.50	3.22	3.66	2.73	3.53
	w/ Ψ_{noisy}	4.72	4.11	3.22	2.89	3.74
	w/ $\Psi_{refined}$	4.99	3.93	5.00	3.18	4.28

Table 2. Source separation performance of Demucs v3 [38] and CrossNet-Open-Unmix [39] trained on different training datasets. Sub-items below *noisy* dataset indicate data refined with the respective instrument classifiers, denoted as Ψ_{\bullet} .

with Ψ_{noisy} (*refined*). The evaluation metrics used are accuracy, F1 score, precision, and recall for each instrument class and the overall averaged result.

For single-labeled data, the classifier achieves the highest average performance on the *clean* dataset, with an accuracy of 95.1% and an F1 score of 0.906. As *clean* dataset does not contain any noisy labels, the obtained results can be considered an upper bound for the performances of the classifiers. The Ψ trained on *refined* dataset results in slightly lower performance, with an accuracy of 92.8% and F1 score of 0.866, while the *noisy* dataset shows an accuracy of 92.5% and F1 score of 0.860. Although the accuracy, F1 score, and precision are higher for the *noisy* dataset in the *bass*, *drums*, and *other* stems, the performance metrics for *vocals* and recall values across all stems exhibit superior results when trained with the *refined* dataset.

For instrument recognition on multi-labeled data, Ψ trained on *clean* dataset yields an average accuracy of 90.2% and F1 score of 0.907. The *noisy* dataset results in an accuracy of 87.6% and an F1 score of 0.887. The *refined* dataset achieves superior performance, with an accuracy of 89.2% and an F1 score of 0.901, which is comparable to the results obtained from the *clean* dataset. Contrary to the evaluation with single-labeled data, the *refined* dataset generally demonstrates superior performance across all metrics in comparison to the *noisy* dataset. Notably, the recall values are observed to be even higher than those of the *clean* dataset. An in-depth analysis of the multi-instrument classifier results, alongside the performance outcomes of the MSS models, is discussed in Section 5.2.

5.2 Source Separation

The results of MSS models trained on different training datasets are presented in Table 2. In our evaluation, we used Signal-to-Distortion Ratio (SDR) [45], which is calculated using the *museval* toolkit [46]. For all MSS experiments, we report the SDR median of frames and the median of tracks. The Demucs and X-UMX models are

Method	SDR [dB]				
	vocals	bass	drums	other	avg
<i>proposed</i>	4.99	3.93	5.00	3.18	4.28
<i>threshold = 0.5</i>	5.06	4.13	4.77	3.06	4.25
<i>adaptive thresholds</i>	4.70	3.72	3.70	2.62	3.68
<i>train only w/ single-labeled</i>	4.90	3.73	4.54	3.18	4.09
<i>+ finetune w/ multi-labeled</i>	4.33	4.33	4.19	3.14	4.00
<i>self-refining $\times 5$</i>	4.65	3.87	5.07	2.89	4.12

Table 3. Ablation studies on MSS performances with CrossNet-Open-Unmix.

trained on *clean*, *noisy*, and data processed with multi-instrument classifiers, denoted by Ψ_{\bullet} . In this context, Ψ_{\bullet} represents the classifier trained on each respective dataset, as described in Section 5.1.

The baseline for this experiment is established using MSS models trained on the *noisy* dataset. It is noteworthy that all the results presented in the table exceed the baseline performance. For the dataset processed with the multi-instrument classifier $\Psi_{refined}$, average SDR improvements of 2.45 and 2.31 are observed for Demucs and X-UMX models, respectively, in comparison to the *noisy* dataset. Specifically, in $\Psi_{refined}$ case, both Demucs and X-UMX models demonstrate substantial improvements in SDR values across all stems compared to those of Ψ_{noisy} , with the exception of *bass* in the X-UMX model.

5.2.1 Analysis in relation to instrument recognition

In Table 2, it is noteworthy that the performance of $\Psi_{refined}$ exceeds the performance of Ψ_{clean} , even though Ψ_{clean} is trained with a noise-free labeled dataset. This implies the classification performance of Ψ_{clean} is inferior to the classification performance of $\Psi_{refined}$. This discrepancy could be attributed to differences in the data distribution between the MUSDB18 and MDX2023 datasets. Moreover, the number of training samples varies, with 100 samples in the MUSDB18 dataset and 203 samples in the MDX2023 dataset. When refining a partially noisy dataset, employing the same partially noisy dataset can yield advantageous outcomes than using the smaller clean dataset. This observation might be aligned with the findings in [12], which report an improvement in performance when a larger quantity of unlabeled data is present.

An additional factor to consider is the distinctive nature of the MSS model training framework in our approach. MSS models utilize the output of the classifier as input. The performance of the MSS model can be affected differently depending on the type of error in the classifier’s output. For example, assume that the MSS model receives a sample misclassified as a vocal stem when no vocals are actually present (i.e. a false-positive sample for vocals). In this case, the MSS model simply needs to predict silence for the vocals stem and produce it as output, resulting in no significant confusion. Conversely, consider a scenario in which the MSS model receives a sample misclassified as a non-vocal stem (e.g. drums + bass), despite the presence of vocals, resulting in a false-negative sample for vocals. In such a case, the model will attempt to allocate the vocals

Figure 4. Precision and recall curves of the proposed classifier across different thresholds (x-axis) on each instrument. The curves are generated using the MUSDB18 test set (*clean*).

present in the input data to the drum and bass stems. Furthermore, our model differs from traditional MSS training methods as it also accepts multi-stem data as input. In this context, the vocals are present as the correct answer for multiple mislabeled non-vocal stems, which confuses the model. This not only negatively affects the performance of the mislabeled stems but also the vocal stem itself.

As a consequence of the unique characteristics of our training process, false-negative samples have a more significant impact on MSS compared to false-positive samples, highlighting the increased significance of the recall metric. Considering this perspective, the results presented in Table 1 imply the possibility of the sub-optimal performance of MSS trained on outputs of Ψ_{clean} , where the recall values are lower for all stems compared to $\Psi_{refined}$.

5.2.2 Ablation studies

As shown in Table 3, we evaluate the performance of X-UMX under various conditions to better understand the significance of distinct aspects of our proposed method.

Threshold. We conduct experiments to examine the impact of threshold determination for the classifier during the training of MSS models using a classified dataset. The evaluation is performed on the MUSDB18 test set. We observe that reducing the threshold to 0.5 only exhibits an SDR of 0.03 degradation compared to the original threshold value of 0.9. This outcome can be attributed to the fact that only 8% of $\Psi_{refined}$ outputs fall within the range of [0.1, 0.9] upon inference on the MUSDB18 test set. In Figure 4, we present the precision and recall curves for each threshold on individual instruments. It is evident from the curves that the variations within that range for both precision and recall are not substantial. Consequently, the choice between thresholds of 0.9 or 0.5 does not yield any noticeable disparity. Furthermore, we conduct an experiment involving adaptive thresholds for each instrument, where the threshold for each instrument was set to maximize the F1 score of the classification performance. However, we observe a significant degradation in performance across all instruments when employing adaptive thresholds. Maximizing the F1 score necessitates a trade-off between recall and precision, often leading to a decline in recall to

enhance precision. Consequently, the performance of the MSS model experience degradation, aligning with the discussion presented in Section 5.2.1.

Training with multi-labeled data. When training solely with the data estimated as single-labeled, the performance is not as good as that of the proposed method. Incorporating both single- and multi-labeled data for fine-tuning after the initial training on single-labeled data leads to a slightly diminished performance, despite utilizing both types of labeled data during the training process.

Iterative self-refining. Finally, we examine the influence of the iterative self-refining technique on MSS performance. The results indicate that an MSS model trained with a noisy-labeled dataset refined five times through our method does not yield superior performance compared to the proposed model, trained on a dataset refined twice, and the performance difference is insignificant. This observation suggests that excessive refinement iterations do not necessarily lead to improved performance and that refining the dataset twice may be sufficient for optimal results.

6. CONCLUSION

In conclusion, this paper presented a self-refining approach to address the challenges of noisy-labeled data in training music source separation (MSS) models. Our proposed method refines mislabeled instrument tracks in partially noisy-labeled datasets, resulting in only a 1% accuracy degradation for multi-label instrument recognition compared to a classifier trained on a clean-labeled dataset. This study highlights the importance of refining noisy-labeled data for training MSS models effectively and demonstrates that utilizing the refined dataset for MSS yields results comparable to those obtained using a clean-labeled dataset. Considering the real-world scenario of accessibility only to a noisy dataset, MSS models trained on self-refined datasets outperformed those trained on datasets refined with a classifier trained on clean labels. The self-refining approach we introduced offers a promising direction for future research in the field of music information retrieval and has the potential to be extended to other applications requiring robust training on noisy-labeled datasets.

ABSTRACT

Quantifying the difficulty of playing songs has recently gained traction in the MIR community. While previous work has mostly focused on piano, this paper concentrates on rhythm guitar, which is especially popular with amateur musicians and has a broad skill spectrum. This paper proposes a rubric-based ‘playability’ metric to formalise this spectrum. The rubric comprises seven criteria that contribute to a single playability score, representing the overall difficulty of a song. The rubric was created through interviewing and incorporating feedback from guitar teachers and experts. Additionally, we introduce the playability prediction task by adding annotations to a subset of 200 songs from the McGill Billboard dataset, labelled by a guitar expert using the proposed rubric. We use this dataset to weight each rubric criterion for maximal reliability. Finally, we create a rule-based baseline to score each rubric criterion automatically from chord annotations and timings, and compare this baseline against simple deep learning models trained on chord symbols and textual representations of guitar tablature. The rubric, dataset, and baselines lay a foundation for understanding what makes songs easy or difficult for guitar players and how we can use MIR tools to match amateurs with songs closer to their skill level.

1. INTRODUCTION

Guitars have seen a 1.25-million-instrument sales rebound since the coronavirus pandemic, and the public’s fascination with fretted instruments has never been higher [1]. While traditional methods of transferring musical playability knowledge via music schools or private teachers still exist, online resources have made learning to play the guitar more accessible [2]. Indeed, online tools have led to a significant increase in the accessibility of learning *any* musical instrument, with a growing number of children and adults learning to play [3]. In addition, research suggests that informal self-practice can enhance motivation compared to formal teaching [4]. Ultimate Guitar and Chordify are

Figure 1. Physical and cognitive criteria for evaluating the playability of songs on the guitar position during guitar performance. Note that repetitiveness reflects both cognitive and physical factors, and that attentive listening to auditory feedback, while not a criterion itself, is necessary for developing and refining performative gestures.

examples of web-based music services that facilitate the automatic extraction of chord progressions from audio recordings of songs or community-proposed chord transcriptions and present them in a simple and accessible format for the growing group of amateur guitar players to use for practice and pleasure. Currently, Ultimate Guitar and Chordify have 39.7 million and 8 million users, respectively [5, 6].

Navigating the abundance of online chord data on platforms such as Ultimate Guitar or Chordify can be overwhelming, however, particularly for amateur learners seeking suitable pieces to enhance their expertise. While Chordify offers only a chord simplification option, Ultimate Guitar offers four categories of playability: absolute beginner, beginner, intermediate, and expert. Still, these categories may be too broad to suit all individuals. There is a need to establish a method that can predict a song’s difficulty level in a more fine-grained, automated, and preferably interpretable manner to assist learners in selecting appropriate pieces based on their skill level and personal taste.

Burgoyne, “Quantifying the Ease of Playing Song Chords on the Guitar”, in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

The Ultimate Guitar community has proposed a difficulty measurement system, which relied until recently on the input of multiple users, but like any system relying on human annotation, it is difficult to scale and can suffer from low reliability unless annotators are well-qualified and familiar with the annotation scheme.

This paper argues that a robust, reliable, and publicly documented difficulty prediction system could significantly benefit music learners in selecting challenging and rewarding pieces. Our main contributions are: (1) an interpretable guitar playability metric; (2) an extension of the Billboard dataset of 200 playability annotated songs, tested for reliability; and (3) a rule-based baseline for our playability metric. Furthermore, we investigated how well a previously well-performing model of piano playability compares to our rule-based baseline when trained on our dataset. The rule-based baseline and source code for all experiments are available to download.¹ We also include dataset statistics and other information to aid future research on playability.

2. RELATED WORK

We define *playability* as the level of musical proficiency required to perform a musical song on a specific instrument. While it is a crucial aspect of musical analysis and performance, it is a complex and challenging concept to measure or quantify. The playability of musical songs can be influenced by various factors, such as the complexity of the musical structure [7], the instrument of choice [8], and the musical context in which it is played [9]. In addition, individual musical competence for a particular song requires developing physical and cognitive skills and is influenced by personality [10]. Physical skills for the guitar include refining gestural mechanics, both left (fret fingering) and right (strumming) hand positioning [11]; cognitive skills include a comprehensive understanding of music theory, the ability to read musical scores, and attentive listening to the auditory feedback of the instrument for monitoring and planning of the performative gestures [12, 13].

Several studies have attempted to develop methods for automating the estimation of the difficulty level of piano sheet music. In 2012, researchers proposed a method that used MusicXML and seven high-level, instrument-agnostic criteria to determine the difficulty level of a song [14]. They evaluated the accuracy of their criteria by testing them on 50 piano pieces and validated their performance using principal component analysis and human judgement. Although their criteria were not instrument-specific, some of their categories aligned with or were similar to those used in other studies. Another study focused on predicting the difficulty level of piano sheet music using regression [15]. The authors proposed using RReliefF, a method for selecting relevant symbolic music features, to improve their performance, yielding R^2 values of up to .40.

In a recent study, researchers developed a piano score difficulty classification task and a novel difficulty score dataset [16]. They used a gated recurrent unit (GRU) neural

network with an attention mechanism and gradient-boosted trees to train their model on segments of musical scores with various piano-fingering representations. They derived the skill levels for each song from a musical practice-book series, where the editions were ordered based on difficulty. Books 1 and 2 were easier, classified as beginner by the authors; Books 3 and 4 as intermediate; and Books 5 and 6 as professional. They showed that novel piano fingering features were indicative of difficulty. Both machine-learning models performed better than their simple baseline, with the GRU with attention mechanisms performing best.

There has been limited research devoted to the investigation of guitar playability. Some studies have incorporated algorithmic proxies as a means of evaluating guitar playability [17]. Meanwhile, others have primarily focused on left-hand fingering aspects [18]. However, a conspicuous gap in the existing literature is the lack of manual annotation of difficulty by human experts. Like the practice-book dataset, any automatic system for assessing playability requires good human-generated ground truth. To address this challenge and move the scope from piano to guitar playability, we introduce a rubric-based metric to formalise the broad spectrum of playability levels.

3. A RUBRIC FOR GUITAR PLAYABILITY

In order to develop a rubric for guitar-playing difficulty, we interviewed local guitar experts, including guitar teachers, to investigate what they believed makes a song challenging to play, and what they consider when developing teaching material for a student (e.g., why it would or would not be suitable for their students, and how they simplify the chord progressions to make songs more accessible). Based on these interviews, we created a list of categories appropriate for evaluating playability and formulated four difficulty levels within each criterion, with a textual description for each level. We revised this initial draft by considering whether categories had too much overlap, and rephrased the names and level descriptions for each criterion accordingly. We requested and incorporated feedback on the updated rubric from two musical experts, and finally had a guitar expert annotate five songs with the rubric and give feedback as to whether it allowed annotating the data efficiently.

The final version of the rubric is in Table 1. It includes seven criteria: (1) ‘uncommonness of chord’, capturing the possibility of the player having played the chords in the specific song before, where unknown chords increase difficulty; (2) ‘chord finger positioning’, capturing how comfortably spaced the fingers on the guitar fretboard are positioned, wherein chords are more difficult to play if they contain very stretched out or cramped finger positions than when the fingers are close together and in a relaxed position; (3) ‘chord fingering difficulty’, capturing how many fingers a chord requires and the ratio of barre chords played in a song, based on guitar teaching books’ build-up of number of fingers used, and later on to barre chords; (4) ‘repetitiveness’, capturing that a song is easier to play if it has more repetition since it requires less task switching than a less repetitive song; (5) ‘right hand complexity’,

¹ <https://github.com/Marcel-Velez/playability-billboard>

Criterion	Weight	Very difficult (3 points)	Difficult (2 points)	Easy (1 point)	Very Easy (0 points)
Uncommonness of chord	3	A lot of uncommon chords	Some uncommon chords	Few uncommon chords	No uncommon chords
Chord finger positioning	3	Very cramped or very wide fingerspread	Uncomfortable or spread out fingers	Slightly uncomfortable or spread out fingers	Comfortable hand and finger position
Chord fingering difficulty	2	Mostly chords that require four fingers or barre chords	Some chords require four fingers to be played or are barre chords (not A or E)	Most chords require three fingers or are A or E barre chords	Most chords can be played with two or three fingers
Repetitiveness	2	No repeated chord progressions	A few repeated chord progressions	Quite a bit of repetition of chord progressions	A lot of repetition of chord progressions
Right-hand complexity	2	For some chords multiple inner strings are not strummed	For some chords one inner string is not strummed	For some of the chords one or more outer strings are not strummed	For the chords all strings are strummed
Chord progression time	1	Very quick chord transitions	Quick chord transitions	Slow chord transitions	Very slow chord transitions
Beat difficulty (syncopes/ghostnotes)	0	A lot of syncopes or ghostnotes	Some syncopes or ghostnotes	A few syncopes or ghostnotes	No syncopes or ghostnotes

Table 1. Proposed rubric for human annotators evaluating the difficulty of playing the chords of a song on the guitar. Although the rubric functions acceptably using the raw scores from the table header, it has even better predictive power when weighting the criteria according to the factor in the weight column. Note that the beat difficulty criterion provides so little extra information that we recommend omitting it (i.e., setting its weight to zero).

capturing how difficult the strumming is, where dampening or skipping inner strings is thought to be more difficult for strumming than skipping outer strings or just strumming all strings; (6) ‘chord progression tempo’, covering the tempo at which the individual has to switch between chords, wherein matching the correct finger positions is linked to the playability proficiency of the individual; and (7) ‘beat difficulty’, which models the regularity of the beat within a song, a more regular strum being easier to play than irregular strumming, and mixed regularity like that typical of the reggaeton genre being easier than fully irregular beat patterns. Figure 1 visualises these criteria in the context of actual guitar playing and organises them into physical and cognitive factors. The purpose of the rubric is to generate a single, overall playability score as the sum of scores for each rubric category. As will be discussed in more detail below, while a simple unweighted sum of points for each criterion already provides a reliable measure of playability, the reliability is improved even further by using a weighted sum, with uncommonness and finger positioning receiving the most weight and beat difficulty the least.

Our playability rubric focuses on *rhythm guitar* playability over solo guitar playability: in other words, we are not interested in melodies but rather in how difficult it is for guitar players to reproduce the chord progressions and rhythms of Western-style pop music. For MIR research surrounding chords and timing in Western-style pop music, one of the most frequently-used datasets is the McGill Billboard dataset [19]. The original Billboard dataset consists of 740 songs that were part of the Billboard Hot 100 chart between 1958 and 1991 and have been part of the MIREX challenges. Each song has time-aligned chord transcriptions and higher-level structural information, including meter and phrase. Since its release, other researchers have enriched the Billboard dataset with further information (e.g., the Billboard sub-corpus of the CoCoPops project [20] and the

Chord Annotator Subjectivity Dataset [21]). We decided to do the same as a testing ground for our playability rubric, creating the Billboard Playability Dataset.

4. THE BILLBOARD PLAYABILITY DATASET

As a basis for our dataset, we started with the 50 songs that are included in the Chord Annotator Subjectivity Dataset. Of the remaining 690 songs that appear in the original dataset and CoCoPops, we chose a random sample of 150, bringing the total number of songs in Billboard Playability Dataset to 200. In total, these 200 songs comprise 31 205 chords, 27 190 bars, and 5852 phrases.

For each song, we acquired the audio and made an online annotation dashboard with an audio player on the top, the Billboard chord transcriptions (including timing and phrasing information) on the left, and the rubric to the right. To create the dataset, we enlisted the assistance of a guitar expert who has previously demonstrated exceptional guitar skills and experience with other music annotation tasks. We instructed the annotator to perform the songs as written (i.e., without using a capo or making other simplifications, and also not adding extensions beyond those notated in the Billboard dataset), but they were free to choose any appropriate fingering. After using our dashboard to listen and play along with the song, the annotator filled in the rubric. Six of the songs appeared twice, unbeknownst to the annotator, and were scored similarly each time (maximally 5 points different on the weighted scale, whereas the standard deviation across all scores in the dataset was 6.6 points).

Histograms of the overall distributions per rubric criterion are in Figure 2. For one criterion, repetitiveness, the most difficult category was never used, which is somewhat to be expected given that all of the songs in the dataset are mainstream Western pop music. Most pop music tends to have some form of repetition, and not to consist of the unique chords and phrases that are characteristic of more

Figure 2. Histograms of playability scores per rubric criterion.

Bin	Chords	Bars	Phrases
All songs	156.03 (87.92)	135.95 (55.34)	29.26 (12.41)
Easy 25%	139.21 (85.66)	133.17 (44.64)	27.87 (10.87)
Moderate 25%	152.25 (73.79)	132.69 (42.13)	28.63 (9.48)
Hard 25%	158.29 (96.40)	135.59 (65.01)	28.27 (14.10)
Expert 25%	175.20 (89.84)	142.47 (64.69)	31.35 (14.19)

Table 2. Mean, and standard deviation (in brackets) of the number of chords, bars, and phrases for the entire dataset and per playability bins. The playability bins are based on quartiles of the weighted total score of the songs, the easiest having a score lower than 8, moderate lower than 12.5, hard lower than 18, and expert higher than 18.

Song	Artist	Score
Stand By Me	David and Jimmy Ruffin	1
Miss You	The Rolling Stones	2
No Charge	Melba Montgomery	2
Jungle Boogie	Kool and the Gang	2
Sunshine of Your Love	Cream	2
I Don't Need You	Kenny Rogers	28
Man In The Mirror	Michael Jackson	28
One Less Bell To Answer	The 5th Dimension	30
That Girl	Stevie Wonder	31
Do I Do	Stevie Wonder	34

Table 3. Easiest and most difficult songs in the dataset with their weighted playability scores.

experimental genres [22].

5. CAN PLAYABILITY BE MEASURED?

Given the inherent subjectivity in the concept of playability, one could be forgiven for wondering whether predicting playability is a well-posed question at all. Is there any common underlying measure of playability for the guitar, or is it merely a more-or-less arbitrary combination of criteria such as those we collected from guitar teachers for our rubric? To address this concern, we checked our annotator’s scores for *reliability*: if one tries to predict our annotator’s rubric scores from a single parameter per song, what proportion of variance in that parameter is ‘true’ variance as opposed to measurement error? Reliability can also be seen as the extent to which the rubric criteria co-vary, with high reliability indicating high covariance (and thus that all criteria are measuring a common underlying phenomenon), or alternatively, as the proportion of variance explained by the first principal component. Values of 0.7 or higher are desirable for this type of assessment [23].

Formally, we used a family of models known as *partial credit models* to assess reliability [24, 25]:

$$P[x_{ni}] = \frac{e^{\sum_{k=1}^{x_{ni}} \alpha_{ik}(\theta_n - \delta_{ik})}}{\sum_{k'=0}^K e^{\sum_{k=1}^{x_{ni}} \alpha_{ik'}(\theta_n - \delta_{ik'})}} \quad (1)$$

where x_{ni} denotes the rubric score given to song n for criterion i , $x_{ni} \in \{0, 1, \dots, K\}$, θ_n represents the underlying difficulty of song n , the δ_{ik} are threshold parameters for each level of rubric criterion i , and the $\alpha_{ik} > 0$ represent the increase in difficulty score when moving from level $k - 1$ to level k on rubric criterion i . We considered three variants

of the model: (1) the simple partial credit model, for which all α_{ik} are fixed to one (corresponding to a simple tally of rubric scores); (2) the generalised partial credit model, for which α_{ik} is allowed to vary in i but not in k (corresponding to the weighted rubric scores in Table 1); and (3) the extended partial credit model, for which the α_{ik} vary freely.

We fit all three models to the Billboard Playability Dataset using a hierarchical Bayesian implementation in Stan. The model included two hyperparameters μ and σ with priors $\mu \sim N(0, 1)$ and $\sigma \sim \text{Exp}(1)$. Given these hyperparameters, the remaining priors were $\alpha_{ik} \sim \text{Exp}(1)$, $\theta_n \sim N(0, 1)$, $\delta_{ik} \sim N(\mu, \sigma)$. We computed reliability according to the customary partial-credit formula [26]: the variance of the estimated song difficulties θ_n divided by the true difficulty variance. Because the true variance in our model is fixed to unity, we could estimate reliability directly as the variance of the set of posterior means $\hat{\theta}_n$. We compared the three models using approximate leave-one-out cross-validation [27]. The extended partial credit model performed best, but the generalised partial credit model was statistically indistinguishable from it (expected log probability difference = 8.7, $SE = 5.2$). The simple partial credit model was somewhat worse (elpd = 105.5, $SE = 14.2$). All models, however, showed good reliability: 0.74 for the simple partial credit model, 0.84 for the generalised, and 0.86 for the extended.

Given these results, we recommend the generalised partial credit model, which is statistically indistinguishable from the extended model and more parsimonious. The simple 3–3–2–2–2–1–0 weighting scheme accompanying the rubric in Table 1 falls within 90% credible intervals for all α_{ik} values from this model fit. Table 2 provides

some descriptive statistics for the dataset and quartile-based ‘playability bins’ under this weighting, and Table 3 lists the easiest and most difficult songs in the dataset. We can see an apparent increase in the mean number of chords, bars and phrases, which as described later in this paper, inspired us to try classifying difficulty based on length alone.

6. CAN PLAYABILITY BE PREDICTED?

In short, the rubric we developed can be used by expert guitarists to measure playability reliably, especially when weighting the criterion scores according to the generalised partial credit model. Expert annotation is expensive, however, and MIR can add value by automating this process.

6.1 Rule-Based Model

First, we developed a heuristic model as a baseline for comparison against more sophisticated learning methods. For those rubric criteria involving potentially different per-chord difficulties (e.g., fingering difficulty), we used a TF-IDF weighted average of the difficulty heuristic over all chords in the song:

$$\sum_c \text{TF}(c) \times \text{IDF}(c) \times \text{difficulty}(c) \quad (2)$$

where $\text{difficulty}(c)$ represents the difficulty score associated with a specific chord, considering factors such as chord finger positioning (CFP), chord fingering difficulty (CFD), or Right-hand complexity (RHC). In our case, TF is how often a chord appears in a song divided by the number of chords in the said song, and IDF is the log of the total number of songs divided by the number of songs that contain that chord. For the criteria that depend on fingering, we assumed one possible fingering per chord based on an extensive list of set finger positions on the Chordify website. We also had to simplify certain chords for which standard fingerings proved difficult to find, for example, chord with extensions like $\sharp 11$; we added a simplification penalty to compensate.

Uncommonness of chord (UC) uses a difficulty of one for all chords (i.e., it is the average TF-IDF weight).

Chord finger positioning (CFP) requires the guitar diagram and is based on a naïve approach of counting the distance between the lowest and highest played fret, not considering which strings they are played.

$$\text{CFP} = (1 + \text{simplified} \times f_{\text{simple}}) \times \text{finger distance}$$

Chord fingering difficulty (CFD) is based on how many fingers are used, and if a finger is used for more than one string, it is counted as a barre chord. For this criterion, we had three learnable parameters, one for the importance of how many fingers were used, one the importance of barre chords, and one for simplification.

$$\text{CFD} = (1 + \text{simplified} \times f_{\text{simple}}) \times (\text{fingers} * f_{\text{finger}} + \text{bar} * f_{\text{bar}})$$

Repetitiveness (R) is the number of *unique* phrases in a song according to the Billboard annotations.

Right-hand complexity (RHC) is based on apply the rubric level descriptions to fingering diagrams.

$$\text{RHC} = \begin{cases} 0 & \text{if no un-strummed strings} \\ 1 & \text{if outer strings not strummed} \\ 2 & \text{if one inner string not strummed} \\ 3 & \text{if multiple inner strings not strummed} \end{cases}$$

Chord progression time (CPT) is the average chord duration (in s) according to the Billboard annotations.

Beat difficulty (BD) is the ratio of chords that were longer or shorter than the most common chord duration in the Billboard annotations.

Given these preliminary scores per criterion, averaged according to TF-IDF weights as necessary, we iterated over all annotations in Billboard Playability Dataset and grid-searched for the three optimal thresholds, one between each pair of adjacent difficulty levels. For categories with learnable parameters, we extended the grid search accordingly.

6.2 Classification Experiments

In addition to the rule-based model we also trained neural networks on the playability prediction task using two architectures: LSTMs and DeepGRU with attention, which have been applied recently to piano playability [16, 28]. We replicated the same parameter settings as used in these papers. Inspired by our findings on length and difficulty above, we also included models using *only* representation length, with thresholds trained in the same way as the rule-based model.

For each architecture, we tested three distinct types of input: (1) processing each song character by character, which does not explicitly imply chord information (e.g. A:maj \rightarrow ‘A’, ‘:’, ‘m’, ‘a’, ‘j’); (2) splitting each chord into root and quality and treating those as unique input symbols, similar to music-theoretical understanding (e.g. A:maj \rightarrow ‘A’, ‘maj’); and (3) converting each chord into the corresponding guitar tablature, guitar-neck-like encodings displaying each of the six guitar strings with an ‘x’ label if it is skipped, ‘o’ if it is open, or which finger goes on which fret otherwise (e.g., A:maj \rightarrow [‘x’, ‘o’, ‘2:1’, ‘2:2’, ‘2:3’, ‘o’], where ‘2:1’ represents the 2nd fret being played by the first finger).

Given the characteristics of our rubric, we defined a custom loss function OL, which enforces an ordinal-like structure in the class prediction:

$$\text{OL} = \sum_{i=0}^3 \rho_i \times (\text{target} - i) \quad , \quad (3)$$

where ρ_i is the predicted probability of level i for the criterion in question. We trained the models in two settings: first to predict the total weighted playability score, and then to predict each individual criterion in turn. For all training configurations, we subdivided our dataset into 10 sections for our experiments and conducted 10-fold cross-validation.

Model	Input	CFP ↓	CFD ↓	UC ↓	RHC ↓	CPT ↓	BD ↓	R ↓	Aggregate ↓
Rule-based	-	1.04 (0.05)	0.85 (0.04)	0.95 (0.05)	0.78 (0.05)	0.90 (0.05)	1.20 (0.06)	0.93 (0.06)	12.38 (0.52)

Table 4. Playability prediction performances after training on the Billboard Playability Dataset. The columns are the performance when trained on and predicting each of the seven categories independently, followed by the error between all individual categories added together for the baselines and the error when trained to directly predict the aggregated score for the LSTM and DeepGRU models. Performances are reported in mean ordinal loss over 10 fold cross-validation with their standard deviation. The overall best performing model is the LSTM with chords split into root and quality, except for the two time-dependant categories: chord progression time (CPT) and beat difficulty (BD).

7. RESULTS

Our rule-based model performs better than the length-based difficulty predictions except for the chord progression time and beat difficulty category, as seen in Table 4. Since we use three different chords representations, each of which yield different lengths, we show length-based classification results for each representation, but in practice, these differences seem to play a negligible role in playability prediction based on length. All three length baselines-based achieve very similar losses for all categories.

When looking at the machine-learning models, we see that they are more variable, but on average substantially better, than all baseline models, both in classifying each criterion separately and predicting the weighted total difficulty. The only criterion where machine-learning models perform worse is the chord progression time. This criterion expresses the speed difficulty, which is characterised by chord duration. The lack in performance can be explained by the fact that the chord transcriptions which form the input to our model do not contain this duration information. Oddly, both machine learning models do outperform the baseline in predicting beat difficulty, which is also dependent on chord duration. When taking the histogram for this criterion into account, however, this performance can be explained by class imbalance: trying to set thresholds is worse than simply settling on the largest class. The same class imbalance is likely responsible for the partial-credit models assigning such a low weight.

Although there is no obvious best model when looking across performance on the individual criteria, the LSTM does show less variability than DeepGRU, and the LSTM trained on character input performs significantly better on predicting the weighted total score. We expected a bigger difference in input type, with the guitar chord diagram performing the best because this chord representation encodes the most guitar playing information, but this turned out to be the worst performing input type of the three. We hypothesise this is caused by the sequential models not picking up on the guitar or hand-related physics.

8. CONCLUSION

In this paper, we introduced a novel rubric that captures the playability of guitar songs. This rubric comprises seven criteria that can be combined into a single playability score. Next to this rubric, we also introduced the Billboard Playability Dataset, 200 playability annotations for songs from the Billboard dataset, which we used to validate the rubric’s reliability and confirm that indeed, guitar playability can be measured. Following these results, we developed several models for playability prediction. As a baseline, we started with a rule-based model that follows the rubric as mechanically as possible. We then trained and evaluated an LSTM and DeepGRU on three different types of chord representations. The representation encoding the least guitar – only using textual characters – surprisingly performed best, and the representation encoding the most guitar chord information – guitar tablature – performed the worst. Nevertheless both LSTM and DeepGRU outperformed the rule-based model with the LSTM performing the best at predicting the overall playability. In future work, we aim to extend both the dataset and the models to capture more nuances of playability, and we hope this work will encourage and enable more MIR researchers to explore the field of playability and improve online instrument learning environments. Additionally, we envision the potential extension of our research to incorporate MusicXML or GuitarPro formats, enabling the integration of our playability scores and models into widely used music notation software.

9. ACKNOWLEDGEMENTS

We are sincerely grateful to Jeanine Sier, Barbara de Bruin, Robin Willems, and Tom Strandberg for their valuable input and feedback on the rubric, and to Tom again for diligently annotating the songs. This research was supported by the Dutch Research Council (NWO) as part of the project In-Deep (NWA.1292.19.399). Additionally, we would like to express our appreciation to Chordify for their generous support in funding the annotations.

ABSTRACT

Alignment algorithms like DTW and subsequence DTW assume specific boundary conditions on where an alignment path can begin and end in the cost matrix. In practice, the boundary conditions may not be known a priori or may not satisfy such strict assumptions. This paper introduces an alignment algorithm called FlexDTW that is designed to handle a wide range of boundary conditions. FlexDTW allows alignment paths to start anywhere on the bottom or left edge of the cost matrix (adjacent to the origin) and to end anywhere on the top or right edge. In order to properly compare paths of very different lengths, we use a normalized path cost measure that normalizes the cumulative path cost by the path length. The key insight of FlexDTW is that the Manhattan length of a path can be computed by simply knowing the starting point of the path, which can be computed recursively during dynamic programming. We artificially generate a suite of 16 benchmarks based on the Chopin Mazurka dataset in order to characterize audio alignment performance under a variety of boundary conditions. We show that FlexDTW has consistently strong performance that is comparable or better than commonly used alignment algorithms, and it is the only system with strong performance in some boundary conditions.

1. INTRODUCTION

Dynamic Time Warping (DTW) is a dynamic programming algorithm for computing the optimal alignment between two sequences under certain assumptions. In the MIR literature, it is the most widely used method for aligning two audio recordings of the same piece of music. One of its assumptions is the boundary condition of the alignment path: it assumes that the alignment path begins at the origin of the pairwise cost matrix and ends in the opposite corner of the cost matrix. When working with real data like (say) Youtube recordings of a piece of classical music, the boundary conditions are usually unknown a priori and may not satisfy the restrictive assumptions of standard

DTW. This may be due to silence or applause at the beginning or end of videos, or perhaps due to some videos containing only one movement of a piece. This paper seeks to develop a more flexible variant of DTW that can handle a wider range of boundary conditions.

Previous work. There is a very large body of work on variations or extensions of DTW. These works generally fall into one of two categories. The first category focuses on mitigating the quadratic computation and memory costs of DTW. Some works approach this by speeding up an exact DTW computation through the use of lower bounds [1, 2], early abandoning [3, 4], using multiple cores [5, 6], or specialized hardware [7, 8]. Tralie and Dempsey [9] introduce a method for computing exact DTW with linear memory by processing diagonals rather than rows/columns. Other works propose approximations to DTW that require less computation, runtime, or memory. Some approaches include approximate lower bounds [10, 11], approximations of DTW distance [12, 13], imposing bands in the cost matrix to limit extreme time warping [14, 15], computing alignments at multiple resolutions [16, 17], parallelizable approximations of DTW [18], or working with a fixed amount of memory [19]. The second category focuses on extending the behavior of DTW in some way. Some examples in the MIR literature include handling structural differences like repeats and jumps in music [20–22], performing alignment in an online setting [23–25], handling partial alignments [26, 27], using multiple performances to improve alignment accuracy [28], accounting for pitch drift in a capella music [29], and aligning sets of source recordings and mixtures [30].

Shortcomings. Our work aims to make DTW more flexible by focusing on an often overlooked aspect: boundary conditions. The vast majority of previous works on DTW or its variants focus on handling one specific type of boundary condition. For example, DTW (and any of its approximations or efficient implementations) assumes that an alignment path begins at the origin of the cost matrix and ends in the opposite corner. Similarly, subsequence DTW assumes that an alignment path begins somewhere on the longer edge of the cost matrix and ends on the opposite edge. As mentioned above, in many situations the boundary conditions are unknown a priori or may be incompatible with the assumptions of standard alignment methods.

Our approach. FlexDTW is designed to be flexible in handling a wide range of boundary conditions. Assuming that the origin of the cost matrix is in the lower left corner,

Figure 1. Different boundary conditions for the alignment path between two sequences. The full match and subsequence conditions are well handled by standard algorithms, but the other conditions are not.

FlexDTW allows an alignment path to begin anywhere on the left or bottom edge, and it allows the alignment path to end anywhere on the top or right edge. Figure 1 shows several examples of boundary conditions that FlexDTW can handle. To properly compare alignment paths of very different length, it is necessary to use a normalized path cost measure that normalizes the cumulative path cost by the path length. While it is possible to determine the optimal alignment path ending at any position by following the backpointers in the backtrace matrix, this would result in an impractically high computation overhead. The key insight with FlexDTW is that the Manhattan length of an alignment path can be computed by simply knowing the starting and ending location of the alignment path (without knowing the actual path itself). The starting location information can be computed in a recursive manner and stored during the dynamic programming stage, making it possible to compute normalized path costs in an efficient manner.

Contributions. This paper has three main contributions. First, we introduce an alignment algorithm called FlexDTW that handles a wide range of boundary conditions. FlexDTW allows an alignment path to start anywhere on the two edges of the cost matrix adjacent to the origin (e.g. bottom and left edge), and it allows alignment paths to end anywhere on the other two edges (top and right edge). Second, we design a suite of 16 benchmarks based on the Chopin Mazurka dataset [31] in order to characterize audio alignment performance under a variety of specific boundary conditions. Third, we present experimental results showing that FlexDTW has consistently strong performance across all 16 benchmarks that is comparable to or better than the best-performing system from a set of widely used audio alignment algorithms. We provide source code for our implementation of FlexDTW, along with code for running all experiments in this paper.¹

2. SYSTEM DESIGN

In this section we describe the FlexDTW algorithm in detail. To make it clear how FlexDTW relates to previous

work, we begin with a brief overview of DTW and subsequence DTW.

2.1 DTW and Subsequence DTW

Standard DTW estimates the alignment between two feature sequences x_0, x_1, \dots, x_{N-1} and y_0, y_1, \dots, y_{M-1} . It accomplishes this by using dynamic programming to find the optimal path through a pairwise cost matrix $C \in \mathbb{R}^{N \times M}$ under a set of allowable transitions. DTW assumes that the alignment path begins at $(0,0)$ and ends at $(N-1, M-1)$ in the cost matrix. Subsequence DTW is a variant of DTW that finds the optimal alignment between a query sequence x_0, x_1, \dots, x_{N-1} and any subsequence within a (typically longer) reference sequence y_0, y_1, \dots, y_{M-1} . Subsequence DTW assumes that the alignment path includes the entire query sequence but can begin and end anywhere in the reference sequence.

2.2 FlexDTW: Algorithm

FlexDTW is a variant of DTW that seeks to handle a much wider range of boundary conditions. It is designed to handle the boundary conditions of standard DTW, subsequence DTW, as well as many other conditions that are not handled by DTW or subsequence DTW. We first give an overview of the boundary conditions that FlexDTW is designed to handle, describe the main challenge in allowing flexible boundary conditions, introduce a key insight, and then explain the algorithm in detail.

Boundary conditions. Figure 1 shows an overview of the boundary conditions that FlexDTW is designed to handle. In the given figure, the alignment path may begin anywhere along the left edge or bottom edge of the cost matrix, and the alignment path can end anywhere along the top edge or right edge.² Note that the resulting set of allowable alignment paths is a superset that contains all allowable DTW paths and all allowable subsequence DTW paths, in addition to many other types of alignment paths.

Challenge. The main challenge in allowing such flexible boundary conditions is normalization. Because the set of allowable paths has such an enormous variation in path length, one must use a normalized path cost to fairly compare one alignment path with another. (Otherwise, the path with minimum cumulative path cost will simply be the alignment path with fewest elements.) This means that our metric for comparing different alignment paths must normalize the cumulative path cost by some measure of alignment path length. To determine the length of an alignment path ending at position (i,j) , we could simply follow the backpointers in the backtrace matrix, but this introduces an impractically high computational overhead to the algorithm.

Key insight. The key insight with FlexDTW is that the Manhattan length of an alignment path does not require knowing what the actual alignment path is. Assuming that the alignment path is monotonically non-decreasing (as is the case with DTW), computing the Manhattan length of

¹ Code can be found at <https://github.com/anonymized/>.

² We exclude a buffer region near the top left and bottom right corners to avoid short, degenerate paths, as will be explained later.

an alignment path only requires knowing the starting point and ending point of the path. The starting location of any optimal alignment path can be computed recursively with minimal computational overhead and simply stored as an additional piece of information (similar to the backtrace information). Having the starting location of all optimal alignment paths allows us to efficiently calculate normalized path costs without having to perform any backtracking. We can then compare the goodness of alignment paths by comparing their path cost per Manhattan block.

Algorithm. We now describe the FlexDTW algorithm for aligning two feature sequences x_0, x_1, \dots, x_{N-1} and y_0, y_1, \dots, y_{M-1} . Similar to DTW, one must specify a set of allowable transitions and corresponding transition weights. In addition, there is one hyperparameter `buffer` that specifies a minimum allowable path length, which helps to avoid short, degenerate alignment paths. The algorithm consists of five steps, which are described below.

The first step is to compute a pairwise cost matrix $C \in \mathbb{R}^{N \times M}$, where each element $C[i, j]$ indicates the distance between x_i and y_j under some distance metric.

The second step is to initialize three matrices: a cumulative cost matrix $D \in \mathbb{R}^{N \times M}$, a backtrace matrix $B \in \mathbb{Z}^{N \times M}$, and a starting point matrix $S \in \mathbb{Z}^{N \times M}$. In order to allow alignment paths to begin anywhere in either sequence without penalty, we initialize $D[0, j] = C[0, j]$, $j = 0, 1, \dots, M - 1$ and $D[i, 0] = C[i, 0]$, $i = 0, 1, \dots, N - 1$. We also initialize S for all valid starting points for alignment paths. Since the starting locations are all of the form $(0, j)$ or $(i, 0)$, we can efficiently encode the starting locations as a single integer, where positive integers indicate a starting location $(0, j)$ and negative integers indicate a starting location $(i, 0)$. This reduces the memory overhead of matrix S . Accordingly, we initialize $S[0, j] = j$, $j = 0, 1, \dots, M - 1$ and $S[i, 0] = -i$, $i = 0, 1, \dots, N - 1$.

The third step is to compute the elements in D , B , and S using dynamic programming. For a given set of allowable transitions $\{t_1, t_2, t_3\}$ (assumed to be $\{(1, 1), (1, 2), (2, 1)\}$ in the equation below) and corresponding multiplicative weights w_1, w_2, w_3 , the optimal transition $B[i, j]$ can be computed with the following recursive formula:

$$B[i, j] = \arg \min_{k=1,2,3} \begin{cases} \frac{D[i-1, j-1] + w_1 \cdot C[i, j]}{i+j-|S[i-1, j-1]|} & \text{if } k = 1 \\ \frac{D[i-1, j-2] + w_2 \cdot C[i, j]}{i+j-|S[i-1, j-2]|} & \text{if } k = 2 \\ \frac{D[i-2, j-1] + w_3 \cdot C[i, j]}{i+j-|S[i-2, j-1]|} & \text{if } k = 3 \end{cases} \quad (1)$$

The numerator elements in the equation above are cumulative path costs, and the denominator elements are the Manhattan lengths of each candidate path. Once the best transition has been determined, the value of $D[i, j]$ can be updated as:

$$D[i, j] = \begin{cases} D[i-1, j-1] + w_1 \cdot C[i, j] & \text{if } B[i, j] = 1 \\ D[i-1, j-2] + w_2 \cdot C[i, j] & \text{if } B[i, j] = 2 \\ D[i-2, j-1] + w_3 \cdot C[i, j] & \text{if } B[i, j] = 3 \end{cases} \quad (2)$$

Similarly, the value of $S[i, j]$ can be updated as:

$$S[i, j] = \begin{cases} S[i-1, j-1] & \text{if } B[i, j] = 1 \\ S[i-1, j-2] & \text{if } B[i, j] = 2 \\ S[i-2, j-1] & \text{if } B[i, j] = 3 \end{cases} \quad (3)$$

Note that the elements in D still indicate unnormalized path costs (as in DTW), but the decision of which transition is the best is made based on the normalized path cost (i.e. path cost per Manhattan block).

The fourth step is to identify the endpoint of the optimal alignment path. The candidate set of valid ending points is given by $E_{cand} = \{(N-1, j) \mid j = \text{buffer}, \dots, M-1\} \cup \{(i, M-1) \mid i = \text{buffer}, \dots, N-1\}$, which corresponds to any location in the top or right edge in Figure 1. We exclude a user-specified buffer region from the top left and bottom right corners, which ensures that the alignment path is of a certain minimum length. This buffer region helps to prevent the algorithm from selecting short, degenerate alignments paths with low normalized path cost. Given this set of candidate locations, we select the endpoint E_{best} to be

$$E_{best} = \arg \min_{(i,j) \in E_{cand}} \frac{D[i, j]}{i+j-|S[i, j]|} \quad (4)$$

where the objective function is the path cost per Manhattan block.

The fifth step is to backtrace from the selected endpoint using the backpointers in B until we reach an element $(0, j)$, $j = 0, 1, \dots, M - 1$ (on the bottom edge in Figure 1) or $(i, 0)$, $i = 0, 1, \dots, N - 1$ (on the left edge). The resulting alignment path is the final estimated alignment.

2.3 FlexDTW: Hyperparameters

In this subsection we discuss the hyperparameters in FlexDTW and our method for setting them. As mentioned previously, FlexDTW has three kinds of user-defined parameters: a set of allowable transitions, a corresponding set of transition weights, and a buffer hyperparameter that specifies a minimum path length for allowable alignment paths. Note that DTW also requires specifying a set of transitions and transition weights, so FlexDTW has one additional hyperparameter compared to DTW.

Transitions & weights. A typical set of transitions for audio alignment tasks is $\{(1, 1), (1, 2), (2, 1)\}$, which imposes a maximum warping factor of 2. This set is usually preferred to sets that include $(0, 1)$ and $(1, 0)$ transitions, since these transitions can lead to degenerate alignments. We will use this set of allowable transitions throughout this paper, unless otherwise noted. The associated transition weights can be set in many different ways. In FlexDTW, there is one particular setting of transition weights that is of theoretical interest: $w_1 = 2$, $w_2 = 3$, $w_3 = 3$. This setting weights each transition according to its Manhattan distance. Note that in standard DTW (where the alignment path is assumed to start at $(0, 0)$ and end at $(N-1, M-1)$), every allowable alignment path has the same Manhattan

Piece	Files	mean	std	min	max

Table 1. Overview of the original Chopin Mazurka dataset. This is used as the source data to generate the benchmark suite. All durations are in seconds.

distance, so this setting effectively treats every path as being equally likely. It is analogous to a maximum likelihood formulation in which all possibilities are treated as equally likely a priori, and selection is made entirely based on the observations. For this reason, we recommend setting the transition weights in FlexDTW as $w_1 = W$, $w_2 = 3$, $w_3 = 3$, where W can be tuned on a validation dataset. $W = 2$ corresponds to a maximum likelihood formulation, and smaller values of W correspond to a bias towards diagonal alignment paths. In our experiments, we use $W = 1.25$, which provided optimal performance on the training set.

Buffer. The purpose of the buffer is to prevent the algorithm from selecting short, degenerate alignment paths that may have low normalized path cost. For example, silence at the end of one sequence may match silence at the beginning of the other sequence, resulting in a very short alignment path with low normalized path cost. The buffer should be interpreted as the minimum length along one sequence that an alignment path must match in order to be considered a valid path. This could simply be set manually based on knowledge of the task or data. In our case, however, our suite of benchmarks spans such a wide range of sequence lengths and alignment path lengths that a single setting is not ideal. Therefore, we determined the buffer hyperparameter in a data-dependent way for every individual query based on two considerations. First, when one sequence is much longer than the other sequence, the desired behavior is probably a subsequence alignment. In this case, we want the entire shorter (query) sequence to be matched. Second, when the two sequences are approximately the same length, much more flexibility can be afforded and an intuitive parameter is to define the minimum percentage of either sequence that must be matched. Putting these two considerations together, we recommend setting the buffer hyperparameter in the following way: for aligning two sequences of length L_1 and L_2 , set $\text{buffer} = \min(L_1, L_2) \cdot (1 - (1 - \beta) * \frac{\min(L_1, L_2)}{\max(L_1, L_2)})$. This sets the buffer to a fraction of the shorter sequence length, where the fraction is close to 1 when L_1 and L_2 are very different (i.e. the subsequence case) and close to β when L_1 and L_2 are approximately the same. β can thus be interpreted as the minimum fraction of either sequence that must be matched when both sequences are equal in length. We tuned β on the training set and found $\beta = 0.1$ to work well.

3. EXPERIMENTAL SETUP

In this section we describe the suite of 16 benchmarks that we use to characterize the performance of alignment algorithms under a variety of boundary conditions.

Original data. The raw source material for our benchmarks comes from the Chopin Mazurka dataset [31]. This dataset consists of numerous historic recordings of five different Chopin Mazurkas, along with beat-level annotations of each recording. All of the recordings for two of the Mazurkas (Opus 17 No. 4 and Opus 63 No. 3) were set apart for training and development, and the recordings from the other three Mazurkas were set apart for testing. Table 1 provides an overview of the dataset.

Evaluation. To evaluate alignment performance, we consider every pair of recordings of the same Mazurka. This results in $\binom{64}{2} + \binom{88}{2} = 5844$ training pairs and $\binom{64}{2} + \binom{34}{2} + \binom{51}{2} = 3852$ testing pairs. For each pair of recordings A and B , we compare the estimated alignment path against the ground truth beat timestamps in the following manner. At each ground truth beat timestamp in recording A , we compute the alignment error between the estimated corresponding timestamp in recording B (based on the predicted alignment path) and the ground truth corresponding timestamp in recording B (based on the beat annotations). We report aggregate alignment performance as an error rate indicating the percentage of alignments that have an alignment error greater than a fixed error tolerance.

Modifications: Overview. We generated synthetically modified versions of the Mazurka dataset in order to simulate a variety of boundary conditions. Each modified version of the Mazurka dataset contains the exact same number of recordings, but each recording has been modified to study a particular boundary condition. Thus, the number of training pairs and testing pairs is the same as in the original benchmark, but the audio data and corresponding annotations have been modified appropriately. Each benchmark is evaluated as described above. Below, we describe how we constructed each of the 16 benchmarks.

Full Match. The full match benchmark is the Mazurka dataset in its original unmodified form. This boundary condition assumes that both recordings start and end at the beginning and end of the piece. In Figure 1, this corresponds to an alignment path that starts in the lower left corner and ends in the upper right corner.

Subsequence. The subsequence benchmark assumes that one recording matches a subsequence in the other recording. For every pair of recordings A and B , a randomly sampled L -second interval within recording A is selected and aligned against the entirety of recording B . We construct three separate subsequence benchmarks with $L = 20, 30, 40$.

Partial Start. The partial start benchmark assumes that both recordings start together but that one recording ends early (e.g. only contains one movement). For every pair of recordings A and B , we randomly sample a number in the interval $[0.55, 0.75]$, select that percentage of recording A (starting from the beginning), and align the fragment of recording A against the entirety of recording B .

Partial End. The partial end benchmark assumes that both recordings end together but that one recording starts part way through the piece. For every pair of recordings A and B , we randomly sample a number in the interval $[0.55, 0.75]$, select that percentage of recording A at the end (i.e. starting in the middle of the recording and extending until the end), and then align the fragment of recording A against the entirety of recording B .

Partial Overlap. The partial overlap benchmark assumes that both recordings have some temporal overlap, but that one recording contains extra content before the region of overlap and the other recording contains extra content after the region of overlap. For every pair of recordings A and B , we (a) randomly sample a number in $[0.55, 0.75]$ and select that percentage of recording A starting from the beginning, (b) randomly sample a different number in $[0.55, 0.75]$ and select that percentage of recording B at the end, and then (c) align the fragment of A against the fragment of B .

Pre. The pre benchmark assumes that both recordings contain the entire piece but that one recording has a period of silence at the beginning. For every pair of recordings A and B , we prepend L seconds of silence to recording A and align it to the entirety of recording B . We construct three separate pre benchmarks with $L = 5, 10, 20$.

Post. The post benchmark assumes that both recordings contain the entire piece but that one recording has a period of silence after the piece ends. For every pair of recordings A and B , we append L seconds of silence to recording A and align it against the entirety of recording B . We construct three separate post benchmarks with $L = 5, 10, 20$.

Pre-Post. The pre-post benchmark assumes that both recordings contain the entire piece, but that one recording contains extra silence at the beginning and the other recording contains extra silence at the end. For every pair of recordings A and B , we prepend L seconds of silence to recording A , append L seconds to recording B , and then align the two recordings. We construct three separate pre-post benchmarks with $L = 5, 10, 20$.

4. RESULTS

We report experimental results with FlexDTW and several standard alignment algorithms:

- DTW1: Standard DTW with transitions of $(1, 1), (1, 2), (2, 1)$ and corresponding weights 2, 3, 3.
- DTW2: Standard DTW with transitions of $(1, 1), (1, 2), (2, 1)$ and corresponding weights 1, 1, 1.
- DTW3: Standard DTW with transitions of $(1, 1), (1, 2), (2, 1)$ and corresponding weights 1, 2, 2.
- SubseqDTW1: Subsequence DTW with (query, reference) transitions of $(1, 1), (1, 2), (2, 1)$ and corresponding weights 1, 1, 2.
- SubseqDTW2: Subsequence DTW with (query, reference) transitions of $(1, 1), (1, 2), (2, 1)$ and corresponding weights 2, 3, 3.
- SubseqDTW3: Subsequence DTW with (query, reference) transitions of $(1, 1), (1, 2), (2, 1)$ and corresponding weights 1, 2, 2.

- NWTW: A variant of DTW proposed in [21] that allows skip transitions $(0, 1)$ and $(1, 0)$, in addition to the usual $(1, 1), (1, 2), (2, 1)$ transitions. The skip transitions incur a fixed penalty cost γ , which is a hyperparameter that we tuned on the training data.

We assessed the performance of a larger set of DTW versions (with different sets of allowable transitions and corresponding transition weights), but we only include the 3 versions with best performance to avoid overcluttering Figure 2. Of particular note, we did experiment with DTW versions that had $(0, 1)$ and $(1, 0)$ transitions, but always found those versions to perform much worse. Likewise, we considered other versions of subsequence DTW but only include the top 3 versions in Figure 2. The subsequence DTW systems are unique in that they are not symmetric. For these systems, we always assume that the alignment is trying to match the shorter recording against a subsequence in the longer recording. Note that all of the systems above can be used with any feature representation and distance metric. For simplicity, we use standard chroma features (as computed with default parameters in librosa) and a cosine distance metric for all systems.

Figure 2 compares the performance of FlexDTW and the above algorithms on our benchmark suite. For each system, we fixed the hyperparameter settings and evaluated its performance across all 16 benchmarks. Each panel in Figure 2 corresponds to one of the 16 benchmarks, and the different colored bars show the error rate at 200ms tolerance for different systems. On top of each colored bar, we have also overlaid two black horizontal bars indicating the error rate at 100ms tolerance (above) and at 500ms tolerance (below).

There are two things to notice about the results in Figure 2. First, the seven baseline systems only handle a subset of boundary conditions. In other words, each of the baseline systems performs well on certain benchmarks and very poorly on other benchmarks. For example, the DTW systems perform well on the fully matching benchmark (for which they are designed), but they perform terribly on the subsequence benchmarks and perform worse and worse as more silence is prepended or appended to either recording. Likewise, the subsequence DTW systems perform well on the subsequence benchmarks, but they fail on the partial overlap benchmark and have only moderate performance on the pre, post, and pre-post benchmarks. NWTW has strong performance across most benchmarks but fails completely on the subsequence and partial overlap benchmarks. All of the baseline systems completely fail on the partial overlap benchmark, since none are designed to handle that boundary condition. Second, FlexDTW has consistently strong performance across all 16 benchmarks. On all benchmarks, it has a performance that is comparable to or better than the best-performing baseline system. On the partial overlap benchmark, it is the only system that has strong performance, with an error rate that is comparable to its performance on the other benchmarks. These results demonstrate its flexibility in handling a wide range of boundary conditions.

Figure 2. Performance of alignment algorithms on the 16 boundary conditions in our benchmark suite. Colored bars indicate error rate at 200ms error tolerance, and the horizontal bars indicate error rates at 100ms (above) and 500ms (below). Error rates greater than 50% are not shown.

System	1k	2k	5k	10k	20k	50k
DTW	.033	0.14	0.87	3.5	13.8	87.3

FlexDTW	.038	0.16	1.05	4.21	16.9	111.1

Table 2. Average runtime to process a cost matrix of size $N \times N$. Columns indicate different sizes N , and rows indicate different systems. Each reported number is an average over 10 trials, and times are expressed in seconds.

5. ANALYSIS

In this section we conduct several analyses to provide deeper insight into FlexDTW.

Table 2 compares the runtime of FlexDTW and the baseline alignment systems. We measured how long each alignment algorithm took to process a cost matrix of size $N \times N$, where N ranges from 1k to 50k. Each number in the table is an average over 10 trials. FlexDTW and NWTW were implemented in python with numba acceleration, and we used the librosa implementation for DTW and subsequence DTW (also using numba acceleration). All experiments were run on an Intel Xeon 2.40 GHz CPU. For longer sequence lengths, we can see that FlexDTW incurs a 20-25% runtime overhead compared DTW and a 10-15% runtime overhead compared to subsequence DTW. This overhead comes primarily from needing to perform a floating-point division to evaluate every candidate path.

Another drawback of FlexDTW is the additional memory overhead of storing S . We can estimate the memory overhead in the following manner. DTW requires allocating three matrices: the pairwise cost matrix $C \in \mathbb{R}^{N \times M}$, the cumulative cost matrix $D \in \mathbb{R}^{N \times M}$, and the backtrace matrix $B \in \mathbb{Z}^{N \times M}$. Assuming that C and D are matrices of 64-bit floating point numbers and B is a matrix of 8-bit unsigned integers, the total memory cost is $8NM + 8NM + 1NM = 17NM$ bytes. FlexDTW

requires allocating an additional matrix S for storing the starting point locations. If the two sequence lengths are less than $2^{15} = 32768$, then S can be stored as a matrix of 16-bit integers, resulting in an extra memory overhead of $2NM$. If either sequence length is greater than 32768, then S must be stored as a matrix of 64-bit integers, resulting in an extra memory overhead of $4NM$. In summary, the memory overhead is $\frac{2NM}{17NM} \approx 12\%$ for sequence lengths less than 32768 and $\frac{4NM}{17NM} \approx 24\%$ for longer sequences.

We also investigated and identified two main failure modes of FlexDTW. The first failure mode occurs when there is extreme time warping between the two recordings. Because the (1, 1) transition is penalized proportionally less than the (2, 1) or (1, 2) transitions, the algorithm will sometimes take a “shortcut” of (1, 1) transitions to/from an edge of the cost matrix at the beginning or end of the alignment path. The second failure mode occurs when alternate matching paths are selected. For example, in the Mazurka Opus 17 No. 4, the first four measures and the last four measures match, which creates an additional matching alignment path under the flexible boundary conditions of FlexDTW.

6. CONCLUSION

We have introduced a time warping algorithm called FlexDTW that is designed to handle a wide range of boundary conditions. We artificially generate a suite of 16 benchmarks based on the Chopin Mazurka dataset, which characterizes alignment performance in a variety of boundary conditions. In all 16 boundary conditions, FlexDTW has strong performance that is as good or better than a set of widely used alignment algorithms. Compared to the librosa implementation of DTW and subsequence DTW, FlexDTW incurs a runtime overhead of 10-25% and a memory overhead of 12% for sequences less than length 2^{15} and 24% for longer sequences.

7. ACKNOWLEDGMENTS

We would like to thank Kate Perkins for her contributions in the early stages of this project. This material is based upon work supported by the National Science Foundation under Grant No. 2144050.

alexandre.dhooge@algomus.fr

ABSTRACT

Tablature notation is widely used in popular music to transcribe and share guitar musical content. As a complement to standard score notation, tablatures transcribe performance gesture information including finger positions and a variety of guitar-specific playing techniques such as *slides*, *hammer-on/pull-off* or *bends*. This paper focuses on bends, which enable to progressively shift the pitch of a note, therefore circumventing physical limitations of the discrete fretted fingerboard. In this paper, we propose a set of 25 high-level features, computed for each note of the tablature, to study how bend occurrences can be predicted from their past and future short-term context. Experiments are performed on a corpus of 932 *lead guitar* tablatures of popular music and show that a decision tree successfully predicts bend occurrences with an F_1 score of 0.71 and a limited amount of false positive predictions, demonstrating promising applications to assist the arrangement of non-guitar music into guitar tablatures.

1. INTRODUCTION

The guitar, whether acoustic or electric, is (in most cases) a fretted instrument which enforces the playing of discrete pitch values on a chromatic scale. This constraint can be beneficial, as it limits the risk of playing out-of-tune. However, it also prevents microtonal experiments or continuous pitch shifts, which can be a powerful means of musical expressiveness. To overcome this limitation, guitarists can alter the string tension with their fretting hand [1] to reach a completely new pitch, up to several semitones higher. This technique is called string bending, or just *bends*, and is an important part of guitar playing in blues, rock or pop music. Even though bending a string can only increase the pitch of a note, a variety of bend types are used. While guitar players mostly agree over the existing variations, the names used can differ. In this paper, we consider the five bend types described in Gomez’s work [2]: *Basic upward*, *Held*, *Reverse*, *Up & Down*, and *Complex* bends for bends that do not belong to any of the previous categories.

Guitar tablatures, compared to standard staff notation, include fingering information on where to play a note with

a given pitch on the fretboard. Tablatures are therefore an effective notation to display playing techniques, the position of the fretting hand being critical to know how to perform a bend. Examples of bends are shown in a tablature in Figure 1, different bend types are represented with differently shaped arrows. Knowing where and when to use bends is part of the idioms of guitar pop music and an important part of learning this style. However, the variety of bend types can make it difficult to choose how to use them. For instance, a guitarist playing a score that was composed for another instrument may want to add expressiveness using bends, and could need help on deciding which notes to bend and which bend to use. Moreover, a tool suggesting bends could also improve the quality of online tablatures that sometimes do not have guitar techniques annotations.

Could bends be inferred from musical context? Are they correlated to other elements of a score or a tablature such as pitch, rhythm, or hand position? In this paper, we propose to model bent notes and their context through temporal, pitch and tablature related information. Such a representation could be used to predict which notes are bent from a score or a tablature. Our contribution is three-fold: (1) we define a set of high-level features to model bent notes and their context, (2) we conduct a statistical study on bends based on those features, and (3) we propose a method for predicting bends from tablatures.

The rest of this paper is organized as follows: after discussing related works in Section 2, we introduce our modeling choices in Section 3. The dataset and its statistical study are presented in Section 4. We introduce our prediction algorithm in Section 5 and reflect on this work in Section 6.

2. RELATED WORKS

Guitar tablatures are often studied in the audio realm for guitar music transcription [3, 4]. In particular, automatic transcription of playing techniques from audio has also been studied, for instance with hexaphonic microphones [5] or deep learning techniques [6]. Of course, this task is not restricted to guitar and has been applied to other instruments such as the Chinese *guqin*, which also features several string bending techniques [7].

Another related task is the generation of tablatures, which has been studied increasingly in the last decade. Playing techniques can be included in generation frameworks to obtain results closer to actual human performance. The Transformer-XL model presented in [8, 9] can for instance generate tokens representing playing tech-

Figure 1: Excerpt from Lynyrd Skynyrd’s *Free Bird* solo. In the first measure, the first two bends are *basic upward bends*, the remaining ones are *held bends*. In the second measure, the first bend is a *reverse bend*, and the other ones are *up and down bends*. While all bends of this example are whole tones (denoted by *full*), the amplitude of a bend can vary. String movements are labeled above, according to the representation presented in Section 3. An audio rendering of this excerpt is available on the [accompanying repository](#).

niques. Chen et al. [10] also consider *Technique* events, but only for picking-hand techniques, since the generation focuses on fingerstyle guitar. McVicar et al. present in [11] a method to generate tablatures of guitar solo phrases, and fretting-hand techniques are added in a post-processing step. Beyond the case of guitar, playing techniques modeling includes symbolic piano music generation with sustain pedal information [12].

Another large part of guitar tablature MIR research focuses on fingering prediction, where a model is designed to predict the pitch/fret combination for each note of a musical score. This problem has been studied with path-finding algorithms [13] and minimax techniques [14]. More recently, Cheung et al. [15] used a deep learning model to generate fingering annotations, though not for guitar but violin. Those instruments nonetheless share some properties, and a study of fingering prediction on string instruments like the violin or the guitar, compared to other instruments, can be found in [16]. However, the task of using symbolic music to study occurrences of playing techniques is rarely studied. Xie and Li [17] propose to predict playing techniques as a tagging task on symbolic bamboo flute music but, to the best of our knowledge, no such work has been proposed for guitar music.

3. MODELING BENDS IN TABLATURE

To formulate bend prediction as a machine learning task, we adopt a representation for bent notes consisting of four different labels. We also need to pre-process our data to obtain bend-less scores, and musical features that could be used to train a machine learning model. Those considerations are presented hereafter.

3.1 Labeling

In the introduction, we presented the different types of bends that can be encountered in guitar tablatures. Based on this taxonomy, we define 4 labels that represent the motion and current state of the played string:

- \emptyset — the string is not bent;

- \uparrow — the string is bent, causing the pitch to go up;
- \rightarrow — the string was bent previously and is plucked again in that state. The pitch is constant, but is not the one expected from the note’s string/fret position;
- \downarrow — the string was bent and is released, making the pitch go down accordingly.

We define those labels to circumvent the issue with *up & down* and *complex bends* that are not transcribed consistently. Labeling notes with the associated string movements therefore permits representing bends accurately, without loss of generality. Using these labels, all non-bent notes will be labeled \emptyset , *basic upward bends* are labeled \uparrow , *held bends* correspond to \rightarrow , and *reverse bends* are \downarrow . To fit with this representation, *up & down bends* are split into two notes of equal duration, the first one being labeled with \uparrow , and the second one with \downarrow . An example of such labeling on an actual guitar track is shown on top of Figure 1.

While bends can be of different amplitude, we do not include that information in our labeling, as we do not aim at predicting it in this work but only focus on predicting when bends occur. Similarly, we do not distinguish single notes from chords when predicting bends. This means that when the system predicts the presence of a bend in a chord, it does not specify on which string it occurs. The impact of this simplification is however limited, as bends rarely occur inside chords (12% of bend events are found in chords in our corpus).

3.2 Deriving a bend-less score simplification

Since our goal is to predict whether a note is played with a bend, we must start from a *simplified* tablature that does not have any bend information. Removing bend annotations from a tablature is however not a straightforward task since this technique affects the pitch of the performed note. We design the following procedure when translating bent notes from the fret/string space to the pitch space:

- If a note is labeled by \emptyset , its pitch is directly obtained from the string/fret combination;

Figure 2: Excerpt of *Watermelon in Easter Hay*, Frank Zappa, as transcribed [18] by Steve Vai in standard notation (top). Below are two possible tablature representations of this excerpt with (middle), or without (bottom) bends.

- Otherwise, the pitch is the one of the bend arrival note. In particular:
 - if the label is \uparrow or \rightarrow , the arrival pitch is the pitch of the string/fret combination, to which the bend amplitude is added;
 - if the label is \downarrow , the arrival pitch is the one corresponding to the string/fret position, because the string is released to its default state.

This approach is the one chosen by Steve Vai when transcribing Frank Zappa’s melodies to standard notation, as we illustrate in Figure 2. The middle tablature shows how this excerpt is actually played (based on a live performance) and the bottom tablature illustrates how the same excerpt might be played without bends. While it is not an issue in this example, there is an uncertainty regarding where a bent note would be played on the fretboard, without a bend (keeping its destination pitch but losing the technique). A guitar player might indeed choose to play a note on a higher string, if remaining on the same string called for an uncomfortably large hand span. Because deciding arbitrarily of a hand position could introduce bias into our model, we choose not to include any string/fret information concerning the current note in the proposed features for our classification task, as explained hereafter.

3.3 Selected Features

To predict whether a note is bent, we propose an intermediate representation as a set of high-level features, presented in Table 1. Some descriptors focus on the event under scrutiny, while others provide short-term context information, both from the past and the future. Part of the features are derived from standard staff notation and convey *temporal* and pitch information, while others are related to *position* and the tablature space. If the studied event is a chord, the pitch, fret, and string values are averaged over all its constituting notes. While the average might seem an overly simple statistic, experiments with other functionals

Temporal	Duration
	Beat Strength
	Longer than previous Shorter than previous Same duration as previous
Pitch	Number of notes
	Pitch ^(j)
	Pitch jump ^(n±k)
	Accidentals Pitch-class w.r.t scale root
Position	Fret ^(n±k)
	String ^(n±k)
	Fret jump ^(n±2)
	String jump ^(n±2)

Table 1: List of high-level features extracted from the note events. Let n denote the current note index, an exponent on a feature tells on which neighbors it is computed. $k \in \{1, 2\}$ because we discard any positional information related to the current note, and $j \in \llbracket n - 2, n + 2 \rrbracket$. Other features are only computed on n .

such as *min*, *max* or *standard deviation* did not improve the results. We have discarded any open strings for the fret-board features so that the average fret and string represents the actual position of the fretting hand. Apart from absolute/relative duration values, temporal features include the *beat strength*, which is a value between 0 and 1 suggesting how *strong* the beat of a note is. We obtain this value from the default implementation of the `music21` library [19]. These beat strength values have been designed for Western classical music, and therefore may be debatable for pop and rock music. However, they are mostly used here to represent onset times independently of the time signature, while grouping notes that share rhythmic properties.

In addition to the features on the current note, we extract a context of two past and two future note events, as preliminary experiments did not show any benefits of longer contexts. Additional boolean features are provided to recall if a neighboring note event is missing, when a note is preceded or followed by a whole rest for instance. When a note is missing, all corresponding features are set to 0. From this context, we compute the pitch jump between neighboring notes as well as the string and fret jumps when they are defined, *i.e.*, not with respect to the current note – because we do not know where the guitarist would play the note if they were to bend it. We expect these features to help our algorithm derive the hand position on the fretboard, which would be useful since bends are more likely to occur on certain spots of the fretboard, as will be shown subsection 4.2. Furthermore, we add information about the key signature through the number of accidentals (positive for sharps, negative for flats). From those accidentals, we derive the root note of the corresponding pentatonic minor scale (that scale encompassing much of guitar popular music [20]) and store the position of each note on this scale. For example, one sharp would make the root E, and an A would be numbered 5 since it is 5 semitones above E.

\emptyset	\uparrow	\rightarrow	\downarrow	Total
123 231	9627	1270	3314	137 442

4. DATASET

4.1 Guitar Tablature Corpus

Our experiments are performed on the proprietary corpus *MySongBook* composed of 2247 guitar tablatures accurately transcribed by professional musicians in the .gp GuitarPro format. A subset of 932 tracks estimated as *lead guitar* – totaling more than 130 000 notes – was extracted by applying the classification technique from [21]. Our experiments focus on lead guitar parts, as they were felt to feature heavier use of playing techniques. In contrast with the whole corpus, which includes 2.5% of bent notes, our lead guitar sub-corpus indeed contains 10% of bent notes, slightly mitigating the observed class imbalance.

Our work is implemented in *Python* and uses `music21` [19] and `scikit-learn` [22] libraries. To foster reproducibility, all our code is made publicly available (parsing of .gp files, extraction of features, training, and evaluation of bend classification models). We also release the complete set of features extracted on each note of our corpus, plus corresponding labels at: <http://algoramus.fr/code/>.

4.2 Statistical study

Table 2 reports the distributions of bend labels in our corpus. The distribution of bent notes on the fretboard, compared to all notes, is shown in Figure 3. We observe that most bends occur on the top 3 strings in the middle area of the fretboard. This observation differs from notes in general that are played on all strings, and especially on the two middle ones and around the 7th fret. While it is possible that the obtained heatmaps are biased by an over-representation of certain key signatures in the dataset – 43% of the tracks are in G major/E minor or C major/A minor – this bias should affect both heatmaps equally, so their mutual comparison is still possible. Because bent notes are found on both higher strings and higher frets than all notes, their pitch is similarly higher on average, as it can be observed in Figure 4a.

The distribution of *beat strength* values is shown in Figure 4b. Because most beats and sub-beats in a measure have a beat strength of 0.25 or below, no label is mostly played on strong beats. An interesting result is that \uparrow and \downarrow labels appear more often on stronger beats than \emptyset and \rightarrow . This apparent correlation of \uparrow and \downarrow labels with the meter might suggest a link between note expressiveness and accentuation in performance, which would need to be investigated further. In contrast, the \rightarrow label is most often encountered on *weaker* beats. This observation can be linked to the fact that this technique is often used as a quick repetition of the previous note and will thus be played on the next offbeat, like in Figure 1.

The comparison of the duration of notes with or without bends (Figure 4c) confirms that \uparrow and \downarrow labels share some essential properties. Both labels have a proportionally higher tendency to be found on notes with longer duration, even though eighth note is the most common duration for all classes. This figure also confirms that \emptyset and \rightarrow classes share some context properties. Figure 4d shows a strong tendency of \uparrow labels to appear on notes with longer duration than their predecessor. This further supports the hypothesis that bends could be used to emphasize significant notes in a lead guitar part. That result could also be related to the substantial physical effort required to bend a string on short duration notes. The accompanying code provides interactive computation of the distribution of the other features.

5. CLASSIFICATION RESULTS

A decision tree [23] was trained to predict the bend label of a note from its feature representation. We choose this high-level approach to facilitate the interpretation of the results as well as the analysis of the contribution of the features. In addition to the elaboration of a predictive model, conducting our experiments in an explainable AI framework allows us to improve our understanding of the use of bends in this repertoire. We hope that the use of light models enabled by highly expressive musical representations will also contribute to promoting low energy consumption approaches in machine learning for MIR.

5.1 Model performance

Our classifier is trained on 75% of the dataset, and evaluated on the remaining 25%. To avoid some leakage from the training set to the test set, we ensure the split does not separate notes from a same track. We also ensure that the class imbalance is similar in both sets. Duplicate feature vectors are removed track-wise to avoid overfitting due to repeated riffs/patterns. But, we acknowledge the fact that identical feature vectors can be found in different tracks and thus keep duplicates when found in different files.

The confusion matrix of Figure 5 shows the results of the multi-class classification on the joint prediction of all labels. Because the dataset is highly unbalanced, our model is naturally biased towards the \emptyset label. However, it successfully identifies more than half of the \uparrow and \downarrow la-

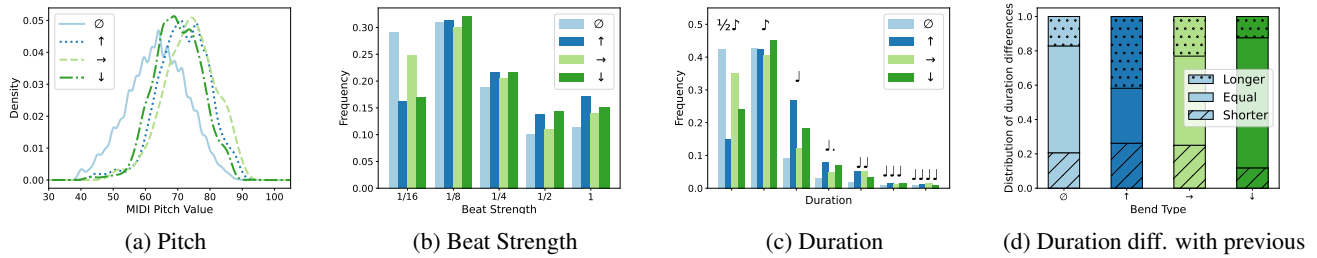

Figure 4: Distribution of four of the extracted features, normalized per bend class.

	\emptyset	\uparrow	\rightarrow	\downarrow
\emptyset	28566 94%	1237 4%	179 < 1%	513 2%
\uparrow	786 36%	1298 59%	94 4%	23 1%
\rightarrow	133 47%	56 20%	83 29%	14 5%
\downarrow	312 40%	37 5%	3 < 1%	424 55%
True label	\emptyset	\uparrow	\rightarrow	\downarrow
Predicted label	\emptyset	\uparrow	\rightarrow	\downarrow

Figure 5: Confusion matrix obtained for classifying each note event to one of the bend class. This matrix was obtained on a split with average performance.

bels. Samples labeled as \rightarrow are often misidentified as \uparrow but this result still shows, presumably, that the model captures the difference between \emptyset and \rightarrow labels. We tried applying SMOTE oversampling [24] to the training data and observed that it doubles the number of correctly identified \rightarrow notes and increases the ratio of well-classified \downarrow notes by approximately 10%. Nevertheless, \uparrow notes *True Positives* (TP) ratio is about the same while the quantity of \uparrow notes misidentified as \rightarrow or \downarrow increases. Similarly, TP ratio of \emptyset notes drops by 5 p.p., so 2000 more notes are wrongly predicted as bent. Because we observed that bent notes are sparse in guitar tracks, we consider that *precision* is more important than *recall* and do not use any oversampling for the rest of our analysis.

5.2 Feature importance

To assess the contribution of each feature, we conduct an *all bend* binary classification experiment where $\uparrow, \rightarrow, \downarrow$ are merged into a single class, versus the \emptyset class. Table 3 shows the importance of the eight most contributing features, computed using the random feature permutation technique introduced in [25] and monitoring its impact on the F_1 score of our model. Temporal and pitch features appear to have a higher impact on classification than position-related features, an observation confirmed by training the binary classifier on selected subsets of features. The results in Figure 6 confirm the dominant influence of pitch features. However, adding gesture and temporal information noticeably improve the results. This result suggests

Figure 6: Average F_1 -scores from 4 different train/test splits for the binary classification task. The leftmost part shows the performance of the decision tree trained on all features, with (Full+) or without (Full) SMOTE oversampling. The rightmost part corresponds to decision trees trained with a reduced set of features. *T* stands for temporal, *Pi* for pitch and *Pos* for position features.

that, while fret context contributes to induce bent notes, a large part of the prediction can be done from the strict musical content as notated in musical scores.

6. PREDICTION ANALYSIS

In addition to the quantitative results presented in the last section, we present a qualitative analysis of selected predictions. Figure 7a shows one bent note wrongly identified as \emptyset and, conversely, one non-bent note identified as \uparrow . Following the decision path provided by the decision tree, we can gain some insight on what feature differences have

Feature	Importance
Pitch	0.20
Pitch jump ⁽ⁿ⁺¹⁾	0.17
Pitch jump ⁽ⁿ⁻¹⁾	0.16
Duration	0.14
Same dur. as previous	0.07
Fret jump ⁽ⁿ⁻²⁾	0.07
String ⁽ⁿ⁺¹⁾	0.05
Pitch ⁽ⁿ⁺¹⁾	0.05

Table 3: Feature importance of the 8 most significant features for the decision tree. Standard deviation of any feature importance is never above 0.005.

(a) Excerpt from *Highway Star*, Deep Purple.

(b) Excerpt from *Jailbreak*, AC/DC.

Figure 7: Examples of predictions obtained with our Full Tree model on two different excerpts. Labels shown represent the predicted label for the current note. Only wrong predictions are shown for clarity. All other notes are labeled correctly.

caused those wrong predictions. Both notes actually have more than half their decision path in common and split on their Pitch jump⁽ⁿ⁺²⁾ value, suggesting that the first discrepancy was due to future context. In particular, the second false prediction did not use any features related to past context. This might also explain this error because the pitch could be obtained by bending on the 10th fret by one semitone – an information that could be derived from future context – but continuity with the previous notes called for playing the note without bend on the 11th fret – an information that should have been derived from past context. Another observation is that, in spite of similar context, the second bent note was misidentified whereas the fourth bent note was not. While those two notes look very similar at first glance, the latter has a longer duration because it is tied to the following eighth note, which illustrates the importance of the *duration* feature. An analysis of the decision paths indeed shows a divergence from the second decision rule, based on that feature. This highlights the presumably strong influence of rhythm in the classification of the first four bent notes, which bypasses pitch features.

Figure 7b also shows a regular note wrongly tagged with a \uparrow label. The decision path for this prediction does not consider any feature related to the next note. It does however use many features concerning the second next note, which was correctly classified as \emptyset , most likely because of its lower duration. The lack of information about the current note’s position was probably critical in that case. The second error on that tablature is an *up & down bend* that was not identified, probably because of the low duration of the involved notes. Nevertheless, this example suggests that our method to obtain a bend-less transcription from an up & down bend might be detrimental to the algorithm performance. Indeed, our procedure has an impact on *duration* and *pitch jump*^(n±1) which are among the most useful features to our algorithm. We observe however that our algorithm predicted correctly six bend labels in the

selected examples with a limited amount of false positives. These encouraging results suggest that our method could be used as a suggestion tool for the idiomatic use of bends.

7. CONCLUSION

In this paper, we proposed a model of guitar bends and discussed how these expressive playing techniques relate to both tablature and score content. Introducing a set of high-level features, we showed that a decision tree can successfully predict bend occurrences with satisfactory precision, in spite of the difficulty of the task due to the low proportion of bent notes in guitar music. In particular, the low performance on predicting \rightarrow labels suggests that our modeling choices could be improved and that held bends might not be considered as an expressiveness technique but rather another way of playing regular notes. An advantage of our approach is the use of a lightweight and explainable algorithm, facilitating its use in an assisted-composition context. In future work, this approach could be extended to other guitar playing techniques, and might benefit from adding more context information like the chord being played over a bar, using rhythm guitar parts aligned with lead guitar. Because bends are arguably more easily performed with the ring finger and little finger than other fingers of the fretting-hand, combining our work with finger prediction technique [16] might also improve prediction performance. Finally, our modeling strategy could also be used to study the playing style of specific guitarists, and evaluate the potential of bends for automatic guitarist identification. Indeed, our approach supposes that bends can be explained by general musical features regardless of the artist. This is debatable since famous players can be identified by their solos (without considering audio nor any playing technique) [26]. It would be interesting to see if bends are artist-dependent and, if so, to develop a model that predicts bends in the style of a specific guitarist.

SELF-SIMILARITY-BASED AND NOVELTY-BASED LOSS FOR MUSIC STRUCTURE ANALYSIS

Geoffroy Peeters

LTCI, Télécom-Paris, Institut Polytechnique de Paris, France

ABSTRACT

Music Structure Analysis (MSA) is the task aiming at identifying musical segments that compose a music track and possibly label them based on their similarity. In this paper we propose a supervised approach for the task of music boundary detection. In our approach we simultaneously learn features and convolution kernels. For this we jointly optimize - a loss based on the Self-Similarity-Matrix (SSM) obtained with the learned features, denoted by SSM-loss, and - a loss based on the novelty score obtained applying the learned kernels to the estimated SSM, denoted by novelty-loss. We also demonstrate that relative feature learning, through self-attention, is beneficial for the task of MSA. Finally, we compare the performances of our approach to previously proposed approaches on the standard RWC-Pop, and various subsets of SALAMI.

1 Introduction

Music Structure Analysis (MSA) is the task aiming at identifying musical segments that compose a music track (a.k.a. segment boundary estimation) and possibly label them based on their similarity (a.k.a. segment labeling). We deal here with MSA from audio. MSA is one of the oldest tasks in Music Information Retrieval¹ but still one of the most challenging. This is due to the difficulty to exactly define what music structure is and hence be able to create annotated datasets to measure progress or train systems. People agree that the structure can be considered from multiple viewpoints² [2] [3], is hierarchical [4] and is partly subjective [5]. Probably because of this complexity, the number of contributions in MSA has remained low despite its large number of applications: audio summarization [6], interactive browsing [7–9], musical analysis [10], tools for researcher (to help chord recognition [11], source separation [12] or downbeat estimation [13]).

To solve the two MSA tasks (boundary detection and segment labeling), three assumptions [14] are commonly used: (1) *novelty* (we assume that segments are defined

by large —novel— changes of the musical content over time), (2) *homogeneity* (the musical content is homogeneous within a given segment) and (3) *repetition* (the musical content —homogeneous or not— can be repeated over time). This has been extended by [15] to a fourth *regularity* assumption (the segment’s durations are regular over time). Combining those allows to construct MSA systems.

1.1 Related works

Over time, a large palette of approaches has been proposed for MSA. We only review the ones related to our work and refer the reader to Nieto et al. [16] for a good overview. We consider three periods according to the nature of the audio features —hand-crafted (HC) or learned by deep learning (DL)—, and the nature of the detection system which uses the audio features — HC or trained by DL —.

First period: HC detection system applied to HC audio features. In these systems HC audio features (such as MFCC or Chroma) were given as input to HC detection system (such as the checkerboard kernel, novelty-score [17]), unsupervised training (such as HMM [6], NMF [18]), supervised (such as OLDA [19]) or pattern matching algorithms (such as DTW [20] or variants [21]).

Second period: DL detection system applied to HC audio features. Over time, more and larger annotated datasets for MSA have been developed; which concomitantly with the development of DL has allowed to reformulate the MSA task in terms of supervised learning. The detection system developed here mainly target the task of boundary detection. For example, [22] [23] [24] propose to train in a supervised way a Convolutional Networks (ConvNet) $\hat{y} = f^\theta(\mathbf{X})$ to estimate if the center of a patch of HC audio features \mathbf{X} is a boundary ($y=1$). Various HC audio features (or combinations of) are used here: Log-Mel-Spectrogram, Pich-Class-Profile through SSM expressed in (time,time) or (time,lag).

Third period: HC detection system applied to DL audio features. To deal with the endless debate about the choice of HC audio features, McCallum et al. [25] propose to learn them. For this, they train an encoder f^θ by minimizing a Triplet Loss (TL) [26] between patches of beat-synchronous Constant-Q-Transform (CQT). For the TL, they propose a Self-Supervised-Learning (SSL) paradigm³ to define the anchor A patch, positive P patch and negative N patch. Using the homogeneity assumption, neighboring times are supposed to be more similar to each

¹ Foote’s paper [1] on SSM was published in 1999.

² musical role, acoustic similarity, instrument role, perceptual tests

³ which does not require any annotated segments and labels

other (therefore used to define A and P) than to distant ones (used to define N). For training they use a very large unlabeled dataset of 28345 songs. This method however does not consider the repetition assumption⁴.

Wang et al. [27] revised McCallum approach in a supervised setting. In this, the patches P (resp. N) are now explicitly chosen so as to have the same (resp. different) annotated segment label than the patches A . This supervised method now consider both the homogeneity and repetition assumption. In another work [28], they propose a spectral-temporal Transformer-based model (SpecTNT) trained with a connectionist temporal localization (CTL) loss to jointly estimate music segments and their labels.

McCallum approach has also been extended by Buisson et al. [29] to take benefit from the hierarchy of structure in music. They show that the obtained deep embeddings can improve segmentation at various levels of granularity.

Rather than learning features for MSA, Salamon et al. [30] proposed to re-use pretrained ones. Those are obtained using encoders previously trained on different tasks (Few-Shot Learning sound event and music auto-tagging). Those are then used as input to a Laplacian Structural Decomposition algorithm for MSA.

1.2 Proposal and paper organization

Following the previous taxonomy, our proposal would belong to the category “DL detection system applied to DL audio features”. Unlike previous feature learning approaches (that rely on a Triplet Loss paradigm), we utilize a more straightforward paradigm (illustrated in Figure 1) which is a succession of two steps, each with its own objective. The two objectives are jointly optimized.

In the **first step**, we learn the parameters θ of an encoder f^θ such that when applied to the sequence of inputs $\{\mathbf{X}_i\}_{i \in \{1 \dots T\}}$ that represent a given track (where T is the length of temporal sequence), the encoded features allows the estimation of a SSM, $\hat{\mathbf{S}}_{ij}^\theta$, which attempts to reproduce a ground-truth SSM, \mathbf{S}_{ij} . For training f^θ we use an approach similar to the SSM-Net approach proposed in [31], i.e. defining a loss which directly compare the obtained SSM $\hat{\mathbf{S}}_{ij}^\theta$ to a ground-truth SSM \mathbf{S}_{ij} .

In the **second step**, we learn a set of kernels \mathbf{K}^θ such that when convolved over the main diagonal of the estimated SSM $\hat{\mathbf{S}}_{ij}^\theta$ it allows the estimation of a novelty score $\hat{\mathbf{n}}_i^\theta$, which attempts to reproduce a ground-truth novelty score, \mathbf{n}_i . This novelty score is usually obtained using a fixed checkerboard kernel [32]. The resulting function is named novelty score since high values in it indicate times where the content change (it is homogeneous before and after). It has been shown that better kernels can be used (for example using multi-scale kernels [33]) and that it is possible to train such kernels \mathbf{K}^θ considered as the kernels of a ConvNet (for example [22] and [23] in the case of a (time,lag) SSM or [24] in the case of a (time,time) SSM, which is our case). This is the approach we follow here.

⁴ N could potentially be in a segment which is a repetition of the segment containing A

Another proposal we make in this paper, is to consider the learning of relative features, i.e. features which are relative to the given track.

Paper organization. We provide an overview of our system in part 2, describe the inputs to our system (part 2.1), detail the two losses (parts 2.2 and 2.3), motivate relative feature learning (part 2.4), detail the architecture of our encoder f^θ (part 2.5) and the training process (part 2.6). In part 3, we provide a large-scale evaluation of our proposal. It should be noted that although we only evaluate our method for the task of segment boundary detection, it can also be used for segment labeling given the clearness of the obtained SSM.

2 Proposal

2.1 Input data $\{\mathbf{X}_i\}$

The inputs $\{\mathbf{X}_i\}$ to our system are simple patches⁵ of Log-Mel-Spectrogram. We didn’t consider beat-synchronous features as in [25] given the non-reliability of beat estimation outside popular music. Using `librosa` [34], we first computed Mel-spectrogram with 80 mel-bands, using a 92ms window length and 23ms hop size. Those are then converted to log-amplitude using $\log(1 + 100 \cdot mel)$. We then aggregate them (mean operator) over time to lead to a 0.1s hop size. The final $\{\mathbf{X}_i\}$ are then patches of 40 successive frames (corresponding to 4s.) with a hop size of 5 frames (corresponding to 0.5s.).

2.2 SSM-loss

Given a sequence of inputs $\{\mathbf{X}_i\}_{i \in \{1 \dots T\}}$, we apply the same encoder f^θ individually to each \mathbf{X}_i to obtain the corresponding sequence of embeddings $\{\mathbf{e}_i^\theta\}_{i \in \{1 \dots T\}}$. Those are then L2-normalized. We can then easily construct an estimated SSM, $\hat{\mathbf{S}}_{ij}^\theta$, using a distance/similarity/divergence g between all pairs of projections:

$$\hat{\mathbf{S}}_{ij}^\theta = g(\mathbf{e}_i^\theta = f^\theta(\mathbf{X}_i), \mathbf{e}_j^\theta = f^\theta(\mathbf{X}_j)), \quad \forall i, j \quad (1)$$

We use here a “scaled” cosine-similarity for g which, because the embeddings are L2-normalized, reduces to

$$\hat{\mathbf{S}}_{ij}^\theta = 1 - \frac{1}{4} \|\mathbf{e}_i^\theta - \mathbf{e}_j^\theta\|_2^2 \in [0, 1] \quad (2)$$

It is then possible to compare $\hat{\mathbf{S}}_{ij}^\theta$ to a ground-truth binary SSM, \mathbf{S}_{ij} , derived from annotations. We consider this as a multi-class (a set of T^2 binary classifications) problem and hence minimize the sum of Binary-Cross-Entropy (BCE) losses. However, given the unbalancing between the two classes in \mathbf{S}_{ij} (which contains much more 0 than 1), we used a weighting factor λ computed as the percentage of positive values in \mathbf{S}_{ij} . The lower λ is, the more we put emphasis on positive ($\mathbf{S}_{ij}=1$) examples:

$$\mathcal{L}_{SSM}^\theta = -\frac{1}{T^2} \sum_{i,j=1}^T (1-\lambda) \left[\mathbf{S}_{ij} \log(\hat{\mathbf{S}}_{ij}^\theta) \right] + \lambda \left[(1-\mathbf{S}_{ij}) \log(1-\hat{\mathbf{S}}_{ij}^\theta) \right] \quad (3)$$

Since the computation of the SSM $\hat{\mathbf{S}}_{ij}^\theta$ is differentiable w.r.t. to the embeddings $\{\mathbf{e}_i^\theta\}$, we can compute $\frac{\partial \mathcal{L}_{SSM}^\theta}{\partial \theta}$:

⁵ We utilized patches as input (rather than frames) because we believe that homogeneity exists at the pattern level rather than the frame level.

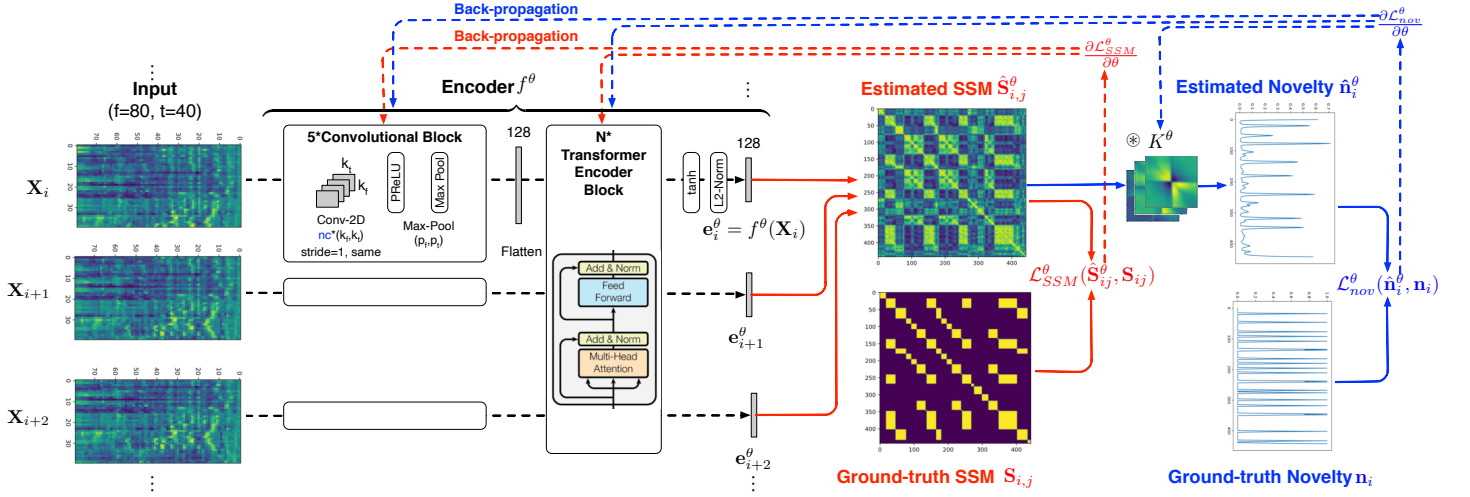

Figure 1. Proposed architecture and training paradigm minimizing a SSM loss \mathcal{L}_{SSM}^θ and a novelty loss \mathcal{L}_{nov}^θ .

$$\frac{\mathcal{L}_{SSM}^\theta}{\theta} = \sum_{i,j=1}^T \frac{\mathcal{L}_{SSM}^\theta}{\mathbf{S}_{ij}^\theta} \left(\frac{\mathbf{S}_{ij}^\theta}{\mathbf{e}_i^\theta} \frac{\mathbf{e}_i^\theta}{\theta} + \frac{\mathbf{S}_{ij}^\theta}{\mathbf{e}_j^\theta} \frac{\mathbf{e}_j^\theta}{\theta} \right) \quad (4)$$

We can then use standard gradient-descent algorithms to optimize θ which will jointly optimize f^θ for all the \mathbf{X}_i .

Optimizing directly \mathbf{S}_{ij}^θ has relationship with Metric Learning / Contrastive Learning in which the A, P, N are chosen based on their similarity (such as in Wang et al. [27]). In comparison, we consider here simultaneously all possible pairs of time as A, P, N . This is actually in line with the fact that we aim at learning features relative to a track (see part 2.4) and we therefore need to consider simultaneously the interaction between all projections \mathbf{e}_i^θ .

2.3 Novelty-loss

We propose to learn the kernels \mathbf{K}^θ such that when convolved with the estimated SSM \mathbf{S}_{ij}^θ (see eq.(2)) along its main diagonal the resulting estimated novelty score \mathbf{n}_i^θ approximate a ground-truth novelty score \mathbf{n}_i . This kernel convolution can be simply implemented as an extra convolution layer (without bias) on top of the estimated SSM \mathbf{S}_{ij}^θ with a sigmoid output activation. We then define the novelty-loss as

$$\mathcal{L}_{nov}^\theta = \frac{1}{T} \sum_{i=1}^T BCE(\mathbf{n}_i^\theta, \mathbf{n}_i) \quad (5)$$

2.4 Relative feature learning

In previous works dealing with feature learning for MSA it is assumed that, once trained, the network f^θ always projects a given segment \mathbf{X}_i in the same way whatever its surrounding context.

We advocate here that for the task of MSA the projection of \mathbf{X}_i should depend on its context. The motivation for doing so is that the features that highlight the temporal structure of a music track usually depend on the track itself. For example, if the instrumentation or the timbre re-

mains constant over the track, the structure may arise from variation of the harmonic content; in other cases, it will be the opposite. Therefore, feature learning for MSA should be made relative-to-a-track.

To let each feature \mathbf{X}_i “know” about surrounding times features $\mathbf{X}_1 \dots \mathbf{X}_{i-1} \mathbf{X}_{i+1} \dots \mathbf{X}_T$ we introduce layers of Self-Attention (SA) [35] in our encoder⁶.

2.5 Network architecture f^θ

The architecture of the encoder f^θ is given in Figure 1. It is made of a succession of 5 consecutive convolution blocks followed by N blocks of Transformer-Encoder.

Each convolution block is made of a 2D convolution followed by a PReLU [36] activation and a 2D max-pooling. The kernel size (k_f, k_t) , the number of channels n_c and pooling size (p_f, p_t) of each layer are the following: layer-1: $(k_f, k_t)=(5,5)$ $n_c=32$ $(p_f, p_t)=(2,2)$, layer-2: $(5,5)$ 32 $(2,2)$, layer-3: $(5,5)$ 64 $(2,2)$, layer-4: $(5,5)$ 64 $(2,2)$, layer-5: $(5,2)$ 128 $(5,2)$. The output of the last convolutional blocks has dimension $(1,1)$ with $n_c=128$ channels and is flattened to a 128-dim vector.

Each input \mathbf{X}_i is independently projected using the convolutional blocks. These outputs are then considered as a temporal sequence which is fed to N blocks of Transformer Encoder (each made up of a SA layer with 8 heads, skip-connection, a normalization layer and two fully-connected layers with an internal dimension of 128). The outputs are then passed to a tanh and L2-normalized. They form a sequence of embeddings \mathbf{e}_i^θ $i=1 \dots T$ with $\mathbf{e}_i^\theta \in \mathbb{R}^{128}$ which are used to compute \mathbf{S}_{ij}^θ .

The size of the kernels \mathbf{K}^θ is fixed to $(41,41)$ which roughly corresponds to 20s. The kernels \mathbf{K}^θ are either initialized randomly or initialized with checkerboard kernels similar to the ones of [32]. In this case, checkerboard kernels have the same size $(41,41)$ but are damped with Gaussian function with different σ (randomly chosen in the range $[3s \ 5s]$). We used 3 different kernels \mathbf{K}^θ which are

⁶Note that the use of the SSM-loss alone does not allow f^θ to encode relative features; this is the task of the SA.

then combined using (1x1) convolution. The diagonal of the resulting feature-map then goes to a sigmoid activation and is considered as the estimated novelty \mathbf{n}_i^θ .

Our architecture remains lightweight with a number of parameters ranging from 268K to 567K depending on the number of Transformer Encoder blocks (from $N=0$ to 3).

2.6 Training.

We train our network by minimizing jointly the two losses defined by eq. (3) and eq. (5):

$$\mathcal{L}^\theta = \alpha \mathcal{L}_{SSM}^\theta + (1 - \alpha) \mathcal{L}_{nov}^\theta \quad (6)$$

We used the ADAM optimizer with a learning rate of 0.001, used early-stopping monitoring \mathcal{L}^θ on the validation data with a patience of 50 and a maximum of 500 epochs.

Considering that we need the whole sequence of embeddings \mathbf{e}_i^θ of a track to compute \mathbf{S}_{ij}^θ and get the gradients $-\frac{\mathcal{L}^\theta}{\theta}$, the mini-batch-size m is here defined as the number of tracks. We used a value of $m=10$ tracks.

2.6.1 Generating ground-truth for training

Ground-truth SSM \mathbf{S}_{ij} . The ground-truth SSM, \mathbf{S}_{ij} , is constructed using annotated segments (start and end time) and their associated labels. We rely on the homogeneity assumption, i.e. we suppose that all times t_i that fall within a segment are identical since they share the same label. If we denote by $\text{seg}(t_i)$ the segment t_i belongs to and by $\text{label}(\text{seg}(t_i))$ its label, we assign the value $\mathbf{S}_{ij} = 1$ if $\text{label}(\text{seg}(t_i)) = \text{label}(\text{seg}(t_j))$ and 0 otherwise. Note that we could relax this identity constraint to allow representing similarity between labels (for example using an edit distance between labels). This is for example important for RWC-POP dataset, where labels denotes some proximities (*verse A* and *verse B*) but are here considered as different. Also, it could be important to consider the case of non-homogeneity of the repetitions and create a ground-truth \mathbf{S}_{ij} made of “sub-diagonals” rather than “blocks”.

Ground-truth novelty score \mathbf{n}_i . The ground-truth novelty score, \mathbf{n}_i , is also constructed using the annotated segments (start and end time). We set \mathbf{n}_i to 1 when segment changes at time i , 0 otherwise. As proposed by [37] we smooth over time the boundary annotations by applying a low-pass filter with a triangular-shape $0.25 \ 0.5 \ 1 \ 0.5 \ 0.25$.

3 Evaluation

We assess here the performance of our proposal using various test sets, compare it to previously published results, conduct an ablation study, and illustrate its results.

3.1 Datasets

For training we used a subset of 693 tracks from the **Harmonix** dataset [38]⁷ and the 298 tracks of the **Isophonics** dataset [39]. For testing we used

⁷ Given the non-accessibility of Harmonix audio, those have been downloaded from YouTube and re-annotation has been necessary because of non-synchronicity of the original annotations.

Datasets	T	S	L	S	L
Harmonix	693	13	17.15		
Isophonics	298	11	15.98		
RWC-Pop-AIST	100	17	14.31		
		Upper		Lower	
SA-Pop (An1)	276	12	15.49	30	5.73
SA-Pop (An2)	175	12	14.64	31	5.67
SA-IA (An1)	444	14	18.32	50	4.43
SA-IA (An2)	244	12.5	18.67	37	7.00
SA-Two (An1)	882	11	18.25	30	6.89
SA-Two (An2)	882	11	17.76	31	6.39

Table 1. Description of the datasets used in our evaluation: number of tracks T , median value of the number of segments per track S , median value of segment duration L in seconds (note that [29] indicate L in number of beats).

- **RWC-Pop-AIST** the 100 tracks of the RWC-Pop [40] with AIST annotations [41] and the following three subsets of the SALAMI [3] dataset:
- **SA-Pop** is the subset of SALAMI tracks with CLASS equal to Popular,
- **SA-IA** is the subset of SALAMI tracks with SOURCE equal to IA (Internet Archive),
- **SA-Two** is the subset of SALAMI tracks with at least two annotations.

For each SALAMI subset we considered the two annotations (An1, An2) and the two levels of flat annotations (Upper, Lower); those correspond to the files `textfile{1,2}_{upper,lowercase}.txt`.

In Table 1 we describe these datasets. According to the values of L our training-sets better match the Upper annotations than the Lower ones of SALAMI. Also, the size of our kernels \mathbf{K}^θ (roughly 20s., see part 2.5) assumes homogeneous segments of roughly 10s. and are therefore closest to the L of Upper annotations.

3.2 Segment detection from novelty score

To get the estimated segment boundaries from the estimated novelty score \mathbf{n}_i^θ we used a simple peak-to-mean ratio algorithm similar to [25]. Using the same notations as [25] eq. (5), we compute the mean with a window of duration $2T=20s$, and then detect local peaks with a threshold $\tau=1.35$ and a minimum inter-distance of $7s$.

3.3 Performance metrics

We evaluate the performance of segment boundary detection using the common Hit-Rate metrics using precision-windows of 3s and 0.5s. We only display here the Hit-Rate F-measures denoted by HR3F and HR0.5F. We used `mir_eval` [43] with `mir_eval.segment.detection` ignoring track start and end annotations (`Trim=True`). We point out that without “trimming” (the start and end time) we would gain +3% on average (from .713 to .743 for RWC-Pop).

Table 2. Results of segment boundary detection using various test-sets and configurations

3.4 Comparison with previous works

In the following we will compare our results with the ones previously published by Grill and Schlüter in [23, 42], McCallum et al. in [25], Salamon et al. in [30], Wang et al. in [27] and Buisson et al. in [29]. We first check if their test-sets match ours.

For SA-Pop, Wang [27] used “a subset with 445 annotated songs (from 274 unique songs) in the “popular” genre”. This roughly matches our SA-Pop (An1)+(An2) which provides 276+175=451 annotations. They used the Upper-case annotations (personal communication).

For SA-IA, McCallum [25] used “the internet archive portion of the SALAMI dataset (SALAMI-IA) consisting of 375 hand annotated recordings”. This is much lower than our SA-IA (An1)+(An2) which provides 444+244=688 annotations. Moreover, it is not clear whether they used the Upper, Lower or Functional annotations.

Finally, for SA-Two, Salamon [30] Table 3 used the Upper-case annotations of tracks with at least 2 annotations (884 tracks); Wang et al. [27] “we treat each annotation of a song separately, yielding 2243 annotated songs in total” and Buisson et al. [29] used the Upper and Lower-case annotations of tracks with at least 2 annotations (884 tracks). This roughly corresponds to our SA-Pop (An1)+(An2) which has 882 tracks.

3.5 Results and discussions

Results are given in Table 2. The upper part shows previously published results, although not all systems were evaluated on all test sets. The middle part shows the results achieved with the best configuration of our system.

For **RWC-Pop-AIST**, we obtained a HR3F=.713⁸ which is comparable to those of Grill and Schlüter (.715). However, for HR.5F our results are below (.399 < .506). This can be explained by the fact that the hop-size of our

⁸ The Precision and Recall at 3seconds are P3F=.735, R3F=0.715

features X_i was chosen large (0.5s) and does not allow to have a precise boundary estimation. We have chosen a large hop size to reduce the size of S_{ij}^θ (hence the computation time and memory footprints); it also allows to keep the size of the K^θ manageable. Because of this, all our results with HR.5F are actually low. Therefore, we only discuss the results for HR3F in the following.

For **SA-Pop**, we obtained a HR3F of .631/.624⁹ for the two Upper annotations (Up./An-1/2) which is slightly above those of Wang et al. (.623). For the two lower annotations (Low./An-1/2) we get a HR3F of .570/.610¹⁰. Wang et al. does not provide these results.

For **SA-IA**, we obtained a HR3F of .520/.511¹¹ for the two Upper annotations and .547/.612¹² for the two Lower annotations. This has to be compared to the .497 (unsynchronized) and .535 (beat-synchronized) obtained by McCallum et al., but as explained, it is not clear whether they used Upper, Lower or Functional annotations.

For **SA-Two**, we obtained a HR3F of .521/.530¹³ for the two Upper annotations. This is slightly lower than the results of Wang et al. (.553), Salamon et al. (.563), Buisson et al. (.597) and largely below the ones of Grill and Schlüter (.623). For the Lower annotations, we obtained a HR3F of .589/.589¹⁴ which is slightly below the ones of Buisson et al. (.611). It should be noted however that in our work we didn’t used any data from SALAMI, neither for training or validation (such as early stopping).

For SA-IA and SA-two, our results are higher for the Lower annotations than the Upper ones. This is surprising since according to Table 1 the characteristics (L value) of our training sets are closer to the Upper case. Also (see footnotes 8–14), our algorithm tends to over-segment when

⁹ P3F=.581, R3F=0.760/ P3F=.566, R3F=0.771 → over-segmentation

¹⁰ P3F=.860, R3F=0.468/ P3F=.877, R3F=0.497 → under-segment.

¹¹ P3F=.435, R3F=0.718/ P3F=.411, R3F=0.751 → over-segment.

¹² P3F=.811, R3F=0.451/ P3F=.756, R3F=0.546 → under-segment.

¹³ P3F=.433, R3F=0.749/ P3F=.442, R3F=0.754 → over-segment.

¹⁴ P3F=.768, R3F=0.523/ P3F=.768, R3F=0.523 → under-segment.

considering the Upper annotation and under-segment when considering the Lower ones. Our kernel size is actually between the L values of the Upper and Lower annotations.

3.6 Ablation study

In the lower part of Table 2 we perform an ablation study of our system. For the SA- $\{\text{Pop,IA,Two}\}$ test-sets, we only perform the study using the Upper/An1 annotations

We first check the optimal number $N \in \{0, 1, 2, 3\}$ of layers of Transformer Encoder. We see that for all test-sets the use of Transformer Encoder ($N > 0$) is beneficial. For RWC-Pop-AIST, the optimal number is $N=3$ while for all three SA- $\{\text{Pop,IA,Two}\}$ test-sets it is always $N=1$.

We then check whether jointly optimizing the two losses L_{SSM}^θ and \mathcal{L}_{nov}^θ of eq. (6) is necessary. We considered three cases: $\alpha=1$ (only optimizing L_{SSM}^θ), $\alpha=0.5$ (optimizing both), $\alpha=0$ (only optimizing \mathcal{L}_{nov}^θ). For all test-sets, we see that optimizing jointly the two losses is highly beneficial: for example, for RWC-Pop-AIST, HR3F=.713 with $\alpha=0.5$, .154 with $\alpha=1$ and .007 for $\alpha=0$.

Finally, we check various configurations of the kernels \mathbf{K}^θ . \mathbf{K}^θ is either [K:train-Init:chck]: trained starting from checkerboard kernels initialisation, [K:train-Init:randn]: trained starting from random initialisations, [K:fix-Init:chck]: fixed (not trained) to checkerboard kernels (we still train the 1x1 convolution). We see that for all test-sets it is beneficial to train \mathbf{K}^θ (the worst results are obtained with [K:fix-Init:chck]). For RWC-Pop-AIST, the results are the same whether kernels are initialized randomly or with checkerboard kernels. For SA- $\{\text{Pop,IA,Two}\}$ the checkerboard kernels initialization is beneficial.

3.7 Examples

Figure 2 illustrates the three kernels \mathbf{K}^θ learned using the [N=3/ $\alpha=0.5$ /K:train-Init:chck] configuration. As one can see, while the middle one looks close to the classical checkerboard kernel of Foote [32] (but with an emphasis on the diagonal), the first seems to highlight the transition from a non-homogeneous to an homogeneous part; while the third seems a re-scaled version of the second (homogeneity at a larger scale). Figure 3 illustrates the \mathbf{S}_{ij}^θ and \mathbf{n}_i^θ obtained by our system on track-01 from RWC-Pop-AIST (chosen as the first item of our test-set). We compare the results when trained in the [N=3 / $\alpha=0.5$ / K:train-Init:chck] configuration and with the untrained system using [K:fix-Init:chck] for the kernels. For comparison we indicate the ground-truth \mathbf{S}_{ij} and \mathbf{n}_i . In this figure, the benefits of training both L_{SSM}^θ and \mathcal{L}_{nov}^θ appears clearly.

Reproducibility. The code and the datasets used in this work are available at: https://github.com/geoffroypeeters/ssmnet_ISMIR2023

4 Conclusion

In this work, we proposed a simple approach for deep learning-based Music Structure Analysis algorithm: we

Figure 2. The three kernels \mathbf{K}^θ learned using the [N=3 / $\alpha=0.5$ / K:train-Init:chck] configuration.

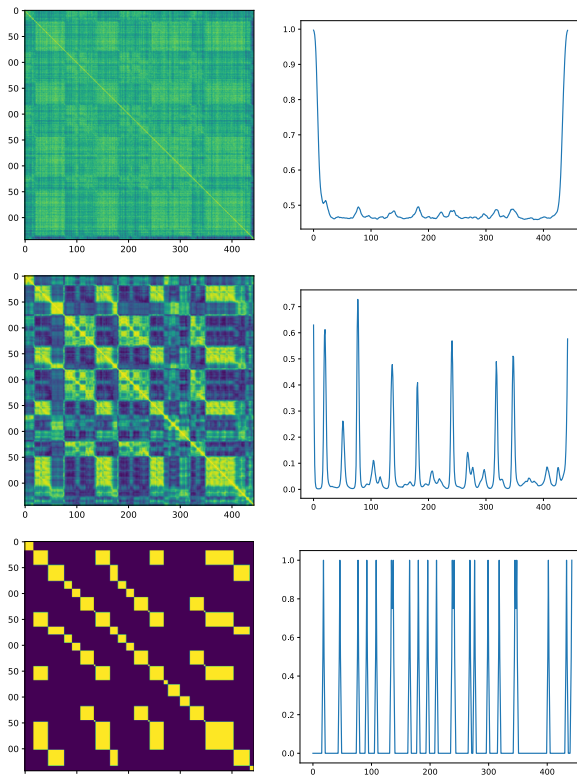

Figure 3. [Top] \mathbf{S}_{ij}^θ and \mathbf{n}_i^θ obtained with untrained system using [K:fix-Init:chck] for the kernels, [Middle] same with [N=3 / $\alpha=0.5$ / K:train-Init:chck], [Bottom] ground-truth \mathbf{S}_{ij} and \mathbf{n}_i .

learn an encoder f^θ such that the resulting learned features allow to best approximate a ground-truth SSM; we jointly learn segmentation kernels that when applied to the estimated SSM we best approximate a ground-truth novelty score. We also propose to learn relative features, i.e. features relative to a track, by introducing Self-Attention layers in our encoder. According to HR3F, our results are either better than previous state-of-the-art (SA-Pop, SA-IA unsynchronous), similar (RWC-Pop-AIST) or worst (SA-Two). Our approach has the advantage to be lightweight (around 500K parameters) and based on criteria which are semantically linked to the task of MSA. Future works will concentrate on making our approach applicable to finer temporal resolutions, therefore allowing improving our performances at HR.5F.

MODELING HARMONIC SIMILARITY FOR JAZZ USING CO-OCCURRENCE VECTORS AND THE MEMBRANE AREA

ABSTRACT

In jazz, measuring harmonic similarity is complicated by the common practice of reharmonization – the altering or substitution of chords without fundamentally changing the piece’s harmonic identity. This is analogous to natural language processing tasks where synonymous terms can be used interchangeably without significantly modifying the meaning of a text. Our approach to modeling harmonic similarity borrows from NLP techniques, such as distributional semantics, by embedding chords into a vector space using a co-occurrence matrix. We show that the method can robustly detect harmonic similarity between songs, even when reharmonized. The co-occurrence matrix is computed from a corpus of symbolic jazz-chord progressions, and the result is a map from chords into vectors. A song’s harmony can then be represented as a piecewise-linear path constructed from the cumulative sum of its chord vectors. For any two songs, their harmonic similarity can be measured as the minimal surface membrane area between their vector paths. Using a dataset of jazz contrafacts, we show that our approach reduces the median rank of matches from 318 to 18 compared to a baseline approach using pitch class vectors.

1. INTRODUCTION

Measuring similarity between songs is important for many music information retrieval tasks, for example, recommendation systems, copyright infringement detection, and genre classification systems. Many different types of features can be used to compare songs, but the specific focus of this paper is on jazz harmony as represented by the symbolic chord progressions found on leadsheets.

The analysis of harmonic similarity has been studied using N-grams [1], parse trees [2, 3], and NLP methods such as TF-IDF, Latent Semantic Analysis (LSA), and Doc2Vec [4]. The approach taken in this paper is based on embedding chord symbols into a vector space through the computation of a co-occurrence matrix [5]. As will be seen when

we describe the data in Section 2, many chord symbols occur only rarely. To reduce computational problems due to sparsity, the dimensionality of chord space should be reduced [6]. A typical machine learning approach for this might use an algorithm such as truncated singular value decomposition after vectorization [7]. In this work, however, we use music theory to reduce the number of effective chord symbols prior to vectorization, which in turn reduces the chord space dimensionality. In the ensuing sections we describe the data, explain our approach to dimensionality reduction, and give computational details of how we compute the co-occurrence matrix. We then explain how the chord vectors generated from the co-occurrence matrix are used to represent chord progressions, and we present a novel harmonic-similarity metric, the *membrane area*.

The experimental part of our paper is based on analyzing contrafacts. In jazz, a contrafact is a song whose harmony is similar to that of another song, but which has a different melody [8]. The tune *I Got Rhythm*, by George Gershwin (1930), is a well-known source of many contrafacts,¹ and there are numerous other examples [9–11]. In addition to the difference in melody, contrafact chord progressions often feature reharmonization, a common practice in jazz that makes chord substitutions in a song while maintaining its harmonic identity [12]. Reharmonization is a core characteristic of jazz – so much so that there are typically reharmonizations from chorus to chorus even in a single performance of a jazz song.

2. THE DATA

The data used in this paper is a corpus of symbolic chord progressions similar to those found in jazz fake books, such as the Real Book [13]. The progressions are mainly from jazz standards, but also include some blues, jazz-blues, modal jazz, and jazz versions of pop tunes. The corpus is derived from a collection distributed with *Impro-Visor*, an open-source music notation program.² Our modifications remove control information used by the Impro-Visor application, retaining the musical content and song-specific metadata. We have performed numerous quality checks on the data, have made corrections where required, and have enriched some of the metadata. The re-

Di Giorgi, “Modeling Harmonic Similarity for Jazz Using Co-occurrence Vectors and the Membrane Area”, in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

¹ https://en.wikipedia.org/wiki/Rhythm_changes

² <https://www.cs.hmc.edu/~keller/jazz/improvisor/>

sulting corpus and the code we used to generate our examples is available on GitHub.³ The Impro-Visor corpus provides chord progressions for 2,612 songs, and is the largest digital collection of jazz chord progressions we know of. For comparison, the applications iRealPro⁴ and Band-in-a-Box⁵ contain chord progressions for roughly 1400 and 226 jazz standards, respectively. The Weimar Jazz Database contains chords for 456 jazz songs.⁶

Of the 134,182 chord symbol instances in the corpus, there are 1,542 unique symbols, of which many are rare, with 20% occurring just once, and 50% fewer than six times. As the corpus consists mainly of jazz standards, there is a preponderance of 7th chords, comprising at least the root, 3rd, 5th, and 7th notes. These types of chords often have additional extensions (9th, 11th, 13th) and chromatic alterations (b9, #9, b5, #5). A common variation of jazz chords replaces the 7th with a 6th for major7 and minor7 chords. As 7th chords are the basic harmonic unit in jazz [14], and make up 77% of our corpus, they are the focus of our approach to dimensionality reduction described in the next section. Of the remaining chords, 16% are three-note chords (triads), and 7% are drawn from a variety of special types, as shown in Table 1, which provides a list of all the types and their frequencies.

Type	Percentage
7 th chords (and extensions)	76.939%
major triads	11.484%
slash chords	4.781%
minor triads	4.320%
sus chords	1.364%
no chord	0.458%
augmented triads	0.392%
major triads add9	0.127%
diminished triads	0.095%
power chords	0.031%
polychords	0.009%

Table 1. Corpus chord types and their frequencies

3. DIMENSIONALITY REDUCTION

Our approach to reducing dimensionality is based on mapping chords to a reduced vocabulary of functionally equivalent symbols (similar to [15]). This is important because 20% of the chords in the corpus occur only a single time (known as *hapax legomena*), and without additional processing, these types of terms would provide no predictive value [16]. Many techniques are used in NLP to better leverage hapax legomena. For example, stemming, lemmatization, and thesauri are all useful. This paper

⁴ <https://www.irealb.com/forums/showthread.php?12753-Jazz-1350-Standards>

⁵ <https://members.learnjazzstandards.com/sp/biab-jazzstandards/>

⁶ <https://jazzomat.hfm-weimar.de/dbformat/dbcontent.html>

takes a similar approach for harmony, making use of music theory to reduce the dimensionality of chord space. Our method is akin to lemmatization, applying concepts from functional harmony to group similar chords into classes (for example, see [17]). Based on standard practices in jazz [12, 18, 19], we reduce the set of 1,542 chord symbols to 61 chord classes, as detailed in the following sections.

3.1 7th Chord Types

Our choice of base chord types is built on the four-note 7th chords diatonically generated from the major scale, and making up 77% of our corpus. These are the major7 (M), minor7 (m), dominant7 (7), and minor7b5 (h), where the symbols shown in parentheses are abbreviations we use in this paper. To these we add a fifth base chord type, the diminished7 (o). Combining the five types with the root notes from the 12 pitch classes yields 60 chord classes. Instances of these classes can occur with extensions or alterations, and we map these to the base class without extension/alteration. For example, we map the symbols Cm9 and Cm11 to the Cm7 class; C7b9, C7#5, and C13 to the C7 class; and CM7#11 to the CM7 class. In addition, in accordance with reharmonization practices, we assign chords such as CmM7 to the Cm7 class and C6 to the CM7 class. We also include the symbol *NC* (no chord) to account for the absence of harmony (0.5% of the corpus).

3.2 Other Chord Type Mappings

In the following discussion, we describe a rationale for mapping the remaining 22.5% of the symbols into classes of the five base types defined above. The mapping choices described in the following discussion are imperfect, but they are simple to implement, and we show they are adequate for our application.

3.2.1 Triads

Triads represent 16% of the corpus. As they do not contain a 7th note, mapping them to the base chord types can be ambiguous. For example, a C major triad shares all of its notes with both the CM7 and C7 chords. We attempt to resolve triad ambiguities using principles from tonal harmony and the local harmonic context. Based on the chord following a triad, we decide whether it has a subdominant, dominant, or tonic function [19]. For example, for a major triad, if the root of the following chord is a fifth down and a member of the major7 or minor7 classes we assign the triad to the dominant7 class with the same root. Otherwise, we assign it to its corresponding major7 class. Major triads with an added 9th are handled in the same way. Augmented triads share their notes with dominant7#5 chords, an alteration of the dominant, and so we map these to the dominant7 class with the same root. Finally, we map all the minor and diminished triads to their corresponding minor7 and diminished7 classes, respectively.

3.2.2 Sus Chords and Slash Chords

Sus chords also have a harmonic function that depends on context [18]. When followed by a dominant7 chord with

the same root, they act like a subdominant and we opt to map them to a minor7 class with a root a fifth above. For example, a G7sus4 would map to a Dm7. Otherwise, they act like a dominant and we map them to the dominant7 class with the same root. Slash chords are chords played over a specific bass note, for example C/G or Dm7/G, where the symbol above (to the left of) the slash is the chord and below is the bass note. If the bass note belongs to the chord above the slash (for example, C/G), it is an inversion. For such cases, we map it to the class of the chord above the slash. Slash chords are also commonly used to represent sus chords. For example, Dm7/G is harmonically equivalent to G9sus4. We map these according to the process for sus chords. For all other slash chords, we map the chord as if the bass note were an extension or alteration of the chord above the slash.

3.2.3 Power Chords and Polychords

Power chords consist of just two notes, a root and a fifth. As they have no 3rd or 7th, they are harmonically ambiguous. With only 42 instances in our corpus, we have opted to map these chords to the no-chord class. With only 12 instances, polychords are also rare. These chords, used mainly by pianists, consist of a lower triad and an upper triad or 7th chord. We map polychords according to their lower structure, interpreting the upper structure as a collection of extensions or alterations.

4. KEY SIGNATURE BASED REPRESENTATION

To make distributional semantics more effective, we transpose all songs to a common key, and represent them in Roman numeral notation. However, transposition requires knowing the correct key of each song, and from extensive manual checking, we know that our database contains a fair number of songs for which the stated key signature is in error. For this reason, we introduce a key signature estimation algorithm, as described in the following section.

4.1 Key Signature Estimation Algorithm

Several authors have proposed key estimation algorithms for music information retrieval tasks [20–24]. However, our objective is not to estimate the key that is cognitively perceived by a listener, but rather a simpler problem, the key signature that minimizes the number of accidentals needed when writing out the song’s chords. Some prior work exists for this [25], however, it is based on machine learning models applied to MIDI data for classical music. Our algorithm selects the key signature most consistent with the chord progression. For each chord in a progression, we map it to one of the described 61 classes, and identify all the major scales it could belong to (excluding diminished7 and no chord classes). The major scale that accumulates the most beats is the resulting estimate of the key signature for that song.

Figure 1 provides a concrete illustration of how the key estimation algorithm works for the case of a short chord progression: A7-Dm7-G7-CM7-CM7. Each column of the

table represents one measure, and in this example, there is one chord per measure. The column labels correspond to the chords, and each row label is a key signature whose major scale diatonically contains one or more of the chords in the progression. As shown, the A7 chord belongs to D major; the Dm7 chord belongs to B♭, C, and F major; G7 belongs to C major; and CM7 belongs to both C and G major. Presuming four beats per measure, C accumulates the most beats (16), and is the resulting key signature estimate.

Example: 6-2-5-1 Chord Progression

		A7	Dm7	G7	CM7	CM7	Totals
Major Scales	B♭		4				4
	C		4	4	4	4	16
	D	4					4
	F		4				4
	G				4	4	8

Figure 1. Illustration of key signature estimation

4.2 Algorithm Evaluation

As already mentioned, there are quite a few songs in our corpus where the key signature is incorrect or in doubt. Nevertheless, it is worthwhile comparing the outputs of our key estimation algorithm with the keys recorded in the corpus. Of the 2,612 songs, the algorithm concurs with the database for 1,763 (67.5%) of them. For the 849 songs with database key signatures that do not agree with our estimates, we use the Circle of Fifths as a distance metric to evaluate the magnitude of differences between the two. Adjacent key signatures on the circle of fifths correspond to major scales that differ in a single pitch class. Table 2 shows the distribution of circle-of-fifths distances between estimated and database key signatures for all of the songs in the corpus. The first row is the distance in number of sharps or flats from the estimated to the database key, where 0 corresponds to agreement. The last column of Table 2 is labelled “Amb.” for ambiguous. There are 123 songs in the database for which the key estimation algorithm returns a non-unique result, finding two or more equally good major scales. This occurs for 4.7% of the songs in the corpus, and when it does our estimation algorithm defaults to the database key.

Dx	6♭	5♭	4♭	3♭	2♭	1♭	0	1♯	2♯	3♯	4♯	5♯	Amb.
Frq	10	22	33	55	99	304	1763	183	22	25	12	1	123

Table 2. Key signature estimation statistics with the circle of fifths distance **Dx** by the frequency of occurrence **Frq**

4.3 Mapping to Roman Numeral Notation

Once a song’s key has been estimated, all the chords in its progression can be mapped to Roman numeral notation. Table 3 shows the Roman numerals corresponding to chord roots for C major. As an example, the sequence of chords A7-Dm7-G7-CM maps to vi7-iim-v7-iM. In our system, we

represent minor keys by their relative major, so the relative minor cadence, Bm7b5-E7-Am7, maps to vii7-iii7-vim.

Root	C	D♭	D	E♭	E	F	G♭	G	A♭	A	B♭	B
RN	i	♭ii	ii	♭iii	iii	iv	♭v	v	♭vi	vi	♭vii	vii

Table 3. Roman numeral notation: chord roots in C major

5. VECTOR REPRESENTATION

Sections 3 and 4 described our approach for reducing the dimensionality of chord space, distilling the 1,542 chord symbols in our corpus to 61 classes. In this section we describe our method for embedding the chord classes into a vector space. Our design objective is that common reharmonizations be close to each other in cosine similarity, and it is known that the co-occurrence matrix can capture this type of characteristic [5, 26–28].

Given a corpus of D chord progressions, with progression $d \in \{1, 2, \dots, D\}$ containing N_d chords with indices $1, 2, \dots, N_d$, we can represent the corresponding sequence of chord symbols as $s_{d,1}, s_{d,2}, \dots, s_{d,N_d}$. We define the symmetric, sliding context window, $W_{k,d}$, of nominal width N_w with the indices $W_{k,d} = [w_l, \dots, (k-1), (k+1), \dots, w_r]$, where the left and right endpoints are $w_l = \max(k - N_w, 1)$ and $w_r = \min(k + N_w, N_d)$, respectively. With these definitions, the (i, j) th element of the co-occurrence matrix, $C_{i,j}$ is computed by

$$C_{i,j} = \sum_{d=1}^D \sum_{k=1}^{N_d} \sum_{w \in W_{k,d}} \begin{cases} 1, & \text{if } s_{d,k} = c_i \text{ and } s_{d,w} = c_j \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

This produces a square, symmetric matrix whose row C_i (or alternatively, column) is a vector representations of the i^{th} chord class c_i . As it will be useful in the following, we normalize each row to have unit length. Because co-occurrence matrices capture contextual information, the vectors of chord classes that have similar harmonic function are expected to be close to each other with respect to the cosine similarity measure, and this seems to be borne out by an inspection of certain chord vectors. For example, of 60 chord classes, the closest vector to the v7 is its tritone substitute, the $\text{bii}7$, and the closest to the iim is the iih , a common substitute from the parallel minor scale (see modal interchange in [19]).

6. MEMBRANE-AREA DISTANCE METRIC

We use the co-occurrence vectors to represent chord progressions in a way that represents each chord type, duration, and metric position, while being robust to reharmonizations. The normalized chord vectors derived from the co-occurrence matrix can be used to plot the path of a song’s progression through 61-dimensional space. Starting from the origin, the sequence of chord vectors can be concatenated from head to tail, beginning with the first, and terminating with the last vector (see Figure 2). Each unit vector is scaled by the number of beats of the chord

it represents, and the result is a piecewise linear function through \mathbf{R}^{61} . The comparison of two songs in this space can be formulated as a trajectory comparison problem, for which there are many existing techniques [29]. The most popular ones, however, are not well adapted to our problem. The Fréchet distance, dynamic time warping, longest common subsequence, and the edit distance are all based on matching and comparing points, and would not directly factor in information about reharmonized chords embodied in the co-occurrence vectors. For this reason, we introduce a new metric that accounts for reharmonizations by computing the membrane area between the paths of two songs.

Expressed formally, we represent song vector paths by piecewise linear functions of the form $\mathbf{f}(t) \in \mathbf{R}^{61}$, where $t \in [0, 1]$ is a parametric variable representing the number of normalized beats traversed in the song. We can move along the entire length of \mathbf{f} in discrete, equal increments, dt , where the starting point of the function, $\mathbf{f}(0)$ at $t = 0$ is the origin, and the end point of the function is at $t = 1$. Given two songs and their corresponding piecewise linear functions, $\mathbf{f}(t)$ and $\mathbf{g}(t)$, and letting $K = 1/dt$, we can define a distance metric between them as the area of a 2D membrane, M , stretched between the two paths. M is calculated as the integral obtained in the limit of

$$M(\mathbf{f}, \mathbf{g}) = \lim_{dt \rightarrow 0} \sum_{k=0}^K \|\mathbf{f}(kdt) - \mathbf{g}(kdt)\| dt, \quad (2)$$

where $\|\cdot\|$ is the Euclidean norm. The piecewise linear functions for two identical chord progressions would, naturally, overlay each other, yielding a membrane area of zero. Two harmonically similar songs should trace out similar paths keeping the membrane area small. For example, two chord progressions that differ in just a tritone substitution will only slightly perturb the path and the membrane area between songs. Figure 2 is a notional illustration of how the measure in Equation 2 is evaluated. The red and blue paths represent two different songs, each having three chords. Each song begins at the origin, and the chord vectors are added head-to-tail to trace out a piecewise linear path. The membrane area metric is approximated by summing the lengths of the N equally spaced black line segments drawn between the two songs. Note that this way of representing the harmony of a song accounts for positions and durations of each chord in the progression, as well as capturing harmonic similarities of chord transitions.

7. EXPERIMENTS

We have designed some experiments based on a set of jazz contrafacts listed in a Wikipedia article.⁷ The list has 252 jazz songs whose harmonies are known to be based on other songs (see also [30]). A subset of 91 contrafacts are available in our corpus, but for 11 of them, only a section of the harmony is borrowed, and we remove these from the list. The basic structure of all of our experiments is the same: for each contrafact, we compute the membrane area

⁷ https://en.wikipedia.org/wiki/List_of_jazz_contrafacts

Figure 2. Conceptual illustration of the membrane-area distance metric for two, 3-chord sequences

distance between it and each of the other 2,611 songs in our corpus. We then sort the songs from smallest membrane area to largest, and note the original song’s rank in that list. Because of reharmonizations, we don’t expect the membrane area to be zero for all contrafact-original pairs, but matches should rank high in the list. Original songs often inspire multiple contrafacts, and some may be closer to each other than to the original. For these reasons, we use the histogram of original song rankings to present the overall performance of our method, and we use the median rank as a method of comparison between approaches.

7.1 Using Co-Occurrence Vectors

We evaluated six variants of our approach using co-occurrence chord vectors. The first three were based on the context window widths $N_w = [1, 2, 3]$. The second three variants used the same context window values, but applied to a filtered version of the chord progressions. For each chord progression, the filter collapses adjacent identical chords to a single instance. For $N_w = 1$, this has the effect of eliminating the co-occurrence of chords with themselves, making the diagonal of the co-occurrence matrix zero. Of the six versions, the best result was obtained for the filtered chord progressions with the context window width $N_w = 1$. Figure 3 shows the histogram of original song rankings for this case. The median rank is 18, meaning that half of the original songs rank in the top 0.7% in harmonic similarity to their contrafacts. As there is some histogram mass out to rank 1,382, the histogram makes use of a log-scale on the x-axis. It is likely that some of the songs ranking better than the original are also contrafacts, as the Wikipedia list is far from exhaustive, but it would require substantial effort and expertise to evaluate this.

As noted, some original songs have inspired many contrafacts. As an example of this in our corpus, there are four known contrafacts of the song *All the Things You Are*. The ranks and membrane areas of the original song for each contrafact are shown in Table 4. The original ranks highly for three of the four contrafacts in the table. As the chord progressions for *Prince Albert* and *All the Things You Are* are identical, their membrane area is zero. The contrafacts

Figure 3. Histogram of original song ranks for 80 contrafacts (median rank = 18)

Ablution and *Boston Bernie* have some chord substitutions, and the original song ranks highly for both of them. The song *I Want More*, however, does quite poorly, with a rank of 758th out of the 2,611 songs in our corpus.

Contrafact	Rank	Membrane Area
<i>Prince Albert</i>	1	0.00
<i>Ablution</i>	1	6.72
<i>Boston Bernie</i>	2	7.72
<i>I Want More</i>	758	26.89

Table 4. Rank and membrane area for *All the Things You Are* against its four contrafacts

To investigate, we use the jazz harmony visualization tool described in [31] to display the chord progressions for these two songs. The visualization shows a tabular format with each rectangle representing a measure. Figures 4 and 5 show *All the Things You Are* and *I Want More*, respectively. The background colors indicate the key the chords belong to. Red is for the main key, which is $A\flat$ for both songs. Other colors indicate modulations. Some chords are embedded in a geometric shape to indicate they are tonicizations: diamonds are secondary dominants, pentagons are borrowed chords. As the figures illustrate, the two songs have some similar chords, however, the sequences of modulations are completely different. Whereas *All the Things You Are* modulates through the tonal centers of C major, $E\flat$ major, G major, and E major, *I Want More* modulates to $D\flat$ major and C minor. After verifying the latter’s chord progression,⁸ we conclude that, harmonically, these two songs have very little in common, and we question the annotation of this song as a contrafact.

7.2 Using Pitch-Class Vectors

To evaluate the effect of using co-occurrence vectors, we compare with a baseline vector embedding scheme based

⁸ Jamey Aebersold play-along book, volume 82, Dexter Gordon

Figure 4. Chord Progression for *All the Things You Are*

Figure 5. Chord progression for *I Want More*

on converting chord symbols to their pitch-class vectors. This is similar to the starting point of the approach used in [32]. We begin by applying the key estimation algorithm described in Section 4.1 to transpose all chords in our corpus to the key of C. Subsequently, each chord in the corpus is converted to a 12-dimensional binary pitch-class vector, with ones in positions corresponding to pitch classes belonging to the chord, and zeroes elsewhere. Thus, for a C7 chord with the notes C, E, G, and B \flat , the corresponding pitch-class vector is [1, 0, 0, 0, 1, 0, 0, 1, 0, 0, 1, 0].

Following a similar schema as for the previous experiment, the pitch-class vectors can be used to construct piecewise linear paths, however, now they are constructed in a 12-dimensional space. We use the membrane area as previously to rank songs by harmonic similarity. Table 5 compares the performance of co-occurrence vectors for the best case (chord progression filtering with a window size of $N_w = 1$) versus pitch-class vectors using three metrics: median rank, mean rank, and mean reciprocal rank. Co-occurrence vectors outperform the pitch-class vectors by a

large margin for each of these criteria.

Vector Type	Median	Mean	MRR
Co-occurrence	18	222	0.305
Pitch-class	318	457	0.200

Table 5. Comparison of median rank, mean rank, and mean reciprocal rank (MRR) for the filtered-progression, co-occurrence vectors ($N_w = 1$) and pitch-class vectors

8. DISCUSSION AND CONCLUSIONS

We showed how co-occurrence vectors can be used to model harmonic similarity, and introduced the membrane area as a evaluation metric that is well-adapted for handling reharmonizations. We use music theory to reduce the dimensionality of chord space, and provide a comprehensive map of all 1,542 chord symbols in our corpus to 61 classes. The results are used to compute a dense co-occurrence matrix without needing to resort to non-parametric approximations such as truncated SVD or gradient descent. Using the cosine similarity measure, we show that the rows of the co-occurrence matrix embody some characteristics of common reharmonizations. Using the normalized rows of the matrix as vector embeddings of chord classes, we modeled songs as piecewise linear paths in \mathbf{R}^{61} . A novel distance metric, the membrane area, was introduced and used as a measure of harmonic similarity between songs. We showed that the similarity metric can be used to retrieve contrafacts from a database of jazz standards, and that it performs significantly better than a baseline system using binary pitch-class vectors as chord embeddings.

Although our approach is successful for contrafact detection, there are several weaknesses that require future work. Our key detection algorithm is simple and static, despite the fact that jazz harmony exhibits many local key changes (e.g. see Figures 4 and 5). We also treat minor keys as equivalent to their relative major, which is not strictly correct. The chord mapping scheme is limited in its ability to distinguish common progressions such as triad progressions i-iv and v-i. A richer chord vocabulary or local key estimation could disambiguate such situations. Our song-level similarity assumes only minor structural differences between pieces. Modifying it to perform sub-sequence matching would overcome this limitation.

We believe that the methods discussed in this paper have many additional applications, such as those in evaluating harmonic complexity [33] and in musicology [34]. We intend to investigate whether our harmonic similarity measure can be used to cluster jazz songs by composer or decade of publication. Although our focus has been on jazz, chords have similar functions across much of Western tonal harmony. For this reason, we believe that this work can be adapted to other genres such as classical, rock, and pop. Furthermore, as our methods are based on capturing the distributional semantics of harmony, the approach may also be useful in discovering harmonic relationships in non-Western music genres.

ABSTRACT

There has been a persistent lack of publicly accessible data in singing voice research, particularly concerning the diversity of languages and performance styles. In this paper, we introduce SingStyle111, a large studio-quality singing dataset with multiple languages and different singing styles, and present singing style transfer examples. The dataset features 111 songs performed by eight professional singers, spanning 12.8 hours and covering English, Chinese, and Italian. SingStyle111 incorporates different singing styles, such as bel canto opera, Chinese folk singing, pop, jazz, and children. Specifically, 80 songs include at least two distinct singing styles performed by the same singer. All recordings were conducted in professional studios, yielding clean, dry vocal tracks in mono format with a 44.1 kHz sample rate. We have segmented the singing voices into phrases, providing lyrics, performance MIDI, and scores with phoneme-level alignment. We also extracted acoustic features such as Mel-Spectrogram, F0 contour, and loudness curves. This dataset applies to various MIR tasks such as Singing Voice Synthesis, Singing Voice Conversion, Singing Transcription, Score Following, and Lyrics Detection. It is also designed for Singing Style Transfer, including both performance and voice timbre style. We make the dataset freely available for research purposes. Examples and download information can be found at <https://shuqid.net/singstyle111>.

1. INTRODUCTION

In recent years, deep learning technologies have significantly advanced the field of Artificial Intelligence Generative Content (AIGC) [1], leading to breakthroughs in Computer Vision for image synthesis and manipulation [2–5], Natural Language Processing (NLP) for text generation and summarization [6–8], and audio signal processing for Text-to-Speech (TTS) generation [9–11]. In particular, advanced generative models such as Variational Autoen-

coders (VAEs) [12–14], Generative Adversarial Networks (GANs) [15, 16], Transformer-based models [17, 18], and Diffusion Models [19, 20] resulted in a series of exceptional TTS models that achieve not only realistic results [9–11, 21] but also explore stylistic and emotional speech synthesis [22, 23] in a more controllable way. However, the development of singing tasks such as Singing Voice Synthesis (SVS) [24–28] and Singing Voice Conversion (SVC) [29] have yet to progress as fast as TTS. One primary reason is the lack of data on several key aspects:

- Lack of high-quality data. Tasks such as SVS and SVC require monophonic, clean, and dry sound singing data with studio quality. Unfortunately, due to the limitations of Source Separation and Denoising technologies [30–33], as well as copyright issues, most available cover songs online cannot meet these quality requirements. Datasets recorded with studio quality are predominantly composed of amateur performances, which often exhibit off-key and cracking issues that could mislead the generative models and diminish their quality.
- Lack of diversity. Most available singing datasets cover only one language, resulting in a severely imbalanced language distribution. For example, there is a fair amount of Chinese singing data, while clean English data is very scarce. In addition, most datasets only focus on one pop singing style, and the distributions of different singing styles and vocal ranges are too narrow.
- Lack of annotations. Many datasets lack proper phrase-level segmentation, lyrics, and scores, and are not aligned at the phoneme level, making it impossible to conduct score-based SVS and more detailed performance control.
- Lack of large-scale data. The current data volume of high-quality singing is still insufficient for deep generative models.

Furthermore, current SVS results are primarily confined to modeling the timbre of singing voices. While there are several good vocoders [11, 21, 34] and acoustic models [10, 35] for SVS based on Ground-Truth control signals (e.g., inputting F0 control signals to the model), the truly creative and artistic aspects of singing, such as expressive performance control, singing styles, vocal techniques, and creative improvisation, have yet to be explored. Again, data limitations play a significant role in this, as most datasets consist of amateur performances or have not

Table 1. A comparison of existing singing datasets. Score means if there is score or performance MIDI file provided. “Perform. MIDI” stands for “Performance MIDI”. “Both” means both performance MIDI files synchronized with the singing audio and sheet music scores are provided. Alignment means whether or not there is duration annotation at the phoneme level for lyrics. “Ama.” stands for “Amateur,” and “Prof.” stands for “Professional.”

yet begun to address the issue of artistic expression.

For example, Style Transfer [36, 37] is a popular technique in deep learning that combines the content of one image or sound with the style of another. For audio processing, some researchers [38, 39] have recently transferred the timbre from one audio source to another while preserving the speech content (similar to SVC). However, the transfer of expressive performance styles embedded below the timbre level remains elusive, mainly because (1) disentangling performance style is much more challenging than timbre features [40] and (2) the scarcity of relevant datasets providing examples of performance styles.

To help address these issues, we introduce a new singing corpus, SingStyle111. We summarize the main contributions as follows:

- (1) SingStyle111 is a large and high-quality singing dataset. It contains 111 songs performed by eight professional singers, spanning 12.8 hours of clean monophonic vocal recordings in studio quality.
- (2) It is a diverse dataset with creative singing. It covers English, Chinese, and Italian songs and incorporates var-

ious singing styles, such as bel canto opera, Chinese folk, pop, jazz, and children. Some performances are creative improvisations based on the original score.

- (3) It demonstrates style transfer in both performance and timbre levels. 80 songs contain at least two distinct singing styles performed by the same singer.
- (4) It includes proper annotations and extracted features. We manually segmented voices into phrases, labeled Performance MIDI files and music score notes and aligned them with the phonemes of lyrics, extracted acoustic features such as Mel-Spectrogram, F0 contour, and loudness curves.
- (5) It applies to different MIR tasks such as SVS, SVC, Singing Transcription, Score Following, Expressive Performance, Lyrics Detection, Singing Style Transfer.
- (6) It is publicly available for research purposes for free.

The rest of this paper is organized as follows: after a brief review of related works, we describe how we collect and process the dataset (Section 3) and show the annotations and analysis (Section 4). Finally, we discuss potential applications in Section 5 followed by conclusions.

2. RELATED WORK

Existing singing voice datasets still have many limitations in fulfilling the requirements for singing research tasks such as Singing Voice Synthesis (SVS) [24, 26–28] and Singing Voice Conversion (SVC) [29]. Table 1 provides an overview of the available public datasets. Datasets such as MIR-1K [52], TONAS [50], and Vocado [51] are restricted by the absence of separated solo vocal tracks or suffer from subpar recording environments with noise, reverberation, and other interferences. These issues hinder their usability in SVS-related tasks. While NHSS [47] and OpenSinger [35] contain clean and dry human vocals, they lack essential musical scores or phoneme-level duration alignment. Consequently, these datasets are unsuitable for training end-to-end synthesis models that convert scores to vocals. Moreover, datasets such as Opencpop [41] and M4singer [42] offer good annotations and recording quality but primarily focus on Mandarin songs and a limited range of pop styles. Additionally, the singing proficiency of performers is inconsistent, with many being amateurs, which affects the overall quality of the dataset.

Another issue that has long been overlooked and misunderstood in singing voice datasets is the difference between Performance MIDI and the actual sheet music score. In Table 1, only Tohoku Kiritan [44], Vocalset [45, 46] and RWC [49] have music scores, while other datasets claimed to have scores that are indeed performance MIDI files. Performance MIDI features expressive performance timings rather than score timings with regular note durations in beats. The melodic pitches in performance MIDI can also differ from those in score melody. Utilizing performance MIDI for singing voice synthesis and claiming it as score-based is, in reality, a deceptive approach that takes advantage of real singing data.

As for the Style Transfer task, Vocalset [45, 46] provides relevant examples, but its scope is limited to singing technique transfer within the bel canto singing style. Furthermore, the dataset predominantly consists of scale exercises using only five vowels and includes only three short songs, which restricts its applicability. Given the limitations of existing datasets, there is a need for a large-scale, high-quality, professional, multilingual, and diverse singing dataset that caters to various styles and includes style transfer examples. In this paper, we introduce a novel dataset designed to address these requirements and facilitate research in SVS-related tasks and style transfer.

3. DATASET DESCRIPTION

3.1 Overview

SingStyle111 is a multilingual singing dataset with style transfer demonstrations. Figure 1 illustrates the data collection pipeline. Following the completion of the recording process, we post-process all recordings and retain all high-quality segments. Thus, our dataset offers two versions: the first version consists of edited full-length songs, and the second version comprises all usable, high-quality vocal segments, incorporating redos from the recording process.

Figure 1. Data collection pipeline.

Figure 2. Distribution of songs according to languages and the number of style demonstrations. For example, English songs have 18 songs with only one style version, 25 songs with two different styles, six songs with three styles, and three songs with four styles.

We preserve these redos for two primary reasons. First, during recording, singers often need to restart due to minor errors, resulting in many redos that far exceed the quantity required for a single song. The high-quality vocals in these redo segments are perfect for segmented training in deep learning and effectively augmenting the dataset. Second, even when the same singer performs the same song using the same style, each rendition exhibits subtle differences. Capturing these variations provides valuable training data for learning multi-modes in singing performance and disentangling a singer’s style with music content. This paper focuses on describing the second version of the dataset.

Upon obtaining the clean and dry vocal segments in audio, we manually annotate them into phrases (music sentences), provide lyrics and score alignment with audio at the phoneme level. We then extract acoustic attributes such as F0 contour, loudness curve, and Mel-spectrogram. Finally, we partition and package the data, incorporating relevant attributes. Section 4 describes this process in detail.

In the following subsections, we delve into the dataset’s repertoire and styles, singer profiles, recording environments, and post-production methods, accompanied by pertinent statistics.

3.2 Repertoire and Style

SingStyle111 comprises 111 songs, of which 80 have at least two different versions performed in distinct styles by the same singer, resulting in a total of 224 song versions. The dataset encompasses three languages: English (372 minutes), Chinese Mandarin (307 minutes), and Italian (88 minutes). Figure 2 illustrates the number of song versions for each language. During song selection, we sought to diversely represent various styles, singing techniques, tempos, and eras.

Figure 3 presents the styles of the original songs and all

Figure 3. Distribution of song styles. Chart(a) describes the original style of the 111 songs, while chart(b) indicates the 224 different style interpretations in the dataset.

style demonstrations. We consolidated several sub-genres into seven broader styles to streamline the pie chart. For instance, Country, Western folk, Chinese pop, and other pop styles were combined into a single pop genre. Likewise, the Rock category contains Soft Rock, Hard Rock, Alternative Rock, etc.

Throughout the data collection process, we instructed singers to exhibit significant differences in style transfer. Sometimes they made appropriate adaptations or improvisations to the original song for better style transfer while preserving the original lyrics, melody, and structure. For example, it is easier for singers to transfer vocal timbres when the key changes. Also, tempo changes and rhythmic variations can dramatically help alter styles, such as transferring a fast and happy song into a slow and melancholic one. Converting singing techniques or adding ornamentations are also prevalent in our style transfer examples. For instance, the dataset includes many demonstrations interchanged among pop, bel canto, and Chinese traditional folk singing; or singing the same song in the distinct pop styles of Adele Adkins and Teresa Teng. In addition, some styles include deliberate emotional changes, for example, contrasting a "plain and lyrical style" with an "exaggerated and highly emotional style."

3.3 Singers

We paid eight professional singers (Table 2) to sing the songs. They have diverse vocal ranges, singing styles, and vocal techniques. They are aged 20 to 63, and all have received formal musical training for more than six years. Six of them are graduates or current students in the voice major at music conservatories. "Male1" is a native American English speaker, and all the others are Chinese. "Female1" has lived in the US for more than five years and received formal English singing training at a music academy. We also removed the English song phrases that have strong foreign accents. All singers have signed agreements to release the dataset for research purposes.

3.4 Recording

We recorded the songs in a professional recording studio with little reverberation or noise. We use a Shure Model

Singer	Language	Style	#Hour	Range
Female1	en, cn	P. C. O. R. F. M. J.	3.73	F#3-A5
Female2	it, en, cn	O. F. M.	1.24	E4-C6
Female3	cn, en	P. C. O. R. F. M. J.	1.58	F#3-F5
Female4	cn, en	P.	1.63	D3-C5
Male1	en	P. R. M.	0.59	D2-G4
Male2	cn, en	P. M. J.	1.35	A2-C5
Male3	it, cn	O. M.	1.16	C4-G5
Male4	cn	P. O. F.	1.51	D#3-A4

Table 2. Singer Information. Here the vocal range is the used range in the dataset. en: English, cn: Chinese, it: Italian, P: Pop, C: Children, R: Rock, O: Opera, F: Chinese Traditional Folk, M: Musical, J: Jazz.

SM81-LC microphone, an Apollo X8 Thunderbolt 3 audio interface, Heritage Audio 73jr as the pre-amplifier, and Pro Tools Studio as DAW software. All singings are pure vocal only and recorded at 44,100 Hz sampling rate with 24 bits per sample in wav format.

In most recording sessions, singers wear headphones to listen to the accompaniment. However, in some style transfer demonstrations, accompaniments and headphones may not always be used. Despite this, singers must ensure they maintain the correct key and consistently stay within it throughout the performance.

3.5 Production

We employed several essential post-production techniques to refine and clean the recorded data. First, we edited the raw recordings to retain only high-quality clips, filtering out noisy sections, mistakes, and mispronunciations. A small portion of singer Male3's singing clips were further edited with pitch-tuning. To achieve a consistent volume balance, we applied different gain levels in each clip. Moreover, we incorporated a compressor for all recording clips to prevent extreme dynamic fluctuations. Lastly, we maximized the output volume using a limiter, setting the output ceiling at -0.6 dB. After production, we obtained clean and dry vocal tracks with similar output volumes.

4. ANNOTATION AND ANALYSIS

This section presents the annotation process, including both manual annotation and automatic analysis. We first segment the audio clips into music phrases, for which we then manually identify corresponding lyrics and music scores. By combining automatic algorithms and manual efforts, we align lyrics phonemes and score notes to their corresponding audio. Next, we utilize algorithms to extract acoustic attributes such as F0 contour, loudness curve, and Mel-spectrogram. Finally, we highlight the key attributes and explain dataset partitioning and packaging.

Figure 4. An example of phoneme-level annotation using Audacity. The lyrics word, IPA phoneme, and pitch label tracks are aligned with the corresponding audio. “AP” here stands for “aspirate”.

4.1 Phrase-level Segmentation

We further divide the audio segments into smaller musical phrases for two reasons. First, this additional segmentation accelerates model training. Second, from a music perspective, phrases serve as one of the basic music structure units, with emotional expressions and performance controls being highly related to phrase-level structure. Inappropriate segmentation might compromise musical expression due to insufficient phrase structure information. Given the low accuracy of automatic algorithms for phrase segmentation, we manually label them. The result shows that most segmented phrases have lengths between 3 and 12 seconds with one to three breaths. We obtain 6588 phrases in total. No silence is included at the beginning or end of the phrases, except for breath events.

4.2 Lyrics and Score Alignment at Phoneme Level

In this subsection, we describe the lyrics and score annotation process.

Lyrics annotation We first manually find lyrics for each song online and then segment and align the lyrics with each phrase. We manually correct the lyrics to match the actual singing in the data. Secondly, we employ algorithms to translate the lyrics into phonemes. For English¹ and Italian², we utilize tools to translate them into International Phonetic Alphabet (IPA) phonemes [53]. For Mandarin, we use Pinyin³ for phoneme-level alignment and provide a mapping of Pinyin to IPA phonemes for later phoneme-set processing for model training. We did not directly convert Chinese to IPA due to annotation complexity. Thirdly, we obtain an approximate phoneme alignment with audio using the Montreal Forced Aligner [54] and output it into TextGrid files. Finally, we (1) use *Praat* software [55], or (2) convert the TextGrid into txt files and input them to *Audacity* [56] for further manual adjustment of phoneme text and boundaries, as well as breath and silence event annotation (Figure 4).

Performance MIDI and Score annotation We annotated the performance MIDI file and music score for each

singing phrase in the dataset as follows:

- (1) We manually input performance MIDI files that strictly align to singing audio using MIDI piano, including multiple rounds of correction.
- (2) We automatically align MIDI notes with phonemes based on their corresponding time stamps in the audio.
- (3) We search online for music score MIDI files; if no reliable sources are found, we quantize and derive the score from annotated performance MIDI file.
- (4) For online score files, we develop an algorithm that automatically matches each singing phrase’s performance MIDI data to the corresponding phrase in the score MIDI file. Manual matching is required for non-original-style style transfer versions.
- (5) We use the Dynamic Time Warping algorithm to match the performance MIDI data with the score MIDI file within each phrase. We manually verify the mapping results for non-original-style style transfer versions.

All these above steps allow us to annotate the lyrics, performance MIDI, and music score at the phoneme level for our singing voice dataset, ensuring accurate and comprehensive representations of the musical content.

4.3 Acoustic Feature Extraction

F0, or fundamental frequency, is the lowest frequency of a periodic waveform. F0 contour is critical in singing synthesis as it determines the pitch variations of singing performance and largely influences singing quality. It can capture pitch modulations in various singing techniques, such as vibrato, ornaments, and glissando. Many current SVS systems still require the input of ground-truth F0 as a condition to guide the synthesis process. To ensure accurate F0 extraction, we employ a combination of two widely-used models, pYIN [57] and PENN [58]. First, we use pYIN algorithm to identify unvoiced parts, including breaths, silence, and consonants. Then, the PENN algorithm is applied to extract F0 for the voiced parts.

Loudness represents the energy of a sound. It is crucial in singing performance since it largely reflects the dynamic and emotional changes that contribute to the expressiveness of the singing voice. To extract loudness, we first calculate the root-mean-square (RMS) amplitude values from audio and then convert them to decibels. We further ap-

¹ <https://github.com/mphilli/English-to-IPA>

² <https://espeak.sourceforge.net/>

³ <https://github.com/mozillazg/python-pinyin>

ply a moving average window of frame size 30 to obtain a smoother loudness curve.

Finally, we use the Short-Time Fourier Transform (STFT) with a window size of 1024, FFT size of 1024, and hop size of 256 to extract the mel-spectrogram, which shares the same settings with loudness extraction.

5. POTENTIAL APPLICATIONS

This dataset is intended to promote research into a number of different MIR tasks. We consider a variety of interesting relevant problems in this section.

5.1 Singing Style Transfer

Style transfer has to do with music interpretation. Here, “style” refers to performance details that are not constrained by symbolic representations such as traditional notation. If notation gives a song its “identity,” styles are performance characteristics that are shared across performances of different songs. Styles are often associated with genre, e.g., a song can be interpreted in rock, pop, or jazz styles. Styles can be more or less specific than genre, e.g., the style of Louis Armstrong (more specific) or symphonic (less specific). Style transfer is a process of identifying the style of one or more performances and applying it to a new song to create a stylistic performance. SingStyle111 contains many performances where a single singer performs in multiple styles, offering the potential to abstract styles from other information (singer identity, melodies) which is held constant. In the multi-style recordings, singers were asked to exaggerate differences, which should help to learn features that characterize different styles.

5.2 Singing Voice Synthesis

A large motivation for SingStyle111 is the difficulty of finding high-quality musical examples of singing. In particular, the presence of accompaniment and reverberation complicate the process of learning to create the sound of singing voices. Furthermore, lower recording and singing quality are a barrier to learning high-fidelity sounds of professional singing. In addition, SingStyle111 also provides necessary phoneme-level annotations for score-based SVS.

5.3 Singing Voice Conversion

In SVC, we hope to substitute the sound of one voice with the sound of another while maintaining the same melody and style. To promote progress in this area, SingStyle111 has performances of the same song by multiple singers, including male and female voices. Since we have performances of the same song in the same style, SVC can be cast as a sequence-to-sequence problem analogous to many other machine learning tasks such as language translation.

5.4 Expressive Performance

Expressive performance is the general problem of creating a musical performance given a symbolic description such as a melody in common music notation. Notation omits

many details, including loudness, vibrato, pitch variations, changes in vocal timbre, the details of pronouncing lyrics within pitch and rhythmic constraints, and breathiness. Often, connections and transitions from one note to the next are as important as how notes are performed. To learn expressive performance, it helps to have symbolic notation, which can be considered as input constraints, context, or conditioning. In addition, it helps if the notated events are aligned with corresponding time points in the audio. SingStyle111 includes symbolic representations (performance MIDI files and music scores) aligned with audio. The data is especially designed to support machine learning using sequence-to-sequence models from notation to control signals such as pitch contours, loudness, spectrograms, or directly to audio.

5.5 Automatic Singing Transcription

Singing transcription can be regarded as the inverse of expressive performance control: Rather than converting notation to sound, we wish to convert sound into music notation. With transcriptions for all of the singing examples, SingStyle111 provides a wealth of transcription examples for training and evaluating transcription models.

5.6 Score Alignment and Following

Score following [59] is the problem of aligning an audio performance to symbolic notation. Vocal score following is particularly difficult because, unlike most other instruments, voices do not have keys, valves, or frets, so singing cannot be easily reduced to a sequence of distinct discrete states corresponding to musical notes [60]. Real-time score following is the first step in the task of computer accompaniment, in which a computer synchronizes a pre-composed accompaniment to a live performance by a soloist. Score following has also been used for automatic page turning, delivering synchronized comments via mobile phones to symphony orchestra audiences, and as a data collection method for learning music segmentation and other tasks. SingStyle111 contains accurate alignments for learning and evaluation of automatic alignment and real-time score following.

5.7 Lyrics Detection

The common task of understanding lyrics is one that even humans struggle with. SingStyle111 includes the lyrics used by the singers, and lyrics are aligned to the audio down to the phoneme level, facilitating learning and evaluation of various lyrics transcription and alignment tasks.

6. CONCLUSION

In conclusion, we introduce SingStyle111, a large-scale, high-quality, multilingual singing voice dataset that caters to various styles and includes style transfer examples. We provided detailed annotations of lyrics and scores at the phoneme level, together with extracted acoustic features. We will make the dataset freely available for research purposes to facilitate relevant MIR tasks.

ABSTRACT

Lyric translation plays a pivotal role in amplifying the global resonance of music, bridging cultural divides, and fostering universal connections. Translating lyrics, unlike conventional translation tasks, requires a delicate balance between singability and semantics. In this paper, we present a computational framework for the quantitative evaluation of singable lyric translation, which seamlessly integrates musical, linguistic, and cultural dimensions of lyrics. Our comprehensive framework consists of four metrics that measure syllable count distance, phoneme repetition similarity, musical structure distance, and semantic similarity. To substantiate the efficacy of our framework, we collected a singable lyrics dataset, which precisely aligns English, Japanese, and Korean lyrics on a line-by-line and section-by-section basis, and conducted a comparative analysis between singable and non-singable lyrics. Our multidisciplinary approach provides insights into the key components that underlie the art of lyric translation and establishes a solid groundwork for the future of computational lyric translation assessment.

1. INTRODUCTION

Translating lyrics is a prevailing method of enhancing the global appeal and allure of music across a multitude of genres, such as theatre music, animation music, pop music, etc [1]. Furthermore, recent advancements in media technology have facilitated the exchange of intercultural products and globalized fandom culture, resulting in an increase in the popularity of user-translated lyrics across diverse social media platforms [2].

Despite its popularity, lyric translation is acknowledged as a challenging field, requiring an interdisciplinary approach [2]. As early as 1915, it was suggested that an ideal lyric translator should possess expertise in both linguistics and music, highlighting the need for a comprehensive understanding of the principles and techniques used in translation studies, coupled with a background in musicology [3].

Moreover, it is crucial to understand the cultural context of each language, such as different strategies employed for forming rhymes [4]. Because of these challenges, the systematic analysis and evaluation of lyric translation remain an under-researched topic of study. Thus far, only a few have proposed guidelines for scoring the quality of translated lyrics [4, 5]. While these principled approaches have proven successful, they lack automation. Consequently, despite the growing interest in the development of neural lyric translation, its evaluation has predominantly relied on human evaluation, making the evaluation process time-consuming, unreliable, and subjective [6–8].

Our study aims to computationally analyze and evaluate lyric translation based on a comprehensive understanding of lyrics that accounts for their musical, linguistic, and cultural elements. Unlike prior research that only proposed rhyme-scoring guidelines applicable to English [4], our framework is extendable to Japanese and Korean. Though our framework may be limited in its application to specific languages, we strive to provide valuable insights into establishing distinct evaluation rules for phoneme repetition in diverse languages. Our comprehensive framework employs a multifaceted evaluation approach that examines lyric translation from four distinct perspectives: syllable counts, phoneme repetition, musical structure, and semantics. In the remainder of this paper, we explicate the rationale behind our selection of these perspectives by delving into the unique characteristics of lyric translation that differentiate it from general language translation tasks. In addition, we introduce the singable lyrics dataset we collected, which features line-by-line and section-by-section alignment of English, Japanese, and Korean lyrics. Moving forward, we propose robust evaluation metrics for lyric translation and analyze the results of our experiments based on the perspectives mentioned above. Finally, we conclude our paper by reflecting on the profound insights gleaned from our experiment and highlighting possible directions for future research.

2. BACKGROUND

Previous research indicates that linguistic analysis methods designed for standard text may not achieve desired outcomes when used to examine lyrics [9]. Although automated evaluation metrics, such as n -gram-based [10–12] or neural approaches [13], have proven valuable and effective in assessing conventional machine translation tasks, they

Nam, “A Computational Evaluation Framework for Singable Lyric Translation”, in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

fall short in evaluating lyric translation. This is due to the unique characteristics of lyrics that render the translation process subject to many constraints and less direct [14].

One of the most significant constraints is the syllable count. This is because the original and translated lyrics must match the same melody lines, while it is a common practice to tweak the melody to accommodate minor changes in syllable count [4, 15]. In fact, conveying the same message in different languages requires vastly different syllable counts. For example, “Happy New Year” in English consists of 4 syllables, whereas 15 and 9 are required for Japanese (あけましておめでとうございます) and Korean (새해 복 많이 받으세요), respectively. For the numerical comparison, we examined PAWS-X, a dataset that contains 23,659 English sentences paired with human-translated sentences in various languages [16]. The average number of syllables per sentence in the dataset is 50.89 for Japanese, whereas 36.18 per English and 40.40 per Korean. With these statistics, it can be deduced that Japanese necessitates approximately 41% more syllables than English and 26% more syllables than Korean to express an equivalent message. This limitation forces translators to often modify the meaning of original lyrics by adding, omitting, or even tweaking the message. However, translated lyrics still aim to capture the theme, mood, and spirit of the original lyrics [17]. Therefore, while original and translated lyrics need not be semantically identical, they still need to be semantically relevant [4, 18].

It is also crucial to preserve the frequency of phoneme repetition (e.g., rhyme) in translated lyrics, particularly when the music demands it [17]. For instance, some sections, such as choruses, require a substantial degree of phoneme repetition, while others do not. Moreover, due to the inherent connection between lyrics and music, lyrics must be arranged in a way that complements the music [19]. As a result, musically similar sections should maintain resembling linguistic features, including the choice of phonemes and the frequency of phoneme repetition [20].

3. DATASET

Although some websites provide user-translated multilingual lyrics, we found that most of them lack singability, as these translations were focused on delivering the meaning of the original lyrics rather than making them performable. While there are a few singable translations available, they are often not aligned on a line-by-line nor section-by-section basis due to the subjective nature of the lyric structure that there is no universal agreement on what to call a line and what to call a section. The absence of alignment makes it difficult to compare the original lyrics with their translated versions. To address this issue, we collected a set of singable lyrics, sourced from either official lyrics of commercial songs or user-translated ones found on YouTube, meticulously aligned on a line-by-line basis in English, Japanese, and Korean. This approach ensures that lyrics on the same line share the same melodies. Moreover, the dataset divides the lyrics into sections, allowing for section-by-section analysis. Alongside the lyrics, it

Section #	Line #	English (EN)	Japanese (JP)	Korean (KR)
1	1	Twinkle, twinkle, little star	きらきらひかる	반짝 반짝 작은별
	2	How I wonder what you are	おそらのほしよ	아름답게 비치네
	3	Up above the world so high	まばたきしては	서쪽 하늘에서도
	4	Like a diamond in the sky	みんなをみてる	동쪽 하늘에서도
	5	Twinkle, twinkle, little star	きらきらひかる	반짝 반짝 작은별
	6	How I wonder what you are	おそらのほしよ	아름답게 비치네
2	7	Twinkle, twinkle, little star	きらきらひかる	반짝 반짝 작은별
	8	How I wonder what you are	おそらのほしよ	아름답게 비치네
	9	When the blazing sun is gone	みんなのうたが	서쪽 하늘에서도
	10	When he nothing shines upon	とどくといいな	동쪽 하늘에서도
	11	Then you show your little light	きらきらひかる	반짝 반짝 작은별
	12	Twinkle, twinkle, all the night	おそらのほしよ	아름답게 비치네

Table 1. Sample data illustrating the original English lyrics of “Twinkle, Twinkle, Little Star” and their corresponding singable translations in Japanese and Korean, aligned on a line-by-line and section-by-section basis.

provides essential metadata such as genre, artist, original language, and the official status of lyrics. The dataset consists of 162 songs, each having lyrics in the three languages. It covers a diverse range of genres, including 109 K-pop, 23 animation music (e.g., Disney), 13 J-pop, 10 theatre music, and more. Table 1 shows sample data.

4. EVALUATING SINGABILITY

Our primary goal is to develop an evaluation framework that automatically assesses the quality of translated lyrics. One of the most important factors determining the quality is *singability*, defined as not only the ability of being sung, but also the suitability (easiness) of being sung [18]. To ensure such singability, we aim to provide metrics from three distinct perspectives by making sure that they i) maintain the song’s melodic integrity, ii) preserve the degree of phoneme repetition, and iii) consider the underlying musical structure.

To substantiate the reliability of our evaluation metrics, we conducted a comparative analysis of singable lyrics versus non-singable lyrics based on each proposed evaluation metric. In all our comparative analyses, we utilized our dataset for singable lyrics, where official lyrics served as both source and target lyrics, and unofficial functioned as only target lyrics. For non-singable lyrics, we obtained pairs of original singable (source) and human-translated non-singable (target) lyrics, aligned line-wise and section-wise, for 3,642 songs from <https://lyricstranslate.com/>.

Source	Target	Singable	Non-singable
English	Japanese	0.17 (80 songs)	0.74 (1401 songs)
	Korean	0.11 (80 songs)	0.48 (620 songs)
Japanese	English	0.16 (162 songs)	0.39 (589 songs)
	Korean	0.11 (162 songs)	0.31 (73 songs)
Korean	English	0.09 (161 songs)	0.20 (702 songs)
	Japanese	0.12 (161 songs)	0.52 (257 songs)

Table 2. The average line syllable count distance ($D_{iS_{syl}}$) between source and target languages for singable and non-singable lyrics.

Section	English	Japanese (English translation)	Korean (English translation)	pho
$E(A_1)$	Do you wanna build a snowman?	雪だるま作ろう (Let's build a snowman)	같이 눈사람 만들래? (Do you wanna build a snowman?)	
$J(A_1)$	Come on, let's go and play!	ドアを開けて (Please open the door)	제발 좀 나와봐 (Please come out)	0.85,
$K(A_1)$	I never see you anymore	一緒に遊ぼう (Let's play together)	언니를 만날 수 없어 (I can't meet you)	0.73,
$E(A_1)$	Come out the door	どうして (Why)	같이 놀자 (Let's play together)	0.77
$K(A_1)$	It's like you've gone away	出てこないの? (don't you come out?)	나 혼자 심심해 (I'm lonely alone)	
$E(B_1)$	We used to be best buddies	前は仲良く (We were close before)	그렇게 친했는데 (We were close before)	0.92,
$J(B_1)$	And now we're not	してたのに (We used to be)	이젠 아냐 (and we're not)	0.80,
$K(B_1)$	I wish you would tell me why!	なぜ会えないの (Why can't we meet each other?)	그 이유를 알고파 (I want to know the reason why)	0.91
$E(A_2)$	Do you wanna build a snowman?	雪だるま作ろう (Let's build a snowman)	같이 눈사람 만들래? (Do you wanna build a snowman?)	
$J(A_2)$	Or ride our bike around the halls?	自転車に乗ろう (Let's ride a bike)	아니면 자전거 탈래? (or do you wanna ride a bike?)	0.79,
$K(A_2)$	I think some company is overdue	ずっと一人でいると (When I'm alone all the time)	이제는 나도 지쳐 가나봐 (Seems I'm getting tired)	0.73,
$E(A_2)$	I've started talking to the pictures on the walls!	壁の絵とおしゃべりしちゃう (I'm almost talking to the pictures on the walls)	벽에다 말을 하며 놓고 있잖아 (because I've started talking to the walls)	0.82
$J(A_2)$	It gets a little lonely	さびしい部屋で (In a lonely room)	사실은 조금 외로워 (In fact, I'm a little lonely)	0.90,
$K(A_2)$	All these empty rooms	柱時計 (the wall clock)	텅빈 방에선 (In empty rooms)	0.88,
$E(B_2)$	Just watching the hours tick by	見てたりするの (I look at or something)	시계소리만 들려 (All I can hear is the clock's ticking)	0.96

Table 3. Lyric excerpt from “Do You Want to Build a Snowman” from the animation “Frozen,” singable in all languages. Sections A_1 and A_2 form a musically similar pair, while B_1 and B_2 are also musically similar to each other. Each section is denoted as $E(A_1), \dots, E(B_2)$ in English, $J(A_1), \dots, J(B_2)$ in Japanese, and $K(A_1), \dots, K(B_2)$ in Korean.

4.1 Line Syllable Count Distance

It is crucial to preserve the syllable counts between the original and translated lyrics for each line as similar as possible in order to maintain the integrity of a song’s melody [21]. Therefore, it is unsurprising that our evaluation framework incorporates a metric to assess the differences in syllable counts. Let the line syllable counts for a pair of lyrics that consist of n lines, $\mathbf{X} = \{x_1, \dots, x_n\}$ and $\tilde{\mathbf{X}} = \{\tilde{x}_1, \dots, \tilde{x}_n\}$ be denoted as $\{syl(x_1), \dots, syl(x_n)\}$ and $\{syl(\tilde{x}_1), \dots, syl(\tilde{x}_n)\}$ where each element refers to the syllable count of each line. For instance, if the first line of the English lyrics \mathbf{X} is “Silent night holy night” and the corresponding line in the Korean lyrics $\tilde{\mathbf{X}}$ is “Goyohanbam-georukhanbam (고요한밤 거룩한밤)”, the value of $syl(x_1)$ is 6 and $syl(\tilde{x}_1)$ is 8. We define the **line syllable count distance** between a pair of lyrics \mathbf{X} and $\tilde{\mathbf{X}}$ ($Dis_{syl}(\mathbf{X}, \tilde{\mathbf{X}})$) in order to evaluate the disparities in syllable counts, as follows.

$$Dis_{syl}(\mathbf{X}, \tilde{\mathbf{X}}) = \frac{1}{2n} \sum_{i=1}^n \left(\frac{|syl(x_i) - syl(\tilde{x}_i)|}{syl(x_i)} + \frac{|syl(x_i) - syl(\tilde{x}_i)|}{syl(\tilde{x}_i)} \right) \quad (1)$$

We compare the line syllable count distance of singable and non-singable lyrics. As shown in Table 2, non-singable lyrics display a considerably greater $Dis_{syl}(\mathbf{X}, \tilde{\mathbf{X}})$ compared to singable lyrics due to the varying syllable count requirements across languages.

4.2 Phoneme Repetition Similarity

Rhyme, defined as the repetition of a vowel sound and any subsequent sounds [22], has historically been a fundamental element in the realm of poetry, including in Western languages like English. However, the concept of rhyme has not been as prevalent in Japanese or Korean poetry [23]. In fact, traditional Korean poetry did not incorporate this concept [24]. Despite the increasing tendency to adopt the concept of rhyme in Japanese and Korean lyrics due to intercultural exchanges, we observed that lyrics in these languages often rely more on repeating grammatical elements. For example, in section A_1 of Table 3, the Japanese pair “tsukurou (作ろう, Let’s build)” and “asobou (遊ぼう, Let’s play)” generates a sense of rhyme because both end

with the same conjugation “ou” meaning “let’s”. Similarly, in Section A_2 , the Korean pair “mandeullae (만들래, Do you wanna build)” and “tallae (탈래, Do you wanna ride)” creates a sense of repetition because both end with “llae” meaning “Do you wanna”. Another example is the repetition of particles at the end of sentences, such as “yo (よ)” and “no (の)” in Japanese and “yo (요)” and “da (다)” in Korean, which convey cultural nuances related to formality. We therefore propose that English, Japanese, and Korean share common ground in adopting phoneme repetition for poetic expression. However, as such repetition is not necessarily called rhyme in Japanese and Korean, we will refrain from using the term “rhyme” and instead employ the term “phoneme repetition.”

We noticed that each section’s degree of phoneme repetition remains consistent across different languages when the lyrics are singable. For example, in Table 3, the first section of the original English lyrics ($E(A_1)$) displays a strong degree of phoneme repetition, with three rhyming pairs: “come-come”, “play-away”, and “anymore-door” (In this paper, we denote a section as an uppercase with a number and a line as a lower case with a number). Similarly, both the Japanese and Korean translations ($J(A_1)$, $K(A_1)$) also exhibit a substantial degree of phoneme repetition, featuring three pairs of repeated phonemes in each: “doa (ドア)”-“dou (どう)”, “tsukurou (作ろう)”-“asobou (遊ぼう)”, “akete (開けて)”-“shite (して)” in Japanese, and “gachi (같이)”-“gachi (같이)”, “mandeul (만들)”-“eonnireul (언니를)”, “mandeullae (만들래)”-“simsimhae (심심해)” in Korean. However, we realized that it is not fair to directly compare the number of phoneme repetitions when attempting to quantify the degree of phoneme repetition as each language has a different number of vowels and consonants: English has 15 vowels and 24 consonants, whereas Japanese has 5 and 15 and Korean has 21 and 19. Hence, in an attempt to minimize the differences in the number of phonemes, we treated acoustically similar vowels as the same vowel in English, such as ‘IH’-‘IY’, ‘UH’-‘UW’, or ‘EH’-‘AE’ (e.g., ‘mass’ and ‘mess’) [25] because they can still form slant rhymes [26]. Conversely, we considered ‘A’-‘YA’, ‘O’-‘YO’, and ‘U’-‘YU’ as sep-

Source	Target	Singable	Non-singable (Human)	Non-singable (Machine)
English	Japanese	0.14	0.26	0.30
	Korean	0.10	0.15	0.15
Japanese	English	0.13	0.20	0.18
	Korean	0.11	0.13	0.14
Korean	English	0.10	0.10	0.10
	Japanese	0.11	0.10	0.17

Table 5. The average musical structure distance (Dis_{mus}) of singable lyrics and non-singable lyrics.

between lyrics in different languages \mathbf{X} and $\tilde{\mathbf{X}}$, each consisting of m sections, $Dis_{mus}(\mathbf{X}, \tilde{\mathbf{X}})$, is defined as follows:

$$Dis_{mus}(\mathbf{X}, \tilde{\mathbf{X}}) = \frac{1}{m^2} \sqrt{\sum_{i,j=1}^m (diss(X_i, X_j) - diss(\tilde{X}_i, \tilde{X}_j))^2} \quad (5)$$

In Table 5, we provide a summary of the average musical structure distance for singable lyrics, human-translated non-singable lyrics, and machine-translated non-singable lyrics generated by automatically translating official singable lyrics from 80 English, 162 Japanese, and 161 Korean songs using Google Translator. Our findings show that singable lyrics exhibit the lowest Dis_{mus} values, while machine-translated non-singable lyrics display the highest, suggesting that machine-translated ones lack structural coherence the most. As human-translated non-singable lyrics maintain structural coherence in aspects such as word choice and nuances, they demonstrate lower distances than machine-translated counterparts.

5. EVALUATING SEMANTICS

Semantic relatedness to the original lyrics is by no means less fundamental than syllable counts, phoneme repetition, and structural factors [18]. We therefore introduce a fourth metric, semantic similarity, to ensure the semantic relevance of translated lyrics to the original.

5.1 Semantic Similarity

To numerically assess the semantic textual similarity (sts) between a pair of lyrics, we first obtained the contextual embeddings of each text from lyrics using a pre-trained Sentence BERT model¹ [31] and then calculated the cosine similarity between the embeddings. As this model was trained for English, the Japanese and Korean lyrics were automatically translated using Google Translator before obtaining the embeddings.

We started by examining hierarchical semantic similarity using cross-scape plots [32], as shown in Figure 2. Given a pair of lyrics $\mathbf{X} = \{x_1, \dots, x_n\}$ and $\tilde{\mathbf{X}} = \{\tilde{x}_1, \dots, \tilde{x}_n\}$ with n lines each, the first (leftmost) block of the lowest line represents the semantic textual similarity between x_1 and \tilde{x}_1 (denoted as $sts(x_1, \tilde{x}_1)$) while the last (rightmost) block signifies $sts(x_n, \tilde{x}_n)$. The first (leftmost) block of the second-lowest line denotes $sts(x_1+x_2, \tilde{x}_1+\tilde{x}_2)$, and the second block corresponds to $sts(x_2+x_3, \tilde{x}_2+\tilde{x}_3)$. Lastly,

¹ We used all-MiniLM-L6-v2 [30].

Figure 2. Semantic similarity cross-scape plot for the J-pop song “A Thousand Winds” between English and Japanese (Left), English and Korean (Middle), and Japanese and Korean (Right). Any value less than 0 was regarded as 0.

Line #	English	Japanese (English translation)	sts
1	please do not stand at my grave and weep.	私のお墓の前で (in front of my grave)	0.56
2	I am not there. I do not sleep	泣かないでください (please stop crying)	0.27
1, 2	please do not stand at my grave and weep. I am not there, I do not sleep	私のお墓の前で泣かないでください (in front of my grave. please stop crying.)	0.76

Table 6. Semantic textual similarity (sts) between English and Japanese versions of “A Thousand Winds”.

the highest block (line) represents the similarity between the entire lyrics, $sts(x_1 + \dots + x_n, \tilde{x}_1 + \dots + \tilde{x}_n)$.

In each plot of Figure 2, there are semantic disparities at lower levels, but similarities increase at higher (broader) levels. We have two explanations for this. First, the number of musical notes within a single lyric line may be adequate to deliver a specific message in one language but insufficient in another language. Therefore, it is common for a message conveyed in one line in one language to span two lines in another language. As an example, we provide Table 6, which presents the semantic textual similarity (sts) between Japanese and English lyrics of the J-pop song “A Thousand Winds (千の風になつて)”. As demonstrated in the table, the similarity between Japanese and English at a broader level ($sts(x_1+x_2, \tilde{x}_1+\tilde{x}_2)$) can be higher than at the line level ($sts(x_1, \tilde{x}_1)$, $sts(x_2, \tilde{x}_2)$) because Japanese generally requires more syllables than English and it often takes two lines in Japanese to express a single-line message in English. Second, the semantic similarities at broader levels can be higher because of grammatical/linguistic differences. Each language has its own natural word order patterns. For example, in the phrase “I’m going to travel to find the gold,” it is natural in English to mention “I’m going to travel” before “to find the gold.” However, in Japanese and Korean, expressing “to find the gold (金を探しに, 금을 찾으러)” before “I’m going to travel (旅に出る, 떠난다)” is a more typical and natural construction. Table 7 shows that these differences between languages make line-level semantic assessments insufficient. Since lines 1, 2, and 3 in the English version correspond to lines 3, 1, and 2 respectively in the Japanese version, these pairs exhibit low semantic similarities at the line level ($sts(x_1, \tilde{x}_1)$, $sts(x_2, \tilde{x}_2)$, $sts(x_3, \tilde{x}_3)$), while demonstrating higher similarity when considered as a whole ($sts(x_1+x_2+x_3, \tilde{x}_1+\tilde{x}_2+\tilde{x}_3)$).

Considering these factors, it becomes evident that

Line #	English	Japanese (English translation)	<i>sts</i>
1	Dare to try and reach out for heaven	望むように生きるなら (If you want to become what you're meant to be)	0.22
2	You must become what you're meant to be	星からの金を求め (to find the gold from stars)	0.27
3	And bring the gold of heaven to the world	一人旅に出るのよ (Dare to embark on a solo journey)	0.13
1-3	Dare to try and reach out for heaven You must become what you're meant to be And bring the gold of heaven to the world	望むように生きるなら星からの金を求め一人旅に出るのよ (Dare to embark on a solo journey if you want to become what you're meant to be to find the gold from stars)	0.53

Table 7. Semantic textual similarity (*sts*) between English and Japanese versions of “Gold von den Sternen”.

Figure 3. The line-wise (Left) and section-wise (Right) semantic similarity matrices between Japanese and Korean versions of “Wie wird man seinen Schatten los?”

singable lyric translations do not prioritize line-wise semantic similarity. Rather, we observed that singable translations aim to preserve semantic connections at the section level since the organization of the lyric storyline follows a section-wise approach. To illustrate this, we present Figure 3, which displays both line-wise and section-wise semantic similarity matrices for the Japanese and Korean versions of “How do you get rid of your shadow? (Wie wird man seinen Schatten los?)” from the German musical “Mozart!”. As shown in the Figure, the section-wise matrix represents the semantic relatedness more clearly than the line-wise matrix.

Therefore, we propose assessing section-wise semantic relatedness for evaluating singable lyric translation. To achieve this, we define the **semantic similarity** between a pair of lyrics $\mathbf{X} = \{X_1, \dots, X_m\}$ and $\tilde{\mathbf{X}} = \{\tilde{X}_1, \dots, \tilde{X}_m\}$, consisting of m sections and $n = n(X_1) + \dots + n(X_m)$ lines, where $n(X_i)$ denotes the number of lines in the i -th section, as follows:

$$Sim_{sem}(\mathbf{X}, \tilde{\mathbf{X}}) = \sum_{i=1}^m \left(\frac{n(X_i)}{n} sts(X_i, \tilde{X}_i) \right). \quad (6)$$

Table 8 compares singable and non-singable lyrics in terms of line-wise semantic similarities ($\frac{1}{n} \sum_{i=1}^n sts(x_i, \tilde{x}_i)$) and section-wise similarities, using our proposed metric (Sim_{sem}). The table reveals that non-singable translations exhibit high semantic similarity for both line-wise and section-wise measures, with similar values for each. In contrast, singable translations show low line-wise similarity, as expected, since they do not prioritize line-wise semantic similarity. However, when evaluated using section-wise similarity, they display a level of similarity comparable to that between “Machine learning is so easy” and “Deep learning is so straightforward”, which is 0.623 when measured with the same pre-trained model [30].

Source	Target	Singable		Non-singable	
		line	section	line	section
English	Japanese	0.40	0.54	0.64	0.74
	Korean	0.42	0.55	0.70	0.76
Japanese	English	0.47	0.59	0.66	0.72
	Korean	0.52	0.61	0.77	0.79
Korean	English	0.53	0.63	0.78	0.81
	Japanese	0.52	0.61	0.73	0.75

Table 8. The average line-wise semantic similarity and section-wise semantic similarity (Sim_{sem}) of singable and non-singable lyrics.

6. DISCUSSIONS AND CONCLUSIONS

In this paper, we introduced a computational evaluation framework for singable lyric translation, grounded in the musical, linguistic, and cultural understanding of lyrics, comprised of four evaluation metrics, line syllable count distance (Dis_{syl}), phoneme repetition similarity (Sim_{pho}), musical structure distance (Dis_{mus}), and semantic similarity (Sim_{sem}). These metrics are designed to ensure that the translated lyrics maintain the integrity of melodies, degree of phoneme repetition, structural coherence, and semantics of the original lyrics. Our framework is automated, guaranteeing objectivity and efficiency in terms of time and cost. We showed the efficacy of our evaluation metrics by offering comparative statistics between singable and non-singable lyrics. In addition, our analysis revealed that the degree of phoneme repetition in the original lyrics is frequently mirrored in the translated lyrics, musically similar sections tend to share the same phonemes and display comparable degrees of phoneme repetition, and section-wise analysis is better suited for evaluating semantic similarity for lyric translation than line-wise analysis.

Nonetheless, there remains room for improvement. Although we have assembled a singable lyrics dataset, aligned across English, Japanese, and Korean, our dataset has some limitations; it lacks musical information and its volume is limited. As a result, we have not been able to incorporate musical notes into our experiment or conduct comparative studies across various genres. We recognize that an ideal lyric translation evaluation system should take into account the relationship between musical notes and phonemes, as well as adapt to different genres. Moreover, although we have endeavored to incorporate cultural understandings of poetry in different languages, we acknowledge the need for deeper cultural considerations. For example, we noticed that cultural similarities might have an impact on the extent of semantic similarities. This is demonstrated in an English translation of “MIC Drop”, a K-pop song by BTS originally written in Korean, made by YouTuber Iris Phuong. The translated singable lyrics do not include a translation of the term “hyodo (효도, taking care of parents)” as there is no direct equivalent in English, while the Japanese version of the song effortlessly conveys the concept as “kougou (孝行)”. In the future, we aim to expand our dataset to contribute more to lyric translation studies and to further explore the impact of genre and cultural influences on lyric translation.

CHORUS-PLAYLIST: EXPLORING THE IMPACT OF LISTENING TO ONLY CHORUSES IN A PLAYLIST

ABSTRACT

When people listen to playlists on a music streaming service, they typically listen to each song from start to end in order. However, what if it were possible to use a function to listen to only the choruses of each song in a playlist one after another? In this paper, we call this music listening concept “chorus-playlist,” and we investigate its potential impact from various perspectives such as the demand and the objectives for listening to music with chorus-playlist. To this end, we conducted a questionnaire-based online user survey involving 214 participants. Our analysis results suggest reusable insights, including the following: (1) We show a high demand for listening to existing playlists with the chorus-playlist approach. We also reveal preferred options for chorus playback, such as adding crossfade transitions between choruses. (2) People listen to playlists with chorus-playlist for various objectives. For example, when they listen to their own self-made playlists, they want to boost a mood or listen to music in a specific context such as work or driving. (3) There is also a high demand for playlist creation on the premise of continuous listening to only the choruses of the songs in a playlist. The diversities of artists, genres, and moods are more important when creating such a playlist than when creating a usual playlist.

1. INTRODUCTION

The chorus of a song is one of the most distinctive parts in the song. In terms of acoustic aspects, it has been reported that the chorus tends to have louder sound, contain heavier instrumentation and additional vocals, and include the highest-pitch vocal note in a song [1–3]. In terms of cognitive aspects, the chorus tends to be the catchiest, most memorable, and most salient part of a song for emotional expression [4–7]. Moreover, the chorus is often characterized by the property of being a song’s most repeated section [8, 9]. Because of these characteristics, the chorus has attracted academic attention. For example, research has been conducted on music structure analysis including chorus detection [8–35] and its use for music summary generation [36, 37]. In addition, music datasets specializing in choruses have been made publicly available [38].

As for general music listening habits beyond choruses, the amount of time spent listening to music through playlists on music streaming services has increased [39–42]. It has also been reported that this listening time is longer than the time of listening to music via albums [43]. On the services, both playlists that are created by general users and those that are created by professional curators or automatically generated are widely available [42, 44–46]. As a result, Spotify has over 4 billion playlists, for example [42]. With the popularity of playlists, many studies have been conducted on playlist recommendation, generation, and analysis [40, 42, 44, 47–76].

Given the importance of choruses and playlists, we focus on a listening approach in which only the choruses of the songs in a playlist are played one after another. Certain smartphone music player applications such as Vocolle App by DWANGO Co., Ltd., MIXTRAX App by Pioneer Corporation, and KENWOOD Music Control have provided a function to continuously play the choruses of songs or parts including the choruses. However, there has been no academic discussion on the impact of this listening approach. In this paper, we refer to the concept of continuous listening to only the choruses of songs in a playlist as “chorus-playlist.” This concept can be applied not only when a user listens to playlists that she created but also when she listens to playlists created by other users. Under this concept, a user could create a playlist on the premise of continuous listening to only the choruses of the playlist’s songs. Hence, the goal of this paper is to reveal the usefulness of chorus-playlist and provide reusable insights.

To achieve this goal, we conducted a questionnaire-based online user survey involving 214 participants. Our contributions can be summarized as follows.

- To our knowledge, this is the first study investigating the impact of continuous listening to only the choruses of songs in a playlist.
- We reveal user preferences for chorus playback in a playlist (e.g., users prefer to add crossfade transitions between choruses). We also show a high demand and certain user objectives for listening to playlists with chorus-playlist. For example, people often want to listen to their own self-made playlists to boost a mood or in a specific context such as work or driving.
- We show that people tend to be willing to create a playlist for continuously listening to only the choruses of the songs in the playlist. We also reveal important properties in creating such playlists (e.g., the diversity of moods, genres, and artists).

- According to the survey results, we suggest new research topics for the music information retrieval (MIR) community (e.g., song recommendation for users who listen to music with chorus-playlist). We also make several proposals for music streaming platforms to attract users (e.g., when using the chorus-playlist approach, people would be willing to listen to playlists containing hit songs to efficiently check them out).
- We have made a portion of the survey results publicly available on the web to support future studies¹.

2. RELATED WORK

2.1 Chorus Analysis and Detection

The chorus is distinctive compared to other sections of a song in terms of acoustic, structural, and cognitive aspects. In terms of acoustic aspects, it has been known that choruses tend to be louder, to contain heavier instrumentation and more vocals, and to have the highest-pitch vocal note in a song [1–3]. More recently, Balen et al. [77] revealed that choruses have a smaller dynamic range and a greater variety of MFCC-measurable timbres, as compared to other sections. Regarding structural aspects, choruses are usually repeated more than other sections such as intros and verses [8, 9]. As for cognitive aspects, choruses are the catchiest and most memorable sections for listeners [4, 5, 7]. For artists, too, choruses are distinctive in that they are the most salient sections for emotional expression [6]. Given these characteristics, we focus here on choruses as song excerpts, rather than other sections. As we will show in section 7, the chorus is more preferred than other sections for continuous listening in a playlist.

Because of the importance of choruses, many studies have addressed musical structure analysis, including chorus detection, based on music audio signals [8–15, 17–24, 26, 27, 29–32, 34, 35] or lyrics [16, 25, 28, 33]. The accuracy of identifying the chorus section is approximately 80-90% in terms of the F-measure [12, 22, 29, 33]. Accordingly, the feasibility of implementing the chorus-playlist concept on music streaming services is sufficiently high. For songs in which the correct chorus cannot be detected, it is also possible to have users on a service manually correct choruses through a collective intelligence approach [78].

2.2 Playlist Analysis and Recommendation

On today’s music streaming services, playlists have become a central way to listen to music [40–42]. The majority of playlists on services are created by general users rather than professional music enthusiasts [44]. Users create playlists not only for their own listening but also to share their musical preferences with other users such as friends and followers [44, 53, 70]. It has also been reported that playlists can be characterized by certain properties [40, 62, 68, 69, 74, 76] such as song order [42] and low diversity in terms of both artists and genres [70]. In this paper, too, we report objectives for listening to music with

chorus-playlist (section 5) and important properties for creating a playlist to continuously listen to only the choruses of songs in the playlist (section 6).

Although playlists are actively created by users, it is time consuming to manually create a playlist [44]. To ease the process, two approaches have been studied: assisted playlist creation [49–52, 54, 55, 71] and automatic playlist generation [47, 48, 56, 58–61, 63–67, 72, 73, 75]. In song recommendation for a playlist or generation of a playlist, it is typical to consider the song order and/or the audio similarity between songs. Furthermore, there are several studies that automatically extract prominent sections (not only limited to choruses) from individual songs and generate DJ mixes [79] or medleys [80] by connecting them. Music streaming services such as Spotify and Deezer provide functions for automatic playlist generation to promote song discovery by users [45, 46]. In this paper, according to our survey results, we discuss not only new approaches for these research topics but also how to encourage users on music streaming services to more actively interact with playlists and discover novel songs.

3. PARTICIPANTS

We recruited participants for our survey via an online research company in Japan. We limited the participants to those who are Japanese, listened to music an average of at least one day per week via any music streaming service, and had created at least 10 playlists on the service. We paid 51.6 USD (7,000 JPY) to each participant. Although 222 participants answered the questionnaire in sections 4, 5, 6, and 7 through a web browser, to make the analysis results more reliable, we removed the answers from eight participants who submitted improper responses to a free-response question. The remaining 214 participants were diverse in both gender and age range: 89 males (10s: 1; 20s: 29; 30s: 35; 40s: 17; 50s: 7), and 125 females (10s: 1; 20s: 45; 30s: 38; 40s: 25; 50s: 16).

4. PREFERENCE FOR CHORUS PLAYBACK

4.1 Chorus Playback Choices

As explained in section 1, the concept of chorus-playlist enables a user to continuously listen to only the choruses of songs in a playlist. However, some users may prefer to add crossfade transitions between choruses. In this section, we investigate the preferences for chorus playback in chorus-playlist in terms of the following three choices.

- **TimePreChorus:** the playback time before the chorus. The options are “no playback,” “5 seconds,” and “10 seconds.” “No playback” means that only the choruses are continuously played, without any part of the song before the chorus.
- **Crossfade:** whether 1-second crossfade transitions are added between songs. The options are “on” and “off.”
- **TimeChorus:** the playback time for the chorus. The options are “15 seconds,” “30 seconds,” and “adaptive.” In the case of “15 (resp. 30) seconds,” 15 (resp. 30) seconds on a song is played from the beginning of the

¹The data can be downloaded from https://github.com/ktsukuda/chorus_playlist.

first chorus². In the case of “adaptive,” the first chorus is played from beginning to end regardless of its length.

Hereafter, we refer to a combination of these three choices in the form of a triplet such as (TimePreChorus, Crossfade, TimeChorus) = (5 seconds, off, adaptive).

4.2 Dataset

In this survey, the participants listened to playlists that we provided. To reduce bias due to the played songs, we used 120 songs created by professional musicians that we commissioned. That is, we guaranteed that the participants had never listened to any of the 120 songs. Instead of using chorus detection methods introduced in section 2.1, a music expert manually labeled the start and end times of each song’s first chorus to prevent detection errors. For 26 songs that started with the chorus, the expert labeled the start and end times of the second chorus, because the mood and/or beat of such leading choruses are sometimes different from those of the second and subsequent choruses. The average and standard deviation of chorus lengths for the 120 songs were 29.0 and 7.66 seconds, respectively, and 52 songs had choruses longer than 30 seconds.

As the participants had various music preferences, we created diverse playlists by sampling the songs to be included in playlists as follows. First, the 120 songs were plotted in the valence-arousal (VA) space according to their audio features. Next, we applied the k-means algorithm and classified the 120 songs in the VA space into three clusters. We created three playlists by sampling five songs at random for each playlist from one cluster. Similarly, we created three more playlists from another cluster. Finally, we created three playlists containing diverse songs in terms of their moods by randomly selecting one song from each of the two previous clusters and three songs from the remaining cluster. Each playlist’s song order was also determined randomly. In total, we created nine playlists that each comprised five songs. Note that there were no song overlaps between any pairs of playlists.

For each playlist, there were 18 total option combinations (3 options for TimePreChorus × 2 options for Crossfade × 3 options for TimeChorus). For example, for (5 seconds, on, adaptive), we first created an MP3 file by cutting each song in a playlist from five seconds before the first chorus to the end of the chorus and then connecting the songs with crossfade transitions. We then created an MP4 file to simulate the participants’ experience of listening to the playlist on a smartphone application. Specifically, given an MP3 file, we created an MP4 file in which the MP3’s playlist was played and images changed at the same time the song changed in the playlist. Each image contained a song’s title and artist name like in the music playback screen of a music player application (Figure 1)³.

4.3 Procedure

First, we investigated the participants’ preferred option combinations. To this end, three dropdown lists with the

² Thus, if the first chorus is less than 15 (resp. 30) seconds long, the song continues play after the chorus until the total playback time reaches 15 (resp. 30) seconds.

³ The images also include icons of pause, next, and previous buttons.

Figure 1. Interface example from our user survey. In this example, when a participant selects the options (no playback, on, 30 seconds), three playlists satisfying this combination are displayed.

options for each choice were presented to the participants. For each participant, three playlists were selected at random from the set of playlists described in section 4.2. Once the participant had selected an option for each choice, the three playlists (MP4 files) satisfying that option combination were displayed (Figure 1). When the participant changed the combination, the displayed playlists were also changed to those satisfying the new option combination⁴. After listening to playlists for any option combination, the participants reported their most preferred combination such as (10 seconds, on, 30 seconds), by selecting those options from the dropdown lists⁵.

Even if a participant chose “adaptive” as the preferred option for TimeChorus, she may have liked “30 seconds” almost as much. Accordingly, after the above investigation, we investigated the option preferences including such subtle differences. To this end, we displayed each of the 18 options with a six-point Likert scale ranging from “not preferred at all” to “very preferred,” and we asked the participants to rate their preferences for each option.

4.4 Results

Table 1 and Figure 2 indicate the results for the first and second investigations, respectively. In Table 1, we can see that the most popular combination was (5 seconds, on, adaptive). Even participants who chose other combinations also tended to prefer each of these options. In fact, for the results shown in Figure 2, paired Wilcoxon signed-rank tests with Bonferroni correction revealed that the median of “5 seconds” was statistically higher than the other two options for TimePreChorus at $p < 0.01$ ⁶. Similarly, “on” for Crossfade and “adaptive” for TimeChorus were statistically higher than the other options at $p < 0.01$. In particular, it was not obvious that “5 seconds” was the most preferred option for TimePreChorus, making this a useful, reusable insight for realizing chorus-playlist.

A music streaming service could offer the concept of chorus-playlist by implementing a function that enables users to listen to only choruses for all existing playlists on the service. If a service provided this function, it would be ideal to enable users to play playlists with arbitrary option combinations, as we did, to reflect users’ preferences. If it

⁴ Note that the songs contained in the three playlists did not change; only the options for playing them were changed.

⁵ It was not mandatory to listen to the playlists for all 18 option combinations. In fact, most participants reported their most preferred combination by narrowing down their preferences while switching options and listening to the corresponding playlists.

⁶ Throughout this paper, ** (*) in a figure denotes a statistical difference at $p < 0.01$ ($p < 0.05$).

Table 1. Preference distribution for option combinations.

TimePreChorus	Crossfade	TimeChorus	# participants
No playback	On	15 seconds	10 (4.67%)
		30 seconds	3 (1.40%)
		adaptive	38 (17.76%)
	Off	15 seconds	8 (3.74%)
		30 seconds	0
		adaptive	8 (3.74%)
5 seconds	On	15 seconds	26 (12.15%)
		30 seconds	14 (6.54%)
		adaptive	49 (22.90%)
	Off	15 seconds	1 (0.47%)
		30 seconds	1 (0.47%)
		adaptive	16 (7.48%)
10 seconds	On	15 seconds	3 (1.40%)
		30 seconds	6 (2.80%)
		adaptive	22 (10.28%)
	Off	15 seconds	1 (0.47%)
		30 seconds	1 (0.47%)
		adaptive	7 (3.27%)

Figure 2. Preference distributions for each option.

is difficult to implement such a flexible function, chorus-playlist should be provided with the option combination (5 seconds, on, adaptive), which should maximize the average user satisfaction according to this section’s results.

5. DEMAND FOR CHORUS-PLAYLIST

We described above how to implement a chorus-playlist function. In this section, we investigate the demand for listening to existing playlists with such a function.

5.1 Procedure

First, we showed the following description: “Suppose that a function to play only the choruses of the songs in a playlist has become available on the music streaming service that you usually use. Please rate on a scale from 1 (unwilling) to 6 (very willing) how much you would like to use this function to listen to existing playlists that you created.” When the answer was “unwilling,” they were asked to respond freely on why he/she did not want to use it. Otherwise, when the answer was one of the remaining five items, they were asked to respond freely with at least one objective for listening to playlists with the function. We did not set a cap on the number of responses.

Next, in a similar way, we asked the participants to indicate their willingness on a 6-point scale to use the function to listen to existing playlists created by other users. According to their willingness, they were asked to provide free responses as they did for the first question.

5.2 Results

Figure 3 shows the answer distribution. We refer to playlists created by the participant and by other users “self-made playlists” and “others’ playlists.” Only 11 and 3 participants answered “unwilling” for self-made playlists and

Figure 3. Distribution of the willingness to listen to playlists with the chorus-playlist function.

others’ playlists, respectively. The most popular reason for unwillingness was “I believe that there is value in listening to the entire song, including parts other than the chorus.” On the other hand, because 75.2 % (161) and 82.7 % (177) participants for the two respective types of playlists answered “very willing,” “willing,” or “somewhat willing,” we conclude that there is a sufficiently high demand for chorus-playlist.

We manually grouped the free responses on their objectives. When a response included multiple objectives corresponding to different groups, it was assigned to multiple groups. Table 2 lists the top 10 objectives in terms of the group sizes for each of the two kinds of playlists. Each number in parentheses indicates the number of participants who gave that objective. Below, we discuss the results.

In the case of self-made playlists, the top three objectives could be achieved just by continuously listening to the choruses of songs in a playlist. For example, the first objective was “boost a mood.” As self-made playlists usually contain songs that match the user’s own music preferences, the user’s mood would be boosted even when listening to playlists in the usual way [68]. Nevertheless, it is interesting that the participants answered that they wanted to further boost their mood by listening to only choruses. It would be beneficial to recommend songs for a playlist that are suitable for boosting a user’s mood when the user listens to only the choruses in the playlist. For the second objective, the participants answered with various contexts such as “work” and “driving.” When listening to a playlist with the chorus-playlist function in a specific context, there could be various reasons such as “increasing concentration” and “relaxing.” It would be an interesting future work to conduct a more detailed analysis of the contexts in which the conventional playlist listening approach or the chorus-playlist approach are preferred. As for the fourth objective, it is known that people consider it valuable to listen to music with others and let others listen to their favorite songs [81–84]. However, because it takes much time for others to listen to all the songs in a playlist, people may hesitate to introduce their favorite songs. Thus, the participants answered that they wanted to efficiently introduce others such as friends or family to their favorite songs when they listen to music together in person. That is, chorus-playlist could encourage people to interact with others through music in the real world.

On the other hand, regarding the top six objectives for others’ playlists, although those objectives could be achieved by conventional playlist listening, the participants wanted to use the chorus-playlist function to achieve the objectives more efficiently in a shorter time. In particular, as seen from the first, second, fourth, and fifth objectives, there is a strong demand for efficiently discovering and lis-

Table 2. Top 10 free-response objectives for listening to playlists with the chorus-playlist function.

Rank	Self-made playlist	Others' playlist
1	Boost a mood (79)	Find unfamiliar songs that suit my preference (109)
2	Listen to a playlist in a specific context (68)	Listen to hit songs (48)
3	Listen to a playlist within a limited time (46)	Learn other people's music preferences (44)
4	Recommend my favorite songs to others (36)	Listen to songs by unfamiliar artists (37)
5	Explore desired songs (35)	Listen to songs in unfamiliar genres (26)
6	Listen to many songs (23)	Preview a playlist (18)
7	Listen to various songs (20)	Listen to a playlist in a specific context (13)
8	Recall songs listened to in the past (18)	Refer to a playlist for creating my playlists (12)
9	Listen to only the choruses of my favorite songs (19)	Listen to a playlist for a change of pace (9)
10	Sing songs in a playlist (12)	Boost a mood (6)

tening to unfamiliar songs. Accordingly, if a music streaming service provides playlists consisting of hit songs of the past week, songs by a specific artist, or songs in a specific genre with the chorus-playlist function, many users would likely listen to those playlists by using the function. This would enable users to find more new favorite songs and help increase their music listening activity.

In summary, we have revealed that chorus-playlist can generate new interactions between people and music especially when they listen to self-made playlists. Moreover, as discussed above, the results in Table 2 can provide useful insights for both researchers and music streaming services.

6. IMPORTANT PROPERTIES FOR CREATING PLAYLISTS IN CHORUS-PLAYLIST CONCEPT

6.1 Procedure

In section 5, we assumed application of the chorus-playlist concept to existing playlists. However, by taking the concept a step further, a user could create a playlist on the premise of continuous listening to only the choruses in the playlist's songs (for simplicity, we refer to creating such a playlist as "creating a chorus-playlist"). Therefore, we asked the participants how much they would like to create chorus-playlists on the music streaming service that they used regularly. They answered with their willingness on a 6-point scale from "unwilling" to "very willing." We also told the participants that they could also listen to each song from beginning to end through, not just the chorus.

When users create playlists, they consider certain properties such as the diversity of artists and the song order. Hence, we wondered whether there are any differences regarding the importance of these properties when creating a chorus-playlist as compared to creating a usual playlist. To answer this question, we considered the following 11 properties derived from past studies [42, 70]. (1) SongHit: including songs with high popularity. (2) SongNew: including new songs in terms of the release dates. (3) ArtistSame: including as many songs by the same artist as possible. (4) ArtistDiv: including songs by as many different artists as possible. (5) GenreSame: including as many songs in the same genre as possible. (6) GenreDiv: including songs in as many different genres as possible. (7) MoodSame: including as many songs with the same musical mood as possible. (8) MoodDiv: including songs with as many different moods as possible. (9) SongOrder: the song order in the playlist. (10) SongTop: the first song in the playlist. (11) SongLast: the last song in the playlist.

Figure 4. Willingness to create a chorus-playlist.

The participants who answered the first question with anything other than "unwilling" rated the importance of each property in creating a chorus-playlist and in creating a usual playlist on a 6-point scale from "not at all important" to "very important." The 11 properties were displayed in a random order to each participant.

6.2 Results

Figure 4 shows that chorus-playlist creation has the potential to be a new way of enjoying music, because 75.7% (162) participants answered "very willing," "willing," or "somewhat willing," while only 6.07% (13) participants answered "unwilling." Next, as shown in Figure 5, paired Wilcoxon signed-rank tests indicated that statistical differences between the two playlist types were observed for nine properties⁷. Hence, we can say that people tended to emphasize different properties when creating a chorus-playlist as compared to creating a usual playlist. Existing studies on song recommendation for playlists or playlist generation have proposed various methods focusing on the song order in a playlist [54, 61, 64, 73]. However, for chorus-playlist, the SongOrder, FirstSong, and LastSong properties were relatively less important. In contrast, hit songs and new songs were more important for chorus-playlist. Furthermore, the results revealed the importance of diversity in terms of artists, genres, and moods for chorus-playlist. It has been reported that the diversities of artists and genres tend to be low in usual playlists [70]; however, to support users creating chorus-playlists, it would be important to recommend songs to diversify such properties. These results thus open up new recommendation approaches in the MIR community.

7. PLAYBACK METHOD COMPARISON

We have revealed a high demand to try chorus-playlist. In this section, we investigate whether the chorus-playlist playback method is preferred to other playback methods.

7.1 Procedure

For comparison, we used the following two types of playlists. (1) Head-playlist: a user continuously listens to

⁷ Figure 5 shows the results for the 201 participants besides the 13 participants who answered "unwilling." The same statistical differences were obtained even with only the aforementioned 162 participants.

Figure 5. Property importance for playlist creation.

only the head sections of each song in a playlist. (2) 30sec-playlist: a user continuously listens to only the parts after the first 30 seconds of each song in a playlist. We adopted 30 seconds according to the preview samples on a music streaming service (Deezer) [85].

Similarly to the investigation described in section 4, we had the participants listen to each type of playlist by selecting options for two choices. In the head-playlist case, the two choices were 1-second crossfade (options: “on” and “off”) and the playing time from the head of each song (options: “15 seconds” and “30 seconds”). In the case of 30sec-playlist, the two choices were 1-second crossfade (options: “on” and “off”) and the playing time after the first 30 seconds of each song (options: “15 seconds” and “30 seconds”). The participants listened to playlists with each playback method by using their favorite option combinations. Here, each participant was assigned three playlists containing the same songs as those in section 4. Then, they were asked to rate their willingness to listen to self-made playlists with each method on a 6-point scale.

7.2 Results

Figure 6 shows the results. Note that the chorus-playlist results are repeated from “self-made playlists” in Figure 3. Paired Wilcoxon signed-rank tests with Bonferroni correction revealed that the median for chorus-playlist was statistically higher than the medians for head-playlist and 30sec-playlist. It thus became clear that it was not enough to simply play any part of the songs in a playlist continuously, but that it was important for users to be able to play choruses continuously.

8. DISCUSSION AND CONCLUSION

In this paper, we have studied the concept of chorus-playlist. The reusable insights obtained from our user survey can be summarized as follows.

- We showed that there is a high demand for chorus-playlist. When the participants listened to songs in a playlist with chorus-playlist, they tended to prefer to listen to 5 seconds before the chorus, add crossfade transitions between songs, and listen to the chorus from

Figure 6. Willingness for three playlist types.

beginning to end. As discussed in section 7.2, it is more important to play choruses continuously than to play other sections continuously.

- As seen in Table 2, the objectives for listening to music with chorus-playlist were largely different between self-made playlists and others’ playlists. In particular, certain objectives for self-made playlists were unexpected, in that people wanted to enjoy music in a new way with chorus-playlist for objectives such as boosting their mood. These results could provide guidelines for researchers and services to consider new research topics and activate user interaction, respectively.
- We revealed a high demand for creating a chorus-playlist. As in Figure 5, hit songs, new songs, and the diversities of artists, genres, and moods are more important when creating a chorus-playlist than when creating a usual playlist. These results also provide new viewpoints for studies on assisted playlist creation.

We acknowledge a limitation of this paper in that all the participants in our user survey were Japanese. Because peoples’ music preferences, listening behaviors, and music itself vary widely from country to country [86–90], not all of the findings reported here can be generalized. Nevertheless, we believe that this study provides a worthwhile contribution as a first step toward understanding the impact of the chorus-playlist concept. At the same time, this limitation indicates further possibilities such as investigating the differences among countries and cultures. The publicly available dataset of results from our user survey will enable researchers to perform such comparisons.

Another limitation is that the participants did not experience chorus-playlist on the music streaming services they usually used. However, because they answered the survey after experiencing the chorus-playlist concept by listening to the playlists that we provided, we think that they could sufficiently imagine the situation of listening to self-made playlists and others’ playlists with the chorus-playlist approach. We currently provide the chorus-playlist function in a music-related smartphone application (Vocacolle App) and web service (Kiite⁸). In the future, we will investigate the function’s usage in those more realistic environments.

Finally, although we considered only the first chorus of a song (except when a song started with the chorus), the final chorus tends to be longer and contain heavier instrumentation than other choruses [1]. Therefore, it would also be an interesting future work to investigate the impact of differences between choruses in chorus-playlist listening. Moreover, the concept of listening to only choruses can be applied not only to playlists but also to other song lists such as album track lists, which could further enrich and diversify people’s music listening experience.

ABSTRACT

Digital musicology research often proceeds by extending and enriching its evidence base as it progresses, rather than starting with a complete corpus of data and metadata, as a consequence of an emergent research need.

In this paper, we consider a research workflow which assumes an incremental approach to data gathering and annotation. We describe tooling which implements parts of this workflow, developed to support the study of nineteenth-century music arrangements, and evaluate the applicability of our approach through interviews with musicologists and music editors who have used the tools. We conclude by considering extensions of this approach and the wider implications for digital musicology and music information retrieval.

1. INTRODUCTION

Digital humanities research often extends and enriches an evidence base – in the form of digital, machine-accessible corpora – as it progresses, mirroring a methodological process of evidence gathering and preparation that is common and accepted in analogue research. Rather than assuming complete corpus encoding as a prerequisite for digital scholarship, we anticipate that research subjects will more usually be found in un-transcribed and only minimally-catalogued documents. A researcher or team can thereby more effectively support their work by digitising, transcribing, and annotating a corpus incrementally. Resource limitations will generally mean that this is most efficiently carried out in an incomplete way, producing partial editions of short extracts or individual instrumental parts, instead of a complete corpus as an outcome of the investigation. To support this mode of digital scholarship, we propose that incremental workflows, which manipulate and

analyse incomplete sources, should be an explicit consideration for applied MIR assemblies.

We present an example of this approach, from the *Beethoven in the House* project, where musical arrangements and miscellaneous music publications aimed at a domestic market are the subject of the scholarship. In this case, little of the music has been published in modern editions, and no digital editions existed at the start of the research process. Some sources had been photographed and published online before the project began, and the remainder were digitised at the request of the project. Our data model abstracts the musical structures from the surface presented by digital representations themselves, so that our tools can switch transparently between working with digital scores and facsimile images, with measure detection supporting the transition. We also use Linked Data and user-authored, web-based storage, which supports the enrichment of institutional data resources, such as library images, without requiring that scholars have write access to those servers. We focus on chained components and data compatibility rather than trying to build end-to-end tools. Our ambition is that, at the end of the process, the digital tools support our own research, as well as supporting reusability and transparency, since the ‘working materials’ can be published along with the finished results.

In this paper, we consider a research workflow which assumes an incomplete and incremental approach to data gathering and annotation. We describe tooling implementing this workflow, and evaluate the applicability of the approach through interviews with musicologists and music editors who have used the tools. We conclude by considering extensions of this approach and the wider implications for digital musicology and MIR.

2. MUSICOLOGISTS AS DIGITAL RESEARCHERS

Most Information Retrieval implementations are optimised from the perspective of a ‘whole’ or ‘complete’ corpus, produced by some prior acts of digitisation, being interrogated by a user motivated by a single, explicit information need. This approach facilitates the optimisation of retrieval tool engineering, since the elements of the system are well known, and the quality of tools can be transparently

Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

quantified, assessed, evaluated, and compared. Meanwhile Bates's model of berry picking [1] is based on the observation that information needs often develop during the user's interactions with a system, as a part of a research process that takes new findings into account in the search. Different information-seeking strategies and their modes of search and scope of application (whether based on content, features or metadata) are further teased out by Weigl et al [2]. While this does not replace or reject the engineering of MIR tools based on concrete requirements, design, and evaluation, it does suggest we should consider such tools being recomposed as components within a multitude of individualised workflows – where the overall object of the composite workflow cannot be determined a priori. We reflect that this is especially true when MIR tools are used as a means to undertake curiosity-driven research, as they often are in support of digital musicology.

A similar pattern is identified for data as well as tools. Fenlon et al. [3] note the role of selecting and gathering data in the research process so that, as the investigation evolves, so may the subset of the corpus being studied. More recently, Oberbichler et al. [4] have observed that the separation between the management of digital materials and their analysis is less clear for humanities scholarship. They note that the clarity and separation of workflows and responsibilities in digitising, organising, and interrogating collections that make for efficient, maintainable solutions may be problematic in these domains.

For notated music, where data entry remains expensive in terms of time and effort, separating between digitisation, digital editing, metadata organisation, and research can mean that much musical heritage is ruled out from digital research, as digital editors become unwitting gatekeepers of our history. This can have the effect of channelling research into canonical composers and works, and diverting it from less-well-represented areas and niche and regional music [5]. The lack of encoded corpora appropriate to their research has long been identified as an important problem for musicologists [6, 7]. Although it is true that these issues could be addressed by comprehensive and complete mass digitisation and encoding, in the absence of this, an alternative strategy may be required.

We have seen that berry picking can be extended to accept that the research process involves partial and changing research questions, and even that during the investigation, the researcher may add to, correct or enrich the metadata [2]. An alternative interaction model might extend berry picking to acknowledge that this is true for the data itself. Clearly, this may pose problems for statistical evaluation of IR tools, and necessitates consideration of alternative approaches to system and workflow design. Nonetheless we can demonstrate that it is a mode of use aligned with the needs – and limited resources – of digital musicologists.

Given limited resources, we cannot assume that a single scholar, or even a funded research project, can transcribe the complete corpus of music that might be relevant to their investigations – including any comparison or con-

trol groups – prior to research commencing, and even producing a complete digitisation by the end of their investigations may prove impractical. Creating an expectation of the prior existence of these primary objects of study may feed the sense of “disconnect between this research strand and musicological users' needs and requirements” identified by Inskip and Wiering [8]. A better approach would accommodate images or partial editions – transcriptions of only a few bars or one instrumental part – created incrementally as the research progresses.

Many of the basic tools that already exist could be made to accommodate this approach well, indeed the extra information that may be available in a digital environment at a later research stage may help them, supporting a bootstrapping approach to training or parameter tuning. Without musicologist-facing, high-level tools built on these, researchers are more likely to resort to less machine-accessible approaches, such as pen and paper or local spreadsheets.

In this paper we explore this interaction model through a set of prototypes. In the next section, we describe a workflow and tooling designed to support musicological research in previously digitally unavailable music, and discuss how an incremental approach can be supported, before evaluating the approach in subsequent sections.

3. SUPPORTING RESEARCH WITH INCREMENTAL AND INCOMPLETE CORPORA

Musicology, and indeed research more broadly, may involve many activities and strategies, whose selection will be informed both by research topic (see [2]) and the stage at which the research stands. For example, a researcher may start with a literature exploration, then start reviewing music scores through a catalogue, selecting a set of potential subjects to look at more closely and then focus down later. The researcher may scan through the scores, selecting works or passages for further consideration, and rejecting others. This might be followed by closer engagement with the chosen texts, often relating them to extra-musical information. Finally, their investigations will be written up formally.

Teasing apart the steps of this example, and when they are most likely to happen in a research life cycle, we can see the following:

1. Literature exploration (early phase)
2. Catalogue exploration (early phase)
3. Workset selection (early phase)
4. Content exploration (mid phase)
5. Content analysis (mid phase)
6. Connecting music with extra-musical material (mid phase)
7. Visualisation and reporting (end phase)

This is not intended as a complete catalogue of research steps, but illustrates common components, and helps ground our observations. Each of these steps will decompose into tasks that may or may not be carried out

Phase	Step	Example activity	Example tools and media
Early	1. Literature exploration	Makes up-to-date literature survey	RILM, JSTOR Google Scholar Physical browsing
	2. Catalogue exploration	Explores the repertory; identifies a superset for more attention	Library catalogues RISM IMSLP, CPDL Physical browsing
	3. Workset selection	Looks at the music, scans through scores to identify works or passages for detailed consideration	RISM IMSLP, CPDL Specialised corpora Physical sources Image digitisation
Mid	4. Content exploration	Close reading of scores, identifying distinctive parameters that support an emerging thesis	OMR Measure detection Sonic visualiser Piano
	5. Content analysis	Lists spacing and instrumentation of chords at cadences	Humdrum toolkit Music21 Sonic visualiser Spreadsheet Paper
	6. Making Connections	Associates particular orchestration approaches with review and theory texts	Spreadsheet Paper
End	7. Visualisation & reporting	Writes and publishes a journal article	Journal, Published edition Recording, Dataset

Table 1. A typical set of steps in a research lifecycle, with example activities and tools. Although this appears as a list, scholars may jump between these, or pursue several at the same time. The **Beethoven in the House Annotator** supports stages 4 and 5, producing data suitable for stage 7.

in a digital environment, and although broadly sequential, a musicologist may jump backwards at any point to supplement the data they already have. To support such flexible research patterns, we believe it is important to create an ecosystem of tools that read or write compatible data, facilitating researcher-directed methodologies for tool selection and task ordering.

4. THE BEETHOVEN IN THE HOUSE ANNOTATOR: A TOOL SUPPORTING MID PHASE RESEARCH

To investigate the feasibility of an ‘incremental’ interaction model with MIR tools, we have developed a tool to support an active musicological investigation which also embodies the ‘mid phase’ of the research life cycle described above, focussing particularly on steps 4 and 5. The tool’s main purpose is to bring together digitised resources in the form of images and digital scores, and allow a musicologist to view them in a browser, selecting specific extracts for study and then annotating those with scholarly commentary. The resulting annotations are stored, and can be shared and published, including references to the pertinent selections from the digital music resources.

A user entering the **Beethoven in the House Annotator** first selects items to explore in a ‘library’ view – a listing which displays metadata about available musical works, their arrangements and digital resources available. Because the annotator is designed to handle comparisons of the same passage of music as it is realised in different versions, the selected resources are displayed one above

another to aid analysis.

Once works are selected and loaded into the display pane, a musicologist can point and click on individual notes and measures, or click and drag to select larger regions, whether the resource is a facsimile image or a rendered score encoding. Individual selections can be annotated, but also parallel passages in different versions of a work (‘Musical Material’) can be identified (figure 1, left), and these structures themselves annotated (figure 1, right).

Previous annotations can also be viewed and themselves annotated. Thus, the tool can be used for quick browsing or juxtaposition of music and metadata and for detailed labelling of the content.

The **Beethoven in the House Annotator** is built as a web application, and implemented as a MELD (Music Encoding and Linked Data) application [9]¹. As a baseline provision we assume the materials underpinning the musicologist’s investigation are available in image form via IIIF² as well as digital MEI scores when these are available. We further assume that the musicologist has the tools and skills to optionally transcribe whole pieces or extracts and save or convert them as MEI (this can be carried out using music typesetting packages such as Sibelius or Mus-

¹ More precisely, we use data models and the graph traversal library from MELD, with Vue-based application code.

² The International Image Interoperability Framework provides for standardised image delivery through APIs for content and presentation. Although increasingly widespread in use by research collections in particular, it is not yet comprehensively adopted. For the purposes of our research project, required digitized images were provisioned via a local (private) IIIF server where they were not already available over IIIF from the holding collection.

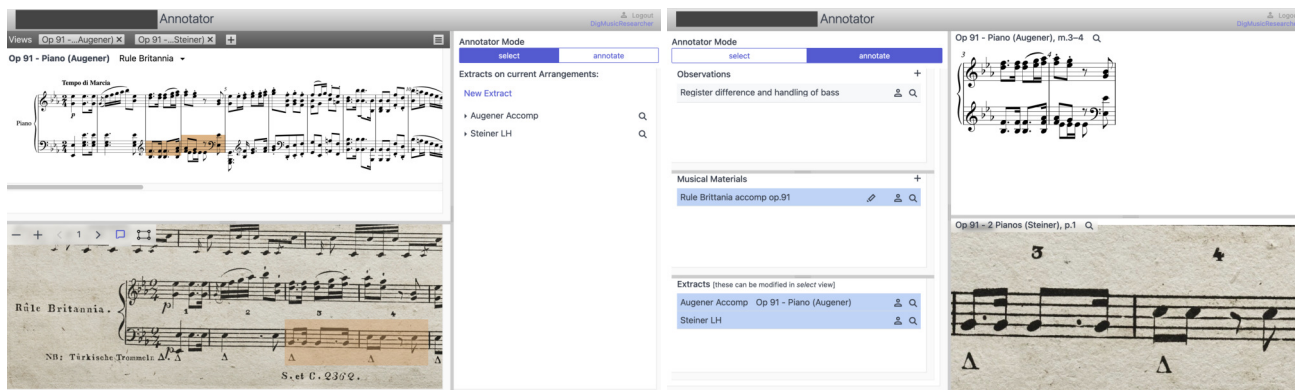

Figure 1. Two screenshots from the **Beethoven in the House Annotator**. **Left:** ‘Musical material’ – Parallel passages recorded as occurring in two different arrangements of Beethoven’s *Wellington’s Sieg* (Op. 91). Selections need not be contiguous or limited to a single part. The upper version here has been retrieved from an MEI file and is displayed using Verovio. The lower version is from a IIF file for which measure locations have been separately detected using the Cartographer tool and stored, along with links to the image, in an otherwise minimal MEI file. **Right:** The annotation view, showing an observation recorded about the musical material shown left. In both cases, structures are saved to the musicologists personal Solid pod, with their login shown upper right.

eScore with the help of plugins).

We also assume the prior existence of well-formed and self-describing catalogue metadata, and we base our prototype on the Linked Open Data published by the Gemeinsame Normdatei (GND) of the Deutsche Nationalbibliothek. We do this with the intention that these could in future be loaded directly where records exist.³

Direct image annotation is possible within our tool. The musicologist may prefer to use a labour-saving measure detection tool, such as Cartographer⁴ or MEI Friend [10], both of which can output MEI with empty measures and image co-ordinates, and which have been successfully tested with our tool. When provided with MEI and IIF resources such as these, our annotation tool allows the researcher to annotate the image measure by measure – giving a semantically-rich anchor for the annotation with relatively low input of manual intervention (see the lower pane in figure 1, left). If the researcher needs a finer level of annotation, then they may fill in additional music notation in the MEI, and can indicate the selective nature of the encoding in the MEI header, a process supported by tools such as MEI Friend.

Our application supports textual Web Annotations [11] made onto conceptually abstracted musical extracts rather than directly onto elements or regions of the image or encoding, allowing parallel material occurring in different arrangements of a work to be annotated together and, at a more basic level, allowing the model to remain agnostic to the different types of media used as evidence (figure 1, right, illustrates an example of an annotation on a passage that has been identified in two arrangements, in one case using the MEI transcript, and in the other a IIF image after a process of measure detection). This uses the Music

³ In practice, the GND is not currently usable for client-side applications due to access control headers. This would still allow the use of a server-cached version of the data. Where other metadata is needed, we draw on the WikiData model.

⁴ <https://cartographer-app.zenmem.de>

Annotation Ontology described by Lewis et al [12].

In order to promote data sharing between tools rather than a single monolithic application, user data is stored as Linked Data in Solid Pods [13], distributed online data storage with fine-grained access control, and for which the user can choose provider. This provides a simple mechanism for data portability between applications, given compatible data structures. The structures written can refer to resources anywhere on the web, and traversal carried out by the MELD library will draw them into the application.

In summary, the **Beethoven in the House Annotator** described above supports our proposed workflow in several ways. Firstly, it is conceived as part of a pipeline of tools publishing compatible Linked Data and MEI, and is already interoperable with existing tools. Secondly, it is intended to provide a low barrier for including evidence materials, allowing the use of any web-published IIF images, complete or partial MEI files, and GND metadata rather than requiring extensive data entry and local servers. Thirdly, it supports the sharing of source data and metadata, along with intermediate observations, within a research team. Finally, as currently implemented, annotations are minimally structured. This supports an evolving research agenda, trading expressiveness against semantic structures.

5. EVALUATING THE BEETHOVEN IN THE HOUSE ANNOTATOR AND ITS WIDER APPLICATION

Whilst the tool’s internal development was aimed at satisfying researcher needs within our own project, two rounds of wider evaluation were carried out, timed to coincide with two phases of application development. These evaluation rounds were carried out as semi-structured interviews following shortly after a combination of a presentation about the Annotator and period of time freely ex-

ploring its functionality over a pre-loaded musical library. In the first round interviews were conducted with musicologists recruited via a Studienkolleg (summer school) located at Beethoven Haus, Bonn, in September 2022. In the second round in March 2023, volunteers from staff at the Beethoven Haus were interviewed. In the first round, we interviewed 9 scholars, and 7 in the second round, of whom 2 had previously been interviewed. This allowed us to assess progress with new and returning users.

5.1 Workflow as data pipeline, low barriers for evidence gathering

The application was regarded by all interviewees as useful in the context of larger musicological research projects and editorial work. Since our interviewees were musicologists and editors rather than engineers and, since we did not demonstrate or present any tools for other steps in the process, this support is based primarily on the interviewer's description of the intended wider context for the app rather than concrete experience. Interviewees did raise important concerns regarding the workflow itself, and these are discussed in 5.5 below, and as further work.

5.2 Sharing of evidence and findings

Users that we spoke to were strongly attracted both by the idea of sharing data and annotations and the option of keeping these private or controlling access – either during the research process or separating draft and publishable work. They immediately identified the equivalence of this approach to paper based methods of publication and regarded using publicly shared annotations as “similar to quoting published books”, although there are concerns about how to verify and attest its quality. It is clear that these features would be easier to realise given user interfaces optimised for these tasks, since the default management interfaces of Solid providers, our principle medium for publication, generally present usability barriers to newcomers. Nonetheless, one user evaluates that the application has the potential to “bring everything together in a way I haven't experienced before” in terms of gathering and sharing knowledge about musical works. This would support the “Nachprüfbarkeit”, or verifiability (literally reviewability) of a conclusion by collecting the evidence in a single place.

Although musicology can appear – at least from its outputs – as the activity of lone scholars, sharing between scholars in an informal way is common, as is the use of student assistance, both of which can benefit from controlled data sharing. Certainly, several participants were explicitly open to a wider set of contributors, one noting that, depending on the quality of the community, “more knowledge can be obtained”. Beyond this, other musicological use cases identified by participants are more commonly team or group activities, such as scholarly music editing or pedagogical uses, with sharing either between teacher and student or between students within a class.

This sharing approach is well supported for our own Linked Data structures, but there are concerns with the

boundaries of that sharing. For example, a Linked Data structure that is publicly shared could annotate a part of an image or score that is not itself publicly available (perhaps for copyright reasons). This would not render the information in the Linked Data unusable, and the URI itself would remain uniquely identifiable, but for some uses would become unavailable. There is no clear way to deduce that one identified element in an MEI file occurs earlier in the piece than another purely from the URI since these semantics are located in the MEI score. Our use of the Music Annotation Ontology brings more aspects of musical selection into the Linked Data domain, but we do not attempt to export musical meaning encoded in MEI into RDF.

5.3 Minimally-structured annotations

The open nature of the annotations and the **Beethoven in the House Annotator** more generally was very clearly important in allowing the musicologists to identify a wide range of contexts in which it would be useful to them. These covered the full range from studying stages in the development of a particular music edition (“Plattensstadien”), systematic musicology, historical approaches, philology and pedagogy. Participants also identified the ease of linking material, both music and annotation material, which is evidence that our low structure approach may have reduced barriers to use. Beyond this (sometimes implicit) validation of our approach, participants identified some structures in annotations to support navigation and discovery.

In the **Beethoven in the House Annotator**, annotations are edited and viewed separately from the score view. In our first version, this view was purely textual, making them harder to navigate, and placing a strong reliance on user-provided labels. Adding musical previews for the second version enhanced findability, but multiple participants noted that an informal taxonomic labelling, such as tags, would enhance this – especially where annotations are shared between users. Data currently available to the application includes metadata and musical locations (where annotations are made on transcribed sources or images on which measure detection has been run). These are not currently used in the annotation listings, but could be, allowing the navigation by measure and source requested by several participants.

5.4 Application-specific responses

The **Beethoven in the House Annotator** builds on rich underlying data models and a complex range of data sources and technologies. An aspect that emerged from the interviews is that the terms chosen for defining key elements in the model did not translate well when designing a user interface. Most users had difficulty navigating the application because their expectations about the terms used did not match with the meaning given to them in the context of the model. Although the learning curve can be conquered, the interviewees expressed that substituting and simplifying the language (in certain cases, hiding structures) would be more beneficial to a quick acclimation into

the application. Although the general-purpose nature of the tool makes the choice of task-specific language difficult, use of clear domain-specific and task-appropriate terms would have been better received by the musicologists and required less detailed briefing.

Although the functionality of the **Beethoven in the House Annotator** is distinctive in ways that were recognised and appreciated, those participants who have worked with comparable applications commented on affordances that they missed from the other tools. In particular, familiarity with EDIROM tools left some participants missing the more advanced navigation system, with, for example, jumping to measure numbers.

5.5 The workflow outside the application

Our workflow acknowledges the poverty of encoded scores but does not, currently, accommodate the lack of digitised images. These, too, have been created according to particular priorities, which may not reflect those of researchers. Libraries and archives must weigh up rarity, value, appearance, physical condition, use and public impact among many other factors when deciding their digitisation policy. Interviewees expressed particular concern for sources located in institutions for whom the burden posed by digitisation in the first place and publication as IIF in the second is too great, while private collectors may have no desire to engage in digitisation at all. Even following the suggestion of one interviewee, and supporting user upload of static images – whether to their own Solid Pods, or some public IIF server operating for the common good – could fall foul of institutional restrictions. This may indicate a need to point our structures at musical regions even where no digital proxy exists at all, something which would require a semantic representation of musical location. Although some progress has been made towards such a representation (see, for example, [14]), further modelling is needed to make a robust system.

Similarly, interviewees speculated about how additions are made to the library that the application presents. Currently, we have no application to support the selection of items from a published catalogue to create and operate on a selected workset (steps 2 and 3 in table 1) or the discovery and data transformation this would require. This has not been the focus of the current research, but it does mean that we have relied on some manual technical interventions that would be unsuitable for the sort of musicologists we target here.

6. CONCLUSIONS AND FURTHER WORK

The research workflow we describe here is one in which a scholar adds and edits data and metadata, and in which research priorities develop throughout. We assert this is expresses, albeit schematically, a common approach in musicological research. Rather than trying to create tools to manage the whole process, we have advocated for smaller tools that can comfortably handle mixed, incomplete and partial data, and accumulate results in a way that is data-

compatible with other applications and IR tools that the researcher might use.

The musicologists interviewed identified a range of contexts for the **Beethoven in the House Annotator**. That these went not only beyond our design for it, but also beyond its capabilities provides evidence of the need for and dearth of tools that support such activities and the diversity of approaches that can and should be considered.

Our interviews also point clearly to further work, with early-phase support – in the form of digitisation, search and retrieval, and workset gathering – being priorities that would help researchers prepare their materials for use with mid phase applications such as our own. Candidates for components of such tooling, such as Cartographer, but also Sonic Annotator and MEI Friend, often already exist, and often have elements that directly support their role in an ecosystem of tools, particularly in terms of data compatibility, but are often seen either as entirely standalone tools or built into workflows in task-specific ways that are not generalised.

Our investigation demonstrates that the workflow into which the **Beethoven in the House Annotator** fits is recognised and valued by musicologists. The flexibility of the annotator tool, in terms of data and functionality, presents many opportunities in support of musicological research. Importantly, we show that it supports or replaces activities currently taking place in forms – such as Word documents, spreadsheets or on paper – that provide few opportunities for scholars to take advantage of either MIR tools in data analysis on the one hand or digital transparency and sharing of results on the other. Thus, it is recognised as going beyond reproducing existing methods, by enhancing and extending them.

7. ACKNOWLEDGMENTS

This research was undertaken by the project ‘Beethoven in the House: Digital Studies of Domestic Music Arrangements’, supported by a UK-Germany funding initiative: in the UK by the Arts and Humanities Research Council (AHRC) project number AH/T01279X/1 and in Germany funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) project number 429039809; with additional support from the UK Software Sustainability Institute Phase 3, funded by the UK Engineering and Physical Sciences Research Council (EPSRC) project number EP/S021779/1.

ABSTRACT

This paper presents a comprehensive investigation of existing feature extraction tools for symbolic music and contrasts their performance to determine the set of features that best characterizes the musical style of a given music score. In this regard, we propose a novel feature extraction tool, named *musif*, and evaluate its efficacy on various repertoires and file formats, including MIDI, MusicXML, and ***kern*. *Musif* approximates existing tools such as *jSymbolic* and *music21* in terms of computational efficiency while attempting to enhance the usability for custom feature development. The proposed tool also enhances classification accuracy when combined with other sets of features. We demonstrate the contribution of each set of features and the computational resources they require. Our findings indicate that the optimal tool for feature extraction is a combination of the best features from each tool rather than those of a single one. To facilitate future research in music information retrieval, we release the source code of the tool and benchmarks.

1. INTRODUCTION

Feature extraction is a pivotal task in contemporary machine learning. Music features can be categorized into two main types: symbolic and audio. While audio features have been subject to extensive research, computational techniques for symbolic music remain comparatively underexplored.

In recent years, there has been an increasing interest in analyzing symbolic scores in music. This encompasses studies on composer [1] and style recognition [2], affective computing [3], music generation [4], analysis of performance [5], and interpretation [6]. The symbolic dimension of music concerns the conceptual representation of musical data [7]. This level has been used in the field of Music Information Retrieval (MIR), with particularly success-

ful outcomes when employed to support multimodal approaches [8], which integrate both audio and symbolic levels through audio-to-score alignment techniques [9]. The symbolic level is also crucial for musicologists, as music scores are the most common source for historical music studies. Musicologists rely on computational tools to extract and analyze musical scores on a large scale [10, 11]. However, traditional manual annotations, such as harmony [12] and cadence [13], are time-consuming and prone to errors. Therefore, computational tools are essential for efficient and accurate musicological analysis. Presently, two primary tools are available for extracting features from symbolic music: *jSymbolic* [14] and *music21* [15]. Although both tools are open-source and widely employed, no comprehensive comparison between them has been conducted yet.

In this paper, we propose a novel set of features that is specifically, although not exclusively, tailored for the analysis of 18th-century Italian opera. We have developed a tool for extracting these features, named *musif*, that is being used for the analysis of operatic music in the *Didone* project¹ [16]. Here, we conduct a comparative study between *musif* and other existing tools, thus providing valuable insights into the strengths and weaknesses of each of them. Additionally, we evaluate the efficiency of each tool and demonstrate that *musif* adds useful features to both *music21* and *jSymbolic*. We observe that, in most cases, a combination of features from multiple tools yields the most powerful feature set. To validate our findings, we test all three tools on various repertoires. We aim to compare the feature sets on file formats with varying levels of representation abilities, such as MIDI, MusicXML, and ***kern*. While MIDI is widespread in computational studies, it is relatively simplistic for written music; MusicXML and ***kern*, instead, are less commonly utilized in MIR but provide more accurate representations when dealing with music scores.

The main contributions of this paper are, therefore, threefold. Firstly, we present a new set of features designed for the study of an under-represented repertoire in music computing literature, i.e., 18th-century Italian opera. Secondly, we introduce *musif*, a new efficient, extensible, and open-source Python tool for feature extraction from symbolic music. Finally, we provide a benchmark of *music21*,

jSymbolic, and musif on a variety of repertoires and file formats.

The whole code used for this study, as well as the code used for the proposed tool, is available at https://github.com/DIDONEproject/music_symbolic_features/.

2. FEATURE EXTRACTION TOOLS

In this study, we compare three tools for feature extraction from symbolic music: jSymbolic [14], music21 [15], and musif. Other tools such as Humdrum² may be used for feature extraction, but they would require a larger effort for assembling different features from various toolkits and organizing them in a usable tabular format. We will describe each one in detail in the following subsections.

2.1 jSymbolic

The jSymbolic tool was initially introduced in 2006 [17] and subsequently updated in 2018 [14]. It is an open-source, Java-based software designed to extract features from both MIDI and MEI files. The latest iteration of jSymbolic is capable of extracting 246 distinct features, some of which are multidimensional and account for a total of 1022 values. However, the actual number of extracted features may vary depending on the user's configuration and the musical composition itself. jSymbolic features relate to pitch statistics, melodic intervals, chords and vertical intervals, rhythm, instrumentation, texture, and dynamics. In addition to these features, jSymbolic is capable of computing certain characteristics that are not readily available in MIDI files. To achieve this, jSymbolic utilizes the MEI file format to determine the number of slurs and grace notes in a given piece. While MEI and other high-informative file formats offer additional features such as pitch names, harmonic analysis, and written dynamic or agogic indications, jSymbolic does not take these into consideration.

The jSymbolic software provides users with the flexibility to customize configurations and features, facilitating the integration of previously existing feature values into newer features. Furthermore, users can extract windowed features by specifying window size and overlap in seconds. jSymbolic does not provide pre-built methods for parallel processing of large corpora, thereby requiring the user to implement a suitable strategy. Lastly, jSymbolic provides output options in both CSV and Weka's ARFF format.

The software is accessible as a self-contained program featuring a Graphical User Interface (GUI) and a Command Line Interface (CLI), as well as as a Java library.

2.2 music21

music21 is a Python toolkit designed for computational music analysis, which was first introduced in 2010 [18]. One of its remarkable features is the capability to parse a wide range of file formats, including MIDI, MusicXML, **kern, ABC, and various others. The music information is represented in an object-oriented hierarchical structure that is

aimed at facilitating the development of novel tools.

After its initial academic publication, music21 was further developed with a set of features presented in 2011 [15]. The latest version of music21 includes 69 features introduced by jSymbolic, as well as 20 characteristics computed using the information parsed from high-informative file formats. These characteristics are related to key, cadence, harmony, and lyrics. Regardless of the input file format, music21 consistently outputs 633 features. However, the number of extracted features may vary since some features are zeroed out when they are not computable.

music21 is a Python module that lacks a CLI or a GUI. It does not have a configuration format; rather, it offers a broad range of methods for developing custom pipelines for different types of music information processing. These methods encompass the creation of new features and some automated high-level inference of music characteristics, such as key [19], as well as tools for windowed analysis.

One disadvantage of music21 is that large music scores may result in deeply nested Python objects with numerous non-picklable attributes attached. This makes the programming process challenging, particularly due to the difficulty of saving these objects to a file.

In this study, we have developed a CLI for utilizing music21 feature extraction tools in a manner comparable to musif. This implementation facilitates parallel processing by distributing the extraction of features across numerous files simultaneously.

2.3 musif

Our software is named musif [20]. It is implemented in Python and built upon the music21 library, and offers an Application Programming Interface (API) with no default settings of significance and a CLI with default settings optimized for most common use cases.

We leverage music21's internal representation, enabling us to extract features from any file format supported by music21. musif is highly customizable and allows users to add custom features as required. After creating the internal representation of the musical score using music21, we extract multiple features and store them in pandas dataframes. This facilitates exporting results in various formats, making musif easily integrable into diverse pipelines.

One limitation of music21 is its restricted ability to serialize complex and large music scores. This restriction also affects the possibility of parallel processing, as Python's single-thread approach necessitates parallelization via processes, which in turn requires context copying and data serialization. Furthermore, parsing large XML files is one of the slowest steps in the feature extraction process. To optimize this procedure, a more favorable strategy would be to store the parsed XML files' logical structure on disk as a cache. We have thus implemented a caching system capable of caching and serializing any music21 object. A restriction to note about the caching system is that the cached scores are read-only. However, this feature enables the writing of parsed scores onto disk and caching of the output from resource-intensive music21 functions into memory.

musif can extract harmony-related features by utilizing standardized harmonic analyses annotated in the Mus-

²<https://github.com/humdrum-tools/humdrum-tools>

Table 1. Computational efficiency of the three feature extraction tools. Each run was repeated twice and the second run times are indicated between parentheses.

File format	Tool	Avg CPU Time (s)	Avg Real Time (s)	Avg RAM (GB)	Max RAM (GB)	Tot. errored files	Tot. files
MIDI	<i>musif</i>	66.30 (13.30)	5.62 (1.14)	9.10 (10.1)	14.2 (19.6)	1	16734
	<i>music21</i>	55.3 (55.2)	4.72 (4.71)	7.12 (7.12)	9.87 (9.94)	0	
	<i>jSymbolic</i>	2.20 (2.20)	1.98 (1.97)	7.97 (7.14)	16.1 (11.7)	14	
MusicXML	<i>musif</i>	15.4 (6.63)	1.32 (0.57)	5.87 (5.12)	12 (10.1)	4	14712
	<i>music21</i>	10.8 (10.8)	0.91 (0.91)	4.30 (4.33)	5.68 (5.55)	0	
**kern	<i>musif</i>	26 (13.1)	2.26 (1.14)	5.20 (4.14)	5.60 (4.92)	0	472
	<i>music21</i>	14.0 (14.1)	1.21 (1.21)	3.08 (3.04)	4.12 (4.18)	0	

eScore file format [12, 13]. Besides, it encompasses a wide range of features, including melodic intervals, harmony, dynamics, tempo, density and texture, lyrics, instrumentation, scoring, and key. Notably, dynamics and tempo are determined by the composer’s text notation rather than by MIDI parameters. Furthermore, our implementation includes all features provided by music21 with the exception of 14 features that utilized the caching system in writing mode. The number of extracted features depends on the complexity of the score and is influenced by both the number of parts and musif’s compatibility with the encoding.

NaN values are used to represent non-computable features in a score. For example, when processing datasets with varying instrumentations, some features may not be available for all scores. These values can be replaced with a default value (e.g., 0) or removed from the corpus by deleting either the score or the related feature. In the CLI, we have implemented a heuristic to determine whether a score should be removed from the extracted corpus if it contains too many NaNs. Specifically, we define r as the ratio between the number of columns without NaN and the total number of rows in the output table. If $r < 0.1$, we compute n_i , which is the number of NaNs in the i th row. We remove rows with n_i greater than $\frac{1}{0.99}q_{0.99}$, where $q_{0.99}$ is the 99% quantile of $\{n_1, n_2, \dots\}$, indicating that 99% of rows are not deleted. The factor $\frac{1}{0.99}$ can be better understood as dividing the $Q_{0.99}$ by 99, thus obtaining an estimate of $Q_{0.01}$, and multiplying it by 100, thus obtaining the expected value of $Q_{1.00}$ based on the first 99% of the data. Put differently, it computes the maximum n_i that we expect if the remaining 1% of rows has a number of NaN “similar” to the previous 99%. Larger values are thus considered outliers. This method was empirically tested on the corpora used in this work (see Section 3), revealing that only a few scores were generally removed while most lines of the output table were retained. In case a score is not deleted, the CLI removes from the table the features that are NaN in that score.

musif also incorporates a post-processing module that facilitates the removal, merging, or substitution of values in specific columns or groups of columns within the extracted data. This functionality proves especially advantageous when dealing with large tables generated by musif from a substantial set of scores, as it minimizes the computational effort required for processing such tables.

Like the other tools, we have implemented the capability to extract features at a window level. However, unlike jSymbolic, in our implementation, the window length is specified in musically relevant units such as score measures rather than seconds. This provides more pertinent informa-

tion for processing music scores.

In contrast to other tools, our solution provides an out-of-the-box capability for processing large corpora through parallel processing, resulting in a reduction of the required time.

The design principles and the features included in musif were presented in a previous publication [20]. The code and documentation of musif is available online³.

3. BENCHMARKING METHODOLOGY

To assess the performance of musif in comparison to other tools, we devised a benchmarking methodology. Initially, we identified several datasets that enable testing of diverse file formats. Subsequently, we developed a standardized protocol based on an AutoML pipeline [21]. We evaluated the computational resources utilized by each tool during extraction and their respective efficacy in various classification tasks.

3.1 Datasets

We selected five datasets to evaluate the performance of the tools in analyzing both Standard MIDI Files (SMFs) and highly informative music score formats. For MIDI analysis, we aimed to test both music scores and performances. As for highly informative file formats for music scores, we chose MusicXML and **kern due to their popularity, availability of large datasets, various conversion tools, and compatibility with common music score editing software such as Finale, Sibelius, and MuseScore. While MEI was considered as an option, the limited availability of datasets in this format led us to leave it for future studies.

In this study, we considered the following datasets:

- **ASAP** [22]: This dataset contains music performances derived from the Maestro dataset [23] and is synchronized with a corresponding score obtained from the MuseScore’s crowd-sourced online library. The dataset comprises 222 music scores in MusicXML and MIDI formats, as well as 1068 music performances in MIDI format. The authors have rectified any significant notation errors found in the music scores. We used this dataset for composer recognition based on music scores and music performances.
- **EWLD** [24]: It contains lead sheets obtained from Wikifonia, a crowd-sourced archive. To reduce errors in music score transcription by inexperienced users, the authors applied algorithmic selection criteria to the dataset.

	<i>Quartets</i>	Composer	363	3	1593	974	633	602	225
	<i>Didone</i>	Decade	1622	8	745	126	633	602	225
MusicXML	<i>ASAP scores</i>	Composer	211	7	710	91	633	602	
	<i>EWLD</i>	Genre	3197	11	724	105	633	602	
	<i>JLR</i>	Attribution	109	3	739	120	633	602	
	<i>Didone</i>	Decade	1636	8	971	352	633	602	
**kern	<i>Quartets</i>	Composer	363	3	734	115	633	602	

Specifically, they retained only scores with simple notation, without modulations and with a single melodic part. Moreover, all scores contained key signatures and chords throughout. The dataset was augmented by incorporating genre and composer details, as well as the year of first performance, composer birth and death dates, precise title, and additional metadata. This was achieved by cross-referencing the dataset with information sourced from secondhandsong.com and discogs.com. We used this dataset for genre recognition.

- **Josquin-La Rue** [25]: This dataset was created within the context of the Josquin Research Project and includes 59 Josquin duos and 49 duos by La Rue. The musical scores underwent a meticulous musicological transcription process. Moreover, the music scores were assigned to two labels based on the security of the attribution, thus resulting in four labels (Josquin secure, La Rue secure, Josquin not secure, La Rue not secure). The musical scores are provided in various file formats including MIDI, MusicXML, **kern, Sibelius, and PDF. We used this dataset for composer classification in a real-world attribution problem.
- **Quartets** [26]: We retrieved a selection of files from the kern.humdrum.org website, consisting of all available string quartets in **kern format by Mozart, Haydn, and Beethoven. While the original sources of these musical scores are not always declared, the encoding quality is generally considered to be at a musicological level. In total, we obtained 363 files. We used this dataset for composer classification.
- **Didone** [16]: With the aim of filling an under-studied repertoire, we curated, analyzed, and transcribed over 1600 arias from 18th-century opera, written by dozens of composers. The music scores were transcribed into MusicXML format using Finale Music software and revised by three musicologists independently. Harmonic analyses were added by expert musicologists using MuseScore software in accordance with a prior standard [12, 13] and were reviewed automatically using the ms3 tool [27]. We also included various metadata in the database such as year and place of premiere, composer, and high-level formal analysis. This database is an ongoing project and will be made freely available in 2024. We utilized this dataset for classifying the period of composition of each piece, each period being defined in decades

(i.e., 1720s, 1730s, 1740s, etc.).

3.2 Experimental setup

After selecting the datasets, a standardized protocol was developed for benchmarking the three aforementioned tools. The protocol is based on an AutoML pipeline [21] and comprises the following steps:

1. **Conversion to MIDI:** The datasets were selected and subsequently converted into MIDI format, resulting in two or three file formats for each dataset: MIDI and either MusicXML or **kern. This step aims to evaluate the impact of notational file formats, such as MusicXML or **kern, on classification tasks. Indeed, although MIDI has limited capacity for representing notational aspects of music, it remains uncertain the extent to which these aspects can determine the accuracy of machine-learning algorithms for music symbolic analysis. MusicXML files were converted using MuseScore 3, and **kern files were processed with the Humdrum toolkit⁴.
2. **Feature extraction:** Features were extracted from MIDI, MusicXML, and **kern files using the methods detailed in Section 2 with default settings and without the use of windows, resulting in one array of features for each file. The purpose of this step was to measure the computational cost of the tools. Therefore, all available files in the datasets were used to obtain a larger number of samples and a more accurate estimation of the computational cost, even if they were discarded in later steps. For instance, MIDI scores were already provided in the ASAP dataset; however, we additionally converted them from the MusicXML files. As a result, we extracted features from more files than necessary. We created a CLI tool in Python for music21 while we utilized the official CLI tools for jSymbolic and musif. Each file format was processed individually, resulting in CSV files for each format. We calculated the average time and RAM usage of each tool. Furthermore, CPU time was collected as a measure of the required time without parallel processing. Lastly, we documented the number of files for which each tool produced errors.
3. **AutoML:** A state-of-the-art machine learning approach was employed using the Python module `auto-sklearn` [21]. The method utilizes Bayesian

⁴ See footnote 2.

Table 3. Accuracies of AutoML using 10-fold cross-validation on the first ten principal components. The best-performing tool is underlined. The best-performing combination is shown in bold.

optimization with surrogate models based on random forests and generates ensembles of models by exploring a vast array of possible architectures. 10-fold cross-validation was used, and the balanced accuracy averaged across the test folds was observed. The best-performing model’s result was used for comparison. To initiate the AutoML process, a list of valid files for each dataset was initially defined, discarding those processed in the previous step but unsuitable for validating the classification task. Subsequently, files were selected for which all tools succeeded in extraction, creating comparable datasets for validation. Finally, classes with a number of samples less than twice the number of cross-validation splits were eliminated from each dataset. Consequently, the number of files and categories used in our study differs from the numbers officially provided by each dataset. The classification task performed depended on the dataset, as shown in Table 2.

We conducted two primary experiments: one utilizing all of the extracted features and another using only the first ten principal components. To achieve this, we standardized the features and applied PCA to obtain the ten first principal components. The rationale for the latter experiment is that a larger feature space typically requires a longer AutoML optimization process and affects the performance of the trained classifiers. As the tools extract varying numbers of features, this experiment enables a principled comparison of the usefulness of the non-redundant information generated by the different tools by homogenizing the number of variables in the AutoML process. In other words, it helps decouple the AutoML optimization capabilities from the number of features.

Due to the overlap between the features extracted with musif and those with music21 with jSymbolic, we also analyzed the concatenation of music21, jSymbolic, and our features. We also observed the performance of musif and music21 when only the native features were used, i.e. when musif was utilized without music21 features and when music21 was run without jSymbolic features. In the following, we denote these feature sets as “native”. We run each feature extraction and AutoML experiment on a Linux machine with 32 GB of RAM and an i7-8700 CPU, ending the AutoML procedure after 30 minutes. We also experimented with longer AutoML processes and more powerful machines for the first 5 columns of tables 4 and 3, but we noticed no significant change in accuracy.

4. RESULTS

Table 1 summarizes the comparative computational efficiency of the three tools. It is observed that jSymbolic outperforms the other tools when no parallel processing is employed. This can be attributed to the superior performance of Java language, which facilitates faster I/O operations and parsing of byte-level structures such as MIDI files. musif’s caching system significantly reduces the time required for feature extraction during multiple runs, such as those performed during the development and debugging of newly added features. For MIDI files, the extraction process can be accelerated by a factor of five. When comparing the time needed for extraction, jSymbolic is still faster than musif. However, our caching system is advantageous when a cache is available. Regarding MusicXML and **kern files, musif and music21 use the same parser engine, making their time values more comparable. In this case, music21 is slightly faster than musif but also attempts to extract a smaller number of features. Nevertheless, musif’s the caching system allows for a 50% reduction in extraction times. The music21 tool proves to be the optimal choice when taking into account RAM utilization.

Table 2 presents the dataset sizes used in our experiments, which are obtained through the protocol detailed in Section 3.2. The sample sizes vary from 109 to 3197, while the number of classes ranges from 3 to 11, depending on the dataset. The music21 feature extraction process produces a fixed set of 602 native features, supplemented by an additional 31 features re-implemented from the jSymbolic feature set. In contrast, jSymbolic consistently extracts a set of 225 features with minor variations. musif extracts a variable number of features depending on its ability to parse different music structures, ranging from 91 to 974 extracted features. The remaining features extracted by musif are computed using the music21 feature extraction methods. It is worth noting that music21 always converts non-computable features to zero, whereas musif allows users to assign different values or perform other operations.

Tables 3 and 4 demonstrate the effectiveness of feature sets in representing significant aspects of music analysis across various repertoires. The results in Table 4 must be interpreted with caution due to the longer AutoML process required by accurate models when using a higher number of features. Overall, music21 and jSymbolic are effective tools for extracting features from MIDI files, while musif

shows promising results for MusicXML files, particularly when utilizing the first ten principal components during validation. This difference in performance can be attributed to the presence of highly correlated features in musif, a consequence of its granularity. We also evaluated combinations of feature sets and found that optimal performance is achieved by employing multiple tools. For MIDI files, jSymbolic is fundamental in achieving model accuracy, but incorporating musif and music21 generally enhances performance. For MusicXML and **kern files, leveraging both musif and music21 yields optimal results, especially when considering the first ten principal components.

When comparing the efficacy of models trained on MusicXML, **kern, and MIDI files, no discernible pattern emerges indicating the superiority of highly informative file formats over SMFs for representing music scores. In fact, the only instances where the MusicXML files exhibit superior performance are in the Josquin-La Rue dataset and genre recognition on the EWLD dataset when all features are utilized. However, for all the remaining tasks, MIDI files demonstrate superior performance. This is likely due to the fact that jSymbolic can only extract features from MIDI files and is simultaneously the most important source of features for music score analysis. Consequently, in this study, the MusicXML and **kern datasets lack some relevant features that can be extracted only when converted to MIDI. Even when comparing only the proposed tool and music21’s performances, MusicXML and **kern files do not show a clear advantage over MIDI files, particularly when considering the combination of both tools. It should be noted that jSymbolic can extract features from MEI as well, thus potentially allowing for better performances.

The effect of missing values on tool performance is a significant concern and may be a contributing factor to the comparatively lower results for MusicXML and **kern files. While music21 substitutes all missing values with 0, musif utilizes a hybrid strategy that entails either removing a row or column from the table (refer to Section 2). The

most effective method for handling missing values remains an open issue.

We assessed the impact of harmonic features on the Didone dataset using musif. Unfortunately, due to the time-consuming nature of harmonic annotations, we were unable to evaluate these features on the other datasets used in this study. We annotated our dataset of more than 1600 opera arias using the standard established in previous works (see Section 2) and extracted melody- and accompaniment-related features with respect to the local key. The extraction of harmonic features resulted in 22 additional features beyond the 126 listed in Table 2 for MIDI files. For MusicXML files, we extracted 265 additional features, raising the total number of extracted features to 617. We observed an overall improvement in classification accuracy when incorporating harmonic features, as demonstrated in Table 5. The only instance where performance was degraded by the inclusion of harmonic features was for MIDI files when all the available features were considered (without PCA). We interpret this degradation as an indication that longer processing times are necessary for AutoML when additional, possibly highly correlated features are introduced.

5. CONCLUSION

This paper presents a comprehensive analysis of tools for extracting features from symbolic music. A strict protocol was defined to compare the tools in terms of efficiency and efficacy across various repertoires and file formats. The results indicate that using multiple tools is the most effective approach, with the optimal tool choice depending on the file format and repertoire.

The study emphasizes the importance of using file formats that are accessible by multiple tools. However, it remains open whether highly informative file formats such as MusicXML, **kern, or MEI are relevant for the automatic classification of symbolic scores. The available set of features indicates that, while these formats remain fundamen-

tal for certain types of musicological research, they do not seem to entail a significant advantage for machine learning tasks.

The problem of NaN values in extracted features from music scores remains unresolved. Further research is required to explore optimal approaches for replacing, removing, or inferring missing values in music applications.

Additionally, the new musif tool was proposed, which can process various file formats using the music21 parsing engine. The tool also includes a caching mechanism to speed up feature development. Moreover, motivated by the experiments presented in this work, we included the whole music21 and jSymbolic tools in the newer versions of musif, easing the extraction of the combined feature sets from large corpora.

6. ACKNOWLEDGEMENTS

This publication is a result of the Didone Project, which has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program, Grant agreement No. 788986. It has also been conducted with funding from Spain’s Ministry of Science and Innovation (IJC2020-043969-IAEI/10.13039/501100011033).

Part of the computational experiments were run at the FinisTerra III cluster of the Galician Supercomputing Center (CESGA). The authors gratefully acknowledge the access to these resources.

ABSTRACT

Research in natural language processing has demonstrated that the quality of generations from trained autoregressive language models is significantly influenced by the used sampling strategy. In this study, we investigate the impact of different sampling techniques on musical qualities such as diversity and structure. To accomplish this, we train a high-capacity transformer model on a vast collection of highly-structured Irish folk melodies and analyze the musical qualities of the samples generated using distribution truncation sampling techniques. Specifically, we use nucleus sampling, the recently proposed "typical sampling", and conventional ancestral sampling. We evaluate the effect of these sampling strategies in two scenarios: optimal circumstances with a well-calibrated model and suboptimal circumstances where we systematically degrade the model's performance. We assess the generated samples using objective and subjective evaluations. We discover that probability truncation techniques may restrict diversity and structural patterns in optimal circumstances, but may also produce more musical samples in suboptimal circumstances.

1. INTRODUCTION

In recent years, developments in natural language modelling have also accelerated the field of symbolic music generation. In this context, the musical events of a music piece are represented as a sequence of symbols or tokens from a fixed vocabulary, and the goal is to learn to generate new token sequences. At present, the autoregressive transformer model [1] is the basis of many symbolic music generation models [2–5]. In this context, a conditional distribution is learned by solving a masked self-prediction task [2–5], and generation is performed with stochastic sampling techniques, e.g., ancestral sampling, or maximization-based search techniques, e.g., beam search.

However, the choice of decoding technique has been shown to impact various qualitative features of generated samples substantially. In [6], the authors showed that generation with *nucleus sampling* yields natural language samples that are more contextualized than those from conventional sampling techniques, and samples of nucleus sampling score higher in human evaluations. More recently, the authors of [7] propose *typical sampling* and show that it reduces degenerate sample generation while exhibiting performance competitive with nucleus sampling. Typical sampling is based on the authors' finding that words in human language are *typical*. More specifically, the authors show that most words of human language are, in fact, not the most likely words (lowest information content (IC)), as measured with a language model, but rather *typical* words, i.e., they have an IC close to the conditional entropy of the language model. Typical sampling explicitly enforces this condition.

We hypothesize that a careful choice of sampling technique could also improve certain aspects of music generated using language models, particularly because in [8], it has been shown that musical events tend to be typical. However, we find that many music generation systems rely on ordinary sampling techniques. In addition, studies on the effect of sampling techniques on musical qualities are limited.

In this work, we study the structural and tonal properties of music generated with different sampling techniques applied to a high-capacity transformer model. Specifically, we measure the IC, long and short-term self-similarities and scale consistency of samples generated with conventional sampling, nucleus sampling, and typical sampling. We test the sampling techniques for a well-calibrated model and for under-calibrated models. We support our findings by performing a listening study. We conduct our experiments on *The Session* dataset [9], a large dataset of well-structured monophonic music in the established musical genre of Irish traditional music. We choose this dataset since we expect it to provide suitable conditions for training a well-calibrated model. Our findings suggest that truncation techniques can address inadequacies of models that are not well-fitted to the data.

2. BACKGROUND AND RELATED WORK

Although maximization-based techniques like beam search work well for directed language generation tasks¹ (such as machine translation and summarization), beam search has been shown to produce dull and repetitive samples for open-ended language generation tasks² [6], an effect that can be observed in music generation as well [10]. It is, therefore, more common to use stochastic sampling techniques³ for open-ended generation tasks. The most obvious method is ancestral sampling, where one token at a time is sampled based on the predicted distribution, conditioned on the previously generated tokens. However, it has been shown that truncating the conditional distribution (by setting the probability of specific tokens to zero, followed by renormalising), can lead to better sample quality than the non-truncated variant. An example of distribution truncation is top- k sampling, where all but the k most probable tokens are zeroed. In [12], the authors showed that top- k sampling generates more coherent samples than the non-truncated variant. In [6], it is explained that the quality improvement of top- k sampling is caused by removing unreliably estimated low-probability tokens, and it is found that top- k sampling mitigates the problem. However, it is also shown that top- k sampling is sensitive to the distribution’s entropy (see Section 3.3), making it hard to select a value of k that fits both high and low certainty conditions. As a solution, they propose *nucleus sampling* that assigns zero probability to the largest set of least probable tokens that together have a probability below a given threshold. The authors find that the samples produced using the technique are preferred by humans over other sampling techniques. Nucleus sampling has been used in music generation in [13–15], but its effects are difficult to quantify without comparisons to the non-truncated case. Although nucleus sampling mitigates the problem of poorly estimated low-probability tokens, it does not prevent generating degenerated repetitive sequences caused by low entropy distributions (see Section 3). As a solution, in [7], the authors propose *typical sampling* and show that this technique prevents degenerated sample generation.

3. ANCESTRAL SAMPLING

Let $p(x_t|x_{<t})$ be the conditional probability of a symbol x_t given previously observed symbols $x_{<t}$ (i.e., the context) and let q be a model fitted to p , e.g., a neural network fitted via likelihood maximization. Given a model q , ancestral sampling samples one token at a time using $x_0 \sim q(\cdot), x_1 \sim q(\cdot|x_0), \dots, x_t \sim q(\cdot|x_{<t})$.

¹ Generation with input sequence conditioning.

² Generation without input sequence conditioning.

³ In the context of generative models, “*sampling techniques*” could refer to a multitude of aspects in the generative pipeline (e.g., Gibbs sampling in restricted Boltzmann machines [11]). In our work, “*sampling techniques*”, refers to techniques for obtaining samples from a trained language model.

3.1 Distribution truncation sampling techniques

In distribution truncation, a truncated distribution \tilde{q} is obtained by zeroing the probability of a subset of tokens and renormalising the resulting distribution. Formally, \tilde{q} is defined by

$$\tilde{q}(x_t|x_{<t}) = \begin{cases} \frac{q(x_t|x_{<t})}{\sum_{v \in V} q(v|x_{<t})} & \text{if } x_t \in V \\ 0 & \text{otherwise} \end{cases}, \quad (1)$$

where V is the set of tokens with nonzero probability in \tilde{q} . For the remainder of this article, we use ‘*conventional sampling*’ to denote sampling from untruncated distributions.

3.2 Nucleus sampling

In nucleus sampling, V is defined as the smallest set such that

$$\sum_{v \in V} q(v|x_{<t}) \geq \tau, \quad (2)$$

where τ is a constant determining the number of tokens to be removed.

3.3 Typical sampling

In typical sampling [7], V is defined in terms of the token information content described below.

Definition 3.1 (Conditional information content). The conditional *information content* (IC) is given by

$$IC(x_t|x_{<t}) = -\log q(x_t|x_{<t}). \quad (3)$$

In computational music perception, IC has been used to model how surprising a musical event is given the musical context [16–18].

Definition 3.2 (Conditional entropy). The conditional entropy is the expected conditional information content

$$H(x_t|x_{<t}) = \mathbb{E}_{x_t \sim q(\cdot|x_{<t})} [IC(x_t|x_{<t})]. \quad (4)$$

The entropy of a distribution explains how confident a model is. It ranges from 0 to $\log n$ where n is the number of symbols in the vocabulary, with 0 indicating that the distribution is deterministic and $\log n$ indicating that the distribution is uniformly random. In typical sampling, the probabilities of tokens with the highest deviation of information from the entropy

$$|H(x_t|x_{<t}) - IC(x_t|x_{<t})| \quad (5)$$

are set to zero. More precisely, let $U = v_1, v_2, \dots, v_n$ be an ascending ordering of the vocabulary in accordance to Equation (5). Then V is defined as the smallest prefix of U such that $q(U|x_{<t}) \geq \tau$. Equation (5) implies that V is restricted by a band around the entropy as shown in Figure 1. Therefore, also the most likely token under q can have zero probability in \tilde{q} . The authors of [7] note that this property, however, lowers the number of degenerately repetitive samples, as opposed to nucleus sampling, without degrading preference in human evaluations.

Figure 1: In typical sampling, a probability band around the entropy (dark-grey) defines the set V of tokens with non-zero probabilities in the truncated distribution.

4. EXPERIMENTS

In this section, we describe the setup for both our objective and subjective experiments, the used data, training details, degradation scenarios, and generation details, as well as objective and subjective evaluation.

4.1 Data

Our experiments are performed on monophonic symbolic music. Specifically, we use the midi-encoded version of the *The Session* dataset [9], consisting of 45,849 traditional Irish folk tunes originally encoded in ABC notation. We discard the 5% longest sequences to lower the computational footprint of the autoregressive transformer model, and partition the dataset in training, validation, and test sets with proportions 10/12, 1/12, and 1/12, respectively. All analyses will be performed on the test set, while our generative models will be trained and optimized on the training and validation sets, respectively. The dataset contains tunes with the same name, corresponding to different versions of the same tune. We ensure that tunes with the same name appear in exactly one of the three sets.

We tokenize the sequences using a modified version of the popular REMI representation [3]. REMI serializes a score bar-wise from left to right. A bar is serialized as a sequence of tokens starting with a bar-delimiter token followed by a serialization of the notes within that bar. Each note is serialized as three tokens indicating the onset within the bar, the pitch and the duration, in that order. The position and duration tokens are quantized to 1/12th of a beat. Contrary to the original REMI implementation, we omit velocity, tempo change and chord symbols, since these are not encoded in the original ABC files either. Similar to [4], we extend the REMI representation with time-signature tokens inserted immediately after the bar token. We base our tokenization implementation on a modified version of the REMI python implementation in MidiTok [19].

4.2 Training

We train a 21-layered Transformer decoder model [20] with relative attention [2, 21] in a self-supervised prediction task. We train the model using Adam optimization [22] with a learning rate of 10^{-4} until no improvement takes place on the validation set during 10 subsequent epochs. The used batch size is 16, and the input sequence length is 512 tokens. Sequences shorter than 512 tokens are zero-padded. The negative log-likelihood (NLL) on the test dataset is measured to be $NLL = 0.30$, which is similar to the result of a recent transformer-based model trained on the same dataset [18]. We thus call this a *well-calibrated model*.

4.3 Model Degradation

In addition to the well-calibrated model, we consider two *under-calibrated models*, which we achieve by intentionally degrading the well-calibrated model. For our first degradation, we scale the logits vector h of the transformer softmax output distribution, i.e.,

$$q(x_t|x_{<t}) = \text{Softmax}(h/r), \tag{6}$$

where $r > 1.0$ is a temperature scale. This degradation increases the distribution’s entropy (uncertainty) while keeping the relative ordering of the probabilities the same. Using temperature scaling, we deliberately increase the probability of token predictions x_t that fit the token context $x_{<t}$ poorly, thereby simulating the failure case of unreliably estimated tokens reported for conventional sampling (see section 2), where truncation techniques are expected to provide better results. We empirically set r to the minimal value that leads to an audible degradation of the generated sequences. This resulted in $r = 1.5$. The NLL of the test data under the temperature-degraded model is measured to be $NLL = 0.31$, which is an increase of 0.01 compared to the well-calibrated model.

Secondly, we consider an unbiased degradation where we perturb the network weights by adding a small amount of Gaussian noise. More specifically, for every weight matrix W of the well-calibrated model, we obtain a degraded weight matrix W' by adding noise z_W to W

$$W' = W + kz_W, \tag{7}$$

where $z_W \sim \mathcal{N}(0, \text{std}(W))$ and k is a constant. We sample the noise vector once and keep it fixed for all our experiments. We empirically set k to be the minimal value where sample degradations are audible, which results in $k = 0.175$. The NLL of the test data under the resulting model is measured as $NLL = 0.36$, which is an increase of 0.06.

4.4 Generation

When generating sequences with the learned models, for all models, we perform conventional sampling, nucleus sampling and typical sampling as described in section 3.

We sample until either the end-of-sequence token is encountered or a maximum length is reached. Due to computing limitations, we fix the maximum sequence length to the 80%-quantile of the dataset song-length distribution. We keep both sequences which terminate with the end-of-sequence token and sequences with the maximum length reached in our sample sets.

4.5 Objective Evaluation

The objective evaluations are performed by calculating different statistics from the generated sequences and comparing the results between different (non-)degradations, sampling types and with the original reference data.

4.5.1 Surprisal

We are interested in the degree of surprisal of the samples generated with the different sampling methods. Similar to [16–18], we measure surprisal using the IC of events. As we do not have access to the data distribution, we interpret the well-calibrated model to be an oracle that approximates the data distribution. We then use the well-calibrated model to measure the mean IC of all events from a specific sampling method and model.

4.5.2 Structural Consistency

We measure structural consistency by investigating the self-similarities of the generated pieces. Similar to [5], we compute a self-similarity distribution from samples of a given sampling method and contrast it with the similarity distribution calculated from real data. To do so, we first compute the similarity between bar pairs separated by measure lags of size t . This is done for each tune x in sample sets D according to

$$l_{i,i+t}^x = \frac{|N(i) \cap N(i+t)|}{|N(i) \cup N(i+t)|}, \quad (8)$$

where the set of notes in the i -th bar is denoted as $N(i)$, and two notes are deemed equal if their pitches, durations, and onset positions within their respective bars are identical. The similarity score $l_{i,j}^x$ between any two bars ranges from 0.0 to 1.0, with a score of 1.0 indicating that the two bars are identical. After computing the similarity for all possible lags in each tune of a sample set D , we calculate the average similarity scores of that sample set by

$$L_t^D = \frac{1}{|D|} \left(\sum_{x \in D} \sum_{j=i+t} l_{i,j}^x \right). \quad (9)$$

Note that eq. (9) does not define a probability distribution and does not, in general, sum to one. For each dataset, we then calculate an overall self-similarity score

$$SS(D) = \frac{1}{T} \sum_{t=1}^T L_t^D, \quad (10)$$

where T is the maximum bar lag considered. $SS(D)$ captures both short-term self-similarities, e.g., repetitions or

variations of motives, and long-term self-similarities, e.g., repetitions or variations of musical segments. Similar to [5], we also consider the deviation of a sample set’s similarity distribution L_t^D to the dataset’s similarity distribution L_t given by

$$SE(D) = \frac{1}{T} \sum_{t=1}^T |L_t - L_t^D|. \quad (11)$$

We interpret this deviation as a measure of how closely the self-similarities of tunes generated with the different sampling techniques follow the self-similarities of tunes found in the dataset. We set $T = 38$ in our experiments (i.e., the smallest maximum number of bars generated by any method).

4.5.3 Tonal Consistency

We are furthermore interested in the tonality coherence of samples generated with the sampling methods. Specifically, we investigate the scale consistency [23], i.e., the maximum percentage of notes fitting a diatonic scale. The scale consistency is therefore calculated by

$$\max_{scale} \frac{\#pitch_in_scale(x, scale)}{\#pitches(x)}. \quad (12)$$

A scale consistency value of 1.0 indicates that all pitches are within a single scale, whereas lower values indicate more complex harmonic structures.

4.6 User Study

In addition to the objective evaluations described above, we also perform a user study to gather subjective evaluations of the tunes’ musical quality, structural properties and complexity. For that, we hosted a website consisting of two pages. The first page explains the purpose of the study, specifically that it aims to evaluate sampling techniques for neural network music generation. Furthermore, the users are instructed to rate the respective tunes using the attributes *overall quality*, *short-term structure*, *long-term structure* and *complexity* using a 5-point Likert scale. The users are also asked to use appropriate headphones or loudspeakers and to announce their level of musical expertise with choices *{Beginner, Intermediate, Expert}*. On the second page, a list of 10 audio widgets is displayed, one for each tune. Below each widget, the Likert scales for the 4 different attributes (as described above) are provided for voting. In addition, the users can click on a “sheet link” that opens a window displaying the tune in staff notation. The 10 tunes for every user constitute the Cartesian product of all three sampling methods (i.e., *conventional*, *nucleus*, *typical*) and all three model modes (i.e., *well-calibrated*, *temperature degradation*, *noise-degradation*) plus a reference tune. It is ensured that every user obtains unique tunes sampled randomly from a set of 500 instances for each of the 10 types, presented in a random order. To prevent biases, every user is allowed to perform the study only once.

Figure 2: Information content of generated data using different sampling strategies and τ values under the well-calibrated model.

5. RESULTS AND DISCUSSION

In this section, we present the results of the experiments described in Section 4. For the figures and tables, we use the abbreviations WELL, NOISE and TEMP for the well-calibrated, noise-degraded and temperature-degraded models, respectively. To these abbreviations, we append CONV, NUCL and TYP for conventional sampling, nucleus sampling and typical sampling correspondingly.

5.1 Objective Evaluation

In the following section, we analyse and discuss the results of our objective and subjective evaluations.

5.1.1 Surprisal

We report the results of the IC estimation in Figure 2 for the truncation degrees $\tau = 0.4, \dots, 1.0$. The samples from the well-calibrated model have the lowest IC and the IC of samples from the temperature-degraded model is higher than the IC of samples from the noise-degraded model. For both nucleus and typical sampling, the IC decreases with decreasing τ . For typical sampling in particular, this suggests that relatively more high information than low information tokens are pruned, similar to what is found in [8]. For most degradation scenarios and sampling methods, a τ value between 0.8 and 0.9 is shown to recover the original data distribution best.

5.1.2 Structural Consistency

We compute the self-similarity (see Equation (10)) for all models and sampling techniques and show the result in Figure 3a. Similarly, we plot the self-similarity deviation (see Equation (11)) in Figure 3b. From Figure 3a, we find that the overall self-similarity of samples produced with typical and nucleus sampling increases as τ decreases. This holds for both degraded models and the well-calibrated model. However, we find that the increase in self-similarity is more moderate for samples generated with typical sampling than those of nucleus sampling, indicating that the removal of highly probable tokens keeps

the self-similarity at more moderate levels. In the temperature degradation scenario, we find that moderate levels of truncation lower the self-similarity deviation for the temperature-degraded model and thereby counteract the temperature degradation (with an optimal τ of 0.8 and 0.6 for nucleus sampling and typical sampling, respectively). In fact, in this scenario, the self-similarity of samples generated with nucleus and typical sampling follows the self-similarity of the reference distribution closer than samples generated with ordinary sampling for most tested truncation strengths. This is not the case for the unbiased noise degradation, where the self-similarity increases with higher truncation strengths, increasing also the deviation from the reference statistics.

5.1.3 Tonal Consistency

We inspect the tonal consistency by calculating the scale consistency (see Equation (12)) and report the results in Figure 3c. For both nucleus and typical sampling, we find that samples generated with low values of τ lead to a higher degree of scale consistency. Furthermore, we find for any given τ that generations from typical sampling have lower scale consistency than samples generated with nucleus sampling. Especially when considering temperature degradation, the scale consistency of nucleus sampling is almost at the level of the reference distribution at $\tau = 0.9$, whereas typical sampling stays low even at high levels of τ . An important observation is that (with the exception of typical sampling in the temperature degradation scenario) there is an optimal τ for both truncation techniques that leads to a recovery of the dataset’s scale consistency statistic in both degradation scenarios.

Similar to the findings in [6] for natural language, our objective evaluations in the high-temperature scenario indicate that the musical statistics of the samples generated with truncation techniques more closely match the statistics of samples from the reference distribution. This finding implies that truncation sampling techniques can be applied to music generative language models, similar to their application in natural language. This can help remove tokens with unreliable probability estimates that do not fit the musical context well. This approach may have implications for more complex datasets and limited resources, where obtaining a well-calibrated model can be challenging.

5.2 User Study

The user study was performed by 38 participants who, according to their self-assessment can be divided into 8 beginners, 18 intermediate and 12 musical experts. The presented melodies (except the *reference*) are generated as described in Section 4.4, with $\tau = 0.8$ for both, nucleus and typical sampling. Table 1 shows the user study results. As there is a high variance for all ratings, we performed for all attributes a Welch’s t-test between all $m = 10$ tune types. Using a desired significance level of $\alpha = 0.05$, the corresponding Bonferroni correction to the

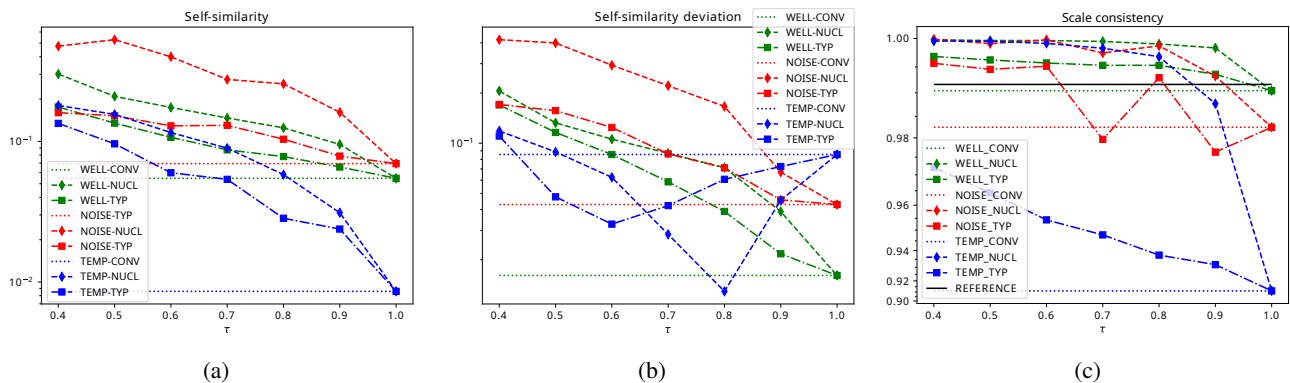

Figure 3: Structural and tonal consistency for different model degradations, sampling strategies and τ values. In (a) the self-similarity of sample sets generated with different sampling techniques is shown. Higher values indicate a higher degree of self-similarities. In (b) the deviation of the generated samples’ self-similarities to the self-similarity and the data reference distribution is shown. A deviation of 0 indicates that the self-similarity of a sample set fits the reference distribution exactly. In (c) the scale consistency of different sample strategies and the reference dataset is shown.

Method	QULT	ST_STR	LT_STR	CPLX
REFERENCE	3.7±1.0	3.8±1.0	3.7±1.1	3.6±0.8

TEMP_CONV	2.1±1.3	2.7±1.1	2.1±1.1	3.7±1.0
TEMP_NUCL	3.4±1.2	3.6±0.9	3.4±1.3	3.4±1.1
TEMP_TYP	2.2±1.1	2.7±0.9	2.4±1.0	3.3±0.8

Table 1: Results showing the mean-opinion scores of the user study \pm the standard deviation. QULT denotes the overall quality estimation, ST_STR the perceived short-term structure, LT_STR the perceived long-term structure and CPLX the perceived complexity of the rated samples.

multiple comparisons problem gives a significance level of $\frac{\alpha}{\frac{1}{2}m(m-1)} = \frac{0.05}{45} = 0.001$. We can see in the first column that the human-composed reference tracks have the highest quality scores on average and that the perceived quality of the tunes tends to degrade for the noise- and temperature degradation cases as expected. The t-test shows that the users’ preference for REFERENCE is significant compared to all samples of the under-calibrated models (with $p < 1 \times 10^{-4}$), except for TEMP_NUCL with $p = 0.37$. This shows that nucleus sampling can potentially improve the sample quality of low-confidence models, while typical sampling is not able to recover any degradations. Furthermore, we find that WELL_CONV, WELL_NUCL and WELL_TYP differ in QULT with $p = 0.07, 0.67$ and 0.37 respectively compared to REFERENCE. This provides some evidence that nucleus and typical sampling improves the sampling quality of well-calibrated models, but this effect is not significant. While nucleus sampling performs well in the temperature-degraded model, we observe some (non-significant) evidence of a lower complexity than conventional and typical sampling in the well-calibrated model (with $p = 0.023$ and $p = 0.044$, respec-

tively). Typical sampling (with $\tau = 0.8$) does not cause significant differences from conventional sampling. As the p -value between NOISE_TYP and NOISE_CONV is also low (but not significant, with $p = 0.06$), there is some evidence that typical sampling slightly reduces the complexity of outputs from under-calibrated models. This could be explained by typical sampling pruning the higher and lower probability events, overall reducing the possible number of events to be sampled. The well-calibrated model performs well with all sampling techniques (no significant differences to REFERENCE), with only some non-significant evidence for lower complexity with nucleus sampling.

6. CONCLUSION

We investigated the effect of distribution truncation sampling techniques on the musical qualities of information content, self-similarity, scale consistency and complexity of samples generated under different degradation scenarios. Our objective evaluations show that a higher truncation strength leads to increased self-similarity and tonal consistency. This trend is more pronounced for samples generated with nucleus sampling compared to samples generated with typical sampling. For a well-calibrated model, we show that the increase in self-similarity and scale consistency leads to an increase in deviations of these metrics from the reference distribution. However, for under-calibrated models, we showed that the deviations from the original data statistics could often be reduced with the correct truncation strategy and carefully selected truncation levels (where a τ between 0.8 and 0.9 seems to be good trade-off value over all experiments). While nucleus sampling carries the risk to reduce complexity of the outputs, this trend could not be observed with typical sampling.

7. ACKNOWLEDGMENTS

ABSTRACT

Every year, several dozen, primarily European, countries, send performers to compete on live television at the Eurovision Song Contest, with the goal of entertaining an international audience of more than 150 million viewers. Each participating country is able to evaluate every other country's performance via a combination of rankings from professional jurors and telephone votes from viewers. Between fan sites and the official Song Contest organisation, a complete historical record of musical performances and country-to-country contest scores is available, back to the very first edition in 1956, and for the most recent contests, there is also information about each individual juror's rankings. In this paper, we introduce MIRoVision, a set of scripts which collates the data from these sources into a single, easy-to-use dataset, and a discrete-choice model to convert the raw contest scores into a stable, interval-scale measure of the competitiveness of Eurovision Song Contest entries across the years. We use this model to simulate contest outcomes from previous editions and compare the results to the implied win probabilities from bookmakers at various online betting markets. We also assess how successful content-based MIR could be at predicting Eurovision outcomes, using state-of-the-art music foundation models. Given its annual recurrence, emphasis on new music and lesser-known artists, and sophisticated voting structure, the Eurovision Song Contest is an outstanding testing ground for MIR algorithms, and we hope that this paper will inspire the community to use the contest as a regular assessment of the strength of modern MIR.

1. INTRODUCTION

The Eurovision Song Contest (ESC) is an annual event wherein several, primarily European, countries compete against one another by performing original, live songs during an internationally televised event. The contest began in 1956 and is typically held in the country of the previous year's winner in the spring.

The content of the musical acts performed during the Eurovision Song Contest is always novel and notably diverse. Contestants are allowed to sing in whichever language they choose, often electing to sing in English to communicate the meaning of their song to a larger base, but some countries (notably France) have historically preferred to sing in their national language. According to the official Eurovision rules, all musical acts must perform an original song that is no more than three minutes in length, with the lead vocals performed live, and acts are limited to only six performers being on stage at any given moment during the performance [1].

Within these constraints, the musical acts of Eurovision are known for their ostentatious performances and camp aesthetics, which are often accompanied with visual spectacles from lightening to elaborate dance. As the contest is an international stage, the musical acts have also been a means in which countries are able to provide meta-political commentary on either national or global events [2, 3]. The contest has been noted as serving as an important platform for global LGBTQ+ visibility, which featured openly gay and transgender performers as early as the 1990s [4].

The winner of the contest is determined as a combination of both expert and panel voting, with no set criteria stated as to what should constitute a winning performance. A combination of the song's content, the visual performance, and the performer's ability to relate to the *zeitgeist* are all presumed to play an important role in determining the winner. Indeed, the Eurovision Song Contest can be and has been analysed from a variety of dimensions, summarised by Wolther as the media, the musical, the musical-economical, the political, the national-cultural, the national-economic, and the competitive [5].

We next detail the rules of the contest before introducing the MIRoVision data set, which contains a multi-faceted collection of historical data that could be used to predict the contest's winner and enable researchers to make deeper inquiries into the history and music of the contest.

1.1 Rules of Eurovision

In order to participate in the Eurovision Song Contest, participating countries work in coordination with the European Broadcasting Union. While each participating country – or more specifically the country's partnered national broadcaster – is allowed to decide for themselves which act to send to participate, the results of the Eurovision Song Contest are determined by voting over three events. These

Baker, "Measuring the Eurovision Song Contest: A Living Dataset for Real-World MIR", in *Proc. of the 24th Int. Society for Music Information Retrieval Conf.*, Milan, Italy, 2023.

three events referred to as the First Semi-Final, the Second Semi-Final, and the Grand Final. It is the Grand Final that typically receives the vast majority of the attention and viewership.

As described on the official Eurovision website¹, all participating countries qualify for two semi-final shows in the week leading up to the Grand Final, which only a subset of the total countries will perform. France, Germany, Italy, Spain and the United Kingdom are automatically included in the Grand Final and are referred to as the 'Big Five'.

After a country has performed, each other country gives two sets of votes for the performance. The first set of votes comes from an expert panel of music industry professionals from within that country. Starting in 2016, the official Eurovision website has published the individual data of each juror from each participating country. The second set of votes comes from viewers from the of the performing country. The votes represent points that are added together and each country can use their set of points, {12, 10, 8, 7, 6, 5, 4, 3, 2, 1} for one and only one country. No juror or television vote can be cast for one's own country. In the semi-finals, voting is limited to only countries participating in their respective show, whereas in the Grand Final, any country is allowed to vote. The Grand Final television show is also characterised by great fanfare surrounding each national jury's announcement of which country they chose to award 'douce points'.

No explicit criteria are given as how any vote should be decided. Said another way, it should not be assumed that all participants attempt to vote for a measure of musical quality. Many factors have been discussed in academic literature on the topic, that suggest there are both geographic and political factors that can play into how countries decide to cast their votes [6–10].

2. MIROVISION DATASET

Data that comprises the MIROVision dataset originates from three primary sources. The first is the official Eurovision website (<https://eurovision.tv/>), the second is the Eurovision World fan website (<https://eurovisionworld.com>), the third are audio features taken directly from the YouTube videos linked in the contestant metadata. The dataset contains five primary types of data: (1) contest meta-data; (2) contest results; (3) voting data; (4) audio features extracted from recorded performances of the musical acts and (5) betting office data. All data for each Eurovision Song Contest is available each year since the year 1956 until present day with the exception of 2020 when the contest was cancelled due to the global COVID-19 pandemic. As of 2016, the official Eurovision website has published data detailing how each of the five jurors from the expert panel have voted on all three nights of the contest. The current release of the data set contains the contestant metadata, contest ranking and voting data of 1719 entries. The dataset is hosted on a GitHub repository.²

¹ <https://eurovision.tv/about/how-it-works>

² <https://github.com/Spijkerket/eurovision-dataset>

In total, 56 countries are represented in the dataset, which includes countries that have been dissolved, renamed, or merged since the inception of the contest in 1956. Voting data for the contest is stored in three tables: (1) votes; (2) contestants; and (3) jurors.

The *votes* table contains data from the contest's beginning in 1956 and indicates how each country's aggregated jury and televoting points were distributed to each other participating country.

The *contestants* table contains all metadata regarding each song entry, such as the artist's name and song title, lyrics, composers and lyricists, the running order and the total points awarded by the jury and televoters in the Semi-Final and Final Rounds respectively. This table also includes links to YouTube videos of live performances from the televised Finals or Semi-Finals, as maintained by the Eurovision World team.

The *jurors* table contains data beginning from the year 2016 and indicates how the five anonymous jurors (designated with letter names A through E) voted for each other country and in which night of the contest. As noted above, countries are unable to vote for themselves, are only able to vote within the Semi-Final they are participating in, whereas all countries are able to vote in the Grand Final.

In addition to the voting tables, the *betting-offices* table provide tables of historical bookmakers' odds for the contest winners, as collected by Eurovision World. The Eurovision Song Contest is a popular target for online betting. Day-of-contest odds are available for 2016 and 2017, and daily odds up to six months prior to the contest are available from 2018 onward, for 10 to 20 betting offices.

3. A PREFERENCE MODEL FOR EUROVISION

The Eurovision Song Contest voting system is iconic, but because the number of contestants varies, it is not possible to use contest scores to make comparisons across years. Moreover, the contest scores do not operate on an interval level of measurement: even within a particular year, a difference of five or ten points may mean something quite different at the top end of the score range than it does at the bottom. With the rich data in the MIROVision set, however, it is possible to fit statistical models with parameters that correspond monotonically to actual contest results but that *do* behave on an interval scale. Such an interval scale is not only interesting musicologically and sociologically, but also for machine-learning applications, as most common loss functions for training implicitly assume interval-scale outcomes. In short, we are looking for a true *measure* of competitiveness in the Eurovision Song Contest, and one that applies stably across years.

In order to achieve these desiderata, the contest results must be sufficient statistics for the model parameters of interest. If we make the stronger assumption that there be only a finite number of sufficient statistics beyond these, then by the Pitman–Koopman–Darmois theorem [11], the model must be a member of the exponential family. That leaves a surprisingly small class of plausible models.

The simplest model requires no sufficient statistics other

than the scores themselves. Under such a model, the probability of the set of scores from any particular country's jury or televoters

$$\Pr[\text{ranking}] \propto \exp(s_1\beta_1 + s_2\beta_2 + \dots + s_N\beta_N), \quad (1)$$

where the coefficients $s_n \in \{12, 10, 8, 7, 6, 5, 4, 3, 2, 1\}$ are the scores awarded from that jury or televoter group to contestant n and the β_n are the model's competitiveness parameters for contestant n . The normaliser $Z_0(\beta)$ for this distribution is the sum of these terms for any valid assignment of scores under the Eurovision system. After M juries and televote groups combine their scores independently to determine a winner, the combined probability

$$\Pr[\text{contest}] = \frac{\exp(s_1\beta_1 + s_2\beta_2 + \dots + s_N\beta_N)}{Z_0(\beta)^M}, \quad (2)$$

where s_1, s_2, \dots, s_N now represent the *total* scores awarded to each contestant. The trouble with this model is that for a typical Eurovision show of 26 contestants, the normaliser contains ${}_{26}P_{10} \approx 19$ trillion terms. The model is thus infeasible in practice, despite its theoretical simplicity.

Most alternatives to this model lose their exponential-family properties. There is, however, an interesting alternative if we are willing to consider Eurovision contest scores from juries and televoters to be *ratings* instead of rankings. Specifically, assume that for each song, juries must award a scores in the set $\{12, 10, 8, 7, 6, 5, 4, 3, 2, 1, 0\}$, but that there is no restriction on how many times they can use each score. While the numerator of such a model remains the same as (1) and (2), its normaliser

$$Z(\beta) = \prod_{n=1}^N \sum_{k \in \{12, 10, 8, 7, 6, 5, 4, 3, 2, 1, 0\}} \exp(k\beta_n), \quad (3)$$

which can be computed easily. Although there are fundamental conceptual and mathematical differences between rankings and ratings [12], if we restrict the outcome space of rating model (3) to allow only outcomes that would also be valid in the ranking model (2), the models are equivalent [13]. Moreover, we can add an extra set of score-level parameters ξ_k to allow (3) to better approximate (2) without sacrificing equivalency on the restricted outcome space:

$$\Pr[\text{ratings}] = \frac{\exp(\sum_n s_n\beta_n) \cdot \exp(\sum_k \xi_k)}{\prod_n \sum_k \exp(k\beta_i + \xi_k)}, \quad (4)$$

where s_n are again the scores from a particular jury or televoter group and $k \in \{12, 10, 8, 7, 6, 5, 4, 3, 2, 1, 0\}$. This model is known in the psychometric literature as the *partial-credit model* [14] and is one of the standard mathematical tools used for assessing the reliability of rubrics, Likert scales, and educational test items with partial credit.

4. FITTING THE PREFERENCE MODEL

We fit the partial-credit model (4) to the MIVision data for all Song Contests since 1975, the year that the $\{12, 10, 8, 7, 6, 5, 4, 3, 2, 1, 0\}$ scoring system was instituted. We

Figure 1. Correspondence between song competitiveness (in cantobels) and final Eurovision Song Contest scores in 2019. The pattern in this year is typical of all other years, with a relatively slow increase in points as competitiveness improves up to about 0.5 cantobels, followed by a rapid increase. Because of the semi-final rounds, the relationship between competitiveness and final score is not a strictly monotonic as in years without semi-finals, but it is still nearly monotonic.

considered every vote available as an individual observation: every country's jury, every country's televotes in years that those votes were counted separately from juries, and all votes from semi-final rounds when they occurred. We made the important but unavoidable assumption that the average competitiveness of a Eurovision entry has remained constant over time, as there are no cross-year comparisons that would make it possible to estimate the model otherwise.

We fit the joint probability model using the Bayesian probabilistic programming language Stan, with normal priors on average country competitiveness and song competitiveness and a multivariate normal prior on ξ for each contest. The complete model code is available in the supplemental material. For interpretive purposes, we fixed the mean of the song competitiveness parameters β to 0 and report them on a $10 \log_{10}$ scale, analogous to the decibel. In honour of the singing at the contest, we deem this unit the *cantobel*. An increase of one cantobel in song competitiveness means that a song improves its chances of receiving one extra point from any given jury by $10^{\frac{1}{10}} \approx 1.26$. Like the decibel scale, an increase of 3 cantobels means that a song approximately doubles its chances of receiving one extra point.

Figure 1 illustrates the typical correspondence between competitiveness in cantobels and actual song contest results. After a slow increase, the slope rapidly increases for highly competitive entries. The Eurovision Song Contest scoring system compresses differences between relatively uncompetitive entries and dramatically exaggerates small differences at the top. While this surely contributes to the exciting television, cantobels are a better scale to use for scientific purposes.

Figures 2 and 3 reveal the heart of the model. The first shows the average song quality, as perceived by the Eurovision Song Contest juries and televoters, over the period from 1975 to 2022. Ukraine, Russia, Italy, and Sweden stand

Figure 3. Median competitiveness of countries’ Eurovision Song Contest entries, 1975–2022, in cantobels with 90% credible intervals. Countries are coloured by their geographic region as defined in the United Nations M49 standard. Ukraine, Russia, Italy, and Sweden stand out as having sent contestants of exceptional competitiveness, although Azerbaijan, the United Kingdom, and Greece’s credible intervals are also strictly greater than zero.

out as having been particularly successful, even though they have suffered almost-wins instead of victories in many years. On average, songs from these countries have been a half cantobel above the average. But the first figure shows that there are dramatic swings from year to year underneath these averages. Even one the most convincing victories from one of the historically strongest countries – Måns Zelmerlöv’s ‘Heroes’, Sweden’s 2015 entry – was preceded and succeeded by much less appreciated acts.

4.1 Jury Model

Jury scores at the Eurovision Song Contest are determined by combining rankings from five independent jurors from each country, each of whom must make a complete ranking of contestants at a show, from best to worst. After averaging these ranks, they are converted to the better-known {12, 10, 8, 7, 6, 5, 4, 3, 2, 1, 0} system that is reported on television. Since 2016, the European Broadcasting Union

Figure 4. Ideal scores for averaging ranks within juries, according to a generalised partial-credit model, with 90% credible intervals. In recent years, the Eurovision Song Contest has used an exponential weighting scheme, but these results suggest that a linear scheme with a small bonus for the top-ranked entry would be sufficient.

has made not only the final scores but also these individual rankings public. They have also publicised that they continue to experiment with the proper way to average the ranks across jurors, currently using exponential decay.³

The theory of partial-credit models offers an alternative, more empirical solution. Rather than taking the scoring rule in (4) as fixed, the *generalised partial-credit model* considers an optimal scoring rule that would lead the model to make the best predictions. Concretely, that would mean considering alternatives to the {12, 10, 8, 7, 6, 5, 4, 3, 2, 1, 0} rule for the main contest, and by extension, to the simpler {1, 2, . . . , N} rule for jury members making a full ranking.

The MIRoVision dataset includes these jury scores, and we fit a generalised partial-credit model to them analogous to the model we fit for the contest overall. The code is available in the supplemental material. Figure 4 shows the results. Like the European Broadcasting Union’s current rule, we arbitrarily fix the maximum score to 12. It seems that rather than replacing the former linear scheme with the current exponential one may be a more effective simply to give a small fixed bonus to each juror’s top-ranked entry. Such a solution would also solve the core issue motivating the exponential weighting, namely that it is undesirable for one juror to have unilateral power to spoil the chances of some other juror’s favourite.

5. PREDICTING WINNERS

The Eurovision Song Contest is also notorious for attracting online and offline bets on the outcome. Since 2015, the EurovisionWorld web site has been collecting the odds posted at a large number of online betting offices, for each day leading up to the contest. These odds can be converted into implicit probabilities of winning, and there is often much discussion in the weeks leading up to the contest about which acts the bookmakers are favouring.

³ <https://eurovision.tv/story/subtle-significant-ebu-changes-weight-individual-jury-rankings>

Year	Country	Actual	Bookmakers
2018	Israel	.87	.24
2018	Cyprus	.12	.37
2018	Germany	.01	.09
2019	Netherlands	.53	.51
2019	Italy	.45	.09
2019	Switzerland	.01	.09
2019	Russia	.01	.02
2021	Italy	.63	.26
2021	France	.35	.22
2021	Switzerland	.02	.05
2022	Ukraine	.98	.62
2022	Sweden	.01	.14
2022	United Kingdom	.01	.06
2022	Spain	.01	.06

Table 1. Probability of winning the Eurovision Song Contest, 2018–2022, given the partial-credit model and perfect information about jurors’ and televoters’ preferences, compared to bookmakers’ implied win probabilities immediately prior to the contest final.

We can use our model fits to compare the bookmakers’ predictions to the actual probabilities countries had to win given jurors’ and televoters’ preferences and the assumptions of the partial-credit model. To compute these probabilities, we reshuffled the draws from our Bayesian samples independently for each country and tallied how often these would have been the highest, taking advantage of the fact that competitiveness in cantobels is a sufficient statistics for actual contest outcomes. Table 1 presents the results. Both 2019 and 2021 were rather close contests, whereas 2018 and 2022 had clearer frontrunners. The bookmakers markedly mis-called 2018, but have been more accurate since. If one had been able to place stakes at the online betting offices with perfect knowledge of the jurors’ and televoters’ preferences, one would have quadrupled one’s stake on average (before paying out the bookmakers’ sometimes shockingly high margins on Eurovision odds).

6. CONTENT-BASED CONTEST PREDICTIONS

Perfect information is of course never available, but perhaps deep learning and content-based MIR offer something? Self-supervised music representation learning has advanced considerably in recent years. It has successfully been applied to many downstream tasks, including music tagging [16], genre classification, key detection and emotion recognition [17, 18]. These foundation models are generally pre-trained in an unsupervised, end-to-end fashion on raw audio samples. By defining an auxiliary loss objective on large quantities of music and using data perturbations, models are able to learn effective and robust representations.

To evaluate whether a pre-trained foundation model is able to predict preferences, we extracted embeddings on all song entries using the TUNe+ [19] and MERT [18] models. On every window of 2 seconds, an embedding vector of 512 feature dimensions is computed for the TUNe+ model. The

Model	L1	L2
TUNe+ [19]	0.828 (0.039)	1.063 (0.052)
MERT [18]	0.820 (0.019)	1.025 (0.027)

Table 2. L1 (MAE) and L2 (RMSE) losses and their standard deviations after training two state-of-the-art audio embeddings to predict the competitiveness of Eurovision Song Contest entries from 1975–2022, in cantobels.

MERT model returns 25 representation layers, and 1024 feature dimensions on 5-second windows. For every song entry between 1975 and 2022, a single embedding vector is calculated by taking the arithmetic mean along the time dimension for TUNe+ and along the representation layers for MERT respectively. This results in 1 261 embeddings in total. For every song entry, we took 4 000 draws from the fitted model for song competitiveness (in cantobels) and treated these as our targets Y ; using 4 000 draws instead of a single point estimate more accurately averages over our uncertainty about song competitiveness, given the inherently limited number of rankings available for any single edition of the contest. We freeze the pre-trained TUNe+ and MERT models and perform a linear probe using the mean-squared error between (\hat{y}, y) . We use 5-fold cross-validation and sample all song entries from two years within each decade between 1975 and 2023 as our validation set.

Our results in Table 2 show that we can achieve RMSE of 1.025 cantobels by way of training a linear layer on embeddings extracted from a pre-trained foundation model. These models are not specifically trained or designed for our downstream task of preference prediction, e.g., features extracted by the different layers in MERT vary in their downstream task performance, and we leave further improvements to future work. But to contextualise the result, the overall standard deviation of our Eurovision competitiveness ratings is 1.064 cantobels, which means that state-of-the-art MIR audio embeddings are able to predict 7.2% of the variance in Eurovision Song Contest competitiveness.

7. CONCLUSION

We present MIRoVision, a collection of data and tools for studying the Eurovision Song Contest and applying music information retrieval to several types of data generated from the contest. One of our key results is a model for converting the highly non-linear contest scores into a well-behaved interval-scale measurement we dub the *cantobel*. Cantobels facilitate understanding of fluctuations in the contest over time and more accurately represent both the competitiveness and the uncertainty surrounding the competitiveness of Eurovision Song Contest entries. They also behave better with the standard loss functions used in machine learning systems, and allow us to predict a small but meaningful portion of variance in contest outcomes. We hope this result is sufficiently tantalising to encourage the community to try their own models – the Eurovision Song Contest offers a fresh set of contestants every year – and to find their own creative uses for this rich musicological data source.

EFFICIENT SUPERVISED TRAINING OF AUDIO TRANSFORMERS FOR MUSIC REPRESENTATION LEARNING

Pablo Alonso-Jiménez Xavier Serra Dmitry Bogdanov

Music Technology Group, Universitat Pompeu Fabra, Barcelona

pablo.alonso@upf.edu

ABSTRACT

In this work, we address music representation learning using convolution-free transformers. We build on top of existing spectrogram-based audio transformers such as AST and train our models on a supervised task using patchout training similar to PaSST. In contrast to previous works, we study how specific design decisions affect downstream music tagging tasks instead of focusing on the training task. We assess the impact of initializing the models with different pre-trained weights, using various input audio segment lengths, using learned representations from different blocks and tokens of the transformer for downstream tasks, and applying patchout at inference to speed up feature extraction. We find that 1) initializing the model from ImageNet or AudioSet weights and using longer input segments are beneficial both for the training and downstream tasks, 2) the best representations for the considered downstream tasks are located in the middle blocks of the transformer, and 3) using patchout at inference allows faster processing than our convolutional baselines while maintaining superior performance. The resulting models, MAEST,¹ are publicly available and obtain the best performance among open models in music tagging tasks.

1. INTRODUCTION

The goal of representation learning is to develop features that are suitable for a variety of tasks, rather than being specific to the training objective. In the context of audio, these features are sometimes referred to as embeddings, and they typically have a much lower dimensionality than the original signals, making them easier to store and process. When the embeddings are well-suited to a downstream task, it is often possible to achieve good performance using shallow models that require few resources to train and run. Additionally, using a single embedding model to feed several shallow classifiers or regressors is more efficient than

having individual end-to-end models, and it simplifies addressing new related tasks with minimal additional effort. As a result, embedding models are valuable for a diverse range of applications, from quick prototyping without requiring detailed knowledge of audio processing to large-scale processing of industrial audio databases.

The universal success of transformers in text [1], vision [2], and audio [3] tasks motivate further research using this architecture for music representation learning. However, most state-of-the-art (SOTA) models are based on convolutional neural networks (CNNs) [4–7]. We hypothesize that transformers are not ruling this domain yet because they require large amounts of data and computational power to overcome their convolutional counterparts, while such resources are not always available. To address these challenges, we propose leveraging a large collection of 3.3 M tracks annotated with public-domain metadata from Discogs and using techniques to train transformers efficiently. Specifically, we focus on PaSST [8], a method that has demonstrated remarkable performance in the AudioSet [9] benchmark. This method uses patchout, a technique consisting of discarding parts of the input to regularize the training process, while also allows reducing the GPU memory and computations required for training. In this work, we investigate the effectiveness of this technique for music representation learning, considering the impact of specific design aspects.

We focus on the impact of using different combinations of tokens from different blocks of the transformer as embeddings, starting the training from different pre-trained weights from publicly available models, using different input segment lengths, and using patchout at inference time to speed up the embedding extraction. Our experiments show that the best performance is obtained by extracting embeddings from the middle of the transformer and initializing it with weights pre-trained on other audio tasks. Contrary to previous studies based on CNNs, our transformers benefit from long input segments both in training and different downstream scenarios. Finally, we show that, on certain patchout conditions, our transformers are able to double the inference speed of an EfficientNet-B0 baseline while producing embeddings that obtain better performance on downstream tasks. Moreover, this approach has the advantage of being entirely configurable at inference time, allowing the throughput/performance tradeoff to be adapted to the task at hand.

The remainder of this paper is structured as follows: In

¹ Music Audio Efficient Spectrogram Transformer. Code for training: <https://github.com/palonso/MAEST>. This model is part of Essentia models: <https://essentia.upf.edu/models.html>

Section 2 we present existing works related to this study. The experimental setup is presented in Section 3, and the proposed experiments and results are in Section 4. Finally, we conclude in Section 5.

2. BACKGROUND

In this section, we review the literature on music representation learning to motivate the selection of our training task and discuss existing audio and music transformers and justify our architecture and training approach. Finally, we introduce existing works on music representation learning with transformers.

2.1 Music representation learning

Some authors have pursued general-purpose representation models to address simultaneously speech, audio event, and music tasks, which led to the proposal of challenges such as HEAR [10] and benchmarks such as HARES [11]. However, for now, there is no evidence that a single training paradigm can yield excellent performance in all the audio domains at the same time. Alternatively, audio representations can be optimized to a single domain leveraging specific data, which tends to produce better performance. In this sense, music-specific representation models are typically evaluated in music description in terms of genre, mood, era, rhythmic properties or arousal and valence estimation, where the annotations are generally on the track level. Additionally, music representation models can be evaluated in more objective tasks such as tempo or key estimation, although, specific models using domain knowledge tend to be better suited for these tasks [12].

Music tagging is a multi-label classification task using a vocabulary that can combine multiple music notions (e.g., genre, moods, eras). Some of the most successful music representation learning approaches are based on music tagging [5, 13–15]. Other directions include training models on editorial metadata [4, 6, 16–20], multi-modal correspondence [21], co-listening statistics [4], contrastive supervised [7, 22–24] and self-supervised [11, 25–28] objectives, music generative models [29], playlist co-occurrences [20, 24], text [7, 30], or combinations of them [4, 19, 24, 29]. While self-supervised approaches have been narrowing the gap with their supervised counterparts, the SOTA models use music tagging [4, 5], or supervised contrastive learning in a single-domain [6] or cross-domain [7] settings. Since the scope of this work is to assess the benefits of transformers, we fix our training task to music tagging for its simplicity, popularity, and empirically shown effectiveness.

2.2 Transformers in audio classification tasks

Transformers have become a popular choice for audio tasks due to their superior performance compared to their convolutional counterparts when sufficient data is available. Lately, AudioSet, with almost 2 M audio event excerpts, has become a popular benchmark led by transformer models. A popular approach consists of applying attention over small overlapping patches (e.g., 16×16)

Model	Init.	GPUs	Time	mAP
AST [3]	ViT	-	-	45.9
PaSST [8]	DeiT	2 RTX 2080ti	24 h	47.6
MaskSpec [31]	FS	64 Tesla V100	36 h	47.3
Beats [32]	FS	16	-	48.7

Table 1. Comparison transformers from the literature in terms of initialization weights, number of GPUs used for training, training time, and mAP obtained in AudioSet.

from the spectrogram using a classification objective. The sequence of spectrogram patches is linearly projected to a 1-D space where a trainable positional encoding signal is added. A trainable classification token is appended to the sequence of projections, and after a number of Transformer blocks it is used to solve the classification task using a linear classifier. This idea was first introduced in the image domain by ViT [2] and adapted to audio spectrograms in AST [3]. PaSST extends this approach by introducing *patchout*, a technique consisting of discarding random patches from the input spectrogram at training time (see Figure 1) [8]. This technique has two benefits. First, by discarding input patches, the training sequence length is significantly reduced, which increases the training speed. Second, it acts as a regularization technique that improves the robustness of the transformer. Additionally, patchout can be combined with other training methods. MaskSpec is a self-supervised pre-training method based on an encoder-decoder architecture where the decoder has to reconstruct the spectrogram from a partial spectrogram altered with patchout [31]. Beats is a transformer trained with a supervised objective and patchout where the labels come from a codebook of randomly initialized vectors that is iteratively optimized [32]. While these techniques prevent the transformers from depending on initializing from weights of pre-trained models, such systems are significantly more resource-demanding. Table 1 compares the mentioned audio transformers in terms of GPUs used for training, training duration, and mean Average Precision (mAP) on AudioSet. Remarkably, PaSST achieves an excellent trade-off between mAP and needed resources. Since we aim to use transformer models that can be trained with a computational budget equivalent to SOTA CNNs (i.e., using consumer-grade GPUs), we focus on the standard patchout training with a supervised objective.

2.3 Music representation learning with transformers

Some works already combined music representation learning and pure-attention-based transformers. S3T combines MoCo’s momentum-based self-supervised contrastive learning with the Swin Transformer [33] architecture to learn music representations for classification [28]. MuLan is an audio representation model trained with cross-domain contrastive learning that aligns the latent representations of associated audio and text pairs. The authors experiment both with a ResNet50 and an AST architecture, with the former obtaining better performance in downstream music tagging tasks [7].

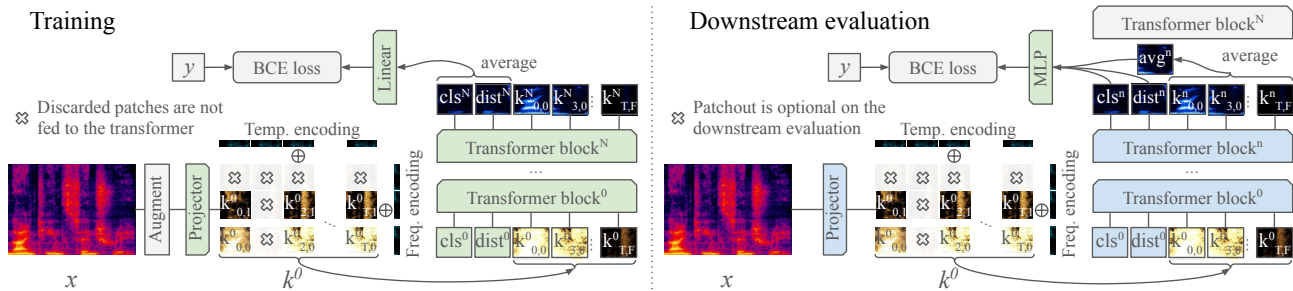

Figure 1. Illustration of our system at the training and downstream evaluation stages where x is the input spectrogram, k^0 is the sequence of tokens after the patchout, y is the target labels, and BCE is the binary cross-entropy loss. Trainable and frozen blocks are colored green and blue respectively.

The limited list of studies combining transformers and music representation learning motivates further research. We propose addressing this by using a simple supervised objective and patchout.

3. EXPERIMENTAL SETUP

We train our models using an in-house dataset with 3.3 M tracks mapped to the Discogs’ public metadata dump.² The training task consists of a multi-label classification of the top 400 music styles from Discogs’ taxonomy. We compare different training configurations in several downstream tasks by training Multi-Layer Perceptrons (MLP) on representations extracted from the transformers.

3.1 Dataset and pre-processing

Our dataset is derived from a pool of 4 M audio tracks mapped to the release information from the Discogs website’s public dump.³ All release metadata, which can include music style tags following a pre-defined taxonomy, is submitted by the community of platform users. *Master releases* group different versions of the same release such as special editions, or remasters. We obtain our training labels, y , at the master release level by first aggregating the style tags of all the associated releases and then discarding master releases with more than five style tags or without any style label among the 400 most frequent among our pool of tracks. We keep tracks longer than 20 seconds. Since the style annotations are done at the master release level, the resulting track annotations are expected to be noisy. We generate validation and testing subsets with approximately 40,000 tracks and a training set with 3.3 M tracks, ensuring that every artist appears on a single split. This pre-processing is similar to our previous work [6], and additional details and statistics about the resulting dataset can be found in the repository accompanying this publication. For now on, we refer to this internal dataset as *Discogs20*.

From every track, we sample 30 seconds from the center of the track and downmix it to a mono channel at 16 kHz. We extract 96-bands mel-spectrograms, x , using 32

ms windows and a hop size of 16 ms compressed with the expression $\log_{10}(1 + 10000x)$ similar to previous works in music tagging [6, 34]. The resulting representations are stored as half-precision floats (16 bits) resulting in 1.3 TB of data. Given that our dataset is in the order of magnitude of AudioSet (1.8 M vs. 3.3 M) and presents similar label density (2.7 average labels in AudioSet and 2.1 in Discogs20), we adopt the sampling strategy used in previous works [8]. Every epoch, we take a balanced sample of 200,000 tracks without replacement using the inverse label frequencies as sample weight. We normalize the input to the mean and standard deviation of the training set.

3.2 Model and training

Our transformer, *MAEST*, has the same architecture as AST [3], ViT [2], or PassT [8], and features 12 blocks of self-attention plus a dense layer resulting in close to 87 million parameters. We use 16×16 patches, $x_{t,f}$, with a stride of 10×10 . Similar to PaSST, we split the positional encoding into time/frequency encodings (te_t, fe_f) and apply patchout by randomly discarding entire rows and columns from the sliced spectrogram. The input sequence of tokens, k^0 , is created as a linear projection of the patches plus the correspondent time/frequency encodings, $k^0_{t,f} = P(x_{t,f}) + te_t + fe_f$, where $P(\cdot)$ is a trainable linear layer.⁴ k^1 to k^{12} represent the output tokens of the respective transformer blocks. Similar to DeiT [35] and PaSST, we extend k^0 with classification (cls^0) and distillation ($dist^0$) trainable tokens, which are initialized with the DeiT or PaSST pre-trained weights in the experiments involving these models.⁵ We take the average of cls^{12} and dis^{12} tokens to feed a linear classifier targeting y .

We use the Adam Optimizer with a weight decay of $1e-4$ and train the model for 130 epochs. We warm up the model for 5 epochs and then keep the learning rate at $1e-4$ until epoch 50. Then the learning rate is linearly decreased to $1e-7$ during 50 additional epochs. We consider two sets of weights for inference: those from the last epoch and

⁴ Since the mel scale is not linear, we considered specialized projectors for each frequency patch. However, this did not improve the performance.

⁵ We considered a teacher-student approach similar to DeiT by using a pre-trained MAEST-30 to generate pseudo-labels that were targeted by the $dist^{12}$ token in the training stage. We decided to omit the experiment details since it did not achieve a significant improvement.

Table 2. Automatic tagging datasets used in the downstream evaluation. The datasets are compared in terms of sample size, number of labels, audio duration (Full Tracks or excerpts of fixed duration), average labels per track, and the splits used in our evaluations.

those obtained by taking the mean of the model’s weights every 5 epochs from epoch 50 using Stochastic Weight Averaging (SWA). We pre-compute the mel-spectrograms for efficiency, which limits the set of data augmentations we could apply. We use mixup [36] with $\alpha = 0.3$ and SpecAugment [37] by masking up to 20 groups of 8 timesteps and up to 5 groups of 8 frequency bands.⁶

Initialization weights. Previous works showed the importance of initializing the transformer to weights pre-trained on ImageNet [3]. To gain further knowledge, we consider three initialization options: the DeiT B \uparrow 384 model pre-trained on ImageNet [35], the PaSST S S16 model pre-trained on mel-spectrograms from AudioSet, and random initialization.

Spectrogram segment length. We consider spectrogram segment lengths of 5 to 30 seconds resulting in the architectures MAEST-5s, MAEST-10s, MAEST-20s, and MAEST-30s. In all cases, we take existing PaSST frequency and temporal encodings and interpolate them to the target shape as an initialization. We use patchout discarding 3 frequency and 15 temporal patches for MAEST-5s and increase the temporal patchout proportionally for models with longer input sequences (e.g., 60 patches for MAEST-20s).

3.3 Evaluation

We evaluate our models in several music automatic tagging datasets covering various musical notions. We consider the popular MagnaTagATune (MTT) and the Million Song Dataset (MSD) with the commonly used training, validation, and testing splits used in [39] and [15] respectively. Additionally, we report the performance of our models in the CALS split, which is an artist-filtered version of the MSD ground truth [40]. Finally, we use the MTG-Jamendo Dataset, a dataset of Creative Commons music containing sub-taxonomies with the tags related to genre (MTGJ-Genre), moods and themes (MTGJ-Mood), and instrumentation (MTGJ-Inst), along with the top 50 tags (MTGJ-T50) in the dataset. We use the official split 0 for all the subsets similar to previous works [5, 30, 41].

⁶ We trained MAEST using 4 Nvidia 2080 RTX Ti GPUs with 12GB of RAM. The training takes 31 hours for MAEST-5 and 48 hours for MAEST-30.

Table 2 summarizes these datasets in terms of size, number of labels, audio duration, average number of labels per track, and used splits.

We evaluate our models by extracting internal representations from different blocks of the transformer and training MLP classifiers on top. Instead of averaging the cls^{12} and $dist^{12}$ tokens as done in the training stage, we consider three types of representations, cls^n , $dist^n$, and the average of the tokens representing the input spectrogram patches (avg^n) after n transformer blocks. Additionally, we evaluate the complementarity of these embeddings training MLP classifiers on stacks of the different tokens. To generate the dataset of embeddings, we average the embeddings extracted from half-overlapped segments across the entire audio available for the tracks in the downstream datasets. The same setup is used for the training, validation and testing stages.

The downstream model is an MLP with a single-hidden layer of 512 dimensions with a ReLU activation and dropout. In the experiments described in Sections 4.1, 4.2, 4.3, and 4.5, we use a batch size of 128, drop out of 0.5 and train the model for 30 epochs. In the downstream evaluation from Section 4.4, we perform a grid search over the following hyper-parameters for each task:

- **batch size:** {64, 128, 256}
- **epochs:** {30, 40, 50, 60, 70, 80}
- **drop out:** {0.5, 0.75}
- **maximum learning rate:** { $1e-3$, $1e-4$, $5e-4$, $1e-5$ }

The MLP is trained with the binary cross-entropy loss using the Adam optimizer with a weight decay of $1e-3$. The learning rate is exponentially raised to its maximum value during the first 10 epochs, kept constant for the number of epochs, and linearly reduced until reaching $1e-7$ at the end of training. After training, we report the performance on the testing set obtained using the weights from the epoch with the highest validation ROC-AUC.

4. EXPERIMENTS AND RESULTS

In this section, we present the conducted experiments and discuss the results.

4.1 Extracting embeddings from the transformer

We are interested in finding the optimal representations from the transformer to be used as embeddings. To do this, we extract representations cls^n , $dist^n$, and avg^n from different transformer blocks $n \in [5, 12]$. To measure the complementarity of these features, we train MLPs fed with stacks of combinations of these representations. In this experiment, we use MAEST-30s initialized with PaSST weights and the MTT dataset.

Figure 2 shows mAP scores obtained with different stacks of embeddings extracted from the different transformer blocks. In accordance with previous studies [29], we find that the embeddings with the best performance are found in the middle blocks of the transformer. This contrasts with the typical behavior of CNNs, where the best

Figure 2. mAP scores obtained with our evaluation setup in the MTT dataset using embeddings extracted from different blocks and tokens transformer. We evaluate the *cls* (c), *dist* (d), and *avg* (a) tokens and stacks of their combinations extracted from the transformer blocks 5 to 12.

features are normally towards the last layers of the model, especially, when the downstream task is well aligned with the training task. Also, concatenating the features benefits the performance. In the remaining experiments, we fix our embedding to the stack ($cls^T, dist^T, avg^T$).

4.2 Impact of the initial weights

Due to the lack of inductive biases present in architectures such as CNNs, transformers are heavily dependent on pre-training. Because of this, many audio transformers are initialized with weights transferred from image tasks [3, 8]. We evaluate the impact of initializing our models from the weights of DeiT [35] (image input), the best single PaSST model [8] (mel-spectrogram input), and random initialization. In this experiment, we use MAEST-10s and its version with SWA weights, MAEST-10s-swa. Although our main focus is to evaluate MAEST on public downstream datasets, we also report their performance on the training task to provide additional insights.

Table 3 shows the performance in both, the training (Discogs20), and a downstream (MTT) task. In both cases, the scores are higher when the training is started from pre-trained weights. Since the PaSST weights result in slightly higher performance, we use this initialization for the remaining of this work. Regarding the SWA, we observe a positive effect on the training task when the model is initialized with pre-trained weights. However, we do not observe improvements in the downstream task.

4.3 Effect of the input segment length

We train MAEST using input segment lengths ranging from 5 to 30 seconds. In our experiments, we keep the frequency patchout constant and proportionally increase the temporal patchout. For our models with segment lengths of 5, 10, 20, and 30 seconds we discard 15, 30, 60, and 90 temporal patches respectively.

Model	RW	DeiT	PaSST
<i>Pre-training task: Discogs20</i>			
MAEST-10s	20.5	22.7	22.8
MAEST-10s-swa	20.1	23.2	23.5
<i>Downstream task: MTT</i>			
MAEST-10s	38.7	40.4	41.1
MAEST-10s-swa	39.0	40.2	41.0

Table 3. mAP scores obtained in the training and downstream tasks using different initializations. We considered Random Weights, and pre-trained weights from DeiT and PaSST.

Table 4 shows the performance of the MAEST models with respect to their input spectrogram segment length in terms of mAP both in the training (Discogs20) and a downstream (MTT) evaluation. While music tagging CNNs tend to reach their peak of performance with receptive fields of 3 to 5 seconds [14], attention-based systems have shown the capability to take advantage of longer temporal contexts [40]. Our models are consistent with this trend, reaching their best performance when trained on segments of 30 seconds. Although even longer segments could be beneficial, we could not use them while keeping the same model size due to GPU memory limitations.

4.4 Performance in downstream tasks

Considering our previous findings, we extend the evaluation of MAEST to a number of downstream datasets. We evaluate MAEST-10s, MAEST-20s, MAEST-30s, and a baseline consisting of embeddings from the penultimate layer of an EfficientNet-B0 (EffNet-B0) architecture [43] trained in the same 400 music style tags from Discogs20 following previous work [6]. Additionally, we report the performance of SOTA models from the literature considering approaches fully trained in the downstream tasks and based on embeddings plus shallow classifiers.

Table 4 shows the results of the different models in terms of ROC-AUC and mAP. We observe that all the MAEST models outperform the baseline in all tasks, confirming the superiority of the proposed approach. Additionally, we achieve a new SOTA for the MTGJ-Genre, MTGJ-Inst, and MSDc datasets, although other models remain superior in the rest of the datasets. Specifically, MuLan [7] obtains higher mAP in MTT, probably because it is

Model	5s	10s	20s	30s

Table 5. ROC-AUC and mAP scores obtained in the downstream tasks. Our baseline consists of an EffNet-B0 architecture trained in Discogs20. Additionally, we report the SOTA results distinguishing models with all parameters trained in the downstream tasks (fully trained) and models evaluated with shallow classifiers. For every task, we mark in bold the best score obtained by a MAEST model and highlight in grey models achieving better performance than the best open alternative. [†] Models not publicly available.

trained on a much larger corpus of 40 M tracks. In MTGJ-Moods, MTGJ-T50, MTT, and MSDs, Musicset-Sup, a model trained on a curated dataset of 1.8 M expert annotations, remains superior [5]. In both cases, the advantage is likely due to the superiority of the training task. Notably, none of these models is public, which makes MAEST the best open music embedding extractor available.

4.5 Faster feature extraction with inference patchout

Inferring with transformers is typically more computationally expensive than with CNNs. To speed up our models, we consider using two types of patchout at inference time: Time-wise, we keep one out of T spectrogram patches. Frequency-wise, we discard specific rows of patches. We experiment with temporal patchout using $T \in [2, 3, 5, 10]$ and frequency patchout of 3 and 4 patches corresponding to the first and the two last blocks, and the two first and two last blocks respectively. The embeddings obtained under different patchout settings are compared in the training and a downstream task following our downstream evaluation approach on the MTT dataset.

Figure 3 shows the mAP scores on the training and downstream tasks under different patchout settings. In the downstream task, even under strong patchout settings, MAEST-30s overcomes the throughput of standard CNN architectures by two to three times while keeping higher mAP. On the training task, this technique is not so effective because the classifier is frozen and cannot adapt to the effects of patchout, and also it operates on tokens from the last block, which requires more computations.

5. CONCLUSION

In this work, we demonstrate the benefits of pure-attention-based transformers for music representation learning and study how different design decisions affect the downstream performance. Our experiments show that the best embeddings come from a stack of features from the middle blocks

Figure 3. mAP scores against throughput for MAEST-30s under different amounts of frequency (F) and time (T) patchout. The radius is proportional to the parameter count and the inference is performed on the CPU.

of the transformer, initializing from weights pre-trained in audio event recognition provides the best performance, and that longer input segments correlate with better results. We evaluate our models in six popular music tagging datasets, and experiment with patchout at inference time, finding that it allows speeding up significantly the transformer while producing embeddings with better performance/speed trade-offs than our convolutional baselines. Finally, we present MAEST, a family of transformers for music style tagging and embedding extraction, which are publicly available and achieve SOTA performance among currently available music representation models.

In future work, we will combine our architecture with additional training objectives combining supervised and self-supervised paradigms. Additionally, we will experiment with longer input segments and teacher-student setups suitable for noisy datasets such as ours.

ABSTRACT

Deep learning systems have become popular for tackling a variety of music information retrieval tasks. However, these systems often require large amounts of labeled data for supervised training, which can be very costly to obtain. To alleviate this problem, recent papers on learning music audio representations employ alternative training strategies that utilize unannotated data. In this paper, we introduce a novel cross-version approach to audio representation learning that can be used with music datasets containing several versions (performances) of a musical work. Our method exploits the correspondences that exist between two versions of the same musical section. We evaluate our proposed cross-version approach qualitatively and quantitatively on complex orchestral music recordings and show that it can better capture aspects of instrumentation compared to techniques that do not use cross-version information.

1. INTRODUCTION

Deep learning (DL) has become a common tool for approaching diverse tasks in music information retrieval (MIR). These approaches usually follow a supervised learning scheme, where a neural network is trained on the annotations of some dataset. For many MIR tasks, however, such annotations are costly to obtain. Recent work has investigated alternatives that require little or no annotations and enable training on large, unannotated datasets.

For certain music genres, there are datasets that contain several versions (i. e., recorded performances) of a musical work. For example, the same classical symphony or concerto can be performed by different orchestras, and several commercial recordings are often available. On such datasets, automatic music synchronization techniques can be used to find alignments between different versions of a work, requiring minimal annotation effort [1, 2].

In this paper, we introduce a conceptually novel approach to audio representation learning that exploits cross-

Figure 1: Visualization of our cross-version approach to representation learning for orchestral music. An anchor (blue) excerpt is selected from a music recording. The positive (green) and negative (red) excerpts are chosen from a different version of the same musical piece. For this, an alignment between versions is needed (gray arrows).

version datasets, thus requiring only alignments between versions and no further human annotations. Our approach aims at learning embeddings of audio excerpts such that musically corresponding excerpts in different versions are mapped to close points in the embedding space (Figure 1).

There are several musical aspects that stay roughly constant across most versions, e. g., pitches, harmonies or rhythm. For orchestral music, aspects of instrumentation (i. e., active instruments or instrument families) are another such property. Instrumentation represents a challenging MIR scenario given the complexity of instrument taxonomies and the difficulty of annotating instrument activity in orchestral music. In our experiments on a dataset of complex orchestral music, we show qualitatively and quantitatively that—by utilizing the correspondences between different versions of a musical section—our proposed representation learning technique is better at capturing aspects of instrumentation and instrument texture compared to approaches that do not exploit cross-version information.

The remainder of the paper is structured as follows: Section 2 covers related work on music audio representation learning, cross-version analysis, and instrumentation in orchestral music. In Section 3, we introduce our proposed approach. In Section 4, we describe our experimental setup, including datasets, our model architecture, and baselines. Section 5 contains qualitative and quantitative results and Section 6 concludes the paper with a discussion of possible future work.

2. RELATED WORK

Several recent contributions have explored so-called self-supervised strategies for learning representations from unannotated music recordings. Often, in these studies, excerpts from a music recording that are in close proximity are considered as positive pairs (i. e., should be mapped to similar representations) whereas excerpts that are further apart (or from other recordings) are negative pairs (i. e., should be mapped to dissimilar representations). This idea is also illustrated in Figure 2. McCallum [3] originally considered this with the aim of learning features for music structure analysis. Wang et al. [4] had a similar use case but used a supervised learning approach. Several authors employed such a strategy for learning more general purpose representations [5–10], often applying additional augmentations. Apart from using temporal proximity, other papers on music representation learning exploit audio-visual or audio-text correspondences [11, 12], use classical features as training targets [13], exploit metadata [14], or investigate music generation models [15].

The approach proposed in this paper is conceptually different since we utilize cross-version datasets, rather than relying on temporal proximity alone. Such datasets contain several recorded versions of a musical work, which may vary in aspects related to musical interpretation, recording conditions, and timbral characteristics of the instruments used. These datasets have been exploited for expressive performance rendering [16] or improved harmonic analysis [17]. Cross-version datasets also allow for investigating model biases and overfitting effects in MIR models through different dataset splits [18]. To our knowledge, the only other work utilizing cross-version information for embedding learning is by Zalkow et al. [19], whose aim was to compress chromagram excerpts for efficient music retrieval. In contrast, we propose to learn representations based on spectrogram-like input features and investigate them for capturing instrument texture.

In the wider machine learning literature, representations are often learned by masking a part of an input and predicting the masked content [20, 21]. Other strategies utilize multi-modal datasets, e. g., containing text–image [22] or audio–text pairs [23].

Orchestral music has been explored in the context of source separation [24] or melody extraction [25]. The authors in [26] considered instrument family recognition for classical, monotimbral recordings using a supervised learning approach. Other recent papers on instrument activity detection in music recordings [27–29] have also con-

Figure 2: When forming triplets of audio excerpts, the anchor and positive/negative excerpts are chosen according to a maximum/minimum distance τ^p/τ^n .

sidered DL-based, supervised learning approaches, but not within orchestral scenarios.

3. CROSS-VERSION APPROACH TO AUDIO REPRESENTATION LEARNING

In this section, we formalize our proposed cross-version approach to representation learning. The key idea is to utilize correspondences between different versions (i. e., recorded performances played by different orchestras) of the same musical work. We aim to learn embeddings of audio excerpts such that the same musical section in different versions is represented by neighboring points in the embedding space and audio excerpts for unrelated musical sections are mapped to distant points in the embedding space. To this end, inspired by [19], we sample triplets of audio excerpts as in Figure 1, and apply a triplet loss for learning. Musical characteristics that stay roughly constant across different versions of an orchestral work include pitches and harmonies, as well as instrumentation. In later sections, we will analyze to what extent our approach captures pitches or aspects of instrumentation.

Single-Version Approach (SV). We begin by formalizing a common approach to music representation learning that only utilizes temporal proximity inside a single version, see also Section 2 and Figure 2. Let \mathcal{W} be a set of musical works and let V_w be the set of available versions for a work $w \in \mathcal{W}$. We first randomly select a work $w \in \mathcal{W}$ and some version of this work $v \in V_w$. Let T denote the length of v in seconds. We choose an anchor excerpt by uniformly sampling an anchor position $a \in [0, T]$ and extracting the excerpt \mathbf{x}^a of v that is centered around a . To obtain the positive and negative excerpts, we choose a position $p \in [0, T]$ for the positive excerpt \mathbf{x}^p of v such that $|a - p| \leq \tau^p$. Thus, the positive excerpt is in temporal proximity of the anchor excerpt—up to a threshold of τ^p seconds—and is likely to correspond to a musically similar section. In the same way, we choose a position $n \in [0, T]$ for the negative excerpt \mathbf{x}^n of v such that $|a - n| \geq \tau^n$. The negative excerpt is therefore a certain minimum distance of τ^n seconds away from the anchor position, likely corresponding to a musically dissimilar section.¹

¹ Due to repetitions and other structural similarities, there may in fact be some musically related sections that are far apart temporally. In the majority of cases, however, the assumption underlying positive and negative sampling will hold [3].

Embedding Learning. We obtain embeddings by passing these excerpts through a neural network (described in Section 4.2), i. e.:

$$\mathbf{Y} = (\mathbf{y}^a, \mathbf{y}^p, \mathbf{y}^n) = (f(\mathbf{x}^a), f(\mathbf{x}^p), f(\mathbf{x}^n)), \quad (1)$$

where f is a neural network that embeds an audio excerpt \mathbf{x} into an embedding vector \mathbf{y} . Using this triplet, we can apply a standard triplet loss [30] such as:

$$\mathcal{L}(\mathbf{Y}) = \max(0, \|\mathbf{y}^a - \mathbf{y}^p\|_2^2 - \|\mathbf{y}^a - \mathbf{y}^n\|_2^2 + \alpha), \quad (2)$$

where $\alpha \in \mathbb{R}_{\geq 0}$ describes the desired minimum margin between the distance of embeddings for anchor and positive versus the distance of embeddings for anchor and negative.

Cross-Version Approach (CV). For our proposed cross-version approach, we sample triplets in a different fashion. Since we utilize multiple versions per work, we now require $|V_w| \geq 2$. To form a triplet of excerpts, we randomly select some version $v_1 \in V_w$ of a work $w \in \mathcal{W}$. We then sample an anchor position $a_1 \in [0, T_1]$, where T_1 is the length of v_1 in seconds, and extract the corresponding excerpt \mathbf{x}^a of v_1 . To obtain the positive and negative excerpts, we randomly select another version $v_2 \in V_w \setminus \{v_1\}$ of w . As before, let T_2 denote the length of v_2 in seconds. We can find the position $a_2 \in [0, T_2]$ in v_2 corresponding to the same musical position as the anchor a_1 in v_1 using music alignment techniques. With this, we choose a position $p \in [0, T_2]$ for the positive excerpt \mathbf{x}^p of v_2 such that $|a_2 - p| \leq \tau^p$. Thus, the positive excerpt corresponds to the same musical section as the anchor, up to some tolerance of τ^p seconds (in addition to alignment inaccuracies). Similarly, we sample $n \in [0, T_2]$ (with $|a_2 - n| \geq \tau^n$) and extract \mathbf{x}^n . Note that only \mathbf{x}^a is an excerpt of the first version v_1 , whereas both \mathbf{x}^p and \mathbf{x}^n are excerpts of the second version v_2 . As before, we construct a triplet \mathbf{Y} using these excerpts and apply a standard triplet loss.

4. EXPERIMENTAL SETUP

4.1 Dataset and Splits

To show the potential of our representation learning technique, we construct a cross-version dataset of commercial symphonic and opera music recordings, illustrated in Table 1. Our dataset contains an act from an opera (the first act from Richard Wagner’s “Die Walküre”) as well as orchestral pieces by Beethoven, Dvorak and Tschaikowsky. Counting each movement as an individual work, the dataset contains eleven different works in total. We choose the first movement of the Beethoven Symphony, the fourth movement of the Dvorak Symphony and the third movement of the Tschaikowsky Concerto for testing. Since we do not have multiple opera acts that could be split into train and test, we choose an excerpt of the Wagner opera act (measures 697 to 955, corresponding to around twelve minutes), omit this excerpt during training, and use it for testing. We further ensure that the train and test set contain different versions. By splitting our dataset in this fashion,

Composer	Work	Versions	
		Num.	Avg. Duration
Wagner	Die Walküre, Act 1	8	1 h
Beethoven	Symph. 3, Mvmts. 1–4	6	45 min
Dvorak	Symph. 9, Mvmts. 1, 2, 4	6	40 min
Tschaikowsky	Violin Concerto, Mvmts. 1–3	6	35 min
Total duration		20 h	

Table 1: Our cross-version dataset containing several commercial recordings of different orchestral and opera compositions.

we aim to avoid overfitting to specific musical compositions or recording conditions (the latter is also referred to as “album effect” [31]).

For the cross-version approach CV, we obtain an alignment between versions of the same work using state-of-the-art music synchronization techniques involving chroma onset features and multi-scale alignment [2]. For some experiments, we also require pitch-class and instrument activity annotations for our dataset. To this end, we manually encoded a score representation of “Die Walküre” and obtained further scores from the Mutopia project.² Again, we use music synchronization techniques to align score to audio and create the annotations.

4.2 Model

We implement all representation learning approaches using a convolutional neural network that takes a harmonic CQT representation (HCQT, [32]) of an audio excerpt as input and outputs a corresponding embedding vector. The HCQT input consists of 201 frames (at a frame rate of 43 Hz, i. e., roughly 4.7 seconds), three bins per semitone from C1 to B7 (leading to 252 bins), and five harmonics (with frequency multiples of [0.5, 1, 2, 3, 4]).

The model architecture is adapted from [33] and receives an HCQT input patch, processes it through several convolution and max-pooling layers, and outputs a single ℓ_2 -normalized vector (length 128) per input. We take this output as the embedding vector for the center frame of the input patch. In total, the architecture has roughly 1.5 million learnable parameters. We train our network for 200 epochs (with 16 000 triples randomly sampled per epoch) using the Adam optimizer with a learning rate of 0.002. In the interest of reproducibility, we release code and trained models for our approach.³

In line with previous studies on audio representation learning [5–7], we apply a number of augmentations to excerpts during training, including time scaling, pitch shifting, random masking, adding noise and applying random equalization. For all experiments, we set $\tau^p = 0.2$ s. With this, the maximal distance between anchor and positive excerpt is in the same order of magnitude as the typical alignment inaccuracy between versions. We further set

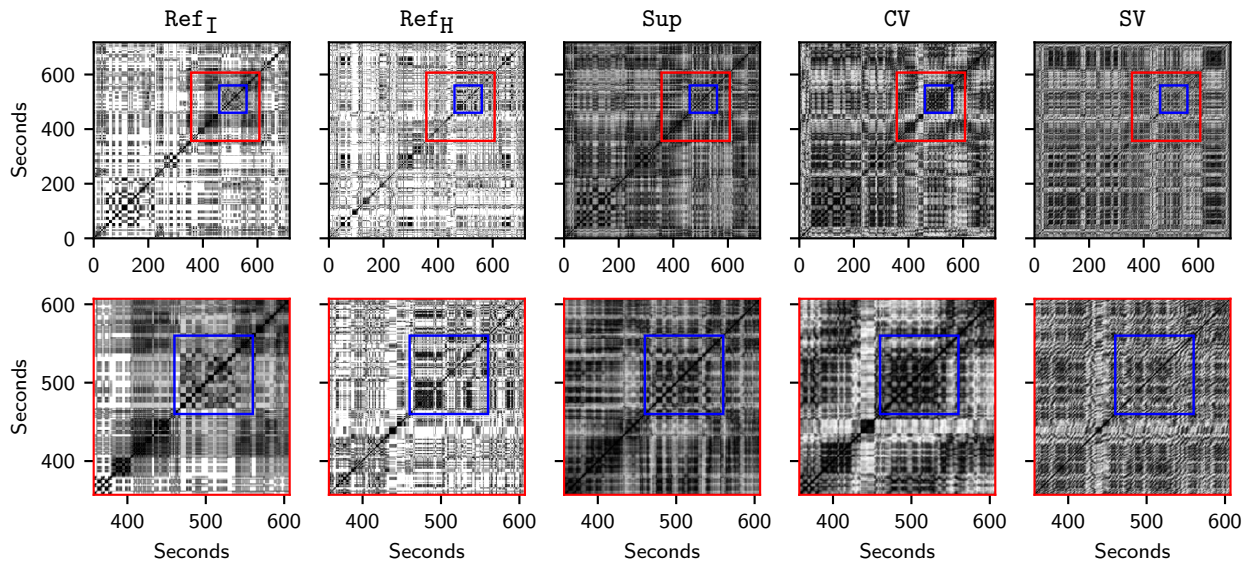

Figure 3: Self-similarity matrices constructed from instrument annotations (Ref_I) and pitch-class annotations (Ref_H), or obtained with a supervised learning system (Sup), the proposed cross-version approach (CV), and a baseline that does not incorporate cross-version information (SV). The lower row shows the sections highlighted in red from above.

$\tau^n = 10.0\text{s}$ and $\alpha = 1.0$. We found that results are stable for a broad range of settings of these parameters.

4.3 Baselines

To investigate the musical properties captured by the representation learning approaches CV and SV , we compare them to several optimistic baselines: First, we extract traditional music audio features. We use mel-frequency cepstral coefficients (MFCC), which are known to capture aspects of instrumentation [34], and Chroma features, which contain the dominant pitch-classes in the recording. Here, our goal is not to outperform MFCC or Chroma , but to compare them to our learned representations. If our learning approaches capture instrumentation, we expect them to behave similar to MFCC s. Likewise, in case they contain pitch-class information, we expect them to perform like Chroma features.

Second, we consider a supervised learning approach Sup where we train a model on instrument activity annotations and use its hidden representations as features. For this, we utilize the same model architecture as for CV and SV and only add a final dense layer with a number of outputs equal to the number of instruments to detect. Rather than using the triplet loss from Section 3, we train this approach by applying a sigmoid activation and binary cross-entropy loss. Note that in contrast to CV and SV , the Sup approach requires instrument activity annotations for the recordings in the training set.

5. RESULTS

5.1 Feature Analysis using Self-Similarity

In order to visualize and compare the representations learned by different techniques, we employ self-similarity

matrices. Such matrices are commonly used for music structure analysis and allow for visualizing structures based on repetition and homogeneity in feature sequences [1]. Here, we use them to analyze our learned representations without the need for additional fine-tuning. This also allows us to directly compare approaches trained with a fixed instrument vocabulary (Sup) to others that are not informed about instruments. We provide an alternative evaluation in Section 5.4.

Given a sequence $X = (x_1, \dots, x_N)$ of (learned) representations of N audio frames, we construct the corresponding self-similarity matrix $S \in \mathbb{R}^{N \times N}$ as follows. We first normalize all representations with respect to the ℓ_2 -norm, yielding $\tilde{X} = (\tilde{x}_1, \dots, \tilde{x}_N)$. We then compute $S(n, m) := \langle \tilde{x}_n, \tilde{x}_m \rangle$ for $n, m \in [1 : N]$. Thus, S contains the cosine similarities between elements of X , and all its entries lie in the interval $[-1, 1]$. By definition, all entries on the diagonal of S are equal to 1. In addition, repeated subsequences appear as path-like structures and homogeneous segments appear as block-like structures, see also [1].

We compare the self-similarity matrices obtained from learned representations to matrices created using reference annotations. First, we represent an instrument activity annotation as a sequence of multi-hot binary vectors (indicating the presence of instruments in different frames). By normalizing and computing the dot product as before, we obtain a matrix corresponding to instrument texture, where blocks indicate segments with similar instrumentation. We will refer to this matrix using the shorthand Ref_I . For example, the start of the middle measure in Figure 1 would be encoded as a vector $(1, 1, 1)^\top$, i.e., all instruments are active, and the end of that measure would be encoded as $(1, 1, 0)^\top$, i.e., only horn and soprano are active. After normalization, the dot product of these vectors is 0.82,

indicating similar instrumentation. Analogously, we construct another matrix Ref_H from a sequence of pitch-class annotations. This matrix captures regions with similar harmonies and pitches.

5.2 Qualitative Results

Figure 3 shows several self-similarity matrices obtained through reference annotations or by different representation learning approaches. The excerpt shown in the upper row is the test excerpt from “Die Walküre” (similar results are obtained on other inputs). The lower row shows magnified sections from above. Darker color indicates higher similarity.

In the Ref_I matrix, arising from instrument annotations as explained in Section 5.1, one can observe many block and checkerboard-like structures. For example, from seconds 460 to 560, different combinations of woodwind instruments are playing together, creating block and checkerboard-like patterns (highlighted in blue). White areas indicate $S(n, m) = 0$, i.e., no common instruments are playing. The matrix Ref_H , on the other hand, indicates harmonic similarities which are mostly distinct from the instrument similarities in Ref_I .

For the Sup system, many of the patterns in Ref_I are replicated, albeit with less detail. This is expected, since this system has been trained on the same kind of annotations that have been used to create Ref_I . Interestingly, many of the patterns present in the Ref_I and Sup matrices also appear for the proposed approach CV , which has not been trained using instrument annotations. In particular, the checkerboard pattern starting at second 460 is captured by CV , as well as many block structures.

There are fewer similarities between CV and Ref_H , indicating that the CV representations are more likely to capture instrumentation rather than pitch-class content. This behavior is encouraged by our augmentation strategy, where we randomly pitch-shift the anchor, positive and negative excerpts.

The matrix obtained through the SV approach is blurry and, unlike the results for CV , fails to capture many of the checkerboard-like patterns present in Ref_I . The example suggests that exploiting cross-version information during training is important for capturing aspects of instrumentation in learned representations.

5.3 Quantitative Results

In order to quantify the correlation between our learned representations and instrument texture, we now apply a procedure for detecting the boundaries of block-like structures in self-similarity matrices. We then compare block boundaries estimated on Ref_I with boundaries from all other matrices. Such procedures are often used in the context of music structure analysis [1, 35].

To detect block boundaries, we first correlate a self-similarity matrix with a checkerboard kernel along the main diagonal, as proposed in [35]. From this, we obtain a novelty curve. We then apply a peak picking procedure using local thresholding on this novelty curve, yield-

Figure 4: Results for different representation learning approaches when comparing estimated structure boundaries to boundaries from Ref_I .

Figure 5: Results for comparing with Ref_H .

ing sparse positions of detected block structures. We do this for all approaches and reference matrices. We finally compare—with a tolerance of up to three seconds—the detected boundaries for all approaches to those of Ref_I , yielding a boundary F-measure. By adjusting the size of the checkerboard kernel in this procedure, we can identify changes of instrument texture on short or larger time scales. For more details on the boundary detection, peak picking, and evaluation procedure, we refer to [1].

Figure 4 shows the results of our quantitative evaluation for different sizes of the checkerboard kernel. The F-measures given are averaged over all recordings in the test dataset. We observe that the supervised approach is best at capturing instrument texture (as encoded by Ref_I) compared to all others, with the highest F-measure of 0.77 for a kernel of eight seconds. CV and MFCC perform roughly on par. This is surprising, since CV is trained without any instrument annotations, while MFCC is known to capture instrumentation. Results for SV deteriorate with larger kernel sizes, dropping to as low as 0.28 F-measure for a kernel of 48 seconds. The proposed approach CV is better at capturing instrument texture than the alternative SV that does not utilize cross-version information.

To examine whether our representations capture information related with harmonies and pitches played, we perform the same evaluation procedure with boundaries from Ref_H (see Figure 5). We obtain low F-measures for both CV and SV (dropping below 0.4 for kernel sizes above 20 seconds for both approaches). In particular, while we observe an advantage of CV over SV for capturing instrumentation, there is no such advantage with regard to

Scenario	AP	AUC	Micro Avg.		Macro Avg.	
			F1	S	F1	S
MFCC	0.777	0.780	0.600	0.890	0.450	0.847
SV	0.708	0.735	0.590	0.871	0.407	0.820
CV	0.753	0.795	0.657	0.872	0.514	0.835
Sup	0.838	0.881	0.772	0.894	0.714	0.874

Table 2: Results for different representation learning approaches when performing instrument classification.

pitch-classes. Additionally, standard Chroma features are clearly superior at capturing the structures in Ref_H . We conclude that the representations learned by our proposed approach CV indeed contain information about instrument texture rather than pitch-classes and harmonies.

5.4 Feature Analysis Using Classification

To gain further insights into the information captured by our learned representations, we also perform an indirect evaluation as typically done in representation learning. Previous studies often rely on training small classifiers on top of learned representations to investigate their usefulness for different downstream tasks [5, 15]. In this section, we complement our self-similarity-based analysis with such a classification-based evaluation strategy.

To this end, we pass individual representation vectors through a small network of dense layers with 128, 64, and 32 hidden units followed by leaky ReLU activations, respectively. The final layer produces outputs for every instrument annotated in our dataset, followed by a sigmoid activation. For each representation learning technique, we train and evaluate such a network using the dataset split as described in Section 4.1. Concretely, we minimize the mean binary cross-entropy loss over all instrument classes on the training set, using stochastic gradient descent with a learning rate of 10^{-4} for 10 epochs. We finally evaluate the classification results on the test set using standard metrics, including ranking-based average precision (AP), mean area under the ROC curves (AUC), F-measure (F1), and specificity (S). For F1 and S, we threshold the predicted probabilities at 0.5 and compute both micro and macro averages of the evaluation scores, where the macro average is not affected by imbalance among instrument classes.

The results of this experiment are shown in Table 2. We observe similar trends as in our self-similarity-based evaluation. As expected, the supervised baseline again yields best results. Our proposed cross-version approach CV clearly outperforms the traditional SV across all metrics (e.g., AP = 0.753 as opposed to 0.708 for SV). Furthermore, CV even improves upon the optimistic MFCC baseline in terms of AUC and F-measure (e.g., micro F1 = 0.657 instead of 0.600 for MFCC). Finally, SV performs worse than MFCC. Overall, the representations learned by our proposed approach CV are more effective for instrument classification compared to the standard SV approach that does not utilize cross-version information.

Scenario	AP	AUC	Micro Avg.		Macro Avg.	
			F1	S	F1	S
Chroma	0.802	0.854	0.591	0.964	0.586	0.963
SV	0.427	0.568	0.001	1.000	0.001	1.000
CV	0.430	0.584	0.021	0.994	0.018	0.994
Sup	0.457	0.612	0.137	0.959	0.122	0.958

Table 3: Results for pitch-class classification using the learned representations.

We repeat this experiment using pitch-classes as the classification targets instead of instruments. Table 3 shows the results of the modified experiment, which are inline with our conclusions from previous sections. Standard Chroma features strongly outperform all learned representations on this task. We conclude that our proposed approach captures instrumentation rather than pitches.

6. CONCLUSION

In this paper, we described a novel audio representation learning approach for cross-version music data and investigated its application to orchestral music. Our approach utilizes the correspondences between different versions of the same musical work. We showed qualitatively and quantitatively that the representations learned by our approach capture aspects of instrumentation. We outperform a standard training strategy that relies on temporal proximity alone.

Our approach can be applied to any kind of cross-version music dataset where alignments between versions can be obtained using standard music synchronization techniques. Future work may apply our approach to other musical scenarios and larger datasets, explore more complex feature extraction networks, investigate alternatives to our triplet loss formulation, or apply the learned representations in the context of different downstream tasks (such as structure analysis). One may also study the impact of design choices such as τ^P and τ^H , the pitch shifting augmentation, or the number of versions used for training.

{t.nakano, m.goto}@aist.go.jp

ABSTRACT

This paper proposes a new music source separation (MSS) model based on an architecture with MLP-Mixer that leverages multilayer perceptrons (MLPs). Most of the recent MSS techniques are based on architectures with CNNs, RNNs, and attention-based transformers that take waveforms or complex spectrograms or both as inputs. For the growth of the research field, we believe it is important to study not only the current established methodologies but also diverse perspectives. Therefore, since the MLP-Mixer-based architecture has been reported to perform as well as or better than architectures with CNNs and transformers in the computer vision field despite the MLP's simple computation, we report a way to effectively apply such an architecture to MSS as a reusable insight. In this paper we propose a model called TFC-MLP, which is a variant of the MLP-Mixer architecture that preserves time-frequency positional relationships and mixes time, frequency, and channel dimensions separately, using complex spectrograms as input. The TFC-MLP was evaluated with source-to-distortion ratio (SDR) using the MUSDB18-HQ dataset. Experimental results showed that the proposed model can achieve competitive SDRs when compared with state-of-the-art MSS models.

1. INTRODUCTION

Music source separation (MSS) is the task of obtaining individual source signals — such as vocals, drums, and bass — from real music acoustic signals. This is an essential technique for various applications, including music information retrieval and music listening interfaces, where the characteristics of individual sound sources are analyzed and utilized. MSS has actually been used to add effects to individual source (instrument) sounds for music appreciation [1] and adjust their volume [1–4], to improve the cochlear implant user's musical experience by adjusting the volume of preferred instruments [5], to synthesize singing voices [6], to acquire feature expressions of singing voices [7], to identify singers [8], to achieve audio-to-lyrics alignment [9,10], to create music mashups [11], to

separate sources for music education [12], and to estimate compatibility between vocals and accompaniment [13].

Currently, the mainstream approaches for MSS use deep neural networks [14, 15], and their performance is improving year by year. For their performance comparison to measure the improvement, MUSDB18 [16] had been used as the common standard data set for the four target sound sources (Vocals, Drums, Bass, and Other). Then MUSDB18-HQ [17], an extended frequency bandwidth version of MUSDB18, was released and has been used for recent evaluations.

As for the current state-of-the-art MSS models, the top-ranked models [18, 19] in the Music Demixing (MDX) Challenge 2021 [20] and the two models presented in two arXiv papers in 2022 [21, 22] have an average SDR (source-to-distortion ratio) over 7 dB for the four sources when using MUSDB18-HQ as training, validation, and test data. These models are explained in the next section.

Such deep MSS models can be classified in terms of the type of input and output used for separation and the type of architecture. The input and output of the models are selected from waveforms, amplitude spectrograms, complex spectrograms, phase spectrograms, etc. The architecture of the models is mainly selected from ResNet, DenseNet, U-Net, and Transformer and is used with layers of Convolutional Neural Networks (CNNs) or Recurrent Neural Networks (RNNs). Simpler architectures based on multilayer perceptrons (MLPs), however, have not been used in state-of-the-art MSS models.

Meanwhile, in the field of computer vision, high-performance architectures based on MLPs have recently been proposed and reported to perform as well as or better than architectures using CNNs or transformers [23, 24]. In addition, those simpler MLP-centric architectures have also been applied in audio-related research, with cases of singing voice synthesis [25] and speech enhancement [26]. However, such MLP-centric architectures have not been applied in the MSS domain, though fully connected layers and MLPs have been used for linear transformation such as embedding and expansion. Since we believe that new perspectives, in addition to the development of established methodologies, are important for the advancement of the research field, this paper investigates how MLP-based architectures can be effectively leveraged for MSS.

As such a modern MLP-centric high-performance architecture, Tolstikhin *et al.* proposed the *MLP-Mixer* [23] that applies MLPs to a $T_p \times C_p$ matrix to estimate the

Table 1. SDRs in MUSDB18-HQ for the state-of-the-art models and our proposed TFC-MLP. The ‘‘Avg.’’ column means the average of the SDR results for the four sources. The ‘‘Per-source’’ column means that the per-source adjustment/tuning has been implemented. The ‘‘Extra’’ column indicates the number of songs added as extra training data, and † means that only mixed sounds were added. Models with ‘‘*’’ are evaluated in MUSDB18 [16], and SDRs for models with ‘‘**’’ are recalculated in MUSDB18-HQ using the pretrained model. A **bold** font indicates the maximum value at each source.

class of an image. The matrix is obtained by dividing the image into patches and embedding each patch into a T_p -dimensional vector, which is called a token, and the number of tokens is the channel dimension C_p . Here, a *token-mixing MLP*, a full connection within an individual token, and a *channel-mixing MLP*, a full connection between tokens (*i.e.*, channel direction), are applied alternately. Given sufficient training data, MLP-Mixer was shown to perform as well as or better than CNNs or transformers.

By extending this MLP-Mixer, for the image reconstruction task, Mansour *et al.* proposed the *Image-to-Image Mixer* [24] that performs better when trained with fewer images than the original MLP-Mixer. The Image-to-Image Mixer transforms images as a 3D tensor ($W \times H \times C$) instead of the 2D matrix ($T_p \times C_p$) and preserves the relative positions of patches to induce a bias towards natural images. In other words, the token-mixing MLP and the channel-mixing MLP are split into three processes of *width-mixing MLP*, *height-mixing MLP* and *channel-mixing MLP*. This also keeps the total number of trainable parameters low, since the size of each dimension of the 2D matrix (*i.e.*, T_p and C_p) obtained by transformation from the 3D tensor is relatively large.

In investigating such MLP-based architectures in the MSS domain, we decided to use a complex spectrogram, which is a reasonable representation for MSS, as the input. Since the size of its complex time-frequency representation is larger than the size of typical images in the computer vision domain, we apply the memory-efficient Image-to-Image Mixer to MSS and report its experimental results.

2. RELATED WORK

As described in Section 1, the state-of-the-art models [18, 19, 21, 22] in the MSS study show that the average SDR score for the four source separations exceeds 7 dB in the

evaluation using MUSDB18-HQ. The SDRs for each of the four sources based on these models are shown in Table 1.

KUIELab-MDX-Net was proposed by Kim *et al.* [18]. It is an architecture that combines an extended version of TFC-TDF-U-Net [27], which separates in the time-frequency domain (*i.e.*, complex spectrogram), and Demucs [28], which separates in the time domain (*i.e.*, waveform). Each source signal i separated by those sub-networks is mixed using source-dependent weights w_i . Specifically, w_i was set to 0.5, 0.5, 0.7, and 0.9 for bass, drums, other, and vocals in MDX Challenge 2021 [20]¹. In KUIELab-MDX-Net, to improve performance, a mechanism called *Mixer* was used to remix the music acoustic signal with the separated signal by using the 1x1 convolution, and different FFT frame sizes were used for each sound source by applying a frequency cut-off trick [20].

TFC-TDF-U-Net used in the KUIELab-MDX-Net is a variant of U-Net architecture that combines the time-frequency convolutions (TFC) block with the time-distributed fully-connected networks (TDF) block. Here, TFC is a dense block of 2D CNNs, and TDF is a block that extracts nonlocal features along the frequency axis, such as correlations between harmonics, by fully connecting the entire frequency range of a single frame of the spectrogram. TDF was inspired by the Frequency Transformation Block (FTB) proposed by Yin *et al.* [29] and was introduced specifically to help separate singing voices [27]. As the other component of KUIELab-MDX-Net, Demucs [28] is a U-Net encoder/decoder structure with waveforms as input and BiLSTM applied to the innermost layer between the encoder and decoder to provide long-range context.

Hybrid Demucs was proposed by Défossez *et al.* [19]. It is a bi-U-Net encoder-decoder model that combines 1D convolution in the time domain and along the frequency

¹ https://github.com/kuielab/mdx-net/blob/Leaderboard_A/README_SUBMISSION.md

axis in the complex time-frequency domain. BiLSTM and local attention were used in the innermost layer, and residual branches, group normalization [30] and GELU were introduced. In addition, better generalization and stability were achieved by penalizing the largest singular value in each layer [31], and overall performance was improved by bagging multiple models.

Band-Split RNN was proposed by Luo *et al.* [21]. It is a state-of-the-art spectrogram-based model that uses complex spectrograms as input and output. By splitting the complex spectrogram input into subbands specifically designed for each sound source, the intrinsic properties and patterns of each source signal are utilized. For a 3D tensor representing the time dimension, frequency dimension, and subband dimension, similar to the Dual-path RNN [32], a sequence-level RNN is first applied across the time dimension, then a band-level RNN is applied across the band dimension. In fact, for Vocals, results showed that the modified utterance-level SDR can be improved by more than 2 dB by setting the bandwidth appropriately. In addition, semi-supervised fine tuning was performed by using pseudo-targets separated from the mixtures using a pre-training model in order to make effective use of songs with only mixtures (1750 songs). The Band-Split RNN currently achieves a state-of-the-art SDR of 8.24 dB in the evaluation using only MUSDB18-HQ as training data.

Hybrid Transformer Demucs was proposed by Rouard *et al.* [22]. The innermost layer, called the bottleneck, of the Hybrid Demucs [19] is replaced by a cross-domain transformer encoder (*i.e.*, time domain and time-frequency domain) that uses self-attention within each domain and cross-attention across domains. Compared to the Hybrid Demucs, the performance is lower when trained with MUSDB18-HQ only, but the SDR was 0.46 dB better when 800 additional training songs were used. Sparse HT Demucs [22], which extended the receptive field using a sparse attention kernel, achieved a state-of-the-art result of 9.27 dB SDR by fine-tuning for each source.

As described above, the MLP-centric architecture has never been applied in state-of-the-art MSS models where the average SDR exceeds 7 dB on MUSDB18-HQ.

3. TFC-MLP

This paper proposes *Time-Frequency-Channel-MLP (TFC-MLP)*, which is a model that leverages the Image-to-Image Mixer architecture [24] to separate music sources using a complex spectrogram as input. This is realized by replacing the height, width, and color (RGB) in the image with the time, frequency, and channel in the complex spectrogram, respectively. In other words, TFC-MLP has a structure that alternates mixing in the time, frequency, and channel dimensions. In this way, we expect to be able to take into account the nonlocal structure. Especially with respect to the frequency dimension, we expect to extract nonlocal relationships along the frequency axis, such as harmonic structures, by connecting the entire frequency range of the spectrogram, as in the FTB [29] and the TDF [27].

The process of the TFC-MLP model is shown in Fig-

ure 1. The complex spectrogram $\mathbf{X}_{\text{STFT}} \in \mathbb{C}^{F_0 \times T_0 \times 2}$ of a 2-channel (stereo) mixture signal is first converted to a 4-channel 3D tensor $\mathbf{X}_{\text{CaC}} \in \mathbb{R}^{F_0 \times T_0 \times 4}$ with the real and imaginary parts represented as channels, a.k.a. complex-as-channels (CaC) [27]. Here T_0 is a fixed length. Then, as with the MLP-Mixer and Image-to-Image Mixer as well as the Vision Transformer (ViT) [33], the patch embedding is first performed using C linear weights of size $P_T \times P_F \times 4$ (Figure 2). This reduces the frequency dimension F_0 to F_0/P_F and the time dimension T_0 to T_0/P_T , which reduces the matrix size and memory consumption in the following frequency-mixing MLP and time-mixing MLP. To compensate for the information loss due to decreasing the resolution in the time-frequency plane and the loss of continuity in the time-frequency direction, we increase the dimension in the channel direction.

The embedded tensor then passes through N MLP-Mixer layers. As shown in Figure 3, each MLP-Mixer layer mixes the tensor with the frequency dimension, then the time dimension, and finally the channel dimension. Such mixing is passed through an MLP consisting of a linear layer, a GELU nonlinearity, and another linear layer, and output without changing the tensor size. The dimension of the tensor at the input/output layer of the MLP is kept constant, and the dimension at the hidden layer is adjusted by multiplying it by a factor f depending on the input dimension. Skip connections and channel layer normalization have also been added to help with the optimization. Here, following the implementation of the Image-to-Image Mixer [24], skip connections are placed before and after the two mixing steps of frequency and time (“Type A”). In addition to that, a version with skip connection and layer normalization added before time-mixing MLP was also implemented (“Type B”). After mixing the time, frequency, and channel dimensions, patch expansion is used to restore the number of time and frequency dimensions for inverse transformation into waveforms and also to match the channel dimension to the number of separated sources.

4. EVALUATION

The proposed TFC-MLP was evaluated using the MUSDB18-HQ dataset [17]. 86 songs were used as training data, 14 songs as validation data, and 50 songs as test data. The music acoustic signals were stereo with a sampling frequency of 44.1 kHz, and four sound sources – “Vocals,” “Drums,” “Bass,” and “Other” – were used for separation. Separation performance was evaluated by calculating SDR using the *museval* Python package². As in most previous studies ([19, 21], etc.), the SDR of each source was calculated by taking the median values over all 1-second segments of each song to obtain the SDR of the track and then taking the median of all tracks.

4.1 Experimental setting

The proposed model was optimized using Adam [34] for the L1 loss between its separated signals and the ground-

²<https://github.com/sigsep/sigsep-mus-eval>

Figure 1. Overview of the TFC-MLP model.

Figure 2. Patch embedding. After dividing the CaC tensor of size $F_0 \times T_0 \times 4$ into patches of size $P_F \times P_T \times 4$, each patch was linearly transformed into $1 \times 1 \times C$ to obtain a 3D tensor of size $F_0/P_F \times T_0/P_T \times C$ (i.e., $F \times T \times C$). This can be implemented as a nonoverlapping CNN.

truth source signals. The Adam parameters were set as no weight decay, learning rate 0.0003, $\beta_1 = 0.9$, and $\beta_2 = 0.999$. The waveform for calculating the CaC spectrogram to be input to the model was normalized so that the mean amplitude of the music acoustic signal was 0 and the standard deviation was 1. The training was distributed across multiple GPUs, with a batch size of 4 on each GPU. In training, we used data augmentation techniques [19], including pitch shift and tempo stretch, randomly swapping channels, random sign flip, random scaling of amplitude, and remixing of stems within one batch.

4.2 Base hyperparameters

Due to the many hyperparameters required for the building of the proposed TFC-MLP model, hyperparameters related to the short-time Fourier transform (STFT) were first determined through preliminary experiments. To obtain \mathbf{X}_{CaC} , the STFT frame size (i.e., FFT size) was chosen as 4096, which had the highest SDR when compared among 512, 1024, 2048, and 4096. As Kim *et al.* [18] also stated, the performance tended to increase with larger FFT size. Therefore the frequency dimension F_0 is 2048. Related to the FFT size, the STFT hop size was investigated among 128, 256, 512, and 1024, and 1024 was selected. Also related to the FFT size and STFT hop size, the number of time frames T_0 in the complex spectrogram was selected as 128 from 32, 64, 128, 256, and 512.

The number of time frames T_0 of 128 based on an FFT size of 4096 and an STFT hop size of 1024 is input to the model, thus the waveform size required for this is equal to $T_w = 1024 \times 128 - 1$ (about 3 seconds). Therefore, it is necessary to train the model while cutting out an ap-

Figure 3. The Mixer layer contains one frequency-mixing MLP, one time-mixing MLP, and one channel-mixing MLP. Before each MLP, a transposition is performed to apply the MLP to the frequency dimension F , the time dimension T , and the channel dimension C . Transposition is also performed before every layer normalization to normalize along the channel dimension C .

proximately 3-second segment of the waveform, and the shift size of 16384 (about 0.37 seconds) was used. Luo *et al.* [21] found that the shorter the shift, the better the modified utterance-level SDR, and they used 0.5 seconds. The above 16384 is short enough compared to 0.5 seconds and can be considered sufficient in this study.

As hyperparameters regarding the model, the dimensions C of the patch embedding were investigated by us. Specifically, 128 and 256 were investigated and 256 was selected. As hyperparameters related to the Mixer layer, 8 and 16 were investigated as the number of layers N and 16 was selected, and the parameter f for adjusting the number of dimensions of the hidden layer of each MLP was selected as 4 from 1, 2, and 4. Dropout in the MLP [25] and skip connections before and after the Mixer layer were also investigated, but they have not yielded better results.

4.3 Experiment

Using the set of hyperparameters determined in Section 4.2 as a basis, we report the SDR scores obtained under the following various conditions for the other hyperparameters.

- Investigation of the results of complex spectrogram loss [21].

Table 2. SDRs for different hyperparameters of the proposed model. The “Seed” column indicates random seeds. In the “Loss” column, “W” indicates that only waveform loss was used, and “W+S” indicates that complex spectral loss was added. The “Epoch” column indicates the number of epochs with the smallest validation loss and the specified number of epochs, where “*” means that validation loss was not considered. Note that “†” means the cases where the number of epochs with the smallest validation loss did not change when training beyond 200 epochs (*i.e.*, the same model was used for the evaluation). A **bold** font indicates the maximum value at each source, both without and with extra training songs.

TFC-MLP					Test SDR in dB					
Type	Seed	(P_F, P_T)	Loss	Epoch	Extra	Avg.	Vocals	Drums	Bass	Other
A	seed 1	(4, 4)	W	134† / 200		7.30	8.91	7.18	6.96	6.14
A	seed 2	(4, 4)	W	166† / 200		7.26	8.84	7.07	6.89	6.22
A	seed 3	(4, 4)	W	109 / 200		6.97	8.32	6.98	6.57	5.99
A	seed 3	(4, 4)	W	283 / 300		6.93	8.49	6.80	6.55	5.87
B	seed 1	(4, 4)	W	190 / 200		7.17	8.92	6.95	6.83	5.96
B	seed 2	(4, 4)	W	191 / 200		7.02	8.59	6.78	6.68	6.01
B	seed 3	(4, 4)	W	157 / 200		6.95	8.56	6.58	6.73	5.91
A	seed 1	(2, 2)	W	189 / 200		7.13	8.58	7.02	6.99	5.91
A	seed 1	(1, 1)	W	175 / 200		6.38	7.40	6.33	6.49	5.30
A	seed 1	(4, 4)	W+S	197 / 200		6.83	8.76	6.60	6.14	5.83
A	seed 1	(4, 4)	W+S	253 / 300		6.72	8.39	6.69	6.02	5.79
A	seed 1	(4, 4)	W	142 / 200	120	7.71	9.42	7.66	7.37	6.39
A	seed 1	(4, 4)	W	200* / 200	120	7.78	9.68	7.75	7.23	6.46

Table 3. The number of model parameters and the average Real Time Factor (RTF) value. The Hybrid Transformer Demucs is denoted as “HT Demucs”. Column “GPU” shows the RTF with a single GPU, and column “CPU” shows the RTF under the condition without a GPU.

Model	GPU	CPU	Params.
Hybrid Demucs	0.14	1.87	83.9 M
HT Demucs	0.17	2.55	26.9 M
TFC-MLP	0.51	12.28	43.2 M

- Investigation of patch size (P_F, P_T) between (4, 4), (2, 2), and (1, 1), using (4, 4) as the basis, halving the FFT size and time dimension T for (2, 2), and halving it further for (1, 1). For (1, 1), the STFT hop size was set to 512 since the FFT size is 1024.
- The number of epochs for training was set to 200 or 300, and models with the smallest validation loss within each epoch-condition were evaluated.
- The results of adding 120 full-length songs (sung in English) to the training data were evaluated.
- For the basic parameter condition, we trained three times with different random seeds.

In the test phase, the model with the smallest validation loss was used for evaluation in each training condition. The signal separated by the proposed model was divided into segments of fixed length T_w with shift width $T_w/4$, which were weighted overlap-added to obtain the final signal. In addition, the *shift trick* [28] was performed 10 times.

4.4 Results and discussions

In addition to the evaluation of SDRs using the MUSDB18-HQ test set, the number of parameters and the

Real Time Factor (RTF) will also be discussed, as file size and the time required for separation may be important in some situations depending on how the MSS model is used.

4.4.1 SDRs

The experimental results are shown in Table 2. The highest SDR score, up to 7.30 dB, was obtained for the Type A model using the patch size of (4, 4) and waveform L1 loss in addition to the base hyperparameters. This was not significantly higher than the state-of-the-art values shown in Table 1, but close performance was achieved.

Focusing on the results for each source with respect to our TFC-MLP, as shown in Table 1, the SDRs for Vocals and Other were 8.91 dB and 6.14 dB, respectively, which were higher than the 8.35 dB and 5.65 dB SDRs for the Hybrid Demucs and the 7.93 dB and 5.72 dB SDRs for the Hybrid Transformer Demucs. This model’s SDR score for Other also exceeded the one obtained using KUIELab-MDX-Net, 5.90. Here, in comparison to the KUIELab-MDX-Net results without waveform information (*i.e.*, excluding processing by Demucs), it is possible that similar or better performance was obtained for Drums and Vocals, although an exact comparison cannot be made because the test data is different (*i.e.*, MUSDB18 was used). In comparison to the Band-Split RNN results, TFC-MLP could not yield a higher SDR for all sound sources. However, the current TFC-MLP does not include a source-specific framework, so addressing this issue is a future challenge.

As for the patch size, the FFT size and other conditions were different due to memory capacity. Therefore, although exact comparisons are not possible, the best results were obtained for (4, 4) in the current results. However, additional study is needed for (2, 2), since it gave results similar to those given by (4, 4). As for complex spectrogram

loss, its SDR was slightly lower than that of all conditions using only waveform loss. Not only comparisons using the real and imaginary parts of the complex numbers, but also losses based on amplitude and phase could be considered.

We also showed that the performance of the models was further improved by using additional training data. As shown in Table 1, compared to the current world’s best model Sparse HT Demucs with 800 songs added as the training data, we obtained competitive results with an SDR of 9.68 dB for the Vocals and 6.46 dB for the Others.

4.4.2 RTF and the number of parameters

As comparison, models were trained for each of the Hybrid Demucs and Hybrid Transformer Demucs. Based on the published source codes, a model parameter setting “80a68df8”³ was used for Hybrid Demucs, and the default parameter setting was used for Hybrid Transformer Demucs. The same implementation for audio synthesis was used for all TFC-MLP, Hybrid Demucs, and Hybrid Transformer Demucs. We used the 50 songs in the MUSDB18-HQ test set to obtain the average of their RTFs.

Table 3 shows the results. The RTF values of TFC-MLP were slower than the other two models. TFC-MLP had an RTF lower than 1.0 (faster than real time) when a GPU was used, but the computation time was long without GPU. This could be due to the large size of the time-frequency spectrogram. As for the number of model parameters, TFC-MLP had more parameters than Hybrid Transformer Demucs, but fewer parameters than Hybrid Demucs.

4.4.3 Comparison with the state-of-the-art models

The proposed TFC-MLP model has some similarities to the state-of-the-art MSS models, which potentially have led to the competitive performance achieved.

- The frequency-mixing MLP is similar to the full connection of frequency dimensions in TDF [27] and the band-level RNN applied across band dimensions in Band-Split RNN [21].
- The time-mixing MLP is similar to the sequence-level RNNs applied across time dimensions in Band-Split RNN [21].
- Increasing the number of the channel dimensions through patch embedding and increasing the number of hidden layer dimensions in MLP are techniques that are usually used regardless of MSS. For MSS, the improvement is potentially related to the increase in channel dimensionality in the encoder part, such as Hybrid Transformer Demucs [22].
- The extra training data improved performance in the state-of-the-art models, and we confirmed the performance improvement with extra training data in TFC-MLP as well.

On the other hand, the following are included in the existing state-of-the-art MSS models but not currently included in our TFC-MLP. They have the potential to improve performance when applied in the future.

- As presented by Défossez *et al.* [19] and Kim *et al.* [18], a hybrid approach that also considers waveforms could improve performance.
- As Kim *et al.* [18], Luo *et al.* [21], and Rouard *et al.* [22] have shown, the introduction of source-specific techniques, such as band splitting, could improve separation performance.
- Deep learning techniques such as model selection methods (*e.g.*, exponential moving average), training stabilization (*e.g.*, singular value decomposition and sparsification), and the introduction of a learning rate scheduler could further improve performance.

Finally, to the best of our knowledge, there are no studies that mix the channel dimension with the time and frequency dimensions as in TFC-MLP. Such a mixer layer used in the TFC-MLP architecture has the advantage of reducing the overall memory usage compared to the original MLP-Mixer, just as the Image-to-Image Mixer reduced the memory usage. This reusable insight of mixing the channel dimension separately could be useful for other studies that have dealt with the time and frequency dimensions so far, but could be extended to the channel dimension.

4.4.4 Future directions

As future work, we plan to improve the performance of TFC-MLP by incorporating the ideas discussed above and further exploring more optimal hyperparameters. For example, increasing the FFT window size by utilizing frequency cut-off trick [20] is expected to improve the performance. Automatic optimization of hyperparameters could also be incorporated.

Future work will also include the visualization of the inside of TFC-MLP for analysis. We could visualize the linear weights used in the patch embedding by converting them back to complex numbers and then calculating their amplitudes. The visualized results could allow us to analyze what local patterns the model is focusing on. However, when we tried it, it was difficult to understand the behavior of the mixer layer due to the mixing of real and imaginary parts during the patch embedding. We are therefore interested in using the amplitude and phase (group delay) instead of the real and imaginary parts so that we can analyze the model in a more comprehensive way.

5. CONCLUSION

This paper has described a new MSS architecture called TFC-MLP that uses complex spectrograms as input. Our contributions are summarized as follows:

- (1) We proposed a simpler MLP-centric MSS architecture that achieves competitive performance compared to state-of-the-art models.
- (2) We reported on some hyperparameter searches that will be useful for other researchers exploring this type of architecture.
- (3) We discussed the similarities and differences between the state-of-the-art models and TFC-MLP, and suggested directions for future research.

SYMBOLIC MUSIC REPRESENTATIONS FOR CLASSIFICATION TASKS: A SYSTEMATIC EVALUATION

ABSTRACT

Music Information Retrieval (MIR) has seen a recent surge in deep learning-based approaches, which often involve encoding symbolic music (i.e., music represented in terms of discrete note events) in an image-like or language-like fashion. However, symbolic music is neither an image nor a sentence, and research in the symbolic domain lacks a comprehensive overview of the different available representations. In this paper, we investigate matrix (piano roll), sequence, and graph representations and their corresponding neural architectures, in combination with symbolic scores and performances on three piece-level classification tasks. We also introduce a novel graph representation for symbolic performances and explore the capability of graph representations in global classification tasks. Our systematic evaluation shows advantages and limitations of each input representation. Our results suggest that the graph representation, as the newest and least explored among the three approaches, exhibits promising performance, while being more light-weight in training.

1. INTRODUCTION

The deep learning boom has profoundly impacted MIR, including research involving symbolic music representations (MIDI, scores, etc.). A large body of recent literature focuses on adapting existing architectures from computer vision and natural language processing to the field of symbolic MIR. These approaches often treat music data as an image (piano roll), as a sequence of language tokens, or, more recently, as a graph. However, a piece of music is neither an image nor a sentence or graph, therefore, a critical question still remains open concerning the choice of input representations for symbolic music.

A source of complexity in symbolic music arises from the different modalities of data such as scores and performances. A score contains information about music notation

and often includes rich hierarchically structured information such as metrical structure and voicing. Symbolic music performances, on the other hand, such as those recorded on a MIDI-capable instrument, consist of a stream of controller events. Extracting a hierarchical structure from such a stream is not a trivial task [1–3]. Furthermore, such performance data omit some of the rich information that a score provides, such as pitch spelling and articulation markings, but instead, it can include information about expression, timing, local tempo, and performance dynamics.

Recent research has produced relatively large datasets containing scores and performances at the symbolic level, including efforts to align these [4–6]. Motivated by these developments, we present an attempt to shed light on questions revolving around the input representation of symbolic music for deep-learning-based MIR. We formulate an empirical framework where we test multiple input representations, models, and piece-level classification tasks.

In terms of input representations, we investigate piano rolls, tokenized sequences, and graphs. We evaluate multiple models based on these representations on three different tasks: composer classification, performer classification, and (playing) difficulty assessment. Furthermore, having datasets containing both performances and their corresponding scores such as ATEPP and ASAP [4, 5], allows us to apply each combination of representation and task to either score or performance. Our goal is to contribute an experimental overview of different symbolic music representations. The contributions of this work are threefold:

1. We investigate the performance and complexity of matrix, sequence and graph input representations, and their corresponding neural architectures (respectively Convolutional Neural Networks, Transformers, and Graph Neural Networks).
2. We compare the impact that the different information contained in symbolic scores and performances has on different piece-level classification tasks.
3. We introduce a new graph representation for symbolic performances, and explore the capability of graph representations in classification tasks.

2. RELATED WORK

The complexity of representing music data has been discussed in the literature [7–9]. Wiggins et al. [10] analyzed

the trade-offs of music representation systems with respect to expressive completeness and structural generality. In the age of deep learning, such considerations are still relevant regarding the variety of machine-readable representations such as piano rolls, MIDI-like sequences, NoteTuples, and Musical Spaces [11, 12]. In this section, we focus on three symbolic representations (matrix, sequence, and graphs) and discuss their respective strengths and limitations.

Music as a Matrix: Similar to audio spectrograms, a pitch-time representation that is typically used as input to a CNN, the piano roll representation of music naturally emerges as the symbolic equivalent. Piano rolls have been widely applied in tasks such as automatic music transcription [13, 14], classification of piece-level attributes such as difficulty and composer [15–18], as well as generation of music accompaniment or performed dynamics [19, 20].

A piano roll is a bare-bones representation of symbolic music data, and, therefore, information such as key signatures, articulation annotations, metrical structure, different instrument parts, and voicing structure are not encoded in the representation [11, 21].

Music as a Sequence: Modeling symbolic music as sequences has a longstanding tradition in MIR. The multiple viewpoint system is a sequence representation that has been widely used for music analysis, generation, and classification [22–25], as well as the basis for cognitively plausible models of expectation [26, 27]. In this system, musical elements are represented by viewpoints [28], which are abstract functions mapping musical events to abstract derived features like pitch, interval, and melodic contour.

With the advances of deep learning-based language models, sequential representation of music as *language tokens* has recently received a lot of attention in sequence-to-sequence generative tasks from automatic orchestration [29] to description-based medley generation [30]. Similar to a stream of MIDI messages, various tokenization schemes encode music features such as pitch, onset time, duration, and velocity sequentially. Besides generation, large-scale pre-training using music sequences has been applied to downstream music understanding tasks [31, 32].

However, tokenized music sequence representations create difficulty for models to learn the dependency of long contexts. Length reduction methods such as Byte Pair Encoding (BPE) [29, 33] aim to address the length overflow problem by replacing the occurrence of frequent subsequences with new tokens.

Music as a Graph: A musical score can also be seen as a graph where notes form the vertices and relations between notes define the edges. Jeong and al. [34] introduced a graph modeling of a musical score for generating expressive performances. Recently, Karystinaios and Widmer [35] presented a new modeling of the score graph based on three different note relations and a Graph Convolutional Network for cadence detection in classical music. A score graph can be homogeneous or heterogeneous, i.e. having one or several types of edges and/or vertices, respectively [36]. We will investigate both heterogeneous and homogeneous score graphs based on the representation used in [35].

Graph Neural Networks have gained popularity in recent years, however, graph learning inherently presents some limitations, such as over-smoothing in deep graph networks [37] and restrictions of Message Passing, where information in graph neural networks flows only between edge relations predetermined by the representation (in contrast to a Transformer architecture where everything is interconnected [38]).

3. METHODOLOGY

In this section, we describe the methodology followed, the corpora used, and the experiments conducted to investigate in-depth the different symbolic representations.

3.1 Representation Design

We briefly introduce a formal definition of each representation type, i.e. matrix, sequence, and graph. An example of the three representations is shown in Figure 1.

3.1.1 Matrix

We define as a matrix representation of music a 2-dimensional array $\mathbf{M} \in \mathbb{N}^{H \times W}$ that depicts musical notes on the time axis, commonly referred to as a piano roll. The vertical axis consists of 128 possible values attributed to the MIDI pitch of note events, where we add three more optional fields for the *una corda*, *sostenuto*, and sustain pedals only applied on the MIDI performances.

In this work, we experimented with multiple channels as used in Onsets and Frames [39]. The onset channel is a binarized roll with activations at onset timestamps, while the frame channel encodes the duration of the note and the velocity of the MIDI event. For scores, the velocity values are substituted by the voice index, i.e. the integer number assigned to a note to indicate the index among the number of independent voices.¹

3.1.2 Sequence

A symbolic music sequence $\mathbf{S} \in \mathbb{N}^{1 \times N}$ is defined by a series of discrete tokens that represent attributes of notes. Vocabularies such as V_{pitch} , $V_{\text{TimeShift}}$, V_{vel} assign semantic meanings to tokens, and different tokenization schemes translate into different grammars of sequence construction. In this work, we test three popular tokenization schemes: *MIDIlike* [40, 41], *REMI* [42], and *CompoundWord* [43] and use the implementation of the *MidiTok* library [44].

As there is no existing tokenizer for processing scores, we implemented custom MusicXML tokenizers following *MidiTok*'s framework, in the style of *REMI* as well as *CompoundWord*. The major difference is the timing of bars and event positions, as well as the addition of score-specific tokens such as V_{keySig} , V_{voice} .²

Byte Pair Encoding (BPE) is a tokenizer add-on technique that has recently been applied to music sequence learning [33]. It consists of a data compression technique

¹This voice information is commonly available in formats such as MusicXML, **Kern, and MEI.

²Full documentation is provided with our open-source tokenizer in the project repository.

Figure 1. Excerpt of Schubert’s *Impromptu Op. 90 No.4* and its input visualizations (from left to right): generic matrix, sequence (REMI-like) and graph.

that replaces the most common token subsequences in a corpus with newly created tokens. BPE increases the vocabulary size and shortens the sequence length. We follow the best results from [33] and adopt a BPE with 4 times the original vocabulary size. On average, this reduced our sequence length between 55 – 65% in both datasets.

3.1.3 Graph

A homogeneous score graph G is defined by a tuple (V, E) of vertices and edges. V is the set of notes in a musical score and $E \subseteq V \times V$. Given a score with N notes, we extract a matrix of k -dimensional note-wise features $X \in \mathbb{R}^{N \times k}$ based on features contained in the score or performance. A heterogeneous score graph $G = (V, E, \mathcal{R})$ also includes a set of relation types \mathcal{R} such that for every edge $e \in E$, e is of type $r \in \mathcal{R}$ if a condition defined by r holds. In our work, we consider the following relations between two notes u, v which define the edges $e \in E$:

- u and v have the same onset, i.e. $on(v) = on(u)$, then $r = onset$;
- The offset of u is the onset of v , i.e. $off(u) = on(v)$, then $r = consecutive$;
- The onset of u lies between the onset of v and the offset of v , i.e. $on(v) < on(u) \wedge on(u) < off(v)$, then $r = overlap$.

The above relations only hold in the case of score graphs. To adapt this to performance graphs, we use a window tolerance t_{tol} , such that if two notes $(u, v) \in E$ and:

- $|on(v) - on(u)| < t_{tol}$, then $r = onset$;
- $|off(u) - on(v)| < t_{tol}$, then $r = consecutive$;
- $on(v) < on(u) \wedge on(u) < off(v)$, then $r = overlap$.

In our configurations, for all graphs created from performance MIDI, we set $t_{tol} = 30$ ms, a perceptual threshold of expressive timing [45]. In addition to the above relations, we consider the possibility of adding an inversely directed edge for the overlap and the consecutive edge types, and we name the inclusion of such edges *inverse edges*. For a homogeneous graph G_{hom} and heterogeneous graph G_{het} , $e \in G_{hom} \implies e \in G_{het}$.

The node features X are divided into two categories, the basic and the advanced features. The basic features are implicitly contained in any score or performance note such as one-hot encoding of pitch class and octave of the note’s pitch, and duration information. The advanced features

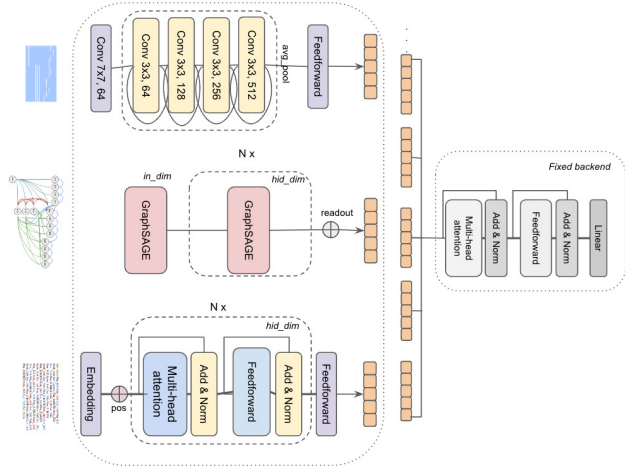

Figure 2. Left: front end for three representations, matrix, graph, and sequence, from top to bottom. Right: fixed back end with attention modules.

contains articulation, dynamics, and notation information from the *Partitura* python package [46]. The detailed computation of these features can be found in original partitura paper [47] and the basis mixer [48].

3.1.4 Information Levels

Given the differences in information captured by symbolic scores and performances (Sec. 1), we run experiments with separate levels of used information. For the base comparison experiments, we input the basic level of information that is present in both modalities: pitch, duration and onset. The advanced level of information for performance includes dynamics (MIDI velocity) and pedals, while for score includes the voice index (Sec. 3.1) as well as score markings such as articulation and dynamics. The results and comparison of each level of information, also with respect to different tasks, will be discussed in Section 4.3.

3.2 Modelling Pipelines

In this work, we evaluate the input representations under the same training pipeline of different piece-level classification tasks, as discussed in Section 3.3. We split our training architecture into two parts, a front end that projects a window of musical context into a 64-dimensional embedding, and a back end that aggregates the embedding for final prediction. The front end is representation-specific while the back end

Table 1. Composer classification results for all representations, on all target subsets of our datasets on the composer classification task using only basic level features. For each subset of data, we present the accuracy score and the macro F1 score with 8-fold cross-validation. See Section 4.1 for explanation of the parameters.

rests fixed. For a fair comparison, we ensure that the same amount of musical context is given for different front ends to learn. For MIDI performances we fix a window of 60 s, and for symbolic scores, we choose a window of 120 beats given that 120 bpm is a common tempo for music.

For the front end, we employ a commonly used architecture for each respective representation domain:

Matrix: Convolutional neural network based on ResNet [49] blocks with channel numbers adapted to our input.

Sequence: Transformer-encoder [50] front end with positional encoding. Each layer includes multi-head attention with 16 heads followed by an Add & Norm layer. For the combined tokens *CPWord* we add separate embedding layers for each token category in the front end.

Graph: Our graph convolution network (GCN) is built by stacking GraphSAGE blocks [51] followed by a global mean pooling layer. We experiment with both heterogeneous and homogeneous GraphSAGE. Note that a heterogeneous network has r times more parameters, where r is the number of distinct edge relation types.

For the fixed back end, we used a multi-head attention block with linear projection heads to the desired number of classes, as shown in Figure 2. To minimize the impact of model capacity on our comparative discussion, we carried out an ablation study to understand the size of the architecture proportional to each kind of representation (Sec. 4.2).

3.3 Tasks and Datasets

In this work, we focus on three tasks: composer classification, performer classification, and difficulty assessment. Each one of these tasks is a piece-level task since a label is attributed per piece. The composer classification consists of predicting the composer of the piece. The performer clas-

sification involves the prediction of the performer among a list of predefined performers included in the data source. Finally, difficulty assessment involves the prediction of a number between 1-9, with 1 being easy and 9 being hard. The difficulty labels were assembled from Henle Music.³

To evaluate the aforementioned tasks, we use two large-scale collections of Western classical piano music that contain corresponding symbolic scores (MusicXML files) and performances (MIDI files), ASAP (1067 performances, 245 scores) and ATEPP (11742 performances, 415 scores). Both datasets contain individual files per movement.

For the composer classification task, we exclude the least populated composer classes for balance in experiments, resulting in 10 classes for the ASAP dataset and 9 classes for the ATEPP dataset. The performer classification task uses MIDI performances of ATEPP with 20 classes. For difficulty, given that both ASAP and ATEPP datasets focus on concert repertoire, the actual classes used range from difficulty 4-9.⁴ For all experiments, we use an eight-fold cross-validation evaluation where 85% of our data is used for training and 15% for testing in each fold.

3.4 Training

We performed hyperparameter optimization sweeps to determine the optimal learning rate and model hyperparameters. Our convergence criteria include early stopping at the 60 epoch breakpoint with the patience parameter set at 0.005 on the validation accuracy. All our experiments are trained on a single A5000 GPU, and the best models, training logs,

⁴ The full distribution of the classes for each task is shown in the supplementary material.

and the code is available in the repository.⁵

4. EXPERIMENTS AND RESULTS

To evaluate the different representations we performed three experiments. Our first experiment focuses on a detailed comparison of the predictive accuracy of the three representations/architectures applied to the composer classification task, since it is the most well-understood task among the three. The second experiment studies the impact of model capacity (number of trainable parameters) per representation. Our last experiment investigates the effect of different levels of input features (see Section 3.1.4) on the three tasks.

4.1 Representations for Composer Classification

Our first experiment is a comparative analysis of the three representations on our two datasets, in the domains of both MIDI performance and MusicXML score with basic level features. For each representation group we test different configurations, i.e. for matrix we experiment with the channel (Chnl) and timestep resolution (Resl), for sequence we change the tokenization scheme (Tokn) and apply BPE, and for graph we investigate the effect of homogeneous or heterogeneous graphs (Multi-rel) and the addition of inverse edges (Bi-dir) (see Sec. 3.1). In Table 1, we present for each data subset the accuracy score and the macro F1 score and their respective standard deviations under 8-fold cross-validation (see Sec. 3.3).

In terms of observations per representation, the matrix representation results indicate no significant differences under different experimental configurations. For sequence representations, the *MIDIlike* and *REMI* tokenization schemes yield comparable performance. However, our experiments suggest that *CPWord* is a more challenging representation to learn in the same setting. Concerning the BPE technique, no significant difference is observed between results with 4 times the original vocabulary and the non-BPE version.

Our graph-based models exhibit similar performance regardless of the configuration of the graph edges. In particular, the effect of reverse edges is not significant, and homogeneous graph convolution already achieves similar results to heterogeneous graph convolutional models, which indicates that implicit structural information contained in the heterogeneous approach is not strictly necessary for piece-level classification tasks.

Overall, we observe that three representations show small performance differences in given experiments, with the matrix-CNN approach having the overall best metric across the experiment groups and sequence have the worst.

Finally, we would like to discuss the *album effect*, which concerns the tendency of classification models to learn non-intended features, such as acoustic features in pieces of the same album [52]. In our case, this effect concerns different performances of the same piece that may give away cues for classification. Training with the entire corpus of performance MIDI, which involves different interpretations of the same piece, yields an average accuracy of 90%

Figure 3. Model capacity vs. macro F1 score for each representation approaches on the *ASAP-composer* task.

(see supplementary material), which is 30% higher for the *ASAP-perf* group. To address this issue, we fix the splits to only contain unseen pieces in the test set, which reduced the accuracy score gap between performance and score. This issue has often been overlooked in literature [53, 54] and a commonly-used dataset split is not piece-specific [16]. Given the recent development of large score-performance datasets, we wish to establish a scientifically correct evaluation split taking into consideration the *piece effect*.

4.2 Complexity

In our second experiment we investigate the impact of model capacity for each representation on the composer classification task using the *ASAP* dataset. We experiment with different hidden dimensions h and the number of layers N on each architecture corresponding to each of the three representations (Sec 3.2), and show our results in Figure 3. Overall, we observe that the GCN achieves its best performance using 1.3M parameters, while architectures for matrix and sequence achieve a similar accuracy at around three times the number of parameters.

Another observation concerns the use of large models for piece-level classification tasks on symbolic data. Large convolution models such as ResNet-18/34/50 [16] are substantially over-parametrized, as our results suggest we can achieve similar results using a reduced version of ResNet-8, using less than half the parameters of the smallest used ResNet architecture. Similar observations can be made for transformers, where scaling the model beyond 4.3M parameters does not further improve the performance. Our most efficient transformer encoder consists of 4 layers of attention modules with a hidden dimension of 256, significantly less than transformers used in previous related work [33].

Finally, we note one aspect of our results after scaling our graph network. While *oversmoothing* [37] (features of graph vertices converging to the same value) is a well-known challenge to train deep GCN, our best performing model is a relatively deep and narrow network consisting of 5 layers with a hidden dimension of 64. One possible interpretation is that convergence of node features does not

complicate training in the graph-level classification context.

4.3 Comparison of Feature Levels and Tasks

As discussed in Section 3.1.4, we are also interested in understanding the impact of different levels of features on the three classification tasks. With this motivation, we performed our third set of experiments, where we adopted the best configuration of models explored in experiment 1 (see Section 4.1). We report the accuracy results in Table 2.

Our results indicate that MIDI performances and MusicXML scores have similar capabilities for distinguishing composers and difficulty. Furthermore, matrix and sequence approaches exhibit better results when learning with performances compared to scores. For the difficulty classification task, in particular, all three representations achieved approximately 40% accuracy on the 6 difficulty levels. Performer classification is more challenging since the difference lies in the timing nuances and dynamic changes instead of the pitch information, which are more prominent in our input representations. In the 20-way classification, our approaches generally achieved around 30% accuracy.

Our observations suggest that the addition of advanced features has a variable impact on the representations. Interestingly, the addition of advanced features does not improve the training from sequence representations in most experiments, which can possibly be explained by the increase in vocabulary size and relative sparsity of such information. Graph structures benefit from the addition of voice edges, especially in the representation of scores, where the performance boosts for both composer and difficulty classification. Notably, the `graph-score` with advanced features configuration achieved the best result in score-based composer classification, when jointly compared with Table 1.

4.4 Transformer vs. GNN: Are We Learning the Same Set of Musical Edges?

A transformer can be seen as a special case of Graph Neural Networks [38]. Assuming a fully connected graph where vertices are tokens in a sequence, we can draw parallels between a GCN and learned attention in a transformer block.

Therefore, we examine attention weights between `NoteOn` tokens in an effort to understand how our graph representation of the score relates to the sequence-based representation. For all pairs of `NoteOn` tokens from music

Figure 4. Visualization of graph edges (all edge types aggregated) and the attention among `NoteOn` tokens for the first measures of *Mozart Piano Sonata No. 12, 1st mvt.*

sequences, we output their attention values and compute the correlation with the aggregated adjacency matrix (with all musical edges constructed in Sec. 3.1). Across the test set of ASAP composer classification on scores, there is a weak positive correlation, with Pearson’s value of 0.212.

In Figure 4, we visualize two measures of music with its constructed graph edges, and the attention across `NoteOn` tokens. We can observe some structural similarities, especially the overlap pattern in both measures, but overall the learned attention spans are much more global while graph edges connect nodes within a local range.

5. DISCUSSION AND FUTURE WORK

In this paper, we presented a series of systematic experiments to investigate the impact of symbolic representations for three piece-level tasks. In terms of simple *classification performance*, we found that for a given task, different representations showed small performance differences, but no clear pattern of superiority emerged. The matrix results were marginally better on average, and usually more robust to hyper-parameter changes. More advanced features were beneficial only for certain tasks and representations.

The *graph representation*, as the newest and least explored among the three approaches, exhibits promising performance, while being more light-weight (in terms of required model complexity – cf. Fig. 3). We observe that homogeneous graphs produce comparable results to heterogeneous graphs for our piece-level classification tasks, and deep GCNs perform better despite over-smoothing. As graphs are arguably a more natural representation for structured artifacts such as musical scores, we believe that they should merit more detailed studies in the future.

Our model complexity experiments demonstrated that commonly used architectures in the literature are larger than necessary for our tasks, as the same results can be achieved with smaller architectures (Section 4.2). Furthermore, we discussed the *album effect* in score-performance datasets, where multiple interpretations of the same composition may cause information leakage. Our results indicate the profound impact of the album effect, and we introduce new evaluation splits to guard against this effect.

6. ACKNOWLEDGEMENTS

This work is supported by the UKRI Centre for Doctoral Training in Artificial Intelligence and Music, funded by UK Research and Innovation [grant number EP/S022694/1], also by the European Research Council (ERC) under the EU's Horizon 2020 research and innovation programme, grant agreement No. 101019375 (*Whither Music?*).

8. APPENDIX

8.1 Album effect

As mentioned in the main paper Section 4, the *Album Effect* remains a non-trivial issue in similar classification tasks. Here we present in Table 4 the same content as the original table (Table 1) from the paper which contains results from the experiment that is trained on the entire performance corpus with overlapping interpretations. Training under this non-piece-specific split, we achieved comparable accuracy (93%) with the literature [16].

8.2 Complexity

8.2.1 Memory

Given that the same amount of music context is input into the models, we are interested in understanding the memory efficiency of the representations. We used the native `numpy` and `cuda` functions to monitor the memory of data and memory changes during training.

In terms of the representation of a single piece of data, sequence is the most compact one while matrix takes $70\times$ more space, given that a lot of redundant pixels are taken in the 2D representation. The size of graph varies depending on the number of nodes and edges, but overall it is in between that of the matrix and sequence.

However, during training we can observe that the sequence is the least memory-efficient representation during training, and it takes $30\times$ compares to the memory usage of matrix and graphs. Given the quadratic complexity of transformer-like architectures, the training memory needed is one of the major limitation of sequence compared to the other representations.

	KB / seg	KB / piece	Training step (MB)
Mtr	819.2	5129.6 ± 3332.7	185.9 ± 105.9
Seq	12.8	77.8 ± 56.7	5548.9 ± 1736.2
Gph	100.5 ± 57.3	610.9 ± 300.0	125.2 ± 103.4

Table 3. Size estimation of each representation with basic level features from ASAP-perf data. We include the average size per segment (60s), average size per piece (as piece have different length), as well as the average allocated memory increase during each training step with a batch size of 1.

8.2.2 Convergence epochs

During training, we also observed a difference in the time it takes the models to convergence, given the 60 epochs convergence criteria defined in Sec 3.4. We first performed learning rate search using `pytorch lightning`'s learning rate finder. Under the suggested learning rate, among different ASAP-perf experiment of composer classification, the matrix have on average 143.0 ± 24.7 epochs to converge, the sequence and the graph have 132.0 ± 31.1 and 262.0 ± 55.7 epochs. During training, the graph models have relatively slower learning progress.

8.3 Dataset class distributions

We present our dataset class distribution for each task in the Table 8.4.

8.4 Silence and voice edges

Besides the onset, consecutive and overlap edges in Sec 3.1, we also add optional silence edges (edges that bridge over silence) to ensure a connected graph. A silence edge $E_{silence}$ is added between a node that's not connected by any consecutive edge and the time-wise closest node before it. The silence edge doesn't carry much music semantic meaning, and its main purpose is to prevent the disjoint subgraphs formed by distinct music sections, in which stops information flow in training.

In the advanced representation of score graph, we input the voicing information as voice edges. Given that we can't guarantee the consistency of voice annotation in MusicXML scores (as they are mostly labeled for visual purposes like beaming), we limit the voice edge connection within a measure: If two notes are labelled with the same voice, then they are connected by a voice edge E_{voice} .

ABSTRACT

The semantic description of music metadata is a key requirement for the creation of music datasets that can be aligned, integrated, and accessed for information retrieval and knowledge discovery. It is nonetheless an open challenge due to the complexity of musical concepts arising from different genres, styles, and periods – standing to benefit from a lingua franca to accommodate various stakeholders (musicologists, librarians, data engineers, etc.). To initiate this transition, we introduce the Music Meta ontology, a rich and flexible semantic model to describe music metadata related to artists, compositions, performances, recordings, and links. We follow eXtreme Design methodologies and best practices for data engineering, to reflect the perspectives and the requirements of various stakeholders into the design of the model, while leveraging ontology design patterns and accounting for provenance at different levels (claims, links). After presenting the main features of Music Meta, we provide a first evaluation of the model, alignments to other schema (Music Ontology, DOREMUS, Wikidata), and support for data transformation.

1. INTRODUCTION

A music analyst, a computational musicologist, a music librarian, and a data engineer are working on a joint project. They need to contribute data from various musical sources, ranging from music libraries, annotated corpora and tune books, to audiovisual archives, radio broadcasts, and music catalogues. All data is eventually merged/aggregated as interconnected corpora, and linked to online music databases (e.g. MusicBrainz, Discogs) and knowledge bases (e.g. Wikidata). This creates opportunities to link cultural heritage artefacts to music industry data (streaming services, music professionals, etc.) and viceversa.

This plot subsumes a recurring challenge for musical heritage projects [1]. Besides the individual requirements

of each stakeholder – possibly rooted in different music genres, periods and datasets, a fundamental requirement is the interoperability of music metadata.

Music metadata (alias bibliographic, or documentary music data) is used to consistently identify and describe musical works, their artists, recordings, and performances. For music industry, it allows for efficient management and distribution of music, which facilitate search and recommendation [2]. When metadata is accurate, it ensures that artists receive proper credit and compensation [3]. For musical heritage, metadata allows for the preservation and dissemination of musical works and traditions, but also aid in the research and study of music history and culture [4]. When integrating both views, metadata can help to promote diversity and inclusivity in the music industry by highlighting lesser-known genres and artists, while integrating information and artefacts of cultural interest [5].

Hence, a model that can consistently describe metadata is highly desirable – as it enables linking entities and concepts from various datasets (e.g. a composer is linked to a tune that has no authors in another collection). Semantic Web technologies can help achieve interoperability, as they facilitate data access and integration, resource discovery, semantic reasoning and knowledge extraction [6]. In the Resource Description Framework [7], data is described as <subject-predicate-object> triples using ontologies, and released as Knowledge Graphs (KGs).

To achieve interoperability, one possibility akin to [8] is to let stakeholders design their own domain-specific ontologies, then use alignment algorithms to find connections between them (e.g. `MusicalWork` and `Composition` referring to the same concept). However, this approach comes with three major drawbacks: (i) ontology alignment is error-prone, hence links would still require manual inspection; (ii) even when alignment is sound, the semantics of classes and relationships may vastly differ across domains, which in turn, may create inconsistent alignments; (iii) it does not address the problem in the long-term.

1.1 Challenges and requirements for interoperability

Another possibility is to reuse current ontologies for music metadata, such as the Music Ontology (MO) [9] and the DOREMUS ontology [10]. However, modelling music metadata across different genres and historical periods, to

accommodate various use cases over heterogeneous data sources poses a number of challenges. First of all, it requires a perspective that harmonises all requirements from different stakeholders – to design a model that can be tailored to different data sources rather than to a single type of dataset. We categorise the main challenges and requirements for metadata interoperability as follows.

1.1.1 Domain specificity hampers interoperability

When looking at current ontologies, MO leans towards modelling discographic data with a focus on contemporary music, whereas DOREMUS is inherently rooted in classical music. These ontologies have been demonstrated to model metadata from MusicBrainz and BBC Music [11], and from classical music libraries and radio broadcasts for concerts programming [12], respectively. Their specificity makes them appealing when downstream applications show considerable overlap in terms of requirements and data. Examples include the reuse of MO in the WASABI project [13], to support the semantic annotation of audio music (emotions, lyrics, structures), but also for music recommendation [14] and listening [15]; and the adoption of DOREMUS by *Philharmonie de Paris*, *Bibliothèque Nationale de France*, and *Radio France*.

Nevertheless, when drifting from discographic data and classical music, or attempting to reuse both models, addressing e.g. cultural heritage requirements while fostering interoperability becomes difficult. Indeed, a model reflecting the view and the interpretations ascribable to a musical genre, stakeholder, or dataset type may be difficult to reuse and extend to other domains. For instance, a music artefact may originate from oral transmission or be the result of a creative process that does not necessarily entail a formal composition process. The latter is common in songwriting, but also in folk music whenever a set of tunes (collected from different manuscripts) allows for the identification of a tune family [16]. Similarly, when expressing relationships between musical artefacts (alias derivations), it is important not to impose any modelling bias that may constrain possible interpretations (e.g. an arrangement having proper musical identity vs simply providing a different instrumentation). This is commonly referred to as “dominance of concept” [12], whose definition should be left to users depending on their data and domain expertise.

Rather than attempting to achieve consensus on musical concepts and jargon, accounting for the interoperability calls for an abstraction layer for music metadata (“*zoom-out*”) that can then be specialised, extended, and adapted to address domain-specific requirements (“*zoom-in*”).

1.1.2 Expressivity is needed at different levels

Another requirement for interoperability and reuse across various data sources is providing expressivity at different degrees, i.e. the possibility to conveniently describe music metadata at the right level of detail. For example, one data source may have granular/detailed information that requires high semantic expressivity (a composition process spread over different time, places, and involving more

artists); whereas others may have basic (only the name of an artist is known) or even incomplete and uncertain information (a composition tentatively attributed to an artist).

Here, the WikiProject Music¹ has been successful in providing expressivity to represent music metadata from different sources. As an extreme case of ontological flexibility, the schema underlying Wikidata – an open-ended, multi-domain KG built collaboratively like Wikipedia – is not specified in a previously agreed ontology, and the high expressivity overly adds complexity to the model. This is due to Wikidata’s scope being the most general.

1.1.3 Provenance is fundamental for data integration

Accounting for provenance is a central requirement for both cultural heritage and music industry. This becomes fundamental when integrating Knowledge Graphs from different datasets and stakeholders – as every single bit of data (each triple) should be attributable to a dataset/KG. Furthermore, integrating provenance is also needed within the context of a single dataset, at least for claims and links.

Claims-Interpretations. Cultural heritage applications often require representing debatable statements or claims [17, 18]. These are usually the result of an interpretation process based on factual or documentary evidence (a dataset, a manuscript, etc.), and following a methodology and/or theory. Examples include personal information (e.g. the year/place of birth of a composer), and authorship claims (e.g. a composition being attributed to an artist).

Links and identifiers. These includes links to artists’ official websites, fan pages, discussion forums, music reviews, record shops; as well as identifiers from music databases (e.g. MusicBrainz, Discogs, AllMusic), streaming platforms (e.g. Deezer, Spotify), and authoritative sources (e.g. ISNI, ISWC, ISRC). As most links and identifiers are crowdsourced or automatically inferred by entity linking algorithms, modelling provenance here promotes traceability and accountability of data sources.

Notably, Wikidata addresses both these requirements, as every triple is considered a statement per se, for which so-called *references* can be appended and ranked. References may include information on the source, whether a computational method was used, and a date of retrieval.

1.2 Our contribution

We leverage the expertise and complementary views of various music stakeholders (musicologists, data engineers, music analysts, and heritage archivists) to contribute:

- The *Music Meta* ontology, a rich flexible model to describe Western music metadata and its provenance at different levels of granularity.
- An example-driven validation of the model, focused on the data elicited from four different stakeholders.
- Code support to create Music Meta KGs without expert knowledge of the model, with automatic alignments to the MO, DOREMUS, and Wikidata.

2. RELATED WORK

Besides metadata, the use of Semantic Web technologies in the music domain has contributed several ontologies, covering a variety of musical aspects and spanning both symbolic and audio music.

Among them, the Music Theory Ontology [19] describe theoretical concepts of compositions, whereas the Music Score [20] and Music Notation [21] propose granular ontologies to represent elements of music scores. OMAC expresses features of musical entities but also musicological claims [22], while the OMRAS project [23] contributed ontologies to describe music chords as well as concepts related to tonality and temperament.

In the audio domain, ontologies describe music production [24], audio features [25], effects [26]; an also model listening habits/taste [27], music-induced emotions [28], music structure [29,30], and musical similarities [31].

These ontologies have specific focus, and many were developed as stand-alone projects, with little or no alignment [32]. Instead, some ontologies focus on achieving interoperability between notations, taxonomies, and formats. These include the Internet of Musical Things [33], where heterogeneous musical objects are envisioned to coexist; the Music Annotation Pattern [34] which allows to model music annotations in the JAMS format [35]; and the Hamse ontology [36] describing musical features for musicological research. Similarly, [37] models abstract annotations of musical works, rather than concrete encodings.

Interoperability at the level of musical content level resulted in successful MIR applications, such as the MIDI Linked Data Cloud [38] – integrating MIDI music to learn embeddings over the resulting KG [39]; and ChoCo [40] – a chord corpus integrating 18 chord datasets and enabling novel workflows for computational creativity [41].

3. THE MUSIC META ONTOLOGY

To derive requirements from various music stakeholders, we leverage the domain expertise and views in Polifonia – a European H2020 project aiming to connect “music, people, places and events” from the 16th century. The interdisciplinarity of Polifonia, involving data engineers, anthropologists, ethnomusicologists, historians of music, linguists, musical heritage archivists, cataloguers, and creative professionals – makes it an ideal testbed for this work.

Music Meta is part of the Polifonia Ontology Network [42], from which we reuse the CORE module. This is done to consistently reuse general-purpose elements of design (e.g. Person, Time, Place) and ontology design patterns. The reuse of this module also ensures alignment with other foundational models (FOAF, Dublin Core, etc.).

The ontology (prefixed as *mm*) is available at the following URI: <https://w3id.org/polifonia/ontology/music-meta/>, and is released as open source project under the CC-BY 4.0 on GitHub².

²<https://github.com/polifonia-project/music-meta-ontology>

3.1 Methodology

The development of Music Meta is driven by eXtreme Design (XD) [43], an agile ontology engineering methodology that makes extensive use of ontology design patterns (ODPs) – small ontologies that work as reusable templates for recurrent modelling problems. An ODP is intuitive and compact, clearly and formally defined, tackles a specific (sub)set of requirements, and is designed for a modular reuse, enabling a pragmatic cognitive analysis [44].

In XD, a story-based approach guides the collection of requirements. A story is a framework for *customers* to describe their needs, and is composed of 4 sections: (i) the persona, a description of a typical user; (ii) the overarching goal they need to address; (iii) the scenario, describing how the goal will be address; (iv) the competency questions (CQs) translating needs into formal requirements. Ontology modelling starts iteratively from the CQs, and is based on the reuse of ODPs and existent templates.

3.1.1 From FRBR to Information Objects/Realisations

At the core of Music Meta lies the use of the Information-Realisation (IR) ODP [45]. An *information object* is a non-physical social object carrying information that can have one or multiple materialisations (*information realisations*). Each realisation is a particular physical object, or event, realising the *information object*, or involving the latter as a participant. Both information object and realisation are intended as information entities (IE), i.e. (social) objects created and/or used to communicate, reason, and specify new entities. This allows to distinguish between a piece of information (e.g. the *content* of a composition) from how it is materialised (e.g. as a performance).

On the other hand, both the Music Ontology [9] and DOREMUS [12] are built on top of different flavours of FRBR [46] (FRBRer and FRBRoo, respectively). FRBR is a conceptual model describing bibliographic resources at four levels: *Work*, *Expression*, *Manifestation*, and *Item*. In contrast, the two levels of the IR pattern map to *Expression* and *Item*, since *Work* and *Manifestation* are said to provide non-informative conceptualisations [45]. Moreover, [47] argues that FRBR’s Works – intended as “entities that pre-exist expressions”, cannot represent improvisations or traditional music, as they do not derive from a formal composition process leading to a realisation. FRBR’s Work is often ambiguously intended as an entity retrospectively created for grouping multiple expressions for cataloguing needs. As for the Manifestation level, while its representation is straightforward in the bibliographic domain (e.g. the printed version of a book), its correspondence in the music domain is not fully intuitive, as it may relate to either a recording, a score, a compact disc, or all the above – thereby introducing complexity and ambiguity.

Nevertheless, being aligned to two levels of FRBR, the IR ODP makes our model leaner and flexible, while still achieving interoperability with FRBR-based (music) ontologies. In fact, IE patterns are meant to boost the semantic integration of contents, tools, platforms, resources that are silo-ed or non-interoperable [45].

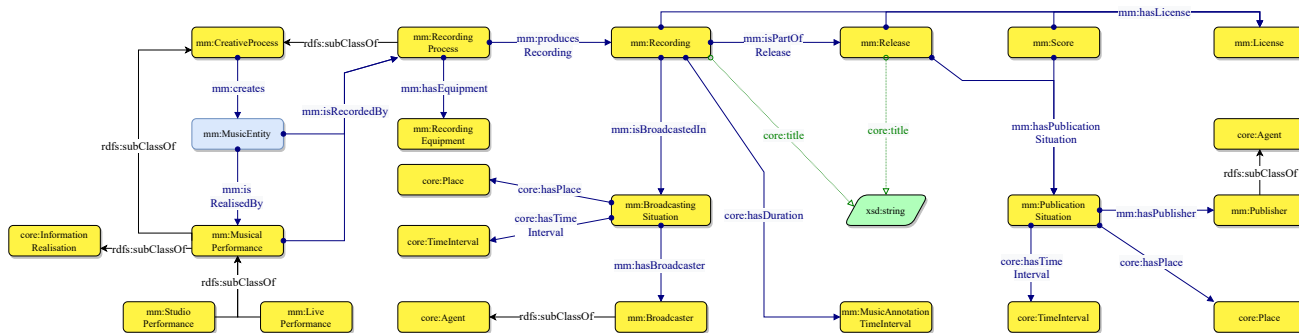

Figure 4. Describing performance, recording, broadcasting, publication, and licensing.

Figure 5. Our pattern to describe provenance with RDF*.

3.3 Conversion rules and code support

To facilitate the reuse of Music Meta and its data conversion into OWL/RDF Knowledge Graphs, we developed PyMusicMeta – a library to map arbitrary music metadata into RDF triples. This enables a practical and scalable workflows for data lifting to create Music KGs without expert knowledge of our ontological model. The library is developed in Python as an extension of RDF-Lib [50].

With each triple, PyMusicMeta adds alignments to the supported schema whenever possible. For example, the pseudo triple `<DavidBowieURI, rdf:type, mm:Musician>` in Music Meta will be complemented with `<DavidBowieURI, rdf:type, http://purl.org/ontology/mo/MusicArtist>` for Music Ontology, `<DavidBowieURI, rdf:type, http://erlangen-crm.org/E21_Person>` for DOREMUS (via the Erlangen Conceptual Reference Model [51]) and `<DavidBowieURI, rdf:type, https://www.wikidata.org/wiki/Q639669>` for Wikidata; to achieve interoperability of the Music KG.

4. VALIDATION AND ADOPTION

Following the XD methodology (c.f. Section 3.1), we validate Music Meta against the competency questions (CQs) driving its design. In this context, testing consists in formulating logical statements for each competency question – using the ontology as a formal model. Logical statements are encoded as SPARQL queries to evaluate the

model. Examples of tested CQs include “*In which time interval did the creation process take place?*” and “*Which is the language of the name/alias of a music artist?*”. The complete list of CQs, together with their correspondent SPARQL queries can be found in the project’s repository. This also contributes a test framework where the ontology is automatically tested using the available SPARQL queries [52], whenever changes occur or new requirements are supported in future versions of Music Meta.

Music Meta has already been used in ChoCo [40], the largest Harmony KG to date, obtained from the integration of 18 MIR datasets⁴. The ontology has also been specialised for folk metadata (Tunes Ontology) and extended to describe music datasets (CoMeta Ontology). All ontologies are part of the Polifonia Ontology Network (PON) and can be found at <https://github.com/polifonia-project/ontology-network>. We also provide documentation, examples, and tutorials⁵.

5. CONCLUSIONS

The interoperability of metadata is an essential requirement for the integration of music datasets, which is currently hampered by the specificity of existent ontologies.

Our work addresses interoperability requirements for the design of the Music Meta ontology – a rich and flexible semantic model for (Western) music metadata across different genres and periods, for various stakeholders and music datasets. The model is based on the Information-Realisation ontology design pattern, allowing to reduce complexity while maintaining alignment to other ontologies (Music Ontology, DOREMUS). We validate Music Meta following the XD methodology, to demonstrate the support of requirements collected from various stakeholders (music analysts, archivists, musicologists, and data engineers). The model has modular design – allowing users to describe music data depending on their specificity and type, while providing provenance support through RDF*.

We are extending the evaluation of Music Meta across cultural heritage and music industry datasets, while working with our stakeholders to specialise the model for the integration and release of Music Knowledge Graphs.

ABSTRACT

Large-scale studies of musical harmony are often hampered by lack of suitably labelled data. It would be highly advantageous if an algorithm were able to autonomously describe chords, scales, etc. in a consistent and musically informative way. In this paper, we revisit tonal interval vectors (TIVs), which reveal certain insights as to the interval and tonal nature of pitch class sets. We then describe the qualities and criteria required to comprehensively and consistently measure displacements between TIVs. Next, we present the Polar Manhattan Displacement (PMD), a compound magnitude and phase measure for describing the displacements between pitch class sets in a tonally-informed manner. We end by providing examples of how PMD can be used in automated harmonic sequence analysis over a complex chord vocabulary.

1. INTRODUCTION

Attempts to autonomously label and analyse harmonic sequences in music constitute some of the longest-standing challenges in music information research (MIR) [1]. Various strategies have been applied to chord sequence identification, including information theory [2], graph theory [3–5], and predictive methods such as Hidden Markov Models [6]. Much attention has been given to developing geometric models of musical distance [7–11].

First proposed by Lewin in 1959 [12] and later, in 2007, [13], the discrete Fourier transform can be applied to collections of pitch classes to produce Tonal Interval Vectors (TIVs), which can be used to describe the tonal qualities of chords and pitch class profiles (PCPs) by revealing their constituent intervals and tonal structures [14]. Yust et al. [15] have employed the Fourier transform as a form of cluster analysis on large groups of weighted PCP sets, while Tymoczko and Yust [16] have explored the relationship between voice-leading and Fourier analysis. Other previous work has focused primarily on the magnitude

components of TIVs [17, 18], which offer a useful but incomplete picture of intervallic content and tonal quality, as transposition is ignored and certain chord types such as major and minor cannot be disambiguated [19]. Furthermore, many existing methods of measuring distance between TIVs are problematic as they are restricted to pairs of chords and are inconsistent when groups of three or more chords are considered. Additionally, many musical distances falter because they do not capture the directional nature of musical harmonic tension or are adversely affected by enharmonic spellings and conflicting chord vocabularies.

We present the Polar Manhattan Displacement (PMD), a method of describing component-wise directional distance (i.e., displacement) between TIVs which utilises both magnitude and phase information. We demonstrate PMD within the context of the 12-tone equally tempered symbolic domain.

PMD addresses all 4,095 possible pitch class combinations and thus can be applied to any chord vocabulary. PMD offers a consistent displacement measure between chord types (e.g., major7, diminished7, etc.) regardless of transposition or the complexity of the chord vocabulary employed. PMD also measures the intervallic displacement between chords, regardless of chord type. In both cases, displacement measurements are unaffected by transposition of an entire sequence, allowing PMD to identify relative harmonic movements regardless of local key structure.

To demonstrate the utility of PMD, we employ a robust chord vocabulary of 13 chord types including triads, 7th chord types, and suspended chords, as well as chromatic and whole tone scales. We measure displacements amongst these chord types and transpositions, and close by presenting example applications of PMD to automated harmonic analysis and discuss potential applications to other areas of music informatics.

2. BACKGROUND

2.1 Pitch Class Profiles & common musical terms

A pitch class profile (PCP) is a vector of 12 binary values, each representing the categorical presence of its corresponding pitch class in the relevant musical context. This context is set within the time domain; unless otherwise specified, we shall be considering notes which occur si-

multaneously. Commonly occurring collections of simultaneous pitch events may be referred to as ‘chords’. A succession of notes occurring sequentially in ascending or descending pitch order is commonly referred to as a ‘scale’. When the time window is increased further and some statistical weighting or filtering is considered, the dominant members of the pitch class set may imply a ‘key’.

Throughout this paper, when referring to the collection of possible PCPs, we exclude the empty PCP $[0,0,0,0,0,0,0,0,0,0,0,0]$ which represents an absence of all pitch classes, resulting in $2^{12} - 1 = 4,095$ possible PCPs. To improve clarity, the terms ‘chord’ and ‘scale’ shall be considered interchangeable with ‘PCP’ unless otherwise noted. The term ‘chord type’ refers to the quality of a chord (e.g., major, minor, etc.) regardless of the chord transposition. A ‘chord’, however, is a specific combination of root and chord type, such as A_{min} or F_{maj7} .

2.2 Chord vocabulary

For transcription and harmonic analysis purposes, it is useful to focus on the subset of PCPs which correspond to certain chord types. Within the domain of all 4,095 PCPs, the choice of chord vocabulary can be a fairly arbitrary decision. Often, smaller vocabularies of simple chords are chosen to simplify experiments and boost performance scores. There is a risk that an over-simplified chord vocabulary can reduce the usefulness of an analytic system, so it is advantageous that a suitably complex chord vocabulary is employed.

For our examples, we restrict ourselves to a vocabulary of 13 chord types (including, by extension, two scales), but the PMD can be applied to any pitch class profile. Our vocabulary included triads: *major*, *minor*, *diminished*, *augmented*, *suspended4*; tetrads: *major7*, *minor7*, *dominant7*, *diminished7*, *half-diminished7*, *minor/major7*, and scales: *chromatic*, *wholetone*. Note that some PCPs can be described using different chord types depending on context, thus some chord types, such as *maj6*, *min6* and *sus2*, are synonymous with other chords already listed in our vocabulary. Regardless of the labels assigned to such synonymous chords, the source PCPs remain the same. For example, PCP $[1,0,0,0,1,0,0,1,0,1,0,0]$ could be described as either C_{maj6} or A_{min7} . Labelling of chords is highly dependent on context and annotator subjectivity. As PMD operates on the basis of underlying PCPs, it is unaffected by such discrepancies in annotation.

2.3 DFTs and Tonal Interval Vectors

By applying a discrete Fourier transform (DFT) to a pitch class profile, we can decompose the PCP into a series of constituent intervallic components. Each of these components will describe the degree to which a particular interval is present within the PCP. Only components $F_1 - F_6$ are required to provide a complete representation, since components $F_7 - F_{11}$ are redundant. Additionally, F_0 reveals the cardinality of the pitch class set; its value is useful for normalisation and allows us to compare any pair of PCPs regardless of the number of pitches present in either.

The resulting 6-dimensional complex vector is referred to as a tonal interval vector (TIV). Scaling may be applied to the various components – often for normalisation purposes, but also in an attempt to more accurately depict perceived cognitive distances between the various interval types within a musical context. [18]

It is worth noting that when generating TIVs, the DFT is applied to the symbolic pitch class vectors and not to audio data. The purpose of the DFT and resulting TIV is to discover the manner in which the pitch classes divide an octave into various musical intervals, and to describe the strength and evenness of each intervallic division.

2.4 Mapping PCPs to TIV space

Each of the 4,095 possible non-empty PCPs produces a unique tonal interval vector. The TIV space therefore is an injection of PCP space: each TIV can be mapped unambiguously to a corresponding pitch class profile. Furthermore, each 6D complex TIV can be represented as a 12-dimensional real-valued vector by converting the complex values of the TIV into magnitude and phase values.

The magnitude and phase values of the recast TIV vector can be represented as a set of 6 tuples (m, p) , where m is an unbounded positive real value, and p is a real value $p \in R$ such that $-\pi \leq p \leq \pi$. We will refer to a magnitude and phase tuple (m, p) as a MagPhase tuple. The set of 6 tuples describing Fourier components $F_1 - F_6$ of a TIV will be referred to as a MagPhase vector.

It has been shown [14,17,18] that converting the Fourier coefficients from complex values to real magnitude and phase values reveals direct correlations to chord type, transposition, and interval ordinality.

2.5 Descriptive properties of Magnitude and Phase

Each TIV Fourier component F_n can be associated with a tonal interval and its complementary inverse interval, e.g. F_1 is associated with the presence of both minor 2nd and major 7th intervals, etc. [14] The magnitude value of a TIV component reflects how strongly the associated interval occurs in the source PCP. For example, F_3 is associated with the presence of major 3rds. Augmented triads (which are composed of nothing but major 3rds) have a maximal F_3 magnitude, whereas diminished 7th chords, which contain no major 3rds, have an F_3 magnitude of 0. Most chords are composed of several interval types and thus have non-zero magnitudes for all 6 components.

Chords containing the same collection of intervals will share a common magnitude profile. This allows some degree of chord classification based on magnitude values. However, magnitude profiles do not convey the ordinal placement of the intervals within the source PCP, meaning that chord types with identical sets of intervals cannot be disambiguated. For example, major and minor triads both contain one of each of the following atomic intervals: $\{m3, M3, P4\}$ and thus will have identical magnitude profiles. For the same reason, magnitude profiles alone do not encode information about the transposition (i.e., the root) of a source PCP, making it impossible to differentiate

C_{dom7} from F_{dom7} or G_{dom7} , for example. By incorporating phase information, both of these shortcomings can be addressed.

3. MOTIVATION

Each component $F_1 - F_6$ of a TIV describes the strength and position of a particular intervallic quality. By measuring the differences between TIV dimensions separately, the intervallic content of TIVs could be exposed and compared. It is reasonable to consider how distances between them might be useful in describing the relationship between their respective PCPs, as well as enabling computational modelling of musical chords and chord sequences, and the automated study of large corpora.

Distance measures are by definition non-directional. However, harmonic transitions are often asymmetrical in practice, e.g., there is a difference harmonically between a $V7 \rightarrow I$ transition and a $I \rightarrow V7$ transition. By measuring displacement between TIVs, both the distance and direction between them are exposed, which increases the descriptive power of the measure.

To extend the difference measure beyond comparisons of isolated pairs of chords, it would be highly advantageous for the measurements to exhibit collinearity under the addition operation. For example, if two chords of the same type a semitone apart have a particular displacement value, it stands to reason that two chords a whole tone apart should have a displacement double that value. Crucially, this would allow multiple displacements to be summed, making it possible to build sequences and represent various progressions between two chords consistently.

Finally, if differences in chord types and intervallic distances between chords were decoupled, displacement between chords could be visualised on a grid whose orthogonal axes represented each quality. The additive collinearity discussed above would ensure that displacement values could be summed consistently, regardless of which displacements were measured or in what order.

This would allow chord sequences to be represented as traversals across a tonal grid. An example of such a grid is displayed in Figure 1. Chord transitions such as $V7 \rightarrow I$ would have the same displacement regardless of the transposition of the pair. For example, $G_7 \rightarrow C_{maj}$ and $A_7 \rightarrow D_{maj}$ would have an identical displacement, despite being in different keys. Such transpositional invariance would enable an algorithm to catalogue and identify commonly occurring functional sequences.

4. POLAR MANHATTAN DISPLACEMENT

To satisfy the criteria outlined in section 3, we propose the Polar Manhattan Displacement (PMD). PMD measures the component-wise displacement between two TIVs by calculating the differences in the magnitude and phase of each component. As each component F_k describes some aspect of the tonal nature of the source chord, this allows us to measure the displacements between chords in an intervallically informed way.

Figure 1. Decoupled chord type and intervallic displacements for the chord transition $G_7 \rightarrow C_{maj}$. There are three routes from $G_7 \rightarrow C_{maj}$; The PMDs of each arrow are summed. All routes result in the same final displacement value. Note that the direction of the progression is significant.

PMD thus borrows from L-1 Manhattan distance but extends it to measure the directional displacements between corresponding magnitudes and phases in each dimension of the polar representation of the TIV plane. The differences are signed, meaning that PMD reflects displacement rather than formal distance. This is advantageous within a musical context because tonal harmony is directional; for example the transition ($C_{maj} \rightarrow G_7$) has a markedly different tonal impact than ($G_7 \rightarrow C_{maj}$).

4.1 Magnitude processing

The processing of magnitude values is straightforward as it involves only scaling and subtraction. After a TIV is extracted from a PCP, the magnitudes of F_1 to F_6 are divided by the value of F_0 . This normalises all magnitudes to the same scale and allows comparison of TIVs having different numbers of pitches in their source PCPs. Further scaling of each component magnitude may be applied to improve the perceptual basis of the space [18] [20]. However, perceptual scaling has not been applied in our study. Following the application of normalisation and scaling, magnitude values are simply subtracted such that the difference between the magnitudes of TIVs U and V is

$$\text{Disp}_{mag}(U \rightarrow V) = (V_{mag} - U_{mag}) \quad (1)$$

4.2 Phase processing

Phase values are simply subtracted in a similar fashion to that presented in section 4.1 such that the angular displace-

Chord type	M1	M2	M3	M4	M5	M6

Min7		X				X
Dim7	X	X	X		X	X
Aug	X	X		X	X	
Sus4				X		
Chrom	X	X	X	X	X	X
WholeTone	X	X	X	X	X	

Table 1. Some common chord types with zero-magnitude components. 'X' indicates a zero-magnitude vector.

ment between TIVs U and V is

$$\text{Disp}_{\text{phase}}(U \rightarrow V) = (V_{\text{phase}} - U_{\text{phase}}) \quad (2)$$

The cyclic nature of phase information necessitates additional processing. Angular phase values θ need to be cyclically wrapped into the interval $-\pi < \theta \leq \pi$ after all additive and subtractive operations on phase values.

4.3 Definition of PMD

Having defined Disp_{mag} in Eq. (1) and $\text{Disp}_{\text{phase}}$ in Eq. (2), we can now present the definition of the Polar Manhattan Displacement. PMD is created by concatenating the 6D magnitude and phase displacement vectors Disp_{mag} and $\text{Disp}_{\text{phase}}$ into one 12D vector.

Given chords (P_j, Q_k) and their corresponding TIVs (U, V) ,

$$\text{PMD}(P_j, Q_k) = \begin{bmatrix} \text{Disp}_{\text{mag}}(U \rightarrow V) \\ \text{Disp}_{\text{phase}}(U \rightarrow V) \end{bmatrix} \quad (3)$$

4.4 Zero-magnitude handling

Some PCPs have various TIV components with zero-valued magnitudes. This indicates that the corresponding interval type is absent from the source PCP. While this is of no consequence when calculating magnitude difference (for the magnitude is simply 0), the associated phase of these components is effectively undefined, complicating the calculation of differences between phase values. In our vocabulary, the following chord types contain one or more zero-magnitude component vectors: $\{\text{maj7}, \text{min7}, \text{dim7}, \text{aug}, \text{sus4}, \text{chrom}, \text{wln}\}$. Table 1 details these zero-magnitude chords and their affected components.

We employ the convention that these phase values are considered to be 0. This preserves the additive properties of PMD and allows multiple displacement values to be added together consistently.

4.5 Investigating displacements of type and interval

As indicated in section 3, it would be highly advantageous (and musically interesting) to find a way to distinguish the degree of displacement due to changes in chord types versus shifts of interval. In this section, we examine to what extent such a decoupling is possible.

For convenience, we present the terms $\text{Disp}_{\text{type}}$ (representing the displacement between chord types) and $\text{Disp}_{\text{intv}}$ (representing the intervallic displacement between any two chords of the same type). We define each with a functional representation, then provide an example of the relevant function in use. We employ the following convention to represent a movement from one chord to another:

$$(P_j \rightarrow Q_k) \quad (4)$$

where j and k denote chord types from our vocabulary and P and Q denote two arbitrary chord roots. For example, the following represents a movement from G_7 to C_{maj} :

$$(G_7 \rightarrow C_{\text{maj}}) \quad (5)$$

where $j = \text{dom7}$, $k = \text{maj}$, $P = G$, and $Q = C$. Note that the direction of the chord transition is significant.

4.5.1 Type-based displacement

A type-based displacement $\text{Disp}_{\text{type}}$ can be derived by calculating the PMD of two chords (P_j, Q_k) having the same root (i.e., $P = Q$) but different types ($j \neq k$). Formally,

$$\text{Disp}_{\text{type}}(j, k) = \text{PMD}(P_j, P_k) \quad (6)$$

where $j \neq k$.

Significantly, these displacement values are consistent for all pairs of chord types (j, k) regardless of the values of root (P) . As an example, the PMD values corresponding to the displacement from a chromatic scale (j) to each of the chords in our vocabulary (k) are detailed in table 2.

4.5.2 Intervallic displacement

Likewise, the intervallic displacement $\text{Disp}_{\text{intv}}$ between any two chords (P_j, Q_k) should ideally be consistent regardless of the chord types involved. In a similar fashion to the calculation of $\text{Disp}_{\text{type}}$, we calculate $\text{Disp}_{\text{intv}}$ by calculating the PMD of two chords (P_j, Q_k) having different roots (i.e., $P \neq Q$) but identical types ($j = k$).

$$\text{Disp}_{\text{intv}}(P, Q, j) = \text{PMD}(P_j, Q_j) \quad (7)$$

where $P \neq Q$. Note that $\text{Disp}_{\text{intv}}$ is a vector of real number values and is not expressed in semitones.

Crucially, the $\text{Disp}_{\text{intv}}$ is largely – but not entirely – independent of chord type j . For all chord types j with uniquely non-zero TIV magnitude components, the $\text{Disp}_{\text{intv}}$ in function of the root interval shift ($P \rightarrow Q$) expressed in semitones is shown in table 3. Chord types j that contain magnitudes of zero (as shown in table 1) have the same PMD as in table 3 for their non-zero components, but both magnitude and phase components of the PMD corresponding to the TIV components with value zero are also zero. By combining tables 1 and 3, the $\text{Disp}_{\text{intv}}$ for all chord types in our vocabulary can be determined.

Table 3. PM Displacements of each ascending transposition interval in semitones for chord types that have no zero-valued TIV magnitudes. Each column is a PMD vector. Note the symmetry of the column values; intervallic distances are constant, while the sign indicates the direction of transposition. To reverse the direction, (i.e., to transpose down) invert the signs of the values. Also, note that only the phase elements are affected by transposition.

Component	Tritone Substitution		$V_7 - I$	
	(G_7, Db_7)	(A_7, Eb_7)	(G_7, C_{maj})	(B_7, E_{maj})

P_6	0	0	3.142	3.142

Table 4. PMD comparisons of a) two tritone substitutions and b) two $V_7 - I$ sequences. Notice that within each pair the PMD values are identical. This indicates that any pair of chords separated by this displacement will constitute a tritone substitution pair or $V_7 - I$ sequence, respectively, regardless of the transposition.

5. PMD EXAMPLES

5.1 Example 1: Tritone substitution

It is well known within musical harmonic practice that certain chords may be substituted for one another to provide alternative or extended versions of an existing or expected harmony. A common example of this is the tritone substitution, wherein a dominant 7th chord can be replaced with a different dominant 7th whose root is a tritone (i.e., an augmented 4th or diminished 5th) away from the original root. The pitches acting as the 3rd and 7th of the original chord are retained, but their functions are swapped. The remaining 2 pitches of the first chord are replaced with other pitches. The overall function is of a new chord that retains the essential character of the original chord, but provides additional harmonic tension.

While issues of perceptual similarity are beyond the scope of the current study, PMD can provide an objective means of numerically describing such relationships. For example, consider the Polar Manhattan Displacements between each of these two tritone substitution pairs: (G_7, Db_7) and (A_7, Eb_7) as detailed in Table 4. Notice that the PMD values are identical. Any pair of chords separated by this displacement will constitute a tritone substitution pair.

5.2 Example 2: $V_7 - I$ detection

There are a number of MIR tasks involving chord estimation, transcription, and automated harmonic analysis that could benefit from the ability to autonomously identify certain chord progressions, particularly those which are harmonically significant. Traditionally, these tasks are hampered by lack of labelled data, inconsistent chord vocabularies, inter-annotator disagreement, etc. As PMD operates on unlabelled symbolic data, it could contribute to addressing such shortcomings and improving performance in automated transcription, labelling, and harmonic analysis. Table 4 describes the displacement between two different $(V_7 \rightarrow I)$ progressions and confirms that PMD can identify and encode the $(V_7 \rightarrow I)$ progression consistently, regardless of key or transpositional context.

6. CONCLUSIONS & FURTHER WORK

We began with a background review of pitch class profiles and some basic terms of musical harmonic structures. We then discussed tonal interval vectors: how discrete Fourier transforms can be applied to PCPs to create TIVs, how TIVs can be represented as vectors containing magnitude and phase values, and how those values describe some aspects of the intervallic construction of a chord. We proposed that it could be useful to measure displacements between these objects, and then described the properties necessary for a robust and self-consistent measure of displacement.

We then presented the Polar Manhattan Displacement, its fundamental components, and the processing required to calculate the measurement of magnitude and phase dif-

ference values. There was a brief description of our chord vocabulary and the need for suitable chord vocabularies, and a brief discussion of how to maintain transpositional invariance when dealing with non-existent magnitude vectors.

Having discussed the criteria for a suitable displacement measure, and detailed the functional components of our proposed measurement algorithm, we demonstrated how these components could be aggregated to create the Polar Manhattan Displacement measure. We then provided two examples of potential use cases of PMD, one involving the autonomous identification of tritone substitutions, and the other, $V_7 - I$ progressions.

Future technical work will involve evaluating the robustness of PMD when employed on audio data and at various scales of temporal granularity. It would be interesting to investigate extension of PMD to process non-binary PCPs, such as weighted PCPs and harmonic pitch class profiles. As the additive properties of PMD allow displacements to be summed, we would also like to extend the application of PMD to chord sequence modelling and analysis. Finally, we would like to deploy PMD as part of a large corpus study to investigate chord similarity and harmonic practice.

7. ACKNOWLEDGEMENTS

This research was partially supported by EPSRC grant EP/R512072/1 and the British Broadcasting Corporation through an Industrial CASE studentship in collaboration with the BBC Audio Research Partnership.
