sical structure. Computational SchA can also aid the expert human analyst by offering several potential solutions, speeding up their ability to parse through a piece of music or potentially unveiling unusual and interesting analytical insights. The computer would not replace the human expert; rather, it would help the analyst find reasonable solutions more quickly, which would be immensely helpful when conducting large-scale corpus studies. Furthermore, inclusion of SchA in MIR and generation tasks may greatly improve results. This injection of computational models with musical theory and/or structure has shown benefits in numerous MIR and generation tasks [14–17].

This paper introduces three main contributions. The first is a new and growing **SchA dataset**, the largest in human- and computer-readable format to date (>140 excerpts). Second, we present a novel **notation software for SchA** in an effort to ease data collection and visualization. Lastly, we describe a **representation of SchA** as a graphical data structure and graph pooling problem.

The following subsections describe SchA in more detail, as well as the relevant history of computational SchA. Section 2 describes our novel dataset and data collection tool. Finally, Section 3 describes how SchA may be represented as a graph data structure.

1.1 Hierarchical Music Analysis

Music is often composed and understood in terms of hierarchical structures such as phrase and rhythmic structure [18, 19], form structure [20, 21], and linear/harmonic structure [22, 23]. In this paper, we focus on the Schenkerian model of harmonic-melodic structure. As mentioned earlier, SchA aims to reveal how harmonies are “unfolded” through linear motion on various levels of structure. Figure 1 shows the relationship between a fugue’s subject melody and its underlying harmony, as well as the hierarchy of melodic tones.

Figure 1: The primary author’s analysis of J.S. Bach’s F major fugue subject from *Das Wohltemperierte Klavier I*.

The annotated score on the upper line shows how notes relate on various levels of structure, forming two theoretical outer voices. Longer stems indicate deeper levels of structure. The reduction on the bottom line exemplifies the underlying harmony that is unfolded by the subject melody. Green-stemmed notes correspond with the deep outer voices of the reduction.

SchA has shown that similar harmonic and motivic features often exist on multiple levels of hierarchy, revealing music’s “fractal” nature [24]. For instance, in Figure 1, the foreground melody within the first full measure (D4-C4-Bb3) can be seen as a *parallelism* of the deep level melody spanning the entire excerpt (C4-Bb3-A3); the two melodies have a similar motivic descending third in step-wise motion. One can also see the first full measure leading into the second measure as a $V^b - I$ motion in the key of V, paralleling the deep level $V^b - I$ shown in the reduction. While these examples are on a very small scale, one can see more complex harmonic and motivic structures unfolded through entire pieces. For instance, see Example 12 in [24] describing Schubert’s *Erlkönig* or Example 2 in [25] describing The Beatles’ *Something*.

Because these same music-theoretical ideas and motifs permeate multiple levels of structure, the use of a carefully-designed machine learning model may reveal such structure in a layered approach. With the rise of machine learning in data science, this calls into importance the need for computer-readable SchA datasets for model training.

1.2 Previous Work and Data for Computational Schenkerian Analysis

The majority of past attempts at computational SchA [26–30] were based on heuristics and rule-based algorithms, and therefore did not require a true computer-readable dataset for SchA. To our knowledge, Marsden [31] was the first to venture towards a machine learning approach, using a humble corpus of six Mozart analyses. He developed a “goodness metric” based on these six analyses to find the best candidate analyses within a massive search space.

More recently, Kirilin designed a probabilistic model for SchA that understands SchAs as maximal outerplanar graphs (MOPs) and learns how likely certain notes *prolong* others using random forests [32, 33]. He defines prolongation as “a situation where an analyst determines that a group of notes is elaborating a group of more structurally fundamental notes.” For instance, the syntax follows the pattern $X(Y)Z$, where the note(s) of Y prolong the motion from note X to note Z .

One potential drawback of Kirilin’s model is that it always considers one musical voice as one theoretical voice. Looking back at Figure 1, for example, we see there is clearly a deep level bass motion from E3 to F3, supporting the upper voice, which follows the motion C4-Bb3-A3. The sixteenth notes of m. 2 act to fill the gap between the lower and upper theoretical voices. An MOP reduction of the melody would force all notes to be understood as a single theoretical voice, thus obscuring the underlying counterpoint of the passage. For this reason, we represent SchA as a more general graph data structure, described further in Section 3.

For his model, Kirilin released the first large-scale computer-readable dataset of symbolic music with corresponding expert Schenkerian analyses, *Schenker41* [6]. This collection consists of 41 excerpts from the common practice period of European art music, with analyses from

Figure 2: Screenshots of a toy Schenkerian analysis in JSON and graphical form as generated by our notation software.

three textbooks [23, 34–36] and an independent, anonymous expert in Schenkerian analysis. Kirilin also created the first computer-readable format for Schenkerian analysis, which describes all prolongations present in an analysis. The text-based format can also encode linear progressions, omitted repetitions, and harmonic context.

The Schenker41 dataset is an important first step towards broader musical-hierarchical research in the MIR community; however, there are some limitations. First of all, the quality of the excerpts chosen are questionable. Kirilin and Jensen recruited three expert Schenkerian analysts to grade textbook analyses as well as their machine learning model’s analyses in their 2015 paper (see Figure 8 in [37]). One would expect the textbook analyses to receive grades of “A-” or greater, allowing wiggle room for differences of opinion. However, many excerpts score lower marks; some were even given failing grades. Given the high proportion of dubious quality “ground truth” data, it is necessary to produce a greater quantity of quality data before successful, generalizable models can be trained.

There are also several Schenkerian symbols and concepts that are not currently represented in the text-based notation. For instance, unfoldings, voice exchanges, and other hierarchical harmonic function information are ignored. Concerning larger pieces, it is vital to understand the harmonic structure in several layers; an F major triad may stand as a local tonic “I” harmony in the foreground that serves to expand a deeper subdominant “IV” of the background, global key of C. Furthermore, more abstract concepts, such as motivic parallelisms, implied tones, and written commentary are eschewed for the sake of simplicity.

2. DATASET AND NOTATION SOFTWARE FOR SCHENKERIAN ANALYSIS

We thus introduce a new large-scale dataset of Schenkerian analyses in human- and computer-readable formats. As of the writing of this paper, the dataset contains 145 analyses from four analysts for a broad range of composers including J.S. Bach, Mendelssohn, Brahms, Bartók, Shostakovich, Gentle Giant, and more. The majority of

analyses were created by the first author (Stephen Ni-Hahn) with consultation from one of the other analysts, who wishes to remain anonymous at this time. Ni-Hahn currently has nearly a decade of experience with SchA including a graduate degree in music theory. The other three analysts are veteran Schenkerian scholars with several decades of experience in the field. The dataset is not static and aims to grow over time. Please contact Stephen Ni-Hahn (stephen.hahn@duke.edu) for questions regarding, and access to the dataset and notation software described in this paper.

Currently, the vast majority of analyses in the dataset describe the hierarchical relationships within fugue subjects by Bach and Pachelbel. Fugue subjects are ideal for preliminary trials with machine learning models since subjects are generally brief, consist of a single instrumental line (which may consist of multiple theoretical voices), generally have clear functional relationships, and each have a definite sense of closure by their end.

Rather than writing out each prolongation explicitly, we produce prolongations as a by-product when assigning a hierarchical *depth* to each note. For example, Figure 2 shows a toy example of an analysis in which the numbers to the left of the note heads indicate depth. Higher depth indicates deeper structure. To retrieve the prolongations, we simply traverse the graph at each depth level (greater than 0), connecting consecutive notes that are at the same level or higher. Custom prolongations that do not occur within this system may be added in a similar fashion to Kirilin’s text format by describing the voice and index of the start, middle, and end notes.

Figures 3 and 4 present simple statistics about our dataset. Figure 3a shows the distribution of excerpt lengths in terms of *verticalities*. A verticality is defined as a point in time where one or both of a treble and bass note exist. Note that this does not measure length of time or number of measures; rather, the number of verticalities describes the number of potentially unique depths in an excerpt. Figure 4 shows the distribution of intervals between consecutive notes in the treble and bass voices at various depths. We see that as depth increases, the distribution of treble in-

(a) Distribution of excerpt length.

Depth	Notes per Depth		Avg. Verticalities per Depth		Num Pieces
	Inclusive	Literal	Inclusive	Literal	Max Depth
0	1815	646	15.6	4.7	0
1	1280	324	11.0	2.8	1
2	957	265	8.3	2.3	8
3	694	258	6.5	2.4	26
4	439	232	5.4	2.9	36
5	208	161	4.6	3.5	33
6	51	41	4.3	3.4	10
7	10	6	5.0	3.0	1

(b) Dataset statistics regarding note depth.

Figure 3: Dataset statistics. Verticality is defined as a point in time where one or both of a treble and bass note exist. “Inclusive” includes notes of higher depth when counting notes of lower depths. “Literal” counts the note depths as they are defined. The final column describes the distribution of max depths over all excerpts. See Section 2 for more details.

Intervals moves from smaller to larger intervals, while bass intervals increasingly concentrate around 0 and 5. These statistics suggest that surface level treble motions in our dataset are mostly stepwise and span larger intervals at deeper levels of structure. Furthermore, deep bass structures tend to hold steady and support the upper voice or move along the circle of fifths by jumping 5 or 7 half steps. Table 3b describes various statistics regarding the notes and depths of our dataset. Columns labeled “inclusive” mean that notes of higher depth are included when counting notes of lower depths. For instance, a depth 4 note is counted in the number of depth 0 notes, while the depth 4 note would not count towards the number of depth 5 notes. The “literal” label counts the note depths as they are defined. The final column describes the distribution of max depths over all excerpts.

Figure 4: Distribution of intervals between consecutive notes at each depth.

2.1 Data Collection Tool

To facilitate easy collection and visualization of Schenkerian data, we introduce a new computer notation system for Schenkerian analyses (see Figure 2 for a screenshot).

As of the writing of this paper, our software is capable of notating up to four voice structures of any length. Simple commands allow the user to adjust the pitches, note depths, harmonic/scale-degree label, notes considered part

of the *Ursatz*, etc. Slurs and beams of the outer theoretical voices are automatically generated based on the depths of the notes. We are currently working on ways to render custom markings, such as voice exchanges, unfoldings, and linear progression beams.

Behind the scenes, the Schenkerian analysis is a simple standardized object in JavaScript Object Notation (JSON), which is *highly generalizable, lightweight, and simple to parse*, and is capable of describing any obscurities within a particular analysis. Our JSON object contains metadata about the analysis, key information, and information on each of four theoretical voices. Metadata describes the analyst, composer, title, subtitle, and any associated written description of the analysis. Furthermore, each theoretical voice is encoded as a list of pitch names, depths, *Ursatz* indices, scale degree/Roman numerals, flagged note indices, sharp/flat/natural indices, and parenthetical indices. Additionally, the JSON object stores “cross voice” symbols such as voice exchange lines and lines indicating related tones across larger spans of time.

Note that it is straightforward to translate between Kirlin’s OPC text notation and our JSON notation. To translate from text to JSON, the notes can be parsed from the musicxml and placed in their appropriate voice. Then note depths may be determined by the location and relative length of their prolongation. Translating from JSON to text is simpler, as one can traverse each depth and retrieve the prolongations.

The software is constructed using languages Javascript/Typescript and the Vue web framework. It is packaged using Electron Forge. Software access can be requested by emailing the first author.

3. SCHENKERIAN ANALYSIS AS A HETEROGENEOUS GRAPH DATA STRUCTURE

As mentioned in Section 1.2, Kirlin’s model simplifies the difficult problem of performing SchA, using a limited version of Yust’s MOP representation for SchA. With a greater amount of data, less compromising representations may be used for modeling. The following section describes how a musical score may be represented as a

algo2e 1 JSON to Clusters

Definitions

$parts \leftarrow \{sop, alto, ten, bass\}$

    return  $\{(sop, j_1), (bass, j_2)\}$  // Closest two notes in outer voices in opposite directions to the inner voice note
end if
    
```

heterogeneous-edge directed graph data structure and how SchA may be conceptualized as a graph clustering problem.

3.1 Graph Music Representation

In what follows, we represent music as a heterogeneous directed graph G , where each node describes a note, and various types of edges describe the relationships between notes. Concretely, G is represented as (\mathbb{A}, X) , where $\mathbb{A} \in \{0, 1\}^{h \times n \times n}$ describes the set of h adjacency matrices (one for each edge type) over n nodes, and $X \in \mathbb{R}^{n \times d}$ is the node feature matrix with d as the number of features. These d features may be learned by a neural network, for instance, to correspond with categorical and numerical musical features.

We adapt the encoding scheme proposed by Jeong et al. [38] for the purpose of Schenkerian analysis. Nodes may be encoded with any musical feature present in the score, such as pitch class, octave, absolute duration, position (absolute or relative), metric strength, etc. We suggest the use of five main edge types: (i) forward edges connect two consecutive notes within a voice, (ii) onset edges connect notes that begin at the same time, (iii) sustain edges connect notes that are played while the source note is held, (iv) rest edges are like forward edges, but imply a rest occurs between the two related notes, and (v) linear edges connect each note with the next notes that occur at specific intervals from the source.

3.2 Schenkerian Analysis as Hierarchical Clustering

With this graphical representation of music, the process of Schenkerian analysis may then be posed as a hierarchical graph clustering problem. Figure 5 presents a toy example of how Schenkerian analysis may be represented as a series

of hierarchical clusters. The clustering between two subsequent levels of Schenkerian analysis is expressed through a *clustering matrix*, $S^{(l)} \in \mathbb{R}^{n_l \times n_{l+1}}$, where n_l is the number of nodes in *clustering* layer l and $n_{l+1} < n_l$ is the number of nodes after one iteration of clustering. We define n_0 to be the total number of notes in the music.

Note that we can understand a clustering between *any* two layers as a single matrix, denoted as $S^{(l_i) \rightarrow (l_j)} \in \mathbb{R}^{n_{l_i} \times n_{l_j}}$; $i < j$, where i and j are the index of the source and destination layers respectively. This single matrix is obtained by simply multiplying all sequential clustering matrices. For example, in Figure 5, to retrieve the matrix describing how all five nodes of the original score are clustered into the two nodes of the final middleground layer, we can multiply each clustering matrix together:

$$S^{(0) \rightarrow (2)} = S^{(0)} \cdot S^{(1)} \cdot S^{(2)} = \begin{bmatrix} 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}^\top.$$

3.3 Converting Schenkerian Analyses from JSON to Matrix Notation

Schenkerian analysis JSON data (collected using our tool described in Section 2.1) requires extra processing to be represented as hierarchical clusters. Here, we provide an algorithm to convert our JSON data into a series of progressively smaller clustering matrices (see Algorithm 1).

Essentially, we first traverse the outer voices of the JSON file, clustering notes of depth 0 into the closest note of higher depth to the left in the same voice. If that note does not exist, it defaults to the closest note of a higher depth to the right. For inner voices, if they do not describe hierarchical depth (all 0 depth), they are clustered 50%-50% between the nearest bass and soprano below and above or left to right, in that order. If the inner voice has

Figure 5: Visualization of Schenkerian analysis as a series of clustering matrices. The bottom row shows a simple score with Schenkerian annotation moving from all notes in the score to more abstracted versions of the score from left to right. The middle row visualizes the music as a graph. The top row shows the ground truth cluster matrices that relate one layer to the next; rows describe nodes before clustering, while columns describe nodes after clustering.

specified depth, it is treated similarly to the outer voices. All depths are then decremented and the process begins again for the next clustering matrix.

3.4 Implications of SchA Graph Clustering

The above formulation of SchA as a graph clustering problem facilitates more generalizable analysis. Whereas Kirilin’s MOP-based model focuses on a single melody as one theoretical voice, a fuller graph representation allows for greater flexibility via any number of theoretical voices. There are, however, several drawbacks with this new approach. Because the clustering works with the notes of the score, it is unclear how to handle cases where multiple theoretical voices converge on a single note. This issue may also be present when handling inner voices of unspecified depth. In our algorithm, we suggest splitting unspecified inner voices 50%-50% between the outer voices, but other approaches may also be reasonable.

Another advantage that the proposed graph clustering representation has over the MOP representation is its ability to cluster multiple notes into one in a single layer. This is particularly common when there are several repeated notes. In a MOP, repeated notes must be given detailed hierarchy, whereas a human expert would generally think of such repetitions as structurally redundant. There are also instances of prolongations that span more than one child, where having only one child would not properly reflect the music. For instance, if the melody over a C major tonic triad (CEG) quickly plays out the upper tetrachord of the scale, G-A-B-C, then the A and B are structurally equal; they both bridge the gap from G to C. On the other hand, allowing multiple children for every prolongation makes the search space for potential solutions orders of magnitude larger.

As the amount of labeled SchA data grows and computational power improves, there is great potential for learning complex relationships via machine learning that may

be unattainable in previous analyses. Deep learning has enjoyed considerable success on analyzing the Bach chorale dataset [39–41], thus we are optimistic that SchA can also be learned for broad datasets from different genres. The proposed dataset, notation software and graph representation provides a promising step towards this goal.

4. CONCLUSION

In this paper, we introduce the largest corpus of Schenkerian analyses in computer-readable format to date. This was largely made possible using our novel SchA notation software, which is natural, interpretable, and enables easy data collection and visualization. Finally, we describe and discuss a novel representation for SchA as a graph clustering problem that allows representation of any possible Schenkerian analysis, avoiding the limitations of MOPs. It is our hope that the growing amount of data and ease of its collection will enable broader research into SchA’s applications.

6. ETHICS STATEMENT

This particular work has no direct negative ethical implications.

We acknowledge that Heinrich Schenker (the inventor of Schenkerian analysis) was racist and nationalist. His sociopolitical views are not condoned by authors of the present work. As originally designed, his style of analysis did not extend far beyond German composers of the common practice era. As we address in Section 1, we do not see Schenkerian analysis as a static analysis defined by Schenker; rather, we see it as a growing and developing set of tools that may be applied to various musical genres, detached from Schenker’s personal views.

DITTO-2: DISTILLED DIFFUSION INFERENCE-TIME T-OPTIMIZATION FOR MUSIC GENERATION

ABSTRACT

Controllable music generation methods are critical for human-centered AI-based music creation, but are currently limited by speed, quality, and control design trade-offs. Diffusion inference-time T-optimization (DITTO), in particular, offers state-of-the-art results, but is over 10x slower than real-time, limiting practical use. We propose **Distilled Diffusion Inference-Time T-Optimization** (or DITTO-2), a new method to speed up inference-time optimization-based control and unlock faster-than-real-time generation for a wide-variety of applications such as music inpainting, outpainting, intensity, melody, and musical structure control. Our method works by (1) distilling a pre-trained diffusion model for fast sampling via an efficient, modified consistency or consistency trajectory distillation process (2) performing inference-time optimization using our distilled model with one-step sampling as an efficient surrogate optimization task and (3) running a final multi-step sampling generation (decoding) using our estimated noise latents for best-quality, fast, controllable generation. Through thorough evaluation, we find our method not only speeds up generation over 10-20x, but simultaneously improves control adherence and generation quality all at once. Furthermore, we apply our approach to a new application of maximizing text adherence (CLAP score) and show we can convert an unconditional diffusion model without text inputs into a model that yields state-of-the-art text control. Sound examples can be found at <https://ditto-music.github.io/ditto2/>.

1. INTRODUCTION

Audio-domain text-to-music (TTM) methods [1–6] have seen rapid development in recent years and show great promise for music creation. Such progress has been made possible through the development of diffusion models [7–9], language models [1, 2], latent representations of audio [10–13] and text-based control [4, 14]. Such control, however, can be limiting for creative human-centered AI

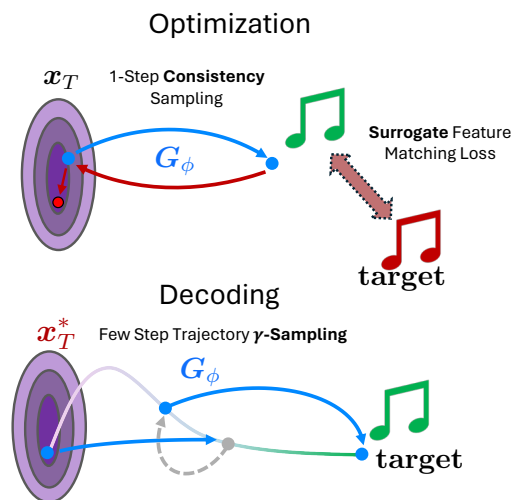

Figure 1: DITTO-2: Distilled Diffusion Inference-Time T-Optimization. We speed up diffusion inference-time optimization-based music generation by 10-20x while improving control and audio quality. (Top) We use diffusion distillation to speed up performance (optimize with 1-step sampling). (Bottom) We then run multi-step sampling for final higher-quality generation (decoding).

music applications, motivating more diverse and advanced control (e.g., melody) that target’s fine-grained aspects of musical composition.

Recent control methods that go beyond text-control fall into training-based and training-free methods. Training-based methods like Music-ControlNet [15] fine-tune DMs with additional adaptor modules that can add time-dependent controls over melody, harmony, and rhythm, offering strong control at the cost of hundreds of GPU hours of fine-tuning for each control. With training-free methods, in particular the class of inference-time *guidance* methods [16, 17], the diffusion sampling process is guided at each step using the gradients of a target control $\nabla_{x_t} \mathcal{L}(\hat{x}_0(x_t))$, where $\hat{x}_0(x_t)$ is a 1-step approximation of the final output. While training-free, the reliance on approximate gradients limits performance [18]. Finally, inference-time optimization (ITO) methods [19, 20] like DITTO [18] offer state-of-the-art (SOTA) control without the need for large-scale fine-tuning via optimizing for noise latents, but suffer from slow inference speeds (10-20x slower than real-time) [18].

In this work, we propose **Distilled Diffusion Inference-Time T-Optimization** (or DITTO-2), a new method for speeding up ITO-based methods by over an order of magni-

tude for faster-than-real-time generation for a wide-variety of controllable generation tasks including inpainting, outpainting, intensity, melody, and musical structure control. Our method works via 1) distilling a pre-trained diffusion model for fast sampling via an efficient, modified consistency model (CM) [21] or consistency trajectory model (CTM) [22] distillation process (only 32 GPU hours on a 40GB A100), (2) performing inference-time optimization using our distilled model with a 1-step *surrogate* objective, and (3) running a final multi-step sampling generation (decoding) using our estimated noise latents for final best-quality results as shown in Fig. 1. We find our approach accelerates optimization 10-20x, improves control, and improves audio quality at all once. Furthermore, we apply our approach to maximize text adherence (CLAP score) and show how an unconditional diffusion model trained without text inputs can yield SOTA text control.

2. BACKGROUND

2.1 Diffusion-Based Music Generation

Audio-domain music generation has become tractable through diffusion-based methods, popularized with models such as Riffusion [3], MusicLDM [23], and Stable Audio [4]. Diffusion Models (DMs) [8, 24] are defined using a closed-form forward process, where input audio is iteratively noised according to a Gaussian Markov Chain. DMs then learn to approximate the score of the probability distribution of the reverse process $\nabla_{x_t} \log q(x_t)$ using a noise prediction model ϵ_θ , which progressively denoises a random initial latent $x_T \sim \mathcal{N}(0, I)$ to generate new data x_0 . For audio-domain DMs, diffusion is performed over spectrograms [15] or on the latent representations of an audio-based VAE [3, 4, 23, 25], with an external vocoder used to translate spectrograms back to the time domain. Though DMs are efficiently trained by a simple MSE score matching objective [8, 26], sampling from DMs typically requires running the denoising process for 100s of iterations (calls to ϵ_θ), and have slower inference than VAEs or GANs [27].

2.2 Fast Diffusion Sampling

Fast diffusion sampling is critical. DDIM [8] or DPM-Solver [28] accelerates DMs to sample in only 10-50 sampling steps. To truly increase speed, however, *distillation* can be used to produce a model that can sample in a *single* step [21, 22, 29, 30]. Two promising DM distillation methods include consistency models (CM) [21] and consistency trajectory models [22]. The goal of CMs is to distill a base DM ϵ_θ into a new 1-step network $x_0 = \mathbf{G}_\phi(x_t, c)$ that satisfies the consistency property $\forall t, t' \in [T, 0], \mathbf{G}_\phi(x_t, c) = \mathbf{G}_\phi(x_{t'}, c)$ or that every point along the diffusion trajectory maps to the same output. Formally, CMs are distilled by enforcing local consistency between the learnable \mathbf{G}_ϕ and an exponential moving average (EMA) copy \mathbf{G}_{ϕ^-} :

$$\mathbb{E}_{t \sim T} (\mathbb{E}_{x \sim \mathcal{D}} \|\mathbf{G}_\phi(x_t, c) - \mathbf{G}_{\phi^-}(\Theta(\epsilon_\theta, x_t, c), c)\|_2^2), \quad (1)$$

Figure 2: (Top) Baseline DITTO runs optimization over a multi-step sampling process to find an initial noise latent to achieve a desired stylized output, incurring a large speed cost. (Bottom) When generating the final output (decoding), the same multi-step diffusion sampling process is used.

where $\Theta(\epsilon_\theta, x_t, c)$ denotes one sampling step from x_t to x_{t-1} using the *frozen* teacher model ϵ_θ and some sampling algorithm (e.g. DDIM).

CMs are not perfect, however, and one-step performance lags behind DM quality [29]. Multi-step “ping-pong” sampling [21] also does not reliably increase quality due to compound approx. errors in each renoising step. CTMs [22], on the other hand, are designed to fix this problem. CTMs bridge the gap between CMs and DMs by distilling a model $x_s = \mathbf{G}_\phi(x_t, c, t, s)$ that can jump from *anywhere* t to *anywhere* s along the diffusion trajectory as shown in Fig. 3. CTMs then use γ -sampling to interpolate between few-step deterministic sampling along the trajectory ($\gamma = 0$) and CM’s “ping-pong” sampling ($\gamma = 1$), allowing a way to balance sampling stochasticity with overall quality. To our knowledge, CTM distillation is unexplored for audio, and CM distillation has only been applied to general audio [31].

2.3 Diffusion Inference-time Optimization

Diffusion inference-time optimization (DITTO) [18–20] is a general-purpose framework to control diffusion models at inference-time. The work is based on the observation that the *initial noise latent* x_T , traditionally thought of as a random seed, encodes a large proportion of the semantic content in the generation outputs [18, 32]. Thus, we can search for an initial noise latent of the diffusion generation process via optimization to achieve a desired stylized output as shown in Fig. 2. We do this by defining a differentiable feature extraction function (e.g. chroma-based melody extraction) $f(\cdot)$, a matching loss function \mathcal{L} (e.g. cross entropy), a target feature \mathbf{y} , and optimize x_T :

$$x_T^* = \arg \min_{x_T} \mathcal{L}(f(x_0), \mathbf{y}) \quad (2)$$

$$x_0 = \Theta_T(\epsilon_\theta, x_T, c), \quad (3)$$

where $\Theta_T(\epsilon_\theta, x_T, c)$ denotes T calls of the model using any sampler Θ . In practice, DITTO is run with a fixed budget of K optimization steps using a standard optimizer (i.e. Adam). This approach allows for any control that can

Figure 3: CTM Distillation for DITTO-2. We distill G_ϕ by minimizing the distance between the jump from x_t to x_s and x_{t-1} to x'_s , where x_{t-1} is generated by sampling with the base model ϵ_θ .

be parameterized differentially, including melody, intensity, and musical structure, as well as editing tasks like inpainting and outpainting. For brevity, we combine Eq. 2 and Eq. 3 into the shorthand $x_T^* = \arg \min_{x_T} \mathcal{L}_\theta^{(T)}(x_T)$.

The downside of DITTO, however, is that it is slow. We need to backpropagate through the *entire* sampling process for each of the K optimization steps and use memory management techniques like gradient checkpointing [33] or invertible networks [19] to handle large memory use that slows down generation. The overall cost of running a single ITO generation is on the order of $4KT$: T -step diffusion chain for K opt. steps, with a factor of 2 from gradient management and 2 from using classifier-free guidance (CFG) [34] to improve quality.

3. METHOD

3.1 Overview

We seek to dramatically speed up the diffusion ITO process to achieve controllable music generation for near-interactive rate music co-creation. To do so, we focus on three critical methodological improvements. First, we leverage **diffusion distillation** to significantly speed up diffusion sampling with an efficient, modified distillation process designed to be used together with ITO methods. Second, we introduce **surrogate optimization**, or the idea of decoupling the task of estimating noise latents from the task of rendering a final output or decoding, which allows us to leverage both fast sampling for optimization for control estimation and multi-step sampling for final, high-quality generation. Third, we combine diffusion distillation with surrogate optimization within the DITTO framework and produce a new, more efficient diffusion inference-optimization algorithm (no gradient checkpointing) as found in Section 3.4.

3.2 Acceleration through Diffusion Distillation

The clearest way to speed up ITO is to simply reduce the number of diffusion sampling steps T . From initial experiments, however, we found that (1) reducing the number of sampling steps T degrades overall generation quality [8], (2) quality degradation makes the optimization gradients weaker (as the outputs are less semantically coherent) leading to control degradation, and (3) achieving close to real-time performance requires < 4 sampling steps, which pro-

duce fully incoherent results on standard DMs. Thus, we employ distillation to speed up the diffusion process [29].

First, we develop CM distillation [21, 29, 31] for ITO-based controllable music generation. For CM distillation, we follow past work [29] for our training recipe, optimizing (1), and also learn an explicit embedding for the CFG scale w in the model $G_\phi(x_t, c, w)$ during distillation following [29]. By distilling CFG, we are able to half the number of total model calls per distilled diffusion sampling step. Once distilled, G_ϕ jumps from x_T to x_0 , allowing for deterministic 1-step sampling and stochastic multi-step-sampling by repeatedly *re-noising* with some $\epsilon \sim N(0, I)$ back to x_{t-1} .

Second, we develop CTM distillation [22] for ITO-based controllable music generation. CTM distillation offers more advantageous speed vs. quality design trade-offs, but comes at a cost of a more complex training procedure. In more detail, CTM distillation normally involves an expensive soft-consistency loss in the data domain with added GAN and score-matching loss terms. As we aim to distill our base model for *surrogate* optimization (see Sec. 3.3), we are able to simplify and speed up the CTM distillation process. First, we remove the image-domain GAN loss to reduce complexity of developing an audio-based GAN loss. Second, we use the consistency term from CTM in local-consistency form [35]:

$$\mathbb{E}_{t, s \sim T} \mathbb{E}_{(x, c) \sim \mathcal{D}} \|G_\phi(x_t, c, w, t, s) - G_{\phi^-}(\Theta(\epsilon_\theta, x_t, c), c, w, t-1, s)\|_2^2. \quad (4)$$

Third, we use the 1-step Euler parameterization of G_ϕ from [22]’s Appendix, which avoids explicitly learning additional parameters for the target step s in order to accelerate distillation. These changes reduce the number of per-training step model calls from 10-30 to 3, leading to a near order-of-magnitude speed up in wall clock time for performing the distillation process. Finally, we upgrade CTM’s unconditional framing for conditional diffusion by incorporating c into the distillation procedure, and adding w directly into the model to distill the CFG weight into an explicit parameter following past work [29], resulting in CFG control at inference but without double the complexity. In total, we perform distillation in as few as 32 GPU hours on an A100, the fastest trajectory-based distillation to our knowledge [22, 35].

3.3 Surrogate Optimization

Given a distilled CM or CTM model, we seek to minimize our inference runtime and maximize control adherence and audio quality. The obvious choice to minimize runtime is to use our distilled model with one-step sampling, but this results in limited audio quality and text-control. To solve this, we first split the ITO process into two separate phases: **optimization**, i.e. the nested loop of optimizing the initial latent over M -step multi-step sampling, and **decoding**, i.e. the final T -step sampling process from the optimized latent x_T^* , where $M = T$ in all past work [18, 19]. In this light, it is clear that the optimization phase is mostly respon-

Algorithm 1 Distilled Diffusion Inference-Time T -Optimization (DITTO-2)

input : G_ϕ , feature extractor f , loss \mathcal{L} , target \mathbf{y} , starting latent \mathbf{x}_T , text \mathbf{c} , optimization steps K , optimizer g , decoding steps $\{\tau_0, \dots, \tau_M\}$, γ , CFG weight w

- 1: // Optimization Loop
- 2: **for** K iterations **do**
- 3: $\mathbf{x}_0 = G_\phi(\mathbf{x}_T, \mathbf{c}, w, T, 0)$
- 4: $\hat{\mathbf{y}} = f(\mathbf{x}_0)$
- 5: $\mathbf{x}_T \leftarrow \mathbf{x}_T - g(\nabla_{\mathbf{x}_T} \mathcal{L}(\hat{\mathbf{y}}, \mathbf{y}))$
- 6: **end for**
- 7: // Decoding Loop
- 8: $\mathbf{x}_t \leftarrow \mathbf{x}_T$
- 9: **for** $t = M$ to 1 **do**
- 10: $\hat{\tau}_{t-1} = \sqrt{1 - \gamma^2 \tau_{t-1}}$
- 11: $\mathbf{x}_{t-1} = G_\phi(\mathbf{x}_t, \mathbf{c}, w, \tau_t, \hat{\tau}_{t-1}) + \gamma \tau_{t-1} \epsilon$
- 12: **end for**

output : \mathbf{x}_0

sible for the control strength and runtime, while decoding is generally responsible for final output quality.

Thus, we fix our final decoding process as multi-step sampling with T steps. Then, we perform control optimization over a **surrogate** objective $\hat{\mathbf{x}}_T^* = \arg \min_{\mathbf{x}_T} \mathcal{L}_\phi^{(M)}(\mathbf{x}_T)$ using some model ϵ_ϕ and $M \ll T$, where our surrogate is more efficient but yields approx. equal latents to our original objective

$$\arg \min_{\mathbf{x}_T} \mathcal{L}_\phi^{(M)}(\mathbf{x}_T) \approx \arg \min_{\mathbf{x}_T} \mathcal{L}_\theta^{(T)}(\mathbf{x}_T). \quad (5)$$

A natural candidate for a surrogate model would be the base DM ϵ_θ with fewer sampling steps. DM performance, however, becomes fully incoherent as $M \rightarrow 1$ [21, 22], causing a significant domain-gap when $M < T$. Alternatively, our distilled models are naturally strong surrogates:

- One-step outputs are generally coherent unlike in base DMs, resulting in more stable gradients when $M = 1$.
- Since distilled models excel at few-step sampling (i.e. < 8) [21, 22], the control domain gap between M and T can be reduced while ensuring coherent outputs.
- CTMs can increase quality with more sampling.

As a result, we use a CM or CTM G_ϕ as our surrogate, optimize with $M = 1$, and decode with $T \in [1, 8]$.

3.4 Complete Algorithm

Given our efficient CTM-based distillation process, and our surrogate objective, we propose a new ITO algorithm for controllable music generation in Alg. 1. Here, we run optimization to estimate control parameters using our surrogate 1-step objective. Then, we use the optimized latent \mathbf{x}_T^* and decode from our surrogate model with T steps using either multi-step CM Sampling (i.e. $\gamma = 1$) or CTM γ -sampling ($\gamma < 1$). Beyond decoupling optimization and decoding, we

also eliminate the need for gradient checkpointing found in the original DITTO method [18]. In total, we reduce the ITO speed from $4KT$ costly operations for DITTO to $K + T$.

4. EXPERIMENTS

To evaluate our proposed method, we follow the evaluation protocol used for DITTO [18] for intensity, melody, music structure, inpainting, and outpainting as described below. Before the full breadth of application tests, however, we explore our design space by comparing different distillation techniques and surrogate options on the task of intensity control. We further conclude with an experiment showing an adaptive sampling surrogate scheme as well a new experiment on maximizing text-adherence (CLAP score).

4.1 Controllable Generation Evaluation Protocol

We benchmark our method on five controllable music generation tasks from DITTO [18] including:

- **Intensity Control** [15, 18]: Here, we control the time-varying volume and overall semantic density to some target intensity curve \mathbf{y} using the extractor $f(\mathbf{x}_0) := \mathbf{w} * 20 \log_{10}(\text{RMS}(\mathbf{V}(\mathbf{x}_0)))$ (i.e. the RMS energy of the vocoder \mathbf{V} outputs smoothed with a Savitsky-Golay filter \mathbf{w}) and $\mathcal{L} = \|f(\mathbf{x}_0) - \mathbf{y}\|_2^2$.
- **Melody Control** [2, 15, 18]: We control the model outputs to match a given target melody $\mathbf{y} \in \{1, \dots, 12\}^{N \times 1}$ (where N is number of frames) using the chromagram of the model outputs $f(\mathbf{x}_0) = \log(\mathbf{C}(\mathbf{V}(\mathbf{x}_0)))$ and $\mathcal{L} = \text{NLLoss}(f(\mathbf{x}_0), \mathbf{y})$.
- **Musical Structure Control** [18]: We control the overall timbral structure of the model outputs by regressing the self-similarity (SS) matrix $f(\mathbf{x}_0) = \mathbf{T}(\mathbf{x}_0)\mathbf{T}(\mathbf{x}_0)^\top$ of Mel Frequency Cepstrum Coefficients (MFCC) \mathbf{T} against a target SS matrix \mathbf{y} like "ABA" form with $\mathcal{L} = \|f(\mathbf{x}_0) - \mathbf{y}\|_2^2$.
- **Inpainting and Outpainting** [16, 18]: Given music \mathbf{x}_{ref} , we can continue (outpainting) or infill (inpainting) \mathbf{x}_{ref} by matching the model outputs over o -length overlap regions $f(\mathbf{x}_0) := \mathbf{M}_{\text{gen}} \odot \mathbf{x}_0$ to the reference $\mathbf{y} = \mathbf{M}_{\text{ref}} \odot \mathbf{x}_{\text{ref}}$ (where \mathbf{M}_{ref} and \mathbf{M}_{gen} denote the overlap masks) and $\mathcal{L} = \|f(\mathbf{x}_0) - \mathbf{y}\|_2^2$.

For brevity, we focus on the $o = 1$ case for outpainting and inpainting (i.e. a gap of 4 seconds) and omit looping given its equivalence. See [18] for a more thorough description.

4.2 Pre-training and Distillation Details

For our base DM, we follow a similar setup and model design to DITTO [18], using the same base model and vocoder. Specifically, we train a 41M parameter Stable Diffusion-style 2D UNet directly over 6-second mel-spectrograms trained on ≈ 1800 hours of licensed music, and MusicHiFi [36] as the vocoder. The base model is trained with genre, mood, and tempo tags similar to [37] rather

Figure 4: DITTO-2 inference speed vs. control MSE vs. audio quality (FAD, denoted by size, smaller is better). Dashed line denotes the cutoff for real-time performance, color denotes ITO method, and subscripts denote number of sampling steps during optimization / final decoding. Applied to intensity control. Trends also hold for CLAP score.

than full text descriptions. Both the CM and CTM surrogate models are distilled using a maximum of $T = 20$ sampling steps, evenly spaced across the trajectory for 4 hours across 8 A100 40GB GPUs on the same data. For DITTO-2, we use Adam. During CTM γ -sampling, we set $\gamma \in [0.05, 0.35]$ as empirically we found that using deterministic $\gamma = 0$ resulted in noticeable audio artifacts that degrade overall quality.

4.3 Metrics

For all tasks, we report the Fréchet Audio Distance (FAD) and CLAP Score with the CLAP [38] music backbone (as for FAD the standard VGGish backbone poorly correlates with human perception [39]), which measure overall audio quality and text relevance respectively across 2.5K generations. FAD is calculated with MusicCaps as the reference [1] dataset. Since our base model uses tags rather than captions, we convert each tag set into captions for CLAP Score calculation using the format “A [mood] [genre] song at [tempo] beats per minute.” Additionally, we report the MSE to the control target for intensity and structure control, and the overall accuracy for melody control.

5. RESULTS

5.1 Design Exploration Results

We study our design space for ITO via a case study on the task of intensity control. Notably, we compare DITTO with our proposed approach using CM and CTM distilled models in Fig. 4. We show runtime in seconds (x-axis), control MSE (y-axis), and FAD (point size) for an array of (M, T) combinations for our base DM, as well as our distilled CTM models (i.e. DM-8/20 corresponds to the base DM with $M = 8, T = 20$). We find that our distilled models are over 10x faster than the standard DITTO (20, 20)

Figure 5: FAD, MSE, and CLAP results on Intensity Control for 1-step optimization, where orange lines denote baseline 20-step performance. MSE increases with more decoding steps for both CM/CTM given the domain gap though beats the baseline with < 4 steps. CM is unable to beat baseline quality due to accumulated errors in multi-step sampling, while multi-step CTM achieves SOTA quality.

configuration, while simultaneously achieving both better audio quality and control adherence. To understand these trends more in depth, specifically as we vary the number of decoding steps for our distilled models, we show both FAD (top), MSE (middle), and CLAP (bottom) in Fig. 5 as a function on number of decoding steps with $M = 1$, where the orange line denotes the baseline DITTO results with $M = T = 20$.

A few key points of DITTO-2 are visible here. Notably, both CM and CTM distilled models are able to achieve *better* control adherence than the base performance, as the shorter optimization process allows convergence to happen more effectively. Additionally, we find that CTM is clearly stronger than CM in terms of quality, as CTM is able to cleanly trade-off quality for control adherence (as sampling with more steps with $M = 1$ introduces a domain gap) and even *improve* baseline quality, while CM exhibits no real quality trend when sampling more due to its accumulated errors in multi-step sampling. In particular, CTM with $M = 1, T = 2$ achieves SOTA control adherence and FAD with faster than real-time. CM and CTM multi-step sampling also improves text relevance above the base DM.

5.2 Benchmark Results

We show full results on our suite of controllable music generation benchmarking results in Table 1. Here, we compare baseline DITTO with DITTO-2, where we display results for the best performing (M, T) setup in each experiment for CM and CTM, where best performance was chosen by finding the setup with the lowest latency (and thus best control adherence) while roughly matching the best overall FAD. As a whole, DITTO-2 achieves comparable or better performance than DITTO on all tasks with an 10-20x speedup, clearing the way for near real-time inference-time

Intensity	Time (s)	FAD	CLAP	MSE

controllable music generation. Specifically, we find that CTM outperforms CM, showing noticeably better quality with similar runtime and control adherence.

5.3 Variable Compute Budget Optimization

Though we are primarily interested in real-time performance (i.e. as fast as possible), we additionally investigated how we can use a varying compute budget during optimization (in terms of runtime). As simply increasing M predictably increases runtime by a multiplicative factor, we designed an *adaptive* schedule for M (denoted as $*$ in Fig. 4) in order to improve downstream decoding performance without increasing runtime significantly. Formally, for K optimization steps, we set the adaptive budget as using $M = 1$ for $\lfloor \frac{K}{2} \rfloor$ iterations, then $M = 2$ for $\lfloor \frac{3K}{8} \rfloor$, and finally $M = 4$ for $\lfloor \frac{K}{8} \rfloor$ iterations, thus allowing a coarse-to-fine optimization process. In Table 2, using the adaptive schedule exhibits the runtime of the $M = 2$ case yet achieves much better FAD and similar control adherence. This shows that given a more flexible compute budget, using an adaptive M schedule balances downstream performance better than simply modifying a fixed M , and allows smoother objective tradeoff between audio quality

and control strength.

5.4 Inference-time Optimization of Text-Control

Past ITO methods for music generation use simple feature extractors $f(\cdot)$ (i.e. chroma or RMS energy) [18] to minimize runtime speed. Given that our method is much faster, however, we can introduce new bespoke control applications with neural network-based feature extractors. Thus, we propose the task of inference-time **text similarity** control. We extract the normalized CLAP audio embedding [38] of our model outputs $f(\cdot) = \text{CLAP}(x_0)$ and, given some natural language caption y , calculate the cosine distance between the output and the normalized CLAP text embedding of the caption $\mathcal{L}(x_0) = 1 - f(x_0)^\top f(y)$.

Using FAD and CLAP score as metrics, we benchmark several configurations including our base DM model with tag inputs, DITTO-2 method with tag inputs, DITTO-2 method with null tag inputs, MusicGen w/melody (1.5B) [2], and MusicGen w.o./melody (3.5B) [2]. For models that take input text, we use captions from MusicCaps [1] as input and for models with tag inputs, we convert MusicCaps captions to tags via GPT-4 as done in past work [15] with tempo extracted from audio. Furthermore, to ablate whether any part of the tag-conditioned training process influences downstream DITTO-2 CLAP control, we retrain and distill our base model *without any text input*, which we denoted U-DITTO-2. In Table 3, we see that DITTO-2 enables SOTA text relevance compared to MusicGen by an over 54% relative improvement (large), thus showing the benefits of ITO-based approaches which allow us to directly optimize for desired downstream metrics, and notably enables fully-unconditional models to have text control *with no paired music-text training*.

6. CONCLUSION

We present DITTO-2: **Distilled Diffusion Inference-Time T-Optimization**, a new efficient method for accelerating inference-time optimization for fast controllable music generation. By utilizing a modified consistency or consistency trajectory distillation process and performing inference-time optimization on efficient surrogate objectives, we speed up past ITO methods by over 10-20x while simultaneously improving audio quality and text control. Furthermore, we find we can leverage the efficiency of our method on new, more complex tasks like text-adherence and show we can convert a fully unconditional diffusion model into a TTM model that yields SOTA results on evaluated metrics.

DataMind Audio

ABSTRACT

We present “The Concatenator,” a real time system for audio-guided concatenative synthesis. Similarly to Driedger et al.’s “musaicing” (or “audio mosaicing”) technique, we concatenate a set number of windows within a corpus of audio to re-create the harmonic and percussive aspects of a target audio stream. Unlike Driedger’s NMF-based technique, however, we instead use an explicitly Bayesian point of view, where corpus window indices are hidden states and the target audio stream is an observation. We use a particle filter to infer the best hidden corpus states in real-time. Our transition model includes a tunable parameter to control the time-continuity of corpus grains, and our observation model allows users to prioritize how quickly windows change to match the target. Because the computational complexity of the system is independent of the corpus size, our system scales to corpora that are hours long, which is an important feature in the age of vast audio data collections. Within The Concatenator module itself, composers can vary grain length, fit to target, and pitch shift in real time while reacting to the sounds they hear, enabling them to rapidly iterate ideas. To conclude our work, we evaluate our system with extensive quantitative tests of the effects of parameters, as well as a qualitative evaluation with artistic insights. Based on the quality of the results, we believe the real-time capability unlocks new avenues for musical expression and control, suitable for live performance and modular synthesis integration, which furthermore represents an essential breakthrough in concatenative synthesis technology.

1. INTRODUCTION

Concatenative synthesis, or audio mosaicing, is a data-driven approach to arrange granular fragments of audio samples, particularly using data sourced from the spectral-temporal features of a target sound. While granular synthesis systems typically rely on combinations of aleatoric parameterization, deterministic automation, and traditional synthesis modulation to achieve complex and evolving textures from sound fragments [1], concatenative synthesis al-

gorithms utilize Music Information Retrieval technology to decide parameters such as the index, amplitude, and pitch of each sound fragment.

Modern music producers are inundated by audio data. Services like Splice offer hundreds of thousands of samples readily available on the cloud, and Kontakt multi-sample libraries can often take up over 10gb of disk space to capture a single instrument. Music Producers generate plenty of their own audio data as well: stems, multi-tracks, long-form recordings, and mix variations account for a large portion of many a music producer’s audio collection. Recent software such as XO by XLN Audio, Sononym, and Ableton Live 12 offer automatic organization of audio files based on various tags and descriptors, but these implementations of MIR technology are more utilitarian than creative in their design and application. Meanwhile, concatenative synthesis options remain sparse since its conceptual inception [2]: Reformer by Krotos is designed to create foley designs, apps like Samplebrain and CataRT [3, 4] are lacking in critical musical areas such as pitch tracking, with the more advanced options having limited accessibility for artists, requiring prior knowledge of Max (FluCoMa, MuBu) or Python (Audioguide).

The Concatenator advances concatenative synthesis in 3 major ways: 1) it is capable of accurately reproducing harmonic and percussive sounds using arbitrary corpora 2) in real-time at scale, 3) affording new levels of control and accessibility. Furthermore, unlike neural audio systems [5], it requires no training and can adapt to arbitrary corpora at runtime. The speed, ease, and scope of The Concatenator offers a fresh paradigm for music producers to interact creatively with their ever-expanding excess of audio data, leading to what we believe is a breakthrough in the field.

2. RELATED WORK

We build on important works in Bayesian inference, particle filters, concatenative synthesis, and applied nonnegative matrix factorization (NMF), which we briefly describe

Driedger’s Technique. From an artistic point of view, the most similar technique to ours is Driedger et al.’s 2015 “Let It Bee” concatenative musaicing technique [6], which uses NMF to learn activations of spectral window templates in a **corpus collection** so that their combination will match a **target** spectrogram. This technique was a fruitful innovation in sound design for electronic music production, as featured heavily on *Zero Point* by Rob Clouth [7],

Cantil, “The Concatenator: A Bayesian Approach To Real Time Concatenative Musaicing”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

using custom software also authored by Clouth. The algorithm was also implemented in an open source python script in 2018 [8], and in Max by the FluCoMa project in 2021 (fluid.bufnmcross) [9], which made NMF-inspired audio mosaicing accessible enough to contribute towards the production of at least two more albums heavily featuring the technique: *Edenic Mosaics* by Encanti (2021) [10] and *Hate Devours Its Host* by Valance Drakes (2023) [11].

We now detail the mathematics of Driedger et al.’s technique, as we borrow a few ideas in our work. Driedger et al. learn H in the equation $V \approx WH$, where V is an $M \times T$ target spectrogram with M frequency bins and T times, W is an $M \times N$ set of N spectral corpus templates that are treated as fixed, and H is a matrix of $N \times T$ learned activations. For instance, W could be the windows of a collection of buzzing bees and V could be an excerpt from The Beatles’ “Let It Be” (hence the title). Driedger et al. use the Kullback-Liebler (KL) divergence loss, an instance of the more general β -divergence [12], to measure the goodness of fit of WH to V . This loss function is

$$D(V||WH) = \sum V \odot \log \left(\frac{V}{WH} \right) - V + WH \quad (1)$$

where \odot , $/$, $+$, and $-$ are all applied element-wise, and the sum is taken over all elements of the resulting matrix. As Lee/Seung show, choosing the right step size turns gradient descent of Equation 1, with respect to W and H , into *multiplicative update rules* that guarantee monotonic convergence. Driedger et al. keep W fixed to force the final audio to use exact copies of the templates, so only the update rule for H is relevant. At iteration ℓ , this is:

$$H_{kt}^\ell \leftarrow H_{kt}^{\ell-1} \left(\frac{\sum_m W_{mk} V_{mt} / (WH^{\ell-1})_{mt}}{\sum_m W_{mk}} \right) \quad (2)$$

Crucially, though, Driedger et al. note that the update rules in Equation 2 alone will lose the timbral character of the templates in W . They hence disrupt ordinary KL gradient descent by performing several increasingly impactful modifications to H before Equation 2 in each step, which are eventually set in stone after L total iterations. First, they avoid repeated windows to avoid a “jittering” effect, allowing a particular window k to only activate once in some r -length interval based on where it’s the strongest:

$$(H_r)_{kt}^\ell \leftarrow \left\{ \begin{array}{ll} H_{kt}^{\ell-1} & H_{kt}^{\ell-1} > H_{ks}^{\ell-1}, |t-s| \leq r \\ H_{kt}^{\ell-1} (1 - \frac{\ell+1}{L}) & \text{otherwise} \end{array} \right\} \quad (3)$$

They also promote sparsity similarly by shrinking all but the top p activations in each column of H_r to create H_p^ℓ . Finally, they encourage *time continuous activations* by doing “diagonal enhancement,” or by doing a windowed sum down each diagonal of H_p , assuming the columns of W are also in a time order.

$$(H_c)_{kt}^\ell = \sum_{i=-c}^c (H_p)_{k+i,t+i}^\ell \quad (4)$$

Since this encourages the algorithm to mash up chunks of W in a time order, it effectively encourages sound grains from the templates than the length of a single window that ordinary NMF would take. Finally, Driedger et al. apply Equation 2 to H_c^ℓ instead of $H^{\ell-1}$ to obtain H^ℓ .

These disruptions remove the guarantee that Equation 1 will be minimized, or that it will even monotonically decrease, but Driedger et al.’s key insight is that the loss function is merely a guide to choose reasonable activations; a suboptimal fit leaves room to better preserve timbral characteristics. We take a similar perspective.

Driedger Tweaks. The idea of spectrogram decomposition used for concatenative musaicing goes back to the work of [13]. Beyond that, the authors of [12] provide some improvements to Driedger et al.’s technique, including mixing corpus windows directly rather than performing phase retrieval on WH . One issue with Driedger et al.’s technique is the sources have to be augmented with pitch shifts to span additional pitches in the target, increasing memory consumption and runtime. The authors of [14, 15] avoid this by using 2D deconvolutional NMF [16] on the Constant-Q transform, whereby pitch shifts are modeled as constant shifts of the activations instead of the templates, saving memory. The other convolutional axis models time history and time shifts, avoiding the need for the diagonal enhancement of Equation 4. The authors apply 2D NMF to both the source and target, so they do not preserve the original sound grains. However, for our preferred style, we want to take the source grains exactly as they are.

Other Concatenative Techniques. Schwarz created an offline concatenative synthesis system dubbed “Caterpillar” that uses the Viterbi algorithm [2], which he later approximated with a real time system, “CataRT” that uses a greedy approach instead of the Viterbi algorithm [3, 4]. Simon’s “audio analogies” is quite similar [17], but instead of a user controlled traversal through timbral space, they use features from some source (e.g. midi audio) to guide synthesis to a target with a different timbre (e.g. real audio of someone playing a trumpet). Caterpillar and audio analogies are both *sequentially Bayesian in nature*, where the *hidden state* is the template to concatenate, and the “observation” is a user-controlled trajectory or features from a source timbre, respectively. The prior transition probabilities are based on temporal continuity. However, they use the Viterbi algorithm, which is computationally intensive and which needs all time history, so it cannot be applied in real time. By contrast, a **particle filter** is a scalable Monte Carlo method for sequential Bayesian inference [18–20]. It is less common in MIR, but it has found use in a few real time MIR applications such as multi-pitch tracking [21], tempo tracking [22, 23], and beat tracking [24].

3. THE CONCATENATOR

The NMF technique of Driedger is not suitable for real-time applications; the gradient update rules of Equation 2 scale linearly in the length of the corpus, leaving all but minutes long corpora usable (Section 3.3), and the equations to suppress repeated windows and promote time con-

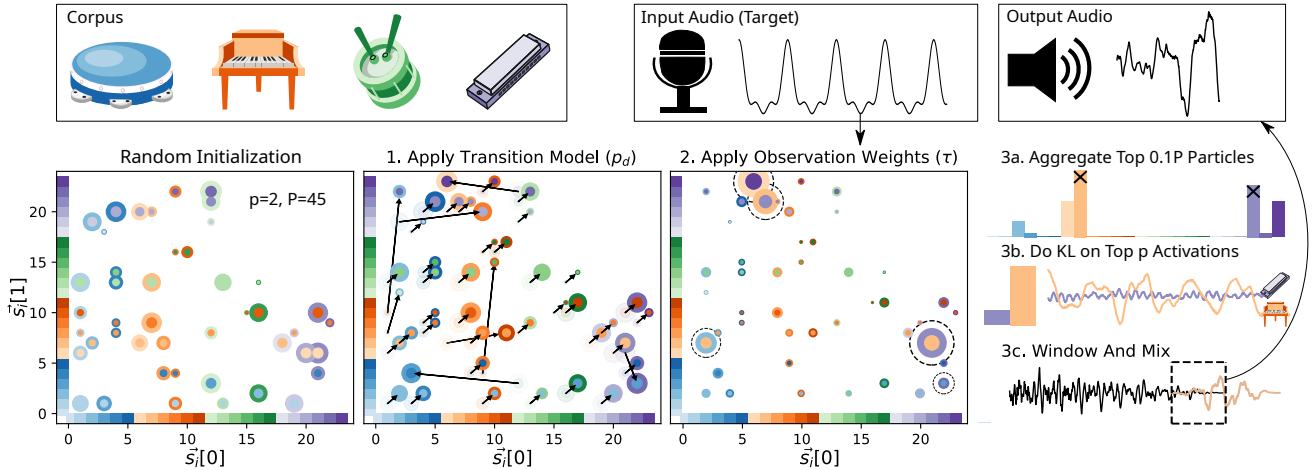

Figure 1. The Concatenator maintains P “particles,” each of which represents p specific corpus windows. Each window moves forward by 1 timestep in the corpus with probability p_d , or otherwise jumps randomly. Then, particles each mix their windows to best match the target, and particles with the top 10% best fits to the target vote on a final set of p windows.

tinuity at each entry of H require knowledge of all activations in H , including future activations. Instead, The Concatenator does many tiny KL-based NMF problems (Equation 2) online in “particles” based on random sampling at each timestep. The particles then vote on a final set of activations to use at that timestep (Figure 1)¹. The random sampling trades off historical context to choose longer grains, with fit to the target audio streaming in. We provide the mathematical and implementation specifics below.

3.1 Sequential Bayesian Formulation And State Space

Formally, The Concatenator uses a sequential Bayesian formulation, where the t^{th} column of the target spectrogram V is the “observation,” at time t . The hidden state indexes p out of N possible windows in the corpus spectrogram W . We use a particle filter to efficiently infer the the best such windows (Section 3.2). Henceforth, we refer to the observations as vectors \vec{v}_t to emphasize that the data is streaming, and we focus on one timestep t at a time.

State space. To keep the state space simple, we decouple which windows are active from their activation weights; we only model the former as the hidden state, while we infer the weights as a best fit under the KL-loss (Equation 1). To control for polyphony directly, we use a p -sparse nonnegative integer-valued vector $\vec{s}_t \in \mathbb{N}^p$ as the hidden state. This vector indexes the p corpus windows that are active at time t , where p is fixed ahead of time. For convenience of implementation, template indices can repeat and are in no particular order:

$$\vec{s}_t[k] \in \{0, 1, \dots, N-1\}, k = 0, 1, \dots, p-1 \quad (5)$$

We then infer the associated nonnegative weights $\vec{h}_t[k]$ for each activation to give the approximation $\vec{\Lambda}_t$ at time t :

$$\vec{\Lambda}_t[m] = \sum_{k=0}^{p-1} \vec{h}_t[k] W_{m, \vec{s}_t[k]} \quad (6)$$

¹ CC musical instrument images adapted from vectorportal.com

In particular, given W , \vec{s}_t , and \vec{v}_t , we apply the update rules of Equation 2 for a pre-specified number L of iterations, using the corresponding columns \vec{s}_t of W

$$\vec{h}_t^\ell[k] \leftarrow \vec{h}_t^{\ell-1}[k] \left(\frac{\sum_m (W_{m, \vec{s}_t[k]})(\vec{v}_t[m]) / (\vec{\Lambda}_t^{\ell-1}[m])}{\sum_m W_{m, \vec{s}_t[k]}} \right) \quad (7)$$

Transition Model. We use the KL-loss (Equation 1) to measure the spectral fit of Λ_t to \vec{v}_t . As in Driedger et al. [6] (Equation 4), however, we are willing to sacrifice fit to take longer grains from the corpus W . To that end, we define the prior **state transition probability** in the as a Factorial Hidden Markov Model (FHMM) [25]. Each \vec{s}_t satisfies the Markov property and is conditionally independent of all previous steps given \vec{s}_{t-1} , but *each component* k of $\vec{s}_t[k]$ also transitions independently of other components, leading to the following transition probability:

$$p_T(\vec{s}_t = \vec{b} | \vec{s}_{t-1} = \vec{a}) = \prod_{k=0}^{p-1} \left\{ \begin{array}{ll} p_d & \vec{b}[k] = \vec{a}[k] + 1 \\ \frac{1-p_d}{N-1} & \text{otherwise} \end{array} \right\} \quad (8)$$

where $p_d \in [0, 1]$ is the “probability of remaining time-continuous.” Intuitively, if $p_d > 0.5$, then we are more likely to continue to use a time-continuous activation than we are to jump to a new random activation, which promotes longer contiguous sound grains from the corpus, even at the expense of a lower fit to the spectral template². As such, p_d a parameter that can be tuned by the artist and set closer to 1 to promote longer grains. We generally find $p_d \in [0.9, 0.99]$ to be effective (Section 4.1).

We must also specify the *observation probability*, which pulls the states closer to matching \vec{v}_t , even if they have to jump away from time continuity; otherwise, the

² This has a similar effect to “extend matches” functionality in Sturm’s MatConcat [26] when a match isn’t found. In our Bayesian framework, such extensions happen on a continuum based on fit to target.

result would sound nothing like the target. Though each component transitions independently, they all contribute jointly to an observation, which makes inference trickier than it is for traditional HMMs.

3.2 Sampling, Observing, And Synthesizing

We now describe how to apply Bayesian inference to find the sequence of corpus windows \vec{s}_t and their activation weights \vec{h}_t that maximize the posterior probability given the transition model in Equation 8 and the observation model below. While the authors of [27] use a similar FHMM applied to multi-pitch tracking, inferring the hidden states via message passing algorithms known as “Max-Sum” [28] and “Junction Tree” [29], we need a faster technique which is also real-time, and which has tunable accuracy that degrades gracefully with restricted computational resources. To that end, we turn to a particle filter.

Our particle filter consists of P particles, each of which is a p -dimensional state vector (Equation 5) that we refer to as \vec{s}_i . The particles traverse the corpus over time, and they each have a weight w_i that keeps track of the posterior probability of its accumulated motion over all timesteps (we now dispense with the time index t on \vec{s}_i and w_i since t will be clear from context). Since each particle is its own estimate of a state that best describes what templates to choose, our goal is to sample them in such a way that (at least some of) the particles are close to capturing activations that maximize the posterior probability given all \vec{v}_t .

Tracking Weights. All particles begin with even weights $w_i = 1/P$. At the beginning of each time step, we sample new indices for each \vec{s}_i according to Equation 8. Then, we multiply each weight by the **observation probability** p_O . Given the KL loss d_i between the i^{th} particle’s spectral approximation $\vec{\Lambda}_i$ (Equation 6) and \vec{v}_t after L iterations of Equation 7, for each particle i , p_O is:

$$p_O[i] = \frac{e^{-\tau d_i}}{\sum_j e^{-\tau d_j}} \quad (9)$$

In other words, the observation probability is a softmax over KL-based goodness of fits of \vec{s}_i to \vec{v}_t , and the softmax has a “temperature” τ . We use a negative exponential since a larger d_i loss indicates a poorer fit using windows \vec{s}_i and hence, should be a lower probability. Intuitively, a higher τ will emphasize particles that fit the observation better, putting more importance on the observation relative than the transition probability. This is tunable and has a similar effect to varying p_d in the transition, as we will explore more in Section 4.1. After multiplying each w_i by $p_O[i]$, we normalize the weights so that they sum to 1.

Resampling. The above is a naive particle filter, but it suffers from “sample impoverishment,” where a few particles stand out with high weights and the rest are stuck with vanishing weights, leaving the system unable to adapt to new observations. To ameliorate this, we compute a standard definition of the “effective number of particles” $n_{\text{eff}} = 1/(\sum_i w_i^2)$, which is maximized when all particles have equal weight $1/P$. If n_{eff} goes below $0.1P$ at a particular time step, we resample the particles with

stochastic universal sampling [30,31], an $O(P)$ resampling technique, and reset all weights to $1/P$ before continuing. This leads to “survival of the fittest” where particles with a higher weight are more likely to be replicated and those with a lower weight are more likely to be eliminated.

Synthesizing audio. After updating the weights, we take a weighted average of the windows in the top $0.1P$ particles, with the option to further boost windows that follow continuously from those chosen in previous steps. We also ignore windows that would be repeated from up to r timesteps in the past (analogous to Driedger’s Equation 3). We then let \vec{s}_t be the top p such windows by weight, and we compute the corresponding activations \vec{h}_t . These steps can be done in $O(Pp)$ time with hash tables and linear time selection. Finally, we mix together the corresponding waveforms from the corpus (as in [12]) and apply a Hann window to overlap-add this audio to the output stream.

3.3 Computational Complexity

The dominant cost of both The Concatenator and of Driedger is computing activations via KL iterations. Given N corpus templates, T times in the target, and a spectral dimension of M , for L KL iterations, the time complexity of Driedger (Equation 2) is $O(LMNT)$. This is a *linear* dependency on the corpus length. So if, for example, Driedger’s technique takes a minute on a target sourcing a corpus that’s a minute in length, it will take 2 hours a 2-hour corpus on that same target. To improve this scaling, the authors of [12] do a greedy nearest neighbors search in the corpus, but this requires tuning and may miss important windows. In fact, our random sampling naturally scales in an even more favorable way. Specifically, given P particles and p windows per particle, the time complexity of our analogous Equation 7 is only $O(LPMpT)$, which does not scale with the corpus size N at all (though P may need to scale with N for the best results (Section 4.1)). As an example, for a 60 minute corpus a window length of 2048 ($M = 1025$, hop=1024) at a sample rate of 44.1khz, using $P = 1000$ and $p = 5$, this is a speedup of nearly 30x over Driedger. Moreover, propagating particles and applying the observation model are also embarrassingly parallelizable at the particle level, which we leverage in our implementation. Finally, while Driedger et al. use $L = 20$ [6], we find that $L = 10$ is sufficient in our context.

3.4 Bells And Whistles (Pun Intended)

Regularizing Quiet Moments in The Corpus. One pitfall using KL-based NMF is that if enough activations are near silence, Equation 7 becomes numerically unstable and the weights \vec{h}_i can approach ∞ . To address this, we modify the KL-loss to include a masked L_2 penalty for \vec{h}_i for the i^{th} particle for the target \vec{v}_t at time t . Given the corresponding approximation $\vec{\Lambda}_i$ (Equation 6), the modified loss is

$$D(\vec{v}_t || \vec{\Lambda}_i) = \left(\sum \vec{v}_t \odot \log \left(\frac{\vec{v}_t}{\vec{\Lambda}_i} \right) - \vec{v}_t + \vec{\Lambda}_i \right) + \frac{\|\alpha \odot \vec{h}_i\|_2^2}{2} \quad (10)$$

where, abusing notation, α is a mask that is a fixed value (we use 0.1) if the corresponding corpus window is less than -50dB and 0 otherwise. Equation 7 then turns into

$$\vec{h}_i^\ell[k] \leftarrow \vec{h}_i^{\ell-1}[k] \left(\frac{\sum_m (W_{m, \vec{s}_i[k]})(\vec{v}_t[m]) / (\Lambda_i^{\ell-1}[m])}{(\sum_m W_{m, \vec{s}_i[k]} + \alpha[k] \vec{h}_i^{\ell-1}[k])} \right) \quad (11)$$

Intuitively, if $s_i[k]$ is a quiet corpus window, $\alpha[k] = 0.1$, which shrinks $\vec{h}_i^{\ell-1}[k]$ down³.

Pitch Shifting. Though we don't use this in Section 4, we implemented Driedger et al.'s technique to increase the pitch coverage of the corpus; that is, we can replicate the corpus in its entirety for different pitch shifts that are chosen up-front. This only incurs a preprocessing cost since the complexity of The Concatenator is independent of corpus length (Section 3.3), which does not impact real-time performance once the system starts. However, our system could choose a different trade-off of space and time complexity by augmenting the state space as the Cartesian product of window indices and pitch shifts. Pitch shifts could be computed on the corpus audio *on demand* whenever a state with a nonzero pitch shift is chosen.

Finally, for a fixed corpus with or without pitch shifts, the user can control a slider that pitch shifts the *target* in real time, so that the chosen windows move relatively to the audio input. This could be used, for example, to harmonize to singing in an interval that's a fifth away.

3.5 How Many Particles?

In practice, few particles are surprisingly effective at capturing windows that fit the target, which we explain with a simple probabilistic argument. Given a corpus with N sound grains (including pitch shifts) and P particles that each capture p windows, suppose also that we have a hypothetical "ideal particle" \vec{s}_t with the p best windows at time t , which are completely disjoint from all current particles; the only way to jump to the best windows is to randomly resample with probability $(1 - p_d)$. Since we use a small hop length relative to the sample rate ($1024/44100 \approx 23$ ms), we have a few timesteps to jump without a large effect on the final audio. Also, there are usually several windows in the corpus that sound acceptably similar to windows in \vec{s}_t . Let δ be the maximum tolerable offset before or after in time for choosing the best windows, and let w be a factor of acceptable windows (e.g. $w = 11$ would consider each window in \vec{x} and its ten most similar in the corpus). Assuming all offsets of acceptable windows are disjoint, then the probability of jumping to at least one of the top k windows of \vec{s}_t , or to one of their acceptably close corresponding offsets, is:

$$1 - \left(p_d + (1 - p_d) \frac{(N - 1 - wk)}{N - 1} \right)^{(2\delta+1)pP} \quad (12)$$

For example, for $p_d = 0.95$, $\delta = 2$ and $w = 11$, and $N = 10000$ (≈ 4 min corpus), the probabilities are 0.747,

³ For a derivation of similar additive constraints on NMF, refer to [32]

Figure 2. Increasing polyphony leads to a better fit (ratios < 1), and increasing particles leads to a better fit, especially for larger corpora like the Woodwinds (≈ 1.6 hrs).

0.936, 0.983 for $k = 1, 2, 3$, respectively. These probabilities all degrade when N gets larger for a larger corpus, but in that case, it is likely that the acceptable w is also larger.

Furthermore, once one of the particles catches on to a good window in the corpus, it is promoted with a high weight and gets carried on to a longer grain. This is similar to how the "patch match" technique in computer graphics [33, 34] computes nearest neighbors of many nearby patches by starting with a random initialization of nearest neighbors, and then well-matched to patches correct the nearest neighbors of spatially adjacent patches [33].

4. EVALUATION

4.1 Quantitative Evaluation

To empirically assess reliability, we do an extensive MIR-style evaluation, which is much more comprehensive than standard evaluation in other concatenative synthesis works.

Effect of Parameters. First, to complement our analysis in Section 3.5, we want to empirically examine how many particles are needed for different sized corpora. We also want guarantee the impact of important parameters in our system for artistic control. We select 3 corpora: Driedger's buzzing bees (small, 66 seconds), a corpus used in *Edenic Mosaics* [10] known as "EdenVIP2," which consists of various real-world percussive sounds (medium, 10.5 minutes), and all Woodwind clips from the pre-2012 UIowa MIS dataset [35] (large, ≈ 1.6 hours). Then, we randomly subsample 1000 30 second clips from the Free Music Archive (FMA)-small dataset [36], each of which we use as a target for the three different corpora for various parameter choices. We use a sample rate of 44.1khz for all corpora, we use stereo audio for the bees and EdenVIP2, and we use mono audio for the Woodwinds.

First, we assess the effect of particles on fit; we fix $p_d = 0.95$, temperature $\tau = 10$, and $r = 3$, using $L = 10$ iterations for all KL operations, and we take $P \in \{100, 1000, 10000\}$. We also compare to Driedger et al.'s technique with $c = 3$ and $r = 3$ using $L = 50$ iterations, though we omit comparisons with Woodwinds due to computational cost (Section 3.3). In all cases, we use frequencies from 0 to 8000hz with a sample rate of 44100hz, a window length of 2048 samples, and a hop length of 1024 samples. Since the spectral similarity of different targets to a particular corpus varies widely, we report the *ratio* of the

Figure 3. Increasing p_d increases the average grain length since windows are less likely to jump at each timestep.

Figure 4. Increasing τ decreases the average grain length since this prioritizes the observation probability.

KL loss in Equation 1 to the KL loss for The Concatenator with $P = 100, p = 5$. Figure 2 shows the results. As expected, an increased polyphony leads to a better fit, as does increasing particles for all but the Bees, though the effect of increased particles is most pronounced for the largest corpus of Woodwinds, which makes sense by Equation 12.

As we noted in Section 2, however, a very good fit may lose the timbral characteristics of the corpus. A lower p helps, but we also need to ensure that grains are long enough. Therefore, we also examine mean grain length for various parameters. Figure 3 shows the result of varying p_d for a fixed temperature $\tau = 10$ and $p = 5$, and Figure 4 shows the result of varying the temperature τ for $p = 5$ and $p_d = 0.95$. As expected, grain length goes up with increased p_d and down with increased τ . In practice, lowering τ and raising p_d will lead to especially long grain lengths, albeit with a lower target fit.

Reproducing Pitch. In addition to fits and grain lengths, we quantify how well The Concatenator reproduces target pitch. Using the Woodwinds corpus, we create targets out of all stems in the MDB-stem-synth dataset [37]. We compare ground truth pitch annotations of the stems to the pitches estimated with CREPE [38] on both

Figure 5. The Concatenator reproduces reasonably correct pitches in the 1.6 hour Woodwinds corpus with targets in MDB-stem-synth, in real time (at $P = 100, 1000$), at all but the lowest octave C1.

the raw target and the synthesized audio for various P , and we break the results down by octave. Figure 5 reports the proportion of pitches correctly identified at each 23ms hop length to within different tolerances, over all stems. Even though CREPE was not trained on concatenated audio, it reports pitch nearly as clearly as on the raw target for most octaves except for C1, which makes sense since the spectral resolution is only 21.5hz. We can mitigate this in the current system by increasing the window, at the expense of temporal resolution. In the future, though, we would like to try a streaming CQT that can better capture lower frequencies. Finally, since the bassoon is the only instrument out of 10 in the Woodwinds that has notes in the C2 octave, additional particles are needed for precise pitch in that octave, which can be explained by w in Equation 12.

4.2 Qualitative Evaluation

This algorithm was tested in a variety of contexts to assess its performance and accuracy for applications in music and sound design. Our Corpora contained audio samples that fell into the following categories: Test Tones, Percussion, Full Mixes, Sample Libraries, Foley, and Driedger Comparisons. Our Targets were single audio files that were designed to test how the Concatenator re-created varying kinds of melody, counterpoint, full mixes, basses, drums, vocals, noise, and prior examples used with the Driedger algorithm. Our tests reveal that the Concatenator performs highly accurately in pitch reproduction for most melodies, two-part harmonies, and full mixes that contain prominent melodic features, while struggling with accurate reproduction of more complex three-part harmony. Given the nature of the particle filter, which rotates through new temporal positions in the corpus at random, some notes are more accurate than others, and some notes are dropped all together, as expected from our quantitative analysis. While this tendency might make the Concatenator unfit for replacing the role of large multi-sample instruments, the vast majority of pitches remain wholly accurate while the aleatoric variation of off-color audio grains may represent an entirely desirable aesthetic quality of its own. Similarly for drums, sometimes transients are incredibly accurate, while other times they sound a little smeared. This tendency is due to the particle filter’s random positioning, and can be improved by increasing the particle amount.

4.3 Supplementary Material / Discussion

We include supplementary material at <https://www.centralie.com/TheConcatenator>. This includes a python prototype for the real-time system that uses port audio [39], audio examples for all corpus/target pairings in Section 4.2, and a video showing artistic examples of what the real time system enables in the loop with Ableton Live.

This is only the beginning. Since The Concatenator exists feedback loop, we expect artists will go much deeper, likely well beyond the “obstacle course” we put it through.

DEEP RECOMBINANT TRANSFORMER: ENHANCING LOOP COMPATIBILITY IN DIGITAL MUSIC PRODUCTION

Muhammad Taimoor Haseeb*

ABSTRACT

The widespread availability of music loops has revolutionized music production. However, combining loops requires a nuanced understanding of musical compatibility that can be difficult to learn and time-consuming. This study concentrates on the 'vertical problem' of music loop compatibility, which pertains to layering different loops to create a harmonious blend. The main limitation to applying deep learning in this domain is the absence of a large, high-quality, labeled dataset containing both positive and negative pairs. To address this, we synthesize high-quality audio from multi-track MIDI datasets containing independent instrument stems, and then extract loops to serve as positive pairs. This provides models with instrument-level information when learning compatibility. Moreover, we improve the generation of negative examples by matching the key and tempo of candidate loops, and then employing AutoMashUpper [1] to identify incompatible loops. Creating a large dataset allows us to introduce and examine the application of Transformer architectures for addressing vertical loop compatibility. Experimental results show that our method outperforms the previous state-of-the-art, achieving an 18.6% higher accuracy across multiple genres. Subjective assessments rate our model higher in seamlessly and creatively combining loops, underscoring our method's effectiveness. We name our approach the Deep Recombinant Transformer and provide audio samples¹.

1. INTRODUCTION

The widespread availability of music loops used in Digital Audio Workstations (DAWs) has revolutionized music production. For example, *Umbrella* by Rihanna, composed using the "Vintage Funk Kit 03" GarageBand loop, transformed a royalty-free sample into a Grammy-winning global hit [2]. However, combining loops requires a nuanced understanding of musical compatibility and mostly relies on manual selection. Furthermore, the vast number of available loops presents a daunting challenge in deciding which loops pair well, leading to a combinatorial prob-

* The first two authors contributed equally.

¹ Samples available at: <https://conference-demo-2024.github.io/demo/>

lem. Finding compatible loops was recognized as one of the grand challenges in MIR research [3].

The loop compatibility problem can be broken down into two sub-problems: the *vertical* problem and the *horizontal* problem. The vertical problem pertains to the layering of different loops — and understanding how rhythm, melody, and harmony interact within a single moment of music — to create a harmonious blend. Conversely, the horizontal problem addresses the sequencing of loops over time, ensuring that transitions between different loops are smooth and maintain the overall coherence of the musical piece. This research focuses on the vertical problem.

A major limitation to applying deep learning to this domain has been the absence of high-quality, labeled, datasets. Previous works propose source separating existing music, extracting loops from each stem, and creating positive pairs [4,5]. Source separation models produce these four stems: *vocal*, *bass*, *drum*, and *other*. The outputs of source separation models are not perfect and often suffer from noise and distortion. Moreover, the "other" category can include a wide range of sounds — for example, entire string sections — and can be too *noisy* for the model to learn what makes two loops compatible. To generate negative samples, loop reversal, beat shifting, or key and tempo modifications are made to a loop in a positive pair. Altering loop characteristics to generate negative samples risks misleading models to distinguish these superficial differences rather than learning true musical incompatibility.

Our proposed solution to the above mentioned problems is to generate positive examples using MIDI datasets containing independent stems for each instrument, synthesizing them into audio, and extracting loops. This provides models with more granular information about *each* instrument when learning loop compatibility. Similarly, we find that while AutoMashUpper (AMU) demonstrates modest success in identifying compatible loops, its strength lies in accurately identifying incompatible loops after we match the tempo, key, and phase of query and target loops — thereby providing more realistic negative samples for model training [1]. Obtaining a large, high-quality, labeled dataset allows us to introduce and examine the application of Transformer-based architectures for addressing the vertical loop compatibility problem.

Our method outperforms the previous state-of-the-art for loop compatibility by 18.6% higher accuracy, proving its versatility and robustness across 13 genres through rigorous evaluations. Our contributions are as follows:

1. **A novel method to generate a large, high-quality, labeled dataset** for models to learn musical compatibility by providing positive and negative loop pairs that

share identical keys, tempos, and phases.

2. **Transformer-based architectures** to enhance accuracy for instrument-level music loop compatibility.
3. **Extensive objective and subjective assessments** demonstrating our method’s effectiveness.

2. RELATED WORK

Two approaches exist in the literature: rule-based and learning-based. Rule-based methods establish a set of rules to generate a compatibility score. In contrast, learning-based methods require positive and negative examples to train models for compatibility prediction. We review both.

2.1 Rule-Based Methods

Davies et al. set the groundwork for loop compatibility [6]. Their model, AutoMashUpper, computes mashability estimation by evaluating a weighted average of harmonic and rhythmic compatibility, and spectral balance across key-adjusted sections within a loop database. Best matching loops are aligned through time stretching and pitch shifting to match the query loop. Davies et al. introduce further improvements in a subsequent study, enhancing their system’s capabilities [1]. Key improvements include the development of a faster algorithm for assessing harmonic similarity, integration of rhythm and loudness for mashability evaluation, and a subjective evaluation to assess the overall mashability of music pieces. Later works use this as a baseline to compare loop compatibility performance.

Lee et al. introduce a framework incorporating both vertical and horizontal dimensions of musical segments to create harmonious mashups [7]. Features include tempo, beat-synchronous chromagram, chord signatures, Mel Frequency Cepstral Coefficients, and volume levels. The system uses a Group of Background Units (GBU) from a specific track, typically comprising multiple background units that adhere to prevalent structures found in popular music genres, forming the foundational layer of a mashup. It evaluates potential lead units to layer atop the established GBUs, which pivots on three factors: Harmonic Matching which determines the harmonic compatibility between lead and background units, Harmonic Change Balance monitors the rate of harmonic transitions between to reduce monotony, while Volume Weighting calibrates the audibility of lead units. The framework computes a vertical mashability score for each candidate pair and selects those with the highest compatibility. Tsuzuki et al. overlay vocal tracks from other artists who have performed the same piece, aligning them with the instrumental track [8].

Bernardes et al. assess the harmonic compatibility of musical tracks through small- and large-scale structures [9]. Small-scale compatibility is determined by blending dissonance and perceptual relatedness, derived from the Tonal Interval Space [10], resilient to instrumental timbral variations. Large-scale compatibility is based on key estimations, aiding in overarching harmonic planning. Software showcases these metrics through interactive visualization to aid in finding harmonically compatible tracks. Maças et al. present MixMash by building on this method [9, 11]. MixMash enhances user interaction through a

force-directed graph that visualizes multidimensional musical attributes like hierarchical harmonic compatibility, onset density, spectral region, and timbral similarity. The visualization represents tracks as nodes with varying distances and connections indicating their compatibility.

2.2 Learning-Based Methods

A major limitation in using Deep Neural Networks to evaluate the compatibility of musical loops has been the lack of adequately labeled datasets. Chen et al. are the first to use neural network models [4]. First, they propose an innovative pipeline to generate a labeled dataset using the Free Music Archive. To create positive samples they employ an unsupervised MSS algorithm that isolates looped content [12]. Negative samples are created by editing a loop in a positive loop pair by doing one of three things: reversing, randomly shifting beats, or rearranging beats of one of the loops. They propose using two architectures, a Convolution Network (CNN) and a Siamese Network (SNN), to learn compatibility between two loops. While both models outperform traditional rule-based systems, the CNN model demonstrates superior performance. Subsequent studies have identified limitations in the proposed data acquisition process. Specifically, it employs multiple heuristics for source separation and does not ensure the outputs consist of distinct instruments, e.g. a positive training example could comprise two similar drum loops [5]. In addition, they restrict their work to hip-hop without exploring how well this approach generalizes to other genres. Finally, they use a two-second input which may not capture the complexity and variability of longer musical pieces.

Huang et al. introduce an alternative method for assembling a training dataset by developing their own supervised music source separation model, which splits tracks into four distinct stems: *vocal*, *bass*, *drum*, and *other*. While it is an innovative approach, it leaves serious gaps in dataset quality. The outputs of source separation models are not perfect and often suffer from noise and distortion. In addition, the "other" category can include a wide range of sounds — e.g. guitars, pianos, trumpets, saxophones, violins, cellos, ambient sounds, synthesizers, reverb, choirs, flutes, clarinets, and even entire string sections. Since professional-grade musical loops contain distinct sounds — a guitar riff, a saxophone lick, a violin jig, etc. — using "other" may be too *noisy* for the model to learn what makes two instrument loops compatible. Similarly, as observed by Chen et al., bass and drum loops seamlessly adapt across most genres and styles when matched for tempo and key, and are somewhat trivial to learn for the model. On the other hand, they generate negative samples by varying the basic characteristics of a loop — key, tempo, or phase shifts. Even though it guarantees incompatibility, simply altering the basic loop characteristics to generate negative examples risks misleading the model to learn to distinguish these superficial differences rather than understanding true musical incompatibility. Instead, we propose training models to determine compatibility between loops sharing identical tempo, key, and phase to mirror choices made in actual music production — a significantly more challenging task. While there are some similarities, Huang

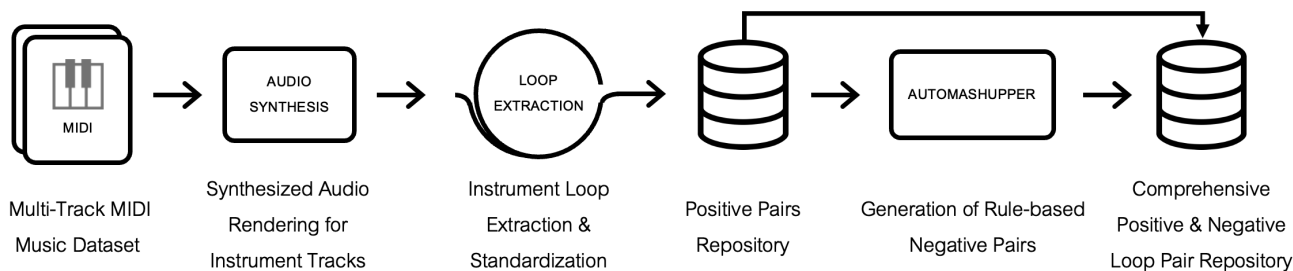

Figure 1. Our dataset generation pipeline takes multi-track MIDI music as input and generates a labeled loop dataset.

et al. do not extract loops and instead use complete stems to train a model on mash-ups involving combinations of vocal and backing track stems; whereas our research delves into the compatibility of instrumental music loops. Therefore, we use Chen et al. as a baseline for our work.

Broadly, despite their utility, these methods do not capture the complex interplay of musical elements, underscoring the necessity for more advanced methods. With the availability of a larger dataset, we introduce and examine the application of Transformer-based architectures for addressing the vertical loop compatibility problem.

3. DATA GENERATION PIPELINE

We introduce a novel self-supervised method to create a large, high-quality, labeled dataset to provide instrument-level granularity. Our method also ensures identical basic attributes — such as tempo, key, and phase — amongst incompatible pairs to compel models to learn compatibility and not focus on such superficial differences.

3.1 Generating Positive Examples

Synthesized datasets have shown promise in enhancing model performance across various music information retrieval tasks, including transcription, understanding compositional semantics, sound synthesis, and instrument recognition [13]. In the absence of an instrument-level labeled dataset, we modify the data collection pipeline proposed by Chen et al. to instead create loops from synthesized data [4]. Similar to Flakh, we generate our dataset by taking songs from the Lakh dataset, rendering MIDI files using sample-based synthesizer and then extracting loops [13, 14]. For this task, we used FluidSynth².

The Lakh MIDI dataset, with over 175,000 unique MIDI files, provides detailed musical score data for various instruments that can be synthesized due to distinct track segmentation. We chose files with significant parts for piano, bass, guitar, and drums. A total of 20,371 files are identified, of which 15,000 were taken at random and rendered [13]. Each MIDI file is split into individual instrument tracks, matched with appropriate patches based on program numbers, and rendered into audio. As observed by Chen et al., when adjusted for tempo and key, drum and bass loops tend to be universally compatible. Therefore, all drum and bass MIDI tracks were removed from synthesis and subsequent creation of positive and negative

pairs [4]. The collected set of 15,000 songs spans 13 genres and 47 instruments. We then use the same method as Chen et al. to extract loops from each rendered audio [4]. Of the 15,000 songs, 12,193 songs have at least one valid loop pair. Specifically, of these 12,193 songs, we obtained 126,746 loops and 90,376 valid positive pairs of loops. This provides our training models with more granular information about *each* instrument loop while learning what constitutes compatibility. Files were separated into training (72,301 loop pairs), validation (9,037 loop pairs), and testing (9,038 loop pairs) — leaving us with a total of 251 hours of positive examples, with roughly equal representation of instruments and genres in each set. To ensure consistency, we standardize the duration of each loop to 10 seconds by either repeating or trimming the loops.

3.2 Generating Negative Examples

Generating pairs of negative loops is a difficult task. One naive approach could be to randomly select combinations from our loop set. However, this does not guarantee incompatibility. Unlike what’s been proposed in similar works, we argue that simply altering the basic loop characteristics to guarantee the generation of negative examples risks misleading the model to learn to distinguish these superficial differences rather than understanding true musical incompatibility. Instead, to reflect real-life music production choices, we train models to determine incompatibility between loops sharing identical tempo, key, and phase. We find that while AutoMashUpper demonstrates modest success in identifying compatible loops, its strength lies in identifying incompatible loops within the same tempo, key, and phase, thus furnishing reliable negative labels for compatibility modeling. Inversely applying the original method focuses on *least* compatible pairs. Harmonic incompatibility finds significant chord progression clashes, rhythmic incompatibility leads to off-sync combinations, and spectral imbalance points to lopsided energy distributions, cultivating disturbances and noise.

We adopt AMU to a subset of loops by drawing, without replacement, 1,500 positive pairs (3,000 loops) from varied genres and instruments. For each loop in this collection, we calculate its incompatibility against every other loop by adjusting the target loop’s keys and tempos to match the query loop and then calculating weighted sums of harmonic, rhythmic, and spectral compatibility between the source and target. For this task, we use a Python im-

² Available at: <http://www.fluidsynth.org/>

plementation³ of the Krumhansl-Schmuckler key-finding algorithm [15], Rubber Band⁴ for sound stretching and pitch-shifting, and weights proposed by Bernardo — 0.4 for both harmonic and rhythmic, and 0.2 for spectral compatibility — to derive an overall compatibility score between loop pairs [16]. After obtaining all scores, the 35 least compatible loops are paired with each loop in the set. We exclude any duplicate pairs, culminating in 95,281 unique negative pairs. More than 1,000 negative pairs are tested at random by the research team to confirm incompatibility. The final pairs are then partitioned into training (76,225 loop pairs), validation (9,528 loop pairs), and testing segments (9,528 loop pairs), leaving us with a total of 264 hours of negative examples. The negative set can be significantly expanded by drawing more pairs at the start.

Data Type	# Loops	# Loop Pairs	# Hours
Training	101,397	148,526	412
Validation	12,674	18,565	51.5
Test	12,675	18,566	51.5
In Total	126,746	185,657	515

Table 1. Overview of data, including positive and negative examples, across training, validation, and test subsets.

4. MODEL ARCHITECTURE

Recent advancements in self-attention networks, particularly the Transformer architecture, provide a new perspective for solving the vertical loop compatibility challenge [17]. In this study, a large labeled dataset allows us to introduce and examine the application of Transformer-based architectures. Specifically, we use the same model architecture as MusicTaggingTransformer (MTT), proposed by Won et al., for its robustness on other MIR tasks [18]. We refer to this adapted Transformer architecture as the Deep Recombinant Transformer (DRT). Initial pre-processing employs MelSpectrogram transformation and AmplitudeToDB conversion of the input, which comprises the summed audio signals of two candidate loops. This is followed by Res2DMaxPoolModule for downsampling, with subsequent convolutional layers and max-pooling operations for detailed feature extraction. The core Transformer architecture is equipped with 256-dimensional attention vectors across four layers and eight heads, PreNorm, Residual structures, and GELU-activated Feed Forward networks for processing. A unique class ([CLS]) token, alongside positional embedding, is added to the feature set for sequence analysis. The output from the Transformer is directed through a sigmoid function, mapping the high-dimensional feature vectors to a binary outcome space, and delineating the likelihood of each audio sample belonging to a specific category. Then, we compute the binary cross entropy loss (BCELoss) to update the parameters of the whole model. Model’s output is between 0 and 1, with values closer to 1 indicating a higher probability that the pair of loops are compatible, and closer to 0 when they are not. Therefore, we can use its output

³ <https://pypi.org/project/pymusickit/>

⁴ <https://breakfastquay.com/rubberband/>

Figure 2. Architecture of Deep Recombinant Transformer.

to estimate the compatibility of any two loops. Dropout (0.1) and batch normalization strategies are implemented to mitigate over-fitting and ensure robust model generalization. This integration of convolutional and Transformer elements captures both local and global audio features for deep and context-aware analysis. To investigate the adaptability and performance of the Transformer architecture for this task, our study explores two distinct configurations: one variant employs two-encoder layers, while the other utilizes four-encoder layers. This enables us to evaluate the impact of architectural depth on model performance.

5. EXPERIMENT SETUP AND EVALUATION

We evaluate the performance of Transformer architectures in identifying compatible loops against the state-of-the-art. Following this, we focus on understanding the impact of our new dataset on model performance. Finally, we conduct a subjective assessment.

5.1 Effect of Using a Transformer

First, we compare the performance of Transformers against CNN-based architectures. We train and evaluate two configurations for the Transformer architecture — two and four encoder layers. For comparison, we explore the performance of the original CNN-based NLC⁵ model proposed by Chen et al. Initially, we adhere to the original NLC specification, applying it to two-second audio segments extracted from our 10-second dataset. However, we also train a modified NLC on a 10-second long input for a fair comparison. Moreover, acknowledging that extended audio contexts may require a deeper CNN architecture, we also train Short-chunk CNN Res [19], a deeper CNN architecture, due to its strong performance on MIR-related classification tasks. We perform hyperparameter optimization for each architecture using unseen validation sets.

⁵ <https://github.com/mir-aidj/neural-loop-combiner>

The first type of evaluation entails a classification task. It assesses a model’s ability to distinguish compatible loops from incompatible ones. We report accuracy and F1 scores for each model. Table 2 summarizes these results.

Model	Accuracy ↑	F1 Score ↑
NLC (2 seconds)	62.25	68.76
NLC (10 seconds)	60.50	70.76
Short Chunk CNN Res	70.50	77.13
DRT (2 Attn Layers)	78.60	82.02
DRT (4 Attn Layers)	80.90	83.66

Table 2. Comparative performance on loop compatibility classification task for models trained using our dataset.

Model	Avg. ↓ Rank	Top ↑ 10	Top ↑ 30	Top ↑ 50
NLC (2 seconds)	43.4	0.25	0.44	0.56
NLC (10 seconds)	51.2	0.13	0.25	0.52
Short Chunk CNN Res	38.3	0.07	0.46	0.77
DRT (2 Attn Layers)	25.7	0.15	0.69	1.00
DRT (4 Attn Layers)	16.2	0.44	0.75	1.00

Table 3. Comparative performance on loop ranking task for models trained using our dataset, using average rank and accuracy in the top-k positions across 100 queries.

Another performance evaluation reported in the research involves ranking candidate loops by compatibility with a particular query loop [4, 5]. This assessment is especially important for a model’s practical use, which seeks to find loops that match a specific query from a large collection of loops. Using AMU, and the unseen test set, we create a collection of candidate loops for each query loop, ensuring that precisely one of these candidates pairs positively with the query. The model’s performance is measured by where the "target loop" ranks in the list, with a higher position indicating better performance. Following the benchmark set by Chen et al., we also assess the compatibility of exactly 100 candidate loops balanced across genres and instruments. Each model is evaluated for accuracy within the top 10, 30, and 50 positions, as well as the mean rank. Table 3 shows these aggregated averages.

The results indicate that the four attention layer Music-TaggingTransformer demonstrates superior performance across loop compatibility classification and ranking tasks. We also observe that models, though not explicitly trained for it, perform well in identifying compatible drum and bass loops, confirming these are relatively trivial to learn.

5.2 Effect of Using Our Dataset

Generating negative examples by altering loop characteristics can mislead models toward learning superficial differences instead of true musical incompatibility. To objectively evaluate this, we create a control dataset using the negative sampling methodology proposed by Chen et al. In this control dataset, the positive pairs remain the same, while for negative pairs we reverse, randomly shift beats, or re-arrange beats of one of the loops. Although reversing

performed best in the original study, the performance differences across the three strategies were small. To account for potential non-transferability to our dataset, we include an equal representation of all three methods in our control set. We retrain the three best-performing architectures from Table 2, and evaluate them, on this control dataset. The classification results are summarized in Table 4 while the retrieval results are summarized in Table 5.

Model	Accuracy ↑	F1 Score ↑
NLC (2 seconds)	66.4	71.4
Short Chunk CNN Res	88.9	89.3
DRT (4 Attn Layers)	88.2	88.7

Table 4. Comparative performance on loop compatibility classification task for models trained using control dataset.

Model	Avg. ↓ Rank	Top ↑ 10	Top ↑ 30	Top ↑ 50
NLC (2 seconds)	13.25	0.57	0.75	1.00
Short Chunk CNN Res	1.0	1.00	1.00	1.00
DRT (4 Attn Layers)	1.0	1.00	1.00	1.00

Table 5. Comparative performance on loop ranking task for models trained using control dataset, using average rank and accuracy in the top-k positions across 100 queries

While all models show improved performance across both tasks, we perform another set of evaluations to determine if these on-paper performance gains are transferable to real-life production scenarios. Here, we evaluate these models, trained on the control set, against the test set generated by our proposed method — where pairs sharing the same tempo, key, and phases are analyzed for compatibility. These results are presented in Tables 6 and 7.

Model	Accuracy ↑	F1 Score ↑
NLC (2 seconds)	50.95	62.49
Short Chunk CNN Res	53.30	67.52
DRT (4 Attn Layers)	54.15	67.93

Table 6. Classification performance of models trained on control set (Table 4), but evaluated on our original test (Table 1) containing loops pairs with identical tempo and keys.

Model	Avg. ↓ Rank	Top ↑ 10	Top ↑ 30	Top ↑ 50
NLC (2 seconds)	50.7	0.13	0.31	0.50
Short Chunk CNN Res	39.4	0.00	0.30	0.85
DRT (4 Attn Layers)	35.8	0.14	0.40	0.67

Table 7. Ranking performance on our original test set using average rank and accuracy in the top-k positions.

While the models trained on the controlled dataset have better performance (Tables 4 and 5) than models trained on our dataset (Tables 2 and 3), they do not generalize for negative samples that are more in line with real-world production choices (Tables 6 and 7). This is because real-life comparison involves two loops that are identical in tempo,

key, and phase, without being reversed or subjected to random beat shifts. Since these models have not encountered such incompatible samples during training, their performance tends to degrade in the production setting.

5.3 Subjective Assessment

Study Methodology: We perform a subjective analysis using Apple loops from GarageBand to evaluate the effectiveness of our proposed method and demonstrate its applicability to high-quality production loops. Based on superior objective performance, three models are selected for this user study: NLC (2 seconds), Short Chunk CNN Res, and DRT (4 Attn Layers). Two variants of each model were included, the first trained on our proposed dataset, and the second trained on the control dataset. For this subjective assessment, we employed a methodology similar to that used by Zhao et al. [20]. We paired one query loop against 99 candidates, within the query loop’s genre, and formulated audio test clips by combining the query loop with the highest-ranked match. Each set contained eight query-target pairs: top matches proposed by each variant of the three models, a human musician-generated pair, and a randomly selected target loop to serve as a control group. Each audio sample was of equal length (10 seconds). A total of 6 such sets were created. The subjects were asked to rate each sample on a 5-point Likert scale according to the following criteria:

- **Seamlessness:** Naturalness of the loop combination.
- **Creativity:** Originality and inventive quality.

The study engaged a total of 37 participants. To qualify, participants were required to have a baseline engagement with music, defined as listening to at least five hours of music per week, to ensure sufficient exposure to music to provide informed feedback. Each survey participant listened to exactly three of the sets chosen at random (24 audio combinations, or 240 seconds of audio). To ensure diverse and representative survey respondents, we employed demographic filtering to include different ages, genders, and cultural backgrounds. The sequence of the presentation was randomized to eliminate any potential bias, and the origins of the pairs were not disclosed to participants.

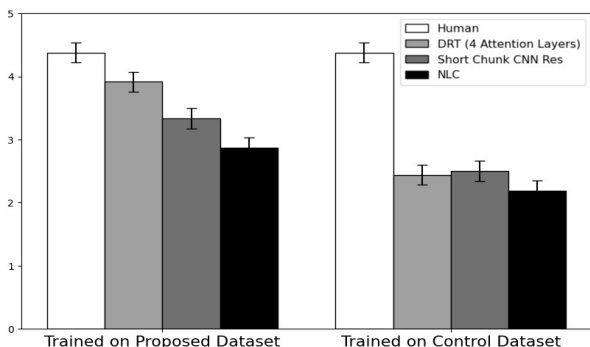

Figure 3. Subjective evaluation results for composition seamlessness computed using within-subject ANOVA.

Results and Analysis: Figures 3 and 4 display our findings from the subjective evaluation. The y-axis represents

Figure 4. Subjective evaluation results for composition creativity computed using within-subject ANOVA.

the mean scores and the error bars denote the Standard Deviation calculated through a within-subject ANOVA [21]. Our model demonstrated superior performance over the control, achieving statistical significance ($p < 0.05$) for both measures. The proposed DRT architecture, trained on our dataset, surpassed other models by a significant performance difference ($p < 0.001$). The participant responses in the survey demonstrated high reliability, as evidenced by a Cronbach’s α of 0.812 [22]. Overall, the scores for our approach were on par with human music compositions.

6. CONCLUSION

We explored the vertical loop compatibility problem in music production. One major limitation to applying deep neural networks in this domain has been the absence of labeled datasets. We presented a novel self-supervised method for generating a large, high-quality, labeled dataset from a multi-track MIDI dataset, containing separate instrument tracks, and synthesizing them into audio to extract loops. This provides our training models with more granular information about each instrument across different genres and provides negative pairs with matching tempo, key, and phase to force models to learn true musical compatibility. A large dataset allows us to introduce and examine Transformer-based architectures. Our architecture employs a larger context window of ten seconds allowing a holistic input representation and consequently better compatibility prediction. Experimental results show that our method outperforms the previous state-of-the-art, achieving an 18.6% higher accuracy across multiple genres. Subjective assessments rate our model higher in seamlessly and creatively combining music loops.

Nevertheless, implementing Transformer architectures demands significant computational resources. Also, while AMU performs well in identifying incompatible pairs, it does not guarantee incompatibility and may contain leakage. Finally, synthesized audio from MIDI may not fully capture the richness of professionally recorded music. This could limit the model’s learning scope, especially regarding timbral and expressive nuances which otherwise may be important to learn. Future work may involve experimenting with more efficient architectures, collecting human-labeled datasets, and synthesizing MIDI using professional virtual instruments for better dataset quality.

ABSTRACT

Music two-tower multimodal systems integrate audio and text modalities into a joint audio-text space, enabling direct comparison between songs and their corresponding labels. These systems enable new approaches for classification and retrieval, leveraging both modalities. Despite the promising results they have shown for zero-shot classification and retrieval tasks, closer inspection of the embeddings is needed. This paper evaluates the inherent zero-shot properties of joint audio-text spaces for the case-study of instrument recognition. We present an evaluation and analysis of two-tower systems for zero-shot instrument recognition and a detailed analysis of the properties of the pre-joint and joint embedding spaces. Our findings suggest that audio encoders alone demonstrate good quality, while challenges remain within the text encoder or joint space projection. Specifically, two-tower systems exhibit sensitivity towards specific words, favoring generic prompts over musically informed ones. Despite the large size of textual encoders, they do not yet leverage additional textual context or infer instruments accurately from their descriptions. Lastly, a novel approach for quantifying the semantic meaningfulness of the textual space leveraging an instrument ontology is proposed. This method reveals deficiencies in the systems' understanding of instruments and provides evidence of the need for fine-tuning text encoders on musical data.

1. INTRODUCTION

Multiclass classification has been a heavily researched topic in Music Information Retrieval (MIR) with many concrete applications such as genre, instrument and emotion recognition [1–4]. Despite the success of Deep (DL) systems for such tasks, recurring deficiencies persist among these problems. These are: (1) the limited availability of large-scale annotated datasets curated by experts, (2) the restricted capability of these systems to infer only a set of predefined classes.

Figure 1: Figure of a pipeline for two-tower multimodal systems. A separate model for each modality is used and their individual representations are projected to a joint audio-text space through a Multi-Layer Perceptron (MLP). This enables direct comparison between audio and textual data. We refer to embeddings obtained before joint-space projection as pre-joint space embeddings.

Music is an ever-evolving art form and as a result, there is an inherent need to make these systems adaptable to new terms/classes [5–7] and infer task-agnostic representations that can be useful for a plethora of downstream tasks with representation learning [8–10]. Zero-shot learning (ZSL) is focused on estimating a classifier capable of inferring unseen, new classes without annotated examples [11–14]. ZSL is often achieved in either of two ways: (1) by decomposing each class into attributes and inferring unseen classes through their related attributes (e.g. genres decomposed into presence or absence of instruments [12]) or (2) using word embeddings from Language Models (LM) [12–14]. The success of contextualized Large Language Models (LLM) has driven the research community predominantly toward the second solution, as it doesn't require experts to define attributes and the mapping between classes and attributes [15–17].

As a result, ZSL for audio classification is primarily focused on connecting the audio and semantic representation spaces. This interconnection can happen in 2 main ways: (1) mapping the audio representations to text space [12, 13], or (2) mapping both of the spaces to a new, joint audio-text space [14, 18–20]. The systems of the second category are named two-tower multimodal systems, where pre-trained audio models and LMs are used as the audio and text encoders respectively. Representations obtained from each modality are then mapped to a joint audio-text space and systems are jointly optimized such

that the audio and text representation are close in the joint space (e.g. the phrase “A rock song track” is similar to the recording of a “rock” song). We will call such representations as embeddings from here on.

This work aims to better understand the properties of existing two-tower systems. We use instrument classification as a case-study to provide insights into the presence (or absence) of semantic properties in the audio, text or joint spaces in addition to reporting classification metrics. Concretely, we consider 3 systems: MusCALL [18], a CLAP [20,21] model trained on speech and music datasets, and a CLAP model trained on music data [21]. We evaluate the performance of these systems on instrument classification using the TinySOL dataset [22]. We would like to highlight that multimodal DL models typically excel at simple tasks and datasets like this.

Furthermore, a novel approach for quantifying the semantic meaningfulness of textual encoders for instrument recognition is proposed.

For reproducibility, our experiments are performed on open-source datasets and the code of our experiments is made publicly available¹, such that they can be reproduced.

2. RELATED WORK

2.1 Zero-shot transfer

ZSL focuses on estimating classifiers for novel, unseen classes without annotated examples. Two-tower systems are not primarily optimized for ZSL but due to the pre-trained textual encoder, novel words or phrases can be interpreted during inference. This property is known as zero-shot transfer (ZST) [23].

Side-information can be used in multiple ways that fall into two categories: (1) decomposing classes into shared attributes and (2) using LMs to represent this information as a text embedding. Despite its success, the first solution requires experts to effectively estimate the relevance of attributes and several classes and is a costly activity. As a result and due to the remarkable results obtained through contextualized LLMs, research has focused on the second option.

Generally, the methodology can be broken down into 3 components: (1) an audio encoder, (2) a textual encoder and (3) a projection to a common space. General purpose audio DL models that have been used as the audio encoder include VGGish [24], PANN [8], HTS-AT [9] and Audio Spectrogram Transformers [25]. For the textual encoder, distributional LMs like GloVe [26], Word2Vec [27] and contextualized LMs like BERT [28] have been thoroughly tested. As each modality produces heterogeneous representations, different methods of establishing comparability have been tested. This is predominantly achieved through projecting audio to text/semantic space [11–13] or a novel, joint audio-text space [18–20].

2.2 Two-tower multimodal systems

Multimodal systems aim to represent data with additional knowledge from multiple modalities. Examples are audio combined with images [29], text [12, 30] or a combination thereof.

Two-tower multimodal systems focus on combining the textual and audio modalities by projecting them in a joint audio-text space. In that space, words that are relevant to a specific song will produce embeddings that will be close in terms of some similarity metric. An illustration of a two-tower system is presented in Figure 1. Information flowing through the audio encoder or textual encoder is referred to as the audio and textual branch respectively. We are also interested in the embeddings obtained through the encoders before projecting them into the joint audio-text space. We will call these the pre-joint spaces from now on.

The text used during training is usually a description of a song and will be referred to as a caption. The text used during inference will be referred to as a prompt.

MusCALL [18] combined a ResNET-50 for audio [31] with a Transformer for text encoding [32], optimized jointly over InfoNCE contrastive loss [33]. Additionally, a weighing mechanism based on caption-caption similarity was incorporated between negative audio-caption pairs. This is based on the premise that similar captions will be given to similar audio. The audio used is private but the training code is publicly available and used for this work.

MuLan [19] experimented with ResNET-50 as well as Audio Spectrogram Transformers [25] for audio encoding and a pretrained BERT model for the text branch. Both were jointly optimized over the Contrastive Multi-view Coding loss [34], which is a cross-modal extension of InfoNCE. Neither the data nor the code is available.

LAION-CLAP tested 6 different combinations of audio and text embedding models, the best one of which was HTS-AT with RoBERTa [35]. The latter is the one that will be used in this paper. The LAION-Audio-630k dataset was formed by combining AudioCaps, CLotho and Audioset.

Generally, research for two-tower systems is limited to testing different combinations of audio and text encoders, optimized jointly over a form of contrastive loss and modality fusion. We believe that closer inspection of their embeddings and evaluation protocol is needed.

3. EVALUATION OF TWO-TOWER SYSTEMS

3.1 Dataset and models

We use the TinySOL dataset which contains 2913 audio clips with a single note played from a single instrument out of a set of 14 instrument classes. This dataset has been chosen as it has consistent recording settings without noise, it is a simple dataset for instrument recognition and finally, confounding factors (compression, sampling rate etc) are minimized. We consider 3 models in total:

1. **Music/Speech CLAP:** [20, 21] A CLAP-based model trained on music/speech data²

² music_speech_epoch_15_esc_89.25.pt

2. **Music CLAP**: [21] A CLAP-based model trained on music data³
3. **MusCALL**: A version of [18], retrained on music data⁴

We use the two pretrained CLAP systems provided by LAION⁵. For this work, the original MusCALL implementation was retrained from scratch, as both the data and trained models used in the original paper are not publicly available. Instead, we train on the LPMusicCaps-MTT [36] dataset, which is built by leveraging the audio and 188 tags from Magna Tag A Tune [37] to artificially generate captions through a GPT-3.5 model. The audio is resampled to 44.1 and 16 KHz for CLAP and MusCALL respectively, and the pre-processing steps described in their respective code repositories are followed.

3.2 Zero-shot transfer for instrument classification

Given an unseen audio segment x^* , a text label l^* and a two-tower system $f(x)$, we want to model the likelihood $P(l^*|x^*)$ based on the embeddings provided by $f(x)$. In the general case, $f \mapsto \mathbb{R}^F$ is a function that represents a two-tower system and maps audio or text information to a joint audio-text space, where F is the dimension of the joint space. Also, let $\delta : (\mathbb{R}^F \times \mathbb{R}^F) \rightarrow \mathbb{R}$ be a function that measures similarity between joint space embeddings. In this approach, we model the $P(l^*|x^*)$ based on δ , as in:

$$P(l^*|x^*) \propto \delta(f(x^*), f(l^*)) \quad (1)$$

Multiclass classification attributes the most probable class to each recording and equivalently, the one that has the maximum likelihood. Given our approximation, the output class for each recording is:

$$c^* = \operatorname{argmax}_{c \in C} \delta(f(x^*), f(c)) \quad (2)$$

for $c \in C$, where $C = \{c_1, c_2, \dots, c_N\}$ is the set of classes that we are interested in.

In our work, the embedding similarity function δ is the cosine similarity:

$$\delta(e_1, e_2) = \frac{e_1 \cdot e_2}{\|e_1\| \cdot \|e_2\|} \quad (3)$$

where $\|\cdot\|$ is the L_2 norm and $e_i \in \mathbb{R}^F$ are embeddings.

3.3 Experiment 1: Are two-tower systems context dependent?

Two-tower systems are typically not trained on single words, but rather longer prompts. As a result, the embedding produced for a single-word text label (e.g. “guitar”) can be very different from the embedding for a longer prompt, with additional context (e.g. “a guitar track”). When using two-tower models for classification, the class label can be wrapped in a prompt such as “A <label>

track” [18], to better match the training distribution. Methods to introduce stochasticity in the prompts used during training have been empirically proven to lead to more robust results [38]. Retraining the systems and testing different ways of augmenting captions used for training is left for future work, but works in image-text [39] and video-text [40] two-tower systems provide some evidence for their usefulness.

The impact of different approaches for giving additional context to a single-word text label during inference has not been well-explored. We explore the prompt sensitivity of each system by slightly changing the text prompt used for zero-shot classification in order to better understand to which extent these systems leverage contextual information. As far as we are aware, we are the first to evaluate the use of different types of prompts for two-tower systems during inference. Specifically, we evaluate 3 systems against 6 different prompts:

1. MusCALL prompt: “A <label> track”
2. Generated definition: “The <label> is a ...”
3. Generated definitions without label words: “The <removed> is a ...”
4. Label word with random context: “<label> <randomly selected lorem ipsum segment>”
5. Musically informed #1: “This is a recording of a <label>”
6. Musically informed #2: “Solo musical instrument sound of a <label>”

The first prompt proposed is the prompt that was used in MusCALL. The second prompt is generated using GPT-3.5 [41]. The third prompt is the same as the second but we removed all instances of the label itself to evaluate the influence of the context on its own. To evaluate if the systems are sensitive to specific words and to further evaluate if the context is useful, the fourth prompt adds random words alongside the label. Lastly, we test 2 musically informed prompts.

As a first metric, we consider Top-k accuracy with $k = \{1, 2, 3\}$. We calculate the cosine similarity between each recording and instrument prompt and sort them. We assign zero-shot class labels as described in Section 3.2 and check if the true label is present in the top-k assigned class labels. Furthermore, we calculate Receiver Operating Characteristic and Precision-Recall Area Under the Curve (ROC-AUC and PR-AUC respectively) following [42].

Figure 2 presents the zero-shot instrument recognition results for the three models across the 6 prompts, as well as the audio-only alternatives that will be described in Section 3.4. Despite the focus on music data, Music CLAP doesn’t display very different results from Music/Speech CLAP. While music-specific systems are generally expected to perform better, this is not the case for two-tower systems. This might be an indication that music requires special treatment, as the metrics approach the state of the art in audio-text [21] and image-text [43] two-tower systems.

³ music_audioset_epoch_15_esc_90.14.pt

⁴ <https://github.com/ilaria-manco/muscall>

⁵ <https://github.com/LAION-AI/CLAP>

Figure 2: Metrics for 6 textual prompts (See Section 3.3), 2 audio based label embeddings (See Section 3.4) and the 3 two-tower multimodal systems. The top row contains top-1 through top-3 accuracy and the bottom ROC-AUC and PR-AUC. The red line represents random choice.

Top-1 accuracy is worse than random for 4 out of 6 textual prompts for MusCALL. This might be caused by the small size of training data used, the absence of instrument-specific captions or their underrepresentation in the captions used, as well as the absence of single-note recordings in LPMusicCaps-MTT. While the metrics are low for MusCALL in most of the cases, a relatively large performance is still evident for the audio-only scenario. This implies that the problem lies in the audio-text alignment or the text branch.

The performance of CLAP models seems to be heavily correlated with the instrument labels themselves. Removing the label from definitions provides evidence that relevant context cannot be leveraged properly. Also, using musically informed prompts doesn't always result in greater or even comparable results. Specifically, top-1 accuracy drops when using the second musically informed prompt for CLAP models, despite the prompt being a more precise description of what is occurring in the audio.

These results suggest that CLAP models do not leverage extra context in the input prompt effectively. Both models performed worse when using relevant context without the instrument word, suggesting that the textual encoders put a lot more emphasis on the presence of specific words rather than the meaning of the prompts themselves. In addition, using a generic prompt provided better results than a musically informed one in most cases. Furthermore, any kind of context added at the prompts seems to harm the performance in most of the cases and provide more evidence that

the model's text encoder cannot properly decompose the sentence to its constituents and use these semantically. Despite this observation, using definitions (prompt 2) seems promising for Music CLAP and for every metric apart from top-1 accuracy.

In the following experiments, we will consider only the "MusCALL prompt" as it leads to the highest top-1 accuracy, when model accuracy surpasses random choice.

3.4 Experiment 2: Inspecting the cosine similarity distributions

As a next experiment, we calculate the cosine similarity between the joint space embeddings of each recording from TinySOL and the MusCALL prompt for each instrument, then compare the similarities of positive pairs vs negative pairs. We define a positive pair as an audio-label pair where the label corresponds to the instrument in the recording, and the negative pairs as all other pairs. Figure 3a presents histograms of similarities for positive and negative pairs when using text prompts. If the audio-text coherence is good, positive and negative histograms should be well separated.

Positive and negative similarity distributions overlap greatly, as can be seen in Figure 3a. As a result, retrieval is far from optimal. Fundamentally, a caption is a multi-faceted sentence. We suspect that treating a sentence as only one embedding point (mean of word embeddings) is fundamentally problematic and greatly hinders the semantic properties of the joint space. A hypothesis that needs

(a) Histogram of cosine similarity between TinySOL data and MusCALL prompts in joint audio-text space.

(b) Histogram of cosine similarity between TinySOL audio data and the mean of intra-class embeddings in joint audio-text space.

Figure 3: Histograms of audio and label embeddings for positive and negative pairs. When using textual prompts (a), the alignment is problematic, as can be seen from the overlap between positive and negative distributions.

testing is that by using composite sentences, a model cannot properly infer the relative embeddings of the sentence constituents.

To further evaluate if the audio encoder produces meaningful representations, we use the mean of intra-class song embeddings as the label embedding. This label embedding takes the role of the prompt embedding in the previous experiment. We generate the embeddings in joint audio-text space for each song. Then, we collect the songs that belong to k -th class c_k and estimate the mean of the embeddings. The latter serves as the optimal embedding that the text label would have to be mapped to in order to maximize performance and will be referred to as the “audio-only” label. Note that this embedding is only optimal in the case of TinySOL data.

The resulting histograms for positive and negative pairs are shown in Figure 3b. They are well separated, indicating that the audio-encoder itself produces meaningful, separable embeddings.

Audio embeddings seem to be of good quality before and after the projection to the joint audio-text space, as the metrics are almost equal before and after projection in Fig-

Figure 4: The histogram of top-2 class similarities for every song in TinySOL. The CLAP models tend to be not very confident while the metrics are greater than the over-confident MusCALL with the worst metrics.

ure 2. The metrics almost double when using any audio-only labels, which further provides evidence that the problem resides in the text branch, or joint-space projection and there remains a large performance gap to bridge.

3.5 Experiment 3: How confident are two-tower systems in their prediction?

We calculate the histogram of the difference between the top-2 candidate classes for each recording [44] to quantify the classification confidence. The similarity between each audio and instrument embeddings is estimated and they are sorted in descending order. The difference between top-2 similarities for each song is then calculated and a histogram of that difference is plotted in Figure 4.

MusCALL seems to be overly confident in its prediction, which is unwarranted given the metrics reported. The opposite can be stated for CLAP models, where despite their better performance, the difference has a median value of 0.05-0.08.

3.6 Experiment 4: Quantitative evaluation of the text branch

While there are datasets that can be used to quantify the semantic properties and/or quality of a LM, there isn’t one that focuses on music. To overcome this lack of text data for the case of instrument recognition, we can utilize instrument ontologies, which encompass semantic similarity of instruments at multiple levels. We propose to leverage them to quantify the semantic similarity between different instruments and instrument families. In this experiment we use the instrument ontology by Henry Doktorski⁶ (HDIO). As every instrument ontology has its limitations [45], repeating the same experiment with other ontologies is left for future work.

We extract the tree based on HDIO and form every possible triplet of TinySOL instrument labels in the tree for a total of $364 = \binom{14}{3}$ combinations of positive word

⁶ <https://free-reed.net/>

Figure 5: Semantic meaningfulness quantification leveraging Henry Doktorski’s instrument ontology. We evaluated the systems over valid triplets obtained through TinySOL labels, as well as every available triplet obtained from the ontology’s labels. Accuracy ranges from 49-59% which stresses that the models do not properly understand musical instruments in depth.

pairs without repetition. The triplets are of the form (*<anchor>*, *<positive>*, *<negative>*) where the *<anchor>* label has to be more semantically similar according to HDIO to the *<positive>* than the *<negative>*, e.g (“violin”, “violoncello”, “trumpet”). Subsequently, every (*<anchor>*, *<positive>*) pair that is linked through the root node of HDIO is excluded. The number of remaining triplets is 273. As a way to quantify semantic meaningfulness with respect to musical instruments, we calculate cosine similarity between the (*<anchor>*, *<positive>*) and (*<anchor>*, *<negative>*) pairs for each system. Triplets for which the similarity is higher for the first pair than the second are considered “correct”, and triplets where this is not the case are considered “incorrect”. We compute the accuracy score as the percentage of correct triples.

We repeat this procedure with every valid triplet from the full ontology, as opposed to just using the instrument labels appearing in TinySOL. This gives us $\approx 443k$ triplets.

The accuracy for triplets from TinySOL and the full HDIO ontology are both presented in Figure 5. We see that half of the triplets are “incorrect” and this means that abstract semantic relations between instruments are not effectively captured in the textual branch, indicating a need for fine-tuning textual encoders on music related data. Note that the accuracy is roughly the same as we would obtain by creating arbitrary triplets, though it is important to highlight that several instruments and instrument categories are words that are not frequently used in English. Closer examination of the validity and usefulness of specific triplet cases (e.g. “stringed”, “plucked”, “violin”) is left for future work.

3.7 Experiment 5: Does joint space mapping introduce noise?

To further examine the origins of the problematic embedding alignment, we repeat zero-shot evaluation with audio-only labels described in Sections 3.4 and semantic mean-

ingfulness evaluation described in 3.6 with the embeddings in the audio space and text space before the joint audio-text space mapping.

A minor performance increment can be seen when using the joint embedding instead of the pre-joint audio embedding, as can be seen in the last two columns of Figure 2, apart from MusCALL where the metrics remain almost the same. We believe that the reduction in dimensionality of the joint space compared to the separate spaces is the underlying cause of these increments.

On the other hand, the accuracy based on HDIO remains the same, except for a decrement observed for Music CLAP and TinySOL subset of HDIO triplets, as can be seen in Figure 5. This could be an indication that the MLP can effectively map knowledge to the joint space. This is a further hint that potentially the problem lies in the LM used and fine-tuning might be needed to enforce musical semantics to be better represented.

4. CONCLUSIONS AND FUTURE WORK

In this paper, we evaluated 3 two-tower multimodal systems for instrument classification. We provided a zero-shot classification analysis and an elaborate evaluation of the audio and text embeddings in the pre-joint and joint audio-text spaces. We also proposed a novel way to quantify the semantic meaningfulness of text embeddings based on triplets derived from an instrument ontology.

Generally, experiments showed that audio encoders are of good quality and hence, the alignment issue might be traced back to the text branch and/or the joint audio-text space mapping. Therefore, a solution could be to freeze the audio encoder and map the text information to audio space. Also, further attention to modality imbalance [46] can be placed with weighing in negative and positive examples [18, 47–50]. Additionally, to avoid sensitivity towards instrument labels and the inability to leverage context, we propose to use text augmentation over captions or masking/removing the words from them. It is important to state that the relation between sentence and word embeddings is not as straightforward as with bag-of-words Language Models [51] and as a result, the way to utilize captions or put additional emphasis on their constituents have to be further tested.

As a result, using two-tower systems might not be very useful for multi-class scenarios, given the large overlap between positive and negative histograms of cosine similarities shown in our experiments. We believe that it is essential for a music terminology similarity corpus to be established. The benefits will be two-fold: (1) it will provide a useful way of quantifying the semantic meaningfulness of the textual branch for two-tower model and (2) it can serve as a baseline to quantify the need for music-informed fine-tuning. Last but not least, genre and emotion ontologies can be used to further evaluate the semantic meaningfulness of language models.

ABSTRACT

This paper describes a streaming audio-to-MIDI transcription method that can sequentially translate a piano recording into a sequence of note-on and note-off events. The sequence-to-sequence learning nature of this task may call for using a Transformer model, which has been used for offline transcription and could be extended for streaming transcription with a causal restriction of the attention mechanism. We assume that the decoder of this model suffers from the performance limitation. Although time-frequency features useful for onset detection are considerably different from those for offset detection, the single decoder is trained to output a mixed sequence of onset and offset events without guarantee of the correspondence between the onset and offset events of the same note. To overcome this limitation, we propose a streaming encoder-decoder model that uses a convolutional encoder aggregating local acoustic features, followed by an autoregressive transformer decoder detecting a variable number of onset events and another decoder detecting the offset events of the active pitches with validation of the sustain pedal at each time frame. Experiments using the MAESTRO dataset showed that the proposed streaming method performed comparably with or even better than the state-of-the-art offline methods while significantly reducing the computational cost.

1. INTRODUCTION

Automatic music transcription (AMT) is a central topic in the field of music information retrieval (MIR), which refers to converting a music recording into a symbolic musical score (MusicXML format) or a piano-roll representation (MIDI format) [1]. It has remarkably been improved with the technical progress of deep learning techniques and the public availability of large-scale music datasets. In this paper, we focus on streaming audio-to-MIDI AMT because it remains relatively unexplored unlike streaming automatic

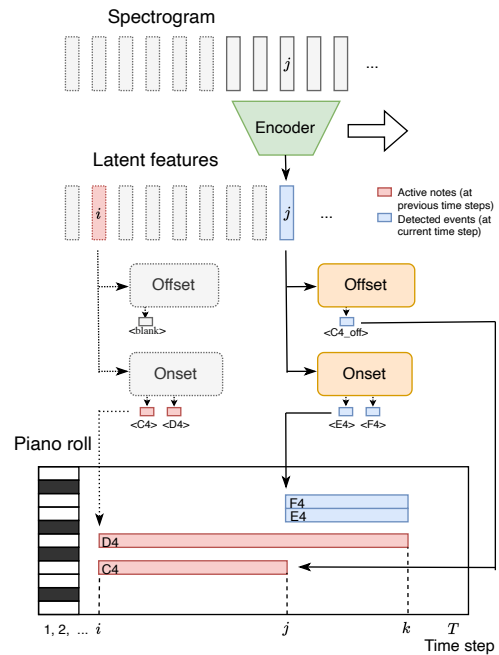

Figure 1. An overview of the proposed streaming audio-to-MIDI piano transcription method aware of onset-offset correspondence.

speech recognition (ASR) [2–4] and forms the basis of real-time music applications such as performance evaluation and interactive jam session. The previous research in [5] applied auto-regressive convolutional recurrent neural network (CRNN) frame-by-frame for piano transcription. The auto-regressive CRNN model can be easily adapted for the online scenario [6]. But the transcription performance for note offsets still has significant room for improvement.

Inspired by the sequence-to-sequence learning for ASR, many studies on AMT have recently attempted to use the Transformer [7] by serializing the polyphonic information of the estimation target [8, 9]. AMT is essentially different with ASR in a sense that the onsets, durations, and pitches of musical notes should be estimated, while the temporal information of output tokens (e.g., words and characters) is not considered in ASR. For audio-to-MIDI piano transcription, one may define the input and output of the Transformer as a sequence of raw audio features (e.g., mel and constant-Q spectrograms) and a sequence of note-on

and note-off events sorted in time and pitch, respectively. The performance of this naive approach, however, is potentially limited. Despite the significant differences in features needed for detecting onsets and offsets, the Transformer decoder estimates these events in a mixed manner. In addition, the correspondence between the onset and offset events of the same note is not guaranteed.

For streaming AMT, one can use the *causal* Transformer that restricts the self-attentive region to a certain number of past frames, which could reduce the computational cost of the basic self-attention mechanism that increases quadratically with the input length. Nonetheless, due to the strong coupling between note events, Transformer-based transcription methods often underperform the state-of-the-art frame-level methods [10, 11], especially in offset detection and velocity estimation.

To overcome these limitations, we propose a streaming audio-to-MIDI piano transcription method based on a novel encoder-decoder architecture (Fig. 1). The encoder is implemented with a convolutional neural network (CNN) that sequentially aggregates latent features from local regions of an input piano recording. The two Transformer decoders that operate framewise are then separately used for detecting a variable number of onset events and offset events for the active pitches with guarantee of onset-offset correspondence. For further improvement, the offset decoder is trained to judge the activation of the sustain pedal in a way of multitask learning.

The main contribution of this study is to develop an efficient streaming encoder-decoder model and pave a way for interactive and responsive applications based on real-time music transcription. We experimentally show that our method performs comparably with a state-of-the-art offline transcription method and outperforms existing sequence-to-sequence transcription methods.

2. RELATED WORK

This section reviews related work on automatic music transcription and sequence-to-sequence transcription.

2.1 Automatic Piano Transcription

Automatic piano transcription (APT) is the most popular form of AMT. Early methods rely on handcrafted features and rule-based algorithms [12–15], while modern methods use deep learning models such as CNNs [16–19], recurrent neural networks (RNNs) [20, 21], and transformers [22, 23]. In APT, the framewise transcription has still been the mainstream approach due to its superior performance and accuracy [10, 24]. In this approach, audio features such as short-time Fourier transform (STFT) spectrograms are mapped to a binary matrix of dimensions $T \times N$ indicating the presence of pitches over time frames, where T represents the number of frames and N the number of pitches. Early transcription methods, mostly based on CNNs, perform comparably at the frame level but underperform in term of note-level.

Onsets and Frames [19] is a major breakthrough in APT

that learns to sequentially predict note onsets and pitches in a multitask framework. To improve the performance, a music language model (MLM) based on a bidirectional long short-term memory (BiLSTM) network is used for modeling the temporal dependency of musical notes. This study has triggered many extensions. Kong et al. [25], for example, proposed a high-resolution piano transcription (HPT) model that simultaneously deals with onset, offset, velocity, and frame prediction tasks. The predicted velocities are used as conditional information to predict onsets, and the predicted onsets and offsets are used to predict frame-wise pitches, forming a hierarchical structure.

Our previous work [24] proposed HPPNet that uses harmonic dilated convolution for constant-Q transform (CQT) spectrograms and an enhanced frequency grouped LSTM (FG-LSTM) as a MLM. This model exhibits improved performance in both frame-level and note-level predictions. To capture long-term temporal and spectral dependencies, Toyama et al. [10] proposed a two-level hierarchical frequency-time transformer (hFT-Transformer) and achieved the state-of-the-art performance on the prediction of note with offset and velocity.

2.2 Sequence-to-Sequence Transcription

Sequence-to-sequence models are able to learn a mapping between input and output sequences of variable lengths and have actively been investigated in many fields such as natural language processing (NLP) and automatic speech recognition (ASR). Such models have recently been implemented with the Transformer or the self-attention mechanism due to its excellent performance. Awiszus et al. [26], for example, proposed a piano transcription model based on an LSTM and a Transformer for frame-level multi-pitch estimation. The performance of this method, however, is limited due to the lack of training data and using improper relative time shifts.

Inspired by this study, Hawthorne et al. [8] proposed a note-level piano transcription model that uses Transformer encoder and decoder in a way similar to the T5 model [27]. The encoder extracts latent features from an input spectrogram and the decoder refers to the input in an autoregressive manner, and the token with the highest probability is selected at each frame. This method achieved promising performance on the MAESTRO dataset and was later extended to multi-track music transcription [9]. However, this sequence-to-sequence transcription method still faces limitations. It encodes all types of note events and absolute time location of each event into a single sequence. This increases the complexity of sequence-to-sequence transformation and also constrains the length of the input sequence.

3. PROPOSED METHOD

This section explains the proposed method of streaming audio-to-MIDI piano transcription based on a single encoder and onset and offset decoders.

3.1 Streaming Transcription

As shown in Algorithm 1, the model takes a spectrogram $\mathbf{X} \in \mathbb{R}^{T \times F_i}$ as input, where T represents the number of frames and F_i represents the number of frequency bins. It outputs an onset sequence list \mathbf{Y} and an offset sequence list $\bar{\mathbf{Y}}$, where each element \mathbf{Y}_t in \mathbf{Y} represents the detected onsets sequence of frame t with sequence length k_t , and each element $\bar{\mathbf{Y}}_t$ in $\bar{\mathbf{Y}}$ represents the detected offsets sequence with sequence length n_t in frame t .

The model consists of one encoder and two decoders (Fig. 2). The encoder is implemented with a CNN that efficiently extracts and aggregates local features from the audio spectrogram \mathbf{X} . The two separate decoders are then used at each frame for detecting a variable number of onset times and judging the offset of the detected notes by focusing on different aspects of the latent features.

More specifically, at each frame t , the encoder takes as input the audio spectrogram around frame t with a receptive field of a fixed size M and outputs a hidden embedding sequence $\mathbf{H}_t \in \mathbb{R}^{F_h \times D}$ in the frequency domain with a sequence length of F_h and the hidden embedding size of D . In addition, positional encodings are incorporated into the encoder hidden states \mathbf{H}_t . Then the decoders receive \mathbf{H}_t with the cross attention (encoder-decoder attention).

For onset detection, the onset sequence \mathbf{Y}_t at frame t is initialized with the beginning-of-sequence token (BOS). The onset events are then detected using the onset decoder Decoder_{on} iteratively until the end-of-sequence token (EOS) is obtained, considering the current encoder hidden state \mathbf{H}_t , the onset sequences $\mathbf{Y}_{1:t-1}$ detected in previous times, the current onset sequence at frame t , and decoder positional encodings. The detected onset events are finally added to the active onsets set \mathbf{A} . The process is repeated throughout the input sequence \mathbf{X} .

The offset events are detected using the offset decoder Decoder_{off} , considering the current encoder hidden state \mathbf{H}_t , the active onsets set \mathbf{A} , and decoder positional encodings. Then active onsets corresponding to the detected offsets are removed from \mathbf{A} indicating the end of notes. It should be emphasized that the offset decoder does not perform sequence prediction. Instead, it predicts the offset for each onset that has been activated in the past time steps all at once.

3.2 Encoder

The encoder is based on the harmonic dilated convolution originally used for HPPNet [24] and uses the same configuration proposed for the acoustic model of HPPNet. It extracts local acoustic features with a fixed receptive field and feeds them to the decoders. There are three sets of convolutional layers with different kernel sizes: three layers with a kernel size of 7×7 , one harmonic dilated convolution layer with a kernel size of 1×3 , and five layers with a kernel size of 5×3 . The resulting receptive field in the time dimension is $M = 39$.

For streaming piano transcription, we use the shifting window approach for sequentially feeding an input spectrogram to the encoder. Instead of feeding the entire spec-

Algorithm 1 Streaming piano transcription. The length of output onset sequence equals to the number of the detected onsets, while the length of offset sequence has an additional output for pedal offset indexed as 0.

rogram at once, we segment it into smaller chunks or windows to simulate real-time processing. These windows are shifted along the time axis, allowing the model to gradually analyze incoming audio data. We define the size of each window based on the desired temporal context for transcription. Typically, smaller window sizes facilitate faster processing but may sacrifice some contextual information, whereas larger window sizes provide more context but may introduce latency. To ensure continuity of transcription and avoid information loss at window boundaries, we apply overlap between consecutive windows.

3.3 Decoder

Both the onset and offset decoders are the same as the decoder of T5 [27] (Fig. 2). In the decoder architecture, the embedding size is set to $D_{dec} = 256$, and decoder layers to $L = 6$, attention head number to $N_{head} = 8$. The multi-layer perceptron (MLP) dimension is set to $D_{mlp} = 1024$. A maximum decoder sequence length $N_{seq} = 64$. The length of the decoder output varies with the number of activated onsets. During the training phase, we use padding and masking to fix the output tokens length of offset decoder to 16.

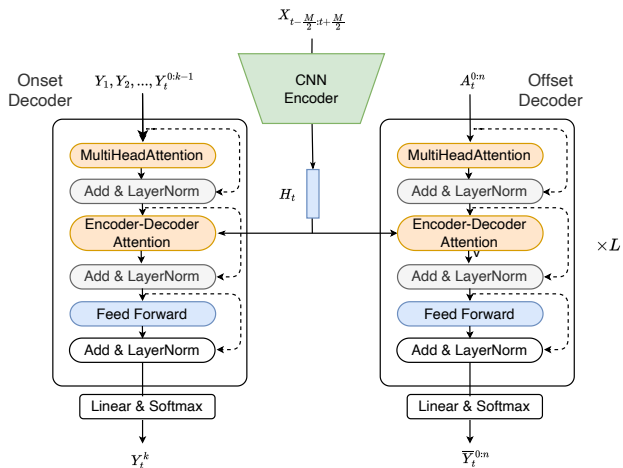

Figure 2. The implementation of the streaming transcription model that uses one encoder for latent feature extraction and two decoders for onset and offset detection.

3.4 Consistent Decoding

Existing piano transcription models that applied onset and offset detection [9, 25] often face issues with mismatched detected onsets and offsets. This is due to the little constraints in the detection processes for onsets and offsets. Although this issue can be addressed with post-processing methods, we prefer to solve it end-to-end within the model. Our proposed architecture makes a constriction to the offset decoder to detect offsets for detected onsets only, and also detects sustain pedal release events to improve performance of note offsets detection.

The onset decoder sequentially outputs onset events in an autoregressive manner while the offset decoder detects all the offset events at once for the active notes detected by the onset decoder with judgement of the sustain pedal. If the offset event for an active note is not detected at the current frame, a special token *BLANK* is obtained as described in Section 4.1.3. The onset decoder considers only notes detected in the past and current frames. The sustain pedal plays a crucial role in expressive piano performance and considerably affects offset detection. The lifting time of the sustain pedal is highly relevant to the absolute offset times and thus determines the duration and decay characteristics of musical notes.

The input of the onset decoder in each step at frame t consists of the onset tokens detected in the previous step and the onset tokens detected at previous frames. This enables to capture long-term dependency between musical notes. By incorporating information from previous frames, the decoder can better understand the context of the current onset detection and facilitate the recognition of typical patterns and structures in the music sequence over time.

4. EVALUATION

This section reports a comparative experiment conducted for evaluating the performance of the proposed and conventional piano transcription methods.

Time	Target Tokens
1	<EOS> <blank>

Table 1. Target tokens for onset decoder(red) and offset decoder(blue).

4.1 Experimental Conditions

We explain the dataset used for evaluation and the input and output data of the proposed method.

4.1.1 Dataset

We used the MAESTRO dataset V3.0.0 [28] composed of about 200 hours of virtuosic piano performances captured with fine alignment between note events and audio recordings. The split of the dataset into training, validation, and test sets was defined officially. The validation set was used for selecting the best-performing trained model based on its performance on unseen data. The dataset also provides information about the states (on or off) of the sustain pedal. The pedal information is crucial for accurately transcribing piano performances as it affects the *actual* durations and offset times of sustained notes.

4.1.2 Input

The original audio recordings were resampled with a sampling rate of 16 kHz. To increase the variation of the training data and reduce the memory footprint, 10-sec segments were randomly clipped from the recordings and the CQT spectrograms were computed on the fly with the nnAudio library [30]. We used the CQT for its capability of capturing both higher and lower-frequency components in the logarithmic frequency domain suitable for analyzing music signals. The lowest frequency was set to 27.5 Hz corresponding to the lowest key of the standard 88-key piano. One octave was divided into 48 frequency bins and the total number of frequency bins was 352. This ensures a fine frequency resolution over the entire audible frequency range. The hop length was set to 320 samples (20 ms), taking the balance between the time resolution and the computational efficiency. After obtaining the CQT spectrogram, the amplitude values were converted to decibels (dB) using transforms available in the torchaudio library.

4.1.3 Output

The vocabulary of output tokens used in our study was the same as that used for the music transformer 3 (MT3) [8, 9] except that time location tokens were not used. This contributes to reducing the length of the output sequence and stabilizing the training. The output vocabulary consists of the following tokens:

Model	Params	Frame-level			Note-level (onset only)			Note-level (onset + duration)		
		P (%)	R (%)	F1(%)	P (%)	R (%)	F1(%)	P (%)	R (%)	F1(%)
Onsets & Frames [28]	26M	92.11	88.41	90.15	98.27	92.61	95.32	82.95	78.24	80.50
Semi-CRFs [29]	9M	93.79	88.36	90.75	98.69	93.96	96.11	90.79	86.46	88.42
HPPNet-sp [24]	1.2M	92.79	93.59	<u>93.15</u>	98.45	95.95	<u>97.18</u>	84.88	82.76	83.80
hFT-Transformer [10]	5.5M	92.82	93.66	93.24	99.64	95.44	97.44	92.52	88.69	90.53
Streaming Seq2Seq (ours)	16M	91.91	91.73	91.75	98.30	94.83	96.52	91.08	87.89	<u>89.44</u>

Table 2. The transcription performances of the existing and proposed methods on MAESTRO V3.0.0 test set.

Model	Segment	Encoder Input Seq-Length	Decoder Output Seq-Length	Latency	Note F1	Note w/ Offset F1
Seq2Seq [8]	4088 ms	511	1024	4088 ms	96.01	83.94
Streaming Seq2Seq (ours)	-	39	64	380 ms	96.52	89.44

Table 3. The transcription performances of sequence-to-sequence transcription models on MAESTRO V3.0.0 test set.

Onsets and offsets (128+128 tokens) Each token represents the presence of an onset or offset of the corresponding pitch given as a MIDI note number.

Pedal states (2 tokens) Two tokens representing the presence and absence of the sustain pedal.

BLANK (1 token) A special token representing silence or absence of any musical event.

BOS and EOS (2 tokens) Special tokens representing the beginning and end of the output sequence.

The onset decoder and offset decoder both need only part of the vocabulary. But we kept the full vocabulary for all decoders to maintain consistency in the model architecture, regardless of whether there is only one decoder or multiple decoders. We set the length of each onset and offset events into 2 frames. During the transcription process, if consecutive onsets or offsets were detected, we only kept the first one and discard the duplicates. To estimate note events from the output of the decoders we used a simple greedy regression algorithm. We then selected the nearest corresponding offsets after the onsets to determine the duration of the notes. If offsets were not detected, we selected the nearest pedal offset as the offsets for the notes or a maximum duration of 4 seconds.

4.1.4 Training

We used the cross entropy loss for training the proposed model. It represents the negative log-posterior probability over output tokens for the ground-truth annotation. For optimization, we utilized the AdamW optimizer [31], which is a variant of the Adam optimizer with weight decay regularization. The mini-batch size was set to 16 and the learning rate was set to 6e-4. A dropout rate of 0.1 was applied to the decoder layers to prevent overfitting. Training was iterated for 200,000 steps with early stopping.

4.1.5 Metrics

The performance of piano transcription was evaluated with the mir_eval library [32] in terms of the precision and re-

call rates and F1 score at the frame and note levels. In the note-level evaluation, an estimated note was judged as correct if its onset time was detected correctly or if both the onset time and duration were estimated correctly. The error tolerance in onset estimation was set to 50 msec as in many studies. The error tolerance in duration estimation was set to the larger of 50 msec or 20% of the ground-truth duration. These metrics were averaged over the test set.

4.2 Experimental Results

We report the experimental results obtained through comparative and ablation studies.

4.2.1 Comparison with Existing Methods

We conducted a comprehensive experiment that compared our method with state-of-the-art methods such as frame-level and event-level transcription methods (Table 2). We found that our method achieved competitive performance and surpassed an event-level transcription method named Semi-CRFs in terms of both the note-level F1-scores with and without duration evaluation. This superiority indicates the robustness of our method in capturing the musical onset events and their corresponding offsets.

4.2.2 Sequence to Sequence Transcription

For comparison, we tested the generic transformer-based sequence-to-sequence transcription model [8] (Table 3). Audio recordings were split into segments of 4088 msec to be fed to the encoder. Since different segments were transcribed independently, the long-term correlation between note events is hard to learn from the data. Moreover, increasing the segment length would exponentially increase the computational complexity of the self-attention layers. It would increase the number of absolute-time-location tokens and further complicates the estimation of time locations for note events.

Thanks to the streaming encoder-decoder architecture, the proposed model kept the actual input length constant

Decoder	Onset	Offset	Pedal	Note-level (onset only)			Note-level (onset+duration)		
				P (%)	R (%)	F1(%)	P (%)	R (%)	F1(%)
1	✓	✓	✓	98.32	93.36	95.73	89.91	85.41	87.56
2	✓	✓		98.23	94.75	96.44	88.11	85.00	86.51
2	✓	✓	✓	98.30	94.83	96.52	91.08	87.89	89.44

Table 4. Ablation study on MAESTRO V3.0.0 test set.

and significantly reduced the computational complexity of the self-attention layers. The length of the encoder input was set to 39 and the maximum length of the decoder output was set to 64. This enables the processing of variable-length audio recordings without the need for segmentation and offers the potential for real-time transcription. Compared with the generic model, our streaming model showed better performance in terms of the note-level F1-scores with and without duration evaluation. This indicates the potential application to streaming and sequence-to-sequence music transcription scenarios.

4.2.3 Latency

The latency of a streaming model refers to the gap between the actual time of an onset or offset event and the time of the event output. Putting the actual computational speed aside, the latency of a non-streaming model is equal to the length of the input sequence because the whole sequence needs to be processed for generating outputs. In contrast, for streaming models, the latency is equal to the length of future frames in the input data stream.

In Table 3, our streaming model had a latency of 380 msec. The CNN-based encoder takes 19 future frames and 19 past frames as input. Even with a short input context, the streaming model still achieved competitive performance on piano transcription. This indicates that onset and offset events could be detected without heavily relying on long-term dependency of acoustic features.

4.2.4 Ablation Study

To verify the effectiveness of sustain pedal detection and that of the separated decoders for onset and offset detection, we conducted an ablation study. Besides the proposed model, we trained a model without pedal detection and another model that uses a single decoder for onset, offset, and pedal detection. The training and evaluation were performed in the same way.

Table 4 shows the performances of the compared methods. We found that removing the pedal detection slightly decreased the note-level F1-score without duration estimation, but significantly degraded the note-level F1-score with duration estimation. This suggests that pedal detection plays a crucial role in estimating note durations. Similarly, using a single decoder for both onset and offset detection degraded both the note-level F1-scores with and without duration estimation, compared with the proposed model. This demonstrated the effectiveness of incorporating pedal detection and a separated decoder for onset and offset prediction for better piano transcription.

5. CONCLUSION

In this paper, we have presented a novel streaming audio-to-MIDI piano transcription method. We tackled an open problem of detecting note onset and offset events from a piano recording in an online manner. Our method is based on a streaming encoder-decoder architecture that combines a convolutional encoder for aggregating local acoustic features with separate transformer decoders for detecting onset and offset events at each time step while validating the use of the sustain pedal.

In extensive experiments with the MAESTRO dataset, our method attained competitive performance, compared with the state-of-the-art offline methods. Our model also outperformed the generic transformer-based sequence-to-sequence model in terms of both accuracy and latency. The ablation study showed the effectiveness of incorporating pedal detection and that of using the separated decoders for onset and offset detection. Our method uses a limited number of incoming frames for detecting the onset and offset events and paved a way for latency-critical practical applications. We achieved a system latency of 380 msec and plan to thoroughly investigate the trade-off between the latency and the transcription performance. Additionally, decoding every frame may not be necessary. Some scenarios might not require such high temporal precision. The setting of the time step also requires further exploration for real-time scenarios.

ABSTRACT

Recent advances in Deep Learning have propelled the development of fields such as Optical Music Recognition (OMR), which is responsible for extracting the content from music score images. Despite progress in the field, existing literature scarcely addresses core issues like performance in real-world scenarios, user experience, maintainability of multiple pipelines, reusability of architectures and data, among others. These factors result in high costs for both users and developers of such systems. Furthermore, research has often been conducted under certain constraints, such as using a single musical texture or type of notation, which may not align with the end-user requirements of OMR systems. For the first time, our study involves a comprehensive and extensive experimental setup to explore new ideas towards the development of a *universal* OMR system—capable of transcribing all textures and notation types. Our investigation provides valuable insights into several aspects, such as the ability of a model to leverage knowledge from different domains despite significant differences in music notation types.

1. INTRODUCTION

Optical Music Recognition (OMR) is a field of research focused on converting written music documents into machine-readable formats, such as Humdrum `**kern`, MEI, or MusicXML [1–3]. This technology holds significant promise for digital musicology, libraries, and academia, facilitating the digitization of scores for further musical analysis, large-scale information retrieval, and making vast musical archives more accessible [4].

Historically, the development of OMR has evolved from relying on basic heuristic methods to a more dynamic application of Deep Learning (DL) techniques [5]. This shift brought new advances to the field, leading to substantial improvements in the accuracy of music score transcrip-

tion [6–9]. However, despite these advances, OMR models still face significant challenges in generalization. The DL methodologies, while robust in specific contexts, often struggle to perform consistently across diverse data distributions [10]. This is particularly evident when dealing with a variety of music notations and textures, from ancient Neumatic chants to modern polyphonic compositions. Most existing OMR works focus on a narrow range of music types (often just one), which limits their usability for more comprehensive archival tasks [11].

In response to these limitations, this paper proposes the conceptualization of a *universal* OMR system capable of processing *all* types of musical notations and textures.¹ The long-term objective is to develop a versatile technology that can adapt to any musical document, regardless of its historical period or stylistic characteristics.

This paper takes the first steps towards such a system by exploring a few alternatives to achieve this goal. In particular, we carry out a specific case study focused on diverse notation types, involving medieval square notation, Mensural notation, and Common Western Modern Notation (CWMN) corpora. We consider whether it is more feasible to develop separate OMR models for each notation or to create a single, all-encompassing model. This dichotomy has not been thoroughly studied before. Separate OMR models for each notation maximize accuracy by addressing specific characteristics, but require extensive resources and individual updates. Conversely, a single, all-encompassing model enhances scalability and maintenance efficiency, benefiting from shared knowledge across notations—a potential advantage in deep learning—although it may struggle with variability. Additionally, we include an intermediate case in which a part of the model is common and only one specialized module is created for each notation, thereby representing a trade-off between the previous pros and cons.

This paper is organized as follows: Section 2 offers background information on OMR. In Section 3, we outline our methodology for analyzing the question at hand and the different training scenarios to leverage the system’s performance. Section 4 details the experimental setup, while

¹ In this work, we will focus on Western notations that share some fundamental characteristics, such as indicating duration with the shape of the music-notation symbols and pitch with their position over a set of staff lines. These also follow a left-to-right reading order.

Section 5 presents the work results and analysis. Finally, we conclude the paper in Section 6, along with potential avenues for future research.

2. RELATED WORK

Modern research in OMR using DL methodologies has led to several successful approaches [4,5,12]. Notably, one approach that stands out is the so-called “end-to-end” formulation. This approach provides a holistic method where images of music notation are directly inputted into the model, which then predicts their content. The end-to-end formulation represents the state of the art in related areas such as text or speech recognition and is now considered by several works in OMR [11, 13–15].

Some works have successfully addressed end-to-end OMR for monophonic staff images, likely because most ancient notations depict monophonic staves. Specific efforts are underway to address other textures such as homophonic scores [6], polyphonic music [7, 16], and vocal pieces [8, 17]. However, despite recent advances in the field, there is still no approach for building a *universal* OMR system capable of handling all this variability of music notation types and textures simultaneously.

The fundamental challenge lies in an unsolved problem in DL models: they perform well when there are regular statistics and abundant data to train on, allowing them to learn the regularities in the distribution properly [10]. This is not the case in the OMR problem, where rich labeled data is scarce and the graphical feature variability is extensive, making it a complex task.

Due to the inherent characteristics of DL methodologies, the existing literature work with analogous or highly similar train-test distributions [11]. Consequently, since there is a lack of research focusing on the development of *universal* OMR systems capable of processing any input score regardless of its content, we propose the first study aimed at developing, understanding, and evaluating a *universal* OMR system for dealing with different notation types simultaneously.

3. METHODOLOGY

Our objective is to explore an initial approach towards developing a *universal* OMR system. Specifically, we consider the case of accounting for different notation types. To achieve this, we consider three different scenarios: (i) a single model per dataset; (ii) a model leveraging all available data; and (iii) a hybrid model, for which some parts are common across all cases, but there are also specific layers tailored to each notation type. We opt for a deep end-to-end model as representative of the state-of-the-art in OMR. Below, we provide a detailed explanation of how this model works and then explain the different approaches selected to address the task.

3.1 Learning framework

The end-to-end OMR model seeks to directly retrieve the music notation from a single staff image. As in recent lit-

erature [11, 13, 14], we assume that a certain preprocessing stage has already separated the staves of the score [18].

Based on other works addressing the OMR challenge [13], a Convolutional Recurrent Neural Network (CRNN) scheme is considered for the end-to-end pipeline. The CRNN architecture incorporates an *encoder*: a block of convolutional layers that learns a set of features from the input image. Then, it includes a *decoder*: group of recurrent stages that model the temporal dependencies of the feature-learning block. Finally, a fully connected network with a softmax activation is used to retrieve a posterio-gram, which is decoded to obtain the predicted *musical symbols*². The Connectionist Temporal Classification (CTC) training procedure [19] is used to achieve an end-to-end scheme, as it allows training the network using unsegmented sequential data.

For training, let $\mathcal{T} \subset \mathcal{X} \times \Sigma^*$ be a set of data where sample $x_i \in \mathcal{X}$ of single staff image is related to symbol sequence $\mathbf{z}_i = (z_{i1}, z_{i2}, \dots, z_{i|\mathbf{z}_i|}) \in \Sigma^*$, where Σ represents the symbol vocabulary used for encoding the music score. Note that the use of CTC to model the transcription task requires the inclusion of an additional “*blank*” symbol in the Σ vocabulary, i.e., $\Sigma' = \Sigma \cup \{\textit{blank}\}$.

At prediction, for a given music staff image input $x_i \in \mathcal{X}$, the model outputs a posterio-gram $p_i \in \mathbb{R}^{|\Sigma'| \times K}$, where K represents the number of frames provided by the recurrent stage. Finally, the predicted sequence $\hat{\mathbf{z}}_i$ is obtained resorting to a *greedy* policy that retrieves the most probable symbol per frame in p_i , later a subsequent mapping function merges consecutive repeated symbols and removes *blank* labels.

3.2 Approaches to OMR for different notation types

In order to explore diverse learning frameworks to assess the transcription performance, we pose three different scenarios that differ in how data is fed to the model and the training strategies for the model layers. An overview of these scenarios is described as follows (illustrated in Figure 1):

Only: In this scenario, one model is trained for each single dataset. This is the baseline of our experiments and it will allow us to compare properly the different approaches selected. It should be emphasized that this training scenario will employ a set of resources and time associated with each corpora. This methodology stands as the current state of the art, as recent research resorted to training individual models as described in Sec.2.

All: For this scenario, all available notation types in this work are merged to train a single model. As commented in the introduction, our long-term objective is to create a *universal* OMR capable of retrieving all types of notation and textures. This option allows us to explore the capabilities and drawbacks of integrating all possibilities in the same model.

² In this work, a *musical symbol* is represented as the conjunction of the glyph or shape and the position within the staff.

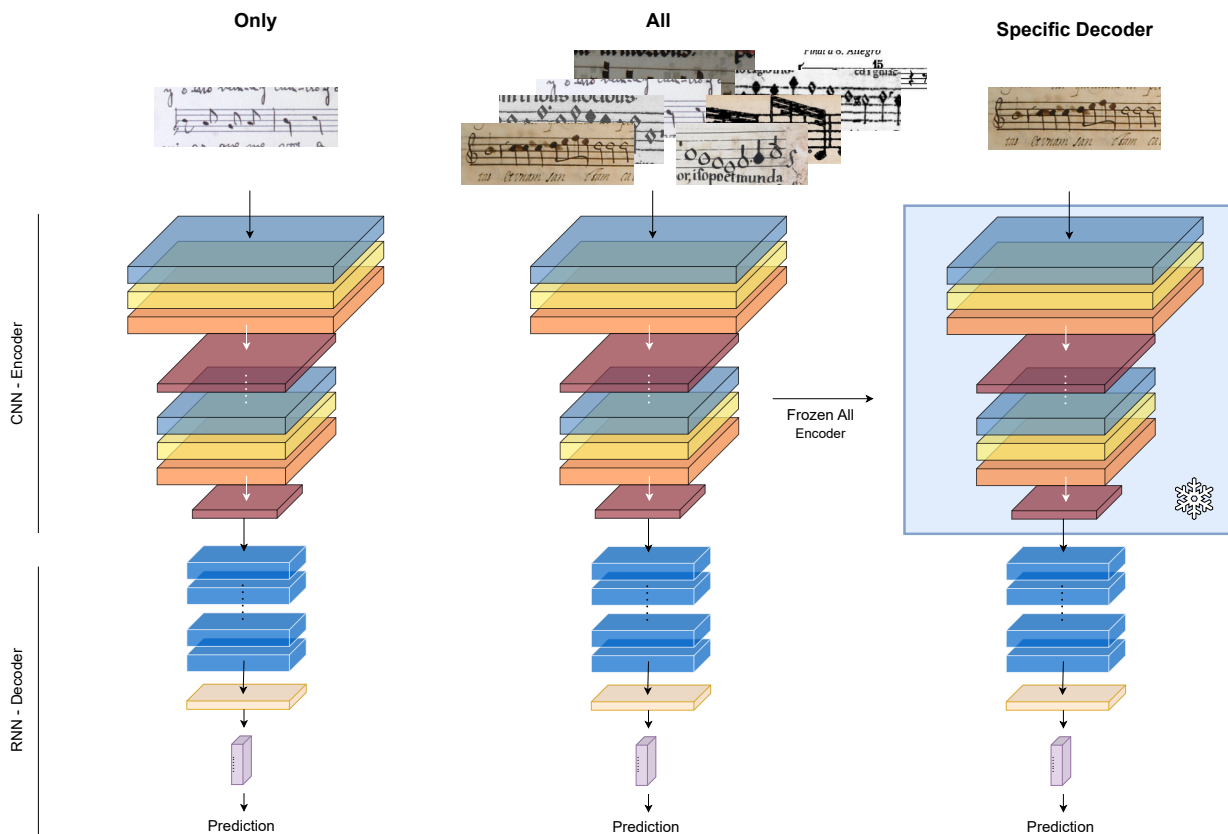

Figure 1: Graphical scheme of the three different approaches considered for this work using the CRNN architecture as the backbone. *Only*: a model trained per notation type individually. *All*: a model trained with all the notation types available for this work. *Specific Decoder*: once the *All* scenario is finished, the encoder (already trained) is frozen to train specific decoders for each notation type.

Specific Decoder: Recent DL approaches pictured the adequacy of learning via a general feature extractor (encoder) [20]. Similarly, we leverage the encoder block of the *All* approach weights as our starting point. By doing so, we establish an already-evaluated feature extractor shared across all corpora. Having the features extracted, we then fine-tune a notation-specific decoder block based on the unique underlying musical context.

The selection of these scenarios helps to study performance but also other important aspects such as maintainability, reusability, or resource leveraging, which are valuable for real-case systems and have been barely analyzed in OMR literature.

4. EXPERIMENTAL SETUP

According to the choices made for the experimental road map, we first introduce the studied evaluation metrics. Later we give further details about the learning model hyperparameters selected and the training techniques used. Eventually, we describe the data collections used for train and evaluation.

4.1 Evaluation

Current OMR systems are designed to serve as a tool. Bearing this in mind, it should be more than interesting

to compute the amount of effort it would take a user to correct the errors made by the system. However, there is not a clear way of properly measuring this case. This is why when evaluating an OMR system we resort to the *Symbol Error Rate* (SER). Given a prediction \hat{z}_i and the ground truth musical symbol sequence z_i , SER is calculated as the average number of elementary editing operations (insertions, deletions, or substitutions) required to convert prediction \hat{z}_i into reference z_i , normalized by the length of the latter. Formally, this is expressed as:

$$SER (\%) = \frac{\sum_{i=1}^{|\mathcal{S}|} ED(\hat{z}_i, z_i)}{\sum_{i=1}^{|\mathcal{S}|} |z_i|} \tag{1}$$

where \mathcal{S} is a set of test data, $ED : \mathcal{Z} \times \mathcal{Z} \rightarrow \mathbb{N}_0$ denotes the string edit distance, and \hat{z}_i and z_i respectively represent the estimated and target sequences.

4.2 Neural model configuration

The CRNN hyperparameters used in this study are based on the ones used in previous works [11, 13]. Authors adopt a 4 Convolutional layer block with batch normalization 2D, Leaky ReLu activation, and max-pooling 2D down-sampling. Feature maps extracted from the encoder, i.e. the Convolutional Neural Network (CNN) block, are introduced into 2 Bidirectional Long Short-Time Memory

(BLSTM) layers with 256 hidden units each and a dropout value of $d = 50\%$ followed by a fully connected network with $|\Sigma|$ units. The architecture described results in a model with 5.3M parameters.

All the models were trained with a batch size of 16 samples—it is important to mention that given the different sizes of the datasets, all the generated batches had the same proportion of samples from each dataset so the network did not adjust to the bigger dataset, i.e., dataset interleaving. The ADAM [21] optimizer was considered, a fixed learning rate of 10^{-3} , and weight decay of 10^{-6} . We iterate over 200 epochs using image augmentation techniques (blur, rotation, contrast, erosion, brightness, etc.), ensuring the robustness of the model, keeping the weights of the model that minimize the SER evaluation metric in the validation partition. The early stopping technique is used with a patience of 20 epochs. Lastly, all experiments were run using the Python language (v3.10.13) with the PyTorch and PyTorch Lightning frameworks on a single NVIDIA GeForce RTX 4090 card with 24GB of GPU memory.

4.3 Datasets

As introduced in Sec.1, music manuscripts depict a great challenge for transcription methods. Their variety in content and appearance poses a still unsolved question. In order to study the adequacy of a *universal* OMR system, we gathered data sources taking into account their variability in terms of notation, graphical appearance, and musical context, aiming to reflect Western musical diversity. A set of 40 different works has been collected that have been grouped to simplify the experimentation and insights reported. Among them, we find square notation, white Mensural notation, and CWMN. A brief description of some dataset features and staves can be found in Table 1 and Fig. 2.

Table 1: Dataset descriptions in terms of notation type, pages, music fragments (staves), and vocabulary sizes.

Notation type	Dataset	Number of pages	Music fragments	Vocabulary size
Square	AUSTRIA	685	4 850	270
	BNE	4 125	27 746	709
	SEILS	151	1 136	206
	GUATEMALA	385	3 263	316
	CAPITAN	97	828	373
Mensural	FMT	348	1 305	425
	CATEDRALES	52	308	245
CWMN	CATEDRALES	52	308	245
	CAMERA-PRIMUS	–	15 000	1 443

Diverse cases have been considered looking for different printers, copyists, authors, and periods considering the more variability the better. The list of datasets used is classified by notation type and ordered temporally below.

4.3.1 Square Notation

Square notation is written on a staff with four lines and three spaces. In this notation, ascending notes are shown as stacked squares, while descending notes are written with

Figure 2: Samples of staves of the different datasets employed in the experimentation.

diamonds. This system of notation appears in liturgical chant books.

AUSTRIA. The Austria dataset contains 685 printed pages of 15th-century manuscripts in German Gothic square notation. Provided by the Austrian Centre for Digital Humanities and Cultural Heritage.³

4.3.2 White Mensural Notation

Notation system used in polyphonic European vocal music. Mensural notation can use different note shapes to denote rhythmic durations. It is written on a staff with five lines and four spaces.

BNE. The “Biblioteca Nacional de España (BNE)” dataset corresponds to the pages from the corpus obtained from the collection of mensural books of the Biblioteca Digital Hispánica.⁴ It comprises multiple authors and printers, e.g., F. Guerrero, H. of G. Scoto or Antonio Gardano, with a size of 4 125 pages. License: public.

SEILS. The “Second Edition of the Il Lauro Secco (SEILS)” dataset consists of 151 printed pages of the “Il

³ <https://www.oeaw.ac.at/> (accessed April 8th, 2024)

⁴ <https://www.bne.es/es/catalogos/biblioteca-digital-hispanica> (accessed April 8th, 2024)

Lauro Secco” collection corresponding to an anthology of 16th-century Italian madrigals in white Mensural notation [22]. License: public.

GUATEMALA. The Guatemala dataset incorporates 383 handwritten pages from a polyphonic choir book, part of a larger collection held at the “Archivo Histórico Arquidiocesano de Guatemala” [23]. License: private.

CAPITAN. The Capitan dataset contains 100 handwritten pages of 17th-century manuscripts in late white Mensural notation extracted from collections found in the “Catedral del Pilar” in Zaragoza [24]. License: private.

4.3.3 Common Western Modern Notation

Current notation system, written in five lines and four spaces. It is capable of indicating to the musician all the parameters to properly interpret the piece, such as dynamics or tempo changes.⁵

FMT. This collection consists of four groups of handwritten score sheets of popular Spanish songs transcribed by musicologists between 1944 and 1960. taken from the “Fondo de Música Tradicional IMF-CSIC”⁶, with a total of 348 images. License: public.

CATEDRALES. The Catedrales dataset contains 52 pages of printed liturgical examples from Málaga, Granada, and Sevilla cathedral archives [25]. License: public.

CAMERA-PRIMUS. The Printed Images of Music Staves (PRIMuS) dataset is a hybrid corpus, i.e., the musical content comprehends the RISM Database⁷ but the images have been obtained using the digital engraver tool Verovio [26]. To the generated images multiple distortions and textures are applied to simulate the look and conditions of the real sources. Although the original dataset consists of almost 100 000 samples, we have randomly selected 15 000 to make it more suitable for our experimentation [27]. License: public.

All the datasets presented use an agnostic output encoding which represents a musical symbol as `glyph:position_in_staff`. This encoding helps transcribe the tokens given their graphical appearance rather than their musical meaning, which can be ambiguous in many situations for the model to learn, making it unsuitable for OMR. Additionally, the agnostic encoding facilitates a straightforward conversion to standard formats such as MusicXML, MEI, or Humdrum `**kern` [28].

5. RESULTS

Table 2 presents the test results obtained with the proposed experimental scheme in terms of the SER (%) metric.

The *Only* scenario acts as our baseline. Here training, validation, and testing splits comprise exclusively samples

⁵ For evaluation, pitch, rhythm and articulation are considered.

⁶ <https://musicatradicional.eu/es/home> (accessed April 8th, 2024)

⁷ <https://rism.info/> (accessed April 8th, 2024).

Table 2: Results in terms of the SER(%) metric for the training scenarios *Only*, *All* and *Specific Decoder*.

Dataset	Only (baseline)	All	Specific Decoder
AUSTRIA	3.77	3.87	3.78
BNE	3.25	3.67	3.31
SEILS	2.71	1.88	1.94
GUATEMALA	2.22	1.87	1.88
CAPITAN	8.60	6.80	7.91
FMT	8.98	5.72	7.11
CATEDRALES	17.34	8.49	17.94
CAMERA-PRIMUS	1.54	3.07	1.60

from each individual dataset. We observe varying performances across different datasets. Notably, the SER metric ranges from 1.54% for the CAMERA-PRIMUS dataset to 17.34% for the CATEDRALES dataset. This indicates significant variability in model performance depending on the dataset size, notation, and graphical features, being the higher values the ones associated with CWMN, where we find more complex musical symbols and context.

When training on the *All* scenario, the model demonstrates performance improvements compared to the *Only* scenario for most datasets. This proves the validity of unifying training pipelines for different notations as the model learns to extract more robust features from the images, which helps in datasets with fewer samples while sacrificing very little accuracy in other datasets, e.g., BNE or CAMERA-PRIMUS. It is worth highlighting the great improvement in the CATEDRALES dataset reducing the SER from 17.34% to 8.49%. On the other hand, we lose accuracy in datasets such as AUSTRIA (from 3.77% to 3.87%), BNE (from 3.25% to 3.67%), and CAMERA-PRIMUS (from 1.54% to 3.07%). This situation reports valuable insights given that on bigger datasets like BNE or CAMERA-PRIMUS with enough data to be trained individually we lose performance, but if we are willing to sacrifice that performance we improve in several datasets. AUSTRIA poses a different situation, due to being the only square notation dataset, the labeling is slightly different to the other corpora increasing the SER metric when merging it with the other datasets.⁸

After training on the *All* scenario, experiment outcomes show the adequacy of merging different datasets to better learn the data features. Thus, in the *Specific Decoder* scenario, the *All* encoder, or CNN, is frozen, and specific decoders were trained for each dataset individually. This approach is aimed at capturing dataset-specific features and learning the underlying musical language of each dataset.

While some datasets exhibited improved performance

⁸ For the *All* scenario we have checked that the tokens predicted are present in the target vocabulary. Without performance variation, such a fact evinces the adequacy of using all data available to train a unique model, to better learn the image features and the inherent difficulty of music when applying OMR without focusing on a specific given dataset.

(e.g., SEILS with a 1.94% SER in the *Specific Decoder* compared to 2.71% SER in the *Only* setup), others experienced only marginal improvements or even a slight degradation in performance (BNE, GUATEMALA, CAPITAN, FMT, CAMERA-PRIMUS). Since this approach could be discarded at first glance for not being the best performing, we make an in-depth explanation of the results obtained in the latter scenario in Sec. 5.1.

5.1 Time-efficient model training

Another important factor to take into account when looking at the experiment results is the time consumption, which is a key factor to better understand the outcomes of this research. Given the datasets presented in this work, we employ a total of 54 436 monophonic staff images with different notation types and graphical features. In Fig. 3, we report the runtime of the experiments presented. When using the training scenario specified as *All* and the configuration explained, the time that took to train the model was 1D 20H 36M 49S. If we evaluate the performance obtained in the *All* scenario we could think that these are the best approaches, as the SER metric poses improvements even in datasets with few samples. However, in real scenarios, this approach would have to be retrained from scratch in case we want to integrate a new dataset⁹. That is why the *Specific Decoder* scenario—where a common CNN is trained and specific decoders, i.e., BLSTMs, are created for each dataset—emerges, given that once the encoder block (CNN) is trained the average time to integrate a new dataset, i.e., train its decoder block, is 1H 6M 11s. This time-efficient model training approach attends more accurately to the end-user requirements in conjunction with better resource management.

This analysis strengthens our proposal of building a *universal* OMR system, that leverages all the existent musical data and is capable of transcribing multiple notation types. In these experiments, we explore the end-to-end architecture for every notation type, which clearly helps as explained in Sec.5. This will allow creating a robust, maintainable, reusable system as a first step never done before towards *universal* OMR.

6. CONCLUSIONS

This work stands out as the first to introduce the *universal* OMR goal, which involves the design, construction, and evaluation of a system capable of retrieving musical content from a document, taking into account different notation types and textures, such as monophonic, homophonic, vocal, polyphonic, etc., and the end-user requirements in real-case scenarios. To achieve this, we studied and compared different settings of real and heterogeneous data corpora to provide invaluable insights into these first steps towards *universal* OMR.

The obtained results validate the capabilities of current OMR state-of-the-art model architectures to transcribe real

⁹ Except if we use Continual Learning techniques [29], yet to be explored in OMR.

Figure 3: Runtime of experiments presented in this work in minutes for the *All*, *Only* (baseline) and *Specific Decoder* scenarios.

documents with different notation types, as the SER(%) rates match those observed in works that exclusively address one notation (either square, Mensural, or CWMN). Moreover, the use of a frozen trained encoder block as a common feature extractor proves to be useful for saving resources, maintaining the system, and reducing training time, since in some cases it considerably improves the overall transcription performance when there are not enough samples.

Future work seeks to expand the presented assortment by considering other textures such as homophony, vocal, or polyphony, to provide further insights and analysis towards *universal* transcription pipelines. Fine-tuning all or certain layers of the encoder would also be relevant, given that differences among datasets manifest in their visual representation rather than in their output. Furthermore, given the results obtained, another promising avenue is to investigate adequate encoding formats to properly represent music from different centuries and textures.

ABSTRACT

In recent years, the quality and public interest in music generation systems have grown, encouraging research into various ways to control these systems. We propose a novel method for controlling surprisal in music generation using sequence models. To achieve this goal, we define a metric called Instantaneous Information Content (IIC). The IIC serves as a proxy function for the perceived musical surprisal (as estimated from a probabilistic model) and can be calculated at any point within a music piece. This enables the comparison of surprisal across different musical content even if the musical events occur in irregular time intervals. We use beam search to generate musical material whose IIC curve closely approximates a given target IIC. We experimentally show that the IIC correlates with harmonic and rhythmic complexity and note density. The correlation decreases with the length of the musical context used for estimating the IIC. Finally, we conduct a qualitative user study to test if human listeners can identify the IIC curves that have been used as targets when generating the respective musical material. We provide code for creating IIC interpolations and IIC visualizations on <https://github.com/muthissar/iic>.

1. INTRODUCTION

In music generation, controlling the generation process with user inputs is essential for creating flexible systems that support a creative human/machine co-creation process [1]. Typically, controls are based on low-level features with a direct musical interpretation, for instance, the pitch of a generative synthesizer [2], or meter, harmony, and instrumentation for symbolic generation [3]. A high-level musical feature that has received little attention in generative composition systems is musical surprisal — how surprising a musical event is to a listener, given the past musical context. The surprisal tends to be high when the

music is complex, when a pitch deviates from the prevailing tonality, or when there is a variation in rhythm [4, 5]. As such, musical surprisal shares similarities with musical complexity, however, it is importantly also affected by *learning*: Repeating complex musical content can lead to decreased surprisal on the repetitions as a result of learning [6]. In contrast, the musical content and the complexity remain unchanged across repetitions.

Studies suggest that the amount of musical surprisal needs to be balanced for music to be deemed preferable [7, 8], which is typically achieved by balancing regularity and novelty [9]. Being able to control surprisal in generated music might help users create compositions that balance regularity and novelty and thus suit listeners' preferences. In addition, if this can be controlled, rather low surprisal could be used indirectly to induce repetitions in machine-generated music and high surprisal to produce novel parts, possibly with high perceived complexity.

In [10], it was proposed to quantify the surprisal of a musical event by its Information Content (IC) conditioned on past musical events. For that, a sequence of musical events is modeled as a stochastic process, where the conditional distribution and, hence, the conditional IC can be estimated. As such, a surprising event is an event that is unlikely to occur under the estimated distribution given the past musical context. In the works of [11], the authors find correlations between the IC of a variable-order Markov model (called IDyOM) [12] and perceived surprise in a controlled pitch anticipation experiment. A correlation between high IC and tonal and rhythmic complexity was shown in [4, 5].

This indicates that the IC of trained sequence models can be used as a proxy for human perception of musical surprisal and that its measurement can identify musical complexity and regularities. This paper proposes a novel framework for generating music with user control over the IC. Specifically, we define an *Instantaneous Information Content* (IIC) measure, which can be calculated at any time point based on the IC of musical events in the recent past and approximates a causal information density. We use the IIC as a fitness score to direct a beam search toward generating samples following a given IIC target curve. Our sampling strategy can be used with any pretrained autoregressive generative music model. We demonstrate our approach in symbolic classical music generation using a

pretrained PIA model [13] and show quantitatively that our approach can generate samples that follow IIC curves extracted from real data. We conducted a qualitative study to test if humans can identify simple IIC curves used for generation. Finally, we analyze relationships between IIC and harmonic, rhythmic, and note density complexity.

2. METHODS

In the following, we describe a method for IC-controlled token sequence generation. Let $\text{IC}^*(t)$ be a target curve with support in the time interval $[0, T]$, representing the desired information content over time of a generated sequence of tokens $\mathbf{x} = x_1, x_2, \dots, x_n \in \mathcal{X}$, with a duration of T seconds. ‘Tokens’ are not necessarily individual notes or note onsets but can be any token type commonly used in Transformer-based music generation systems (e.g., [13–15]). Also, note that we operate on the physical time dimension, not symbolic (score) time measured, e.g., in beats or number of tokens.

Furthermore, let q be a generative sequence model and p an autoregressive *critic model*, used for estimating the the i ’th token’s conditional token information content

$$\text{IC}(x_i|x_{<i}) = -\log p(x_i|x_{<i}), \quad (1)$$

where $x_{<i} = x_1, x_2, \dots, x_{i-1}$. In our context, p will be a Transformer model. The proposed method creates new samples using q with an information content that matches the target curve as measured by p . Our method works as follows: Firstly, we define the *Instantaneous Information Content* (IIC) – a mapping from a (temporally irregular) token sequence and its information content values to a function representing the musical surprisal in the continuous time domain. Secondly, we define an *IC deviation* – a metric for comparing the similarity between a sequence’s IIC curve and the target curve. Finally, we devise a method for generating token sequences with q that minimize the *IC deviation*.

2.1 Instantaneous Information Content

2.1.1 Temporal Localization of IC Estimates

To align the information content of musical events, measured on sequence tokens, with the time-domain target IC (IC^*), we face a challenge: IC is calculated on sequence elements, while IC^* pertains to the time domain. Our solution involves assigning each token a temporal position using a mapping function f , effectively “temporally localizing” or aligning tokens within the musical timeline. Note that f can be constructed by analyzing the specific detokenization method associated with \mathbf{x} ’s tokenization that involves turning a sequence of tokens into a time-based music representation like MIDI¹. In section 3.1, we present an example of such f using the tokenization of [13].

Temporal Localization allows us to map IC tokenizations to their respective time points in the music. This is crucial, especially for analyzing tokenizations of symbolic

music commonly used with Transformers [13–15], where the decoded musical events do not uniformly align in time. Through this approach, IC measured on tokens can be directly compared with the time-domain IC^* , facilitating a coherent analysis across different domains of musical representation.

2.1.2 Interpolation

Let $f : \mathbb{N} \times \mathcal{X} \rightarrow \mathbb{R}$ be a localization function, mapping the i ’th token of sequence $\mathbf{x} \in \mathcal{X}$ to the time domain. The IIC at time t in a piece (represented by token sequence \mathbf{x}), is a real number computed by a time interpolation of \mathbf{x} ’s token ICs:

$$\text{IIC}(t, \mathbf{x}) = \sum_{f(i, \mathbf{x}) < t} \lambda(t - f(i, \mathbf{x}), i) \cdot \text{IC}(x_i|x_{<i}). \quad (2)$$

$\lambda(t, i)$ defines a weighting of the information of the i ’th token and the constraint $f(i, \mathbf{x}) < t$ ensures causality. As a result, the IIC at any time step t is a weighted sum of IC values of past events, using a weighting kernel λ .

The choice of the critic model p in combination with the weight function λ defines different perceptual models of the instantaneous information content. We propose to choose λ so that the recent past is weighted higher than the remote past. More specifically, we define λ as a window function centered around t and equal to zero at time steps greater than t . In this initial work, we chose a Hann window for the following reasons: As it is (half) bell-shaped, it is insensitive to inaccuracies in the temporal localization of recent events. It is smooth at the boundaries, preventing sudden drops as events “leave” the window.

Using the IIC, we quantify the *segment surprisal* of segment $[t_1, t_2]$ by the L^1 norm of the IIC with support restricted to $[t_1, t_2]$ by calculating:

$$\|\text{IIC}|_{t_1}^{t_2}\|_1 = \int_{t_1}^{t_2} |\text{IIC}(t, \mathbf{x})| dt. \quad (3)$$

In section 3.5, we compare segment surprisal with segment-based complexity metrics.

2.2 IC Deviation

Given a sample \mathbf{x} , the *IC deviation* of $\text{IIC}(\cdot, \mathbf{x})$ from the target IC^* is defined as the L^1 norm of their function difference:

$$\|\text{IC}^* - \text{IIC}\|_1 = \int_0^T |\text{IC}^*(t) - \text{IIC}(t, \mathbf{x})| dt. \quad (4)$$

Which is equal to zero if $\text{IC}^* = \text{IIC}(\cdot, \mathbf{x})$ almost everywhere, implying that minimizing eq. (4), aligns the target curve IC^* with the IIC curve. In practice, we compute eq. (4) by the Riemann sum:

$$\|\text{IC}^* - \text{IIC}\|_1 \approx \sum_{i=1}^m |\text{IC}^*(t_i) - \text{IIC}(t_i, \mathbf{x})| \Delta t, \quad (5)$$

¹<https://midi.org/midi-1-0-detailed-specification> where $m\Delta t = T$.

Figure 1. The temporal localization function f and the weight function λ , involved in computing the IIC of x_1, x_2, \dots , a sequence of three notes, at time t_1 .

2.3 Information Content Conditioned Sampling

We can now rank sequences of different lengths according to their proximity to the target IC^* using eq. (5). We use this to guide a beam search to follow the target curve. The beam search is done in iterations. At each iteration, we generate k continuations of the best-performing sample from the last iteration (initially the empty sequence) in parallel. We stop expanding the continuation when the duration of the newly generated content exceeds a predefined step size t' . We then evaluate eq. (5) and keep only the continuation with the lowest IC deviation for the next iteration². We stop when the generation’s duration is T .

3. EXPERIMENTS

3.1 Model and Data

All experiments are performed with a PIA Transformer model [13], a symbolic music generation system pretrained on expressive classical piano performances. The model was trained on data consisting of 1,184 MIDI files of expressive music recorded with high precision on a Yamaha Disklavier [16], as well as a larger dataset of 10,855 MIDI files containing automatically transcribed piano performances [17]. For evaluation, we use the dataset of [18], consisting of performances of 36 Mozart piano sonata movements. The midi files are tokenized using a *structured MIDI encoding* [13], where midi notes, sorted by their onset times, are serialized successively using four tokens *Pitch*, *Velocity*, *Duration*, *Timeshift* in that order. Therefore, every fourth token represents the same token type. *Pitch* is an integer describing the 88-note pitch values on the piano. *Velocity* is an integer describing the 128 possible midi velocity values. *Duration* is an integer representing quantized note duration in seconds:

² Practically, in beam search iteration i , we evaluate the integral of eq. (4) from 0 to it' .

$\{0.02, 0.04, \dots, 1.0, 1.1, \dots, 5.0, 6.0, \dots, 19.0\}$. *Timeshift* is an integer encoding the inter-onset intervals (IOI, i.e., the time durations between subsequent note onsets). *Timeshift* is quantized similarly to the duration token, with the addition of an extra symbol representing a time shift of zero, allowing the model to understand that notes less than 0.02 seconds apart are to be played concurrently. In contrast to the PIA model described in [13], which does non-causal inpainting, we use a causal Transformer based on the Perceiver IO architecture [19] and do continuation generation³. We make these modifications such that the IC calculations ignore future observations. We use the same pretrained model both as the *generator* model q and the *critic* model p and leave the exploration of other critic models for future work.

3.2 IIC

The elements involved in computing the IIC are given in fig. 1. For IIC calculations, we choose to consider only the surprisal of *Pitch* and *Timeshift* tokens, such that the token’s IC represents the surprisal of pitches and IOI. We ignore *Velocity* and *Duration* tokens because they contribute less to the perception of surprise, being mostly related to the performance dimensions dynamics and articulation. This is achieved in the IIC calculation by setting $\lambda(t, i) = 0$ for $i = 2, 6, 10, \dots$ and $i = 3, 7, 11, \dots$ in eq. (2). We choose f such that the pitch token contributes to the surprisal function at its note onset time⁴, and the timeshift token contributes to its surprisal at the onset of the following note (as an IOI is perceived at the onset of the next note). The remaining weights are then defined by the scaled half Hann window

$$\lambda(t, i) = \begin{cases} c_i \frac{1}{L} \cos^2\left(\frac{\pi t}{L}\right) & \text{for } 0 < t < \frac{L}{2}, \\ 0 & \text{otherwise} \end{cases}, \quad (6)$$

where c_i is a weight that takes on two different values for the pitch and timeshift tokens, respectively. c_i is used to weigh the IC of pitches and timeshifts, respectively. For both token types to have equal importance, we estimate a normalization constant empirically by calculating a mean IC over all tokens of the evaluation dataset. The window length is chosen to be $L = 4$ so that the weight is zero after 2 seconds.

3.3 Beam Search Parametrization Study

Using the beam search strategy described in section 2.3, we run initial experiments to determine the effect of parameters associated with the beam search on the similarity between generated samples and target curves IC^* extracted from real music. Specifically, we randomly select 400 snippets of the MIDI files (10 seconds long) and create the IIC curve associated with those snippets. Then, we generate four new samples using our beam search and evaluate the IC deviation between the IIC curve induced by the

³ The model generates sequences using an initial context of real music.

⁴ The note onset times are found by accumulating the time values associated with previous *Timeshift* tokens.

real data and the generated data. We discretize the integral in the IC deviation (see eq. (5)) with $\Delta t = 0.1s$.

To investigate the effect of the step size t' , we fix the number of continuations generated in parallel to $k = 16$ to reduce computation. To investigate the importance of the number of parallel generated samples k , we use a fixed step size of $t' = 0.3s$.

We find that in cases where the generation model q and the critic model p are the same ($p = q$), it is challenging to sample a single continuation $x_i, x_{i+1}, \dots, x_{i+m}$ (using q) that has a high segment surprisal $\|\text{IIC} \left| \frac{f(x_{i+m})}{f(x_i)} \right\|_1$ (measured by p), precisely because the probability of sampling such a continuation is low.

To sample low-probability tokens more efficiently, we propose a heuristic that alters the entropy⁵ of the generating distribution $H(q)$ using a temperature parameter dynamically set using the IIC. Specifically, in iteration $i-1$ of the beam search, we measure $\text{IC}^*(it')$, the target IC at the time where the generation of the continuations halts next time, and calculate a target entropy:

$$H_{target} = \min \left(\frac{\text{IC}^*(it')}{C_H}, H_{max} \right), \quad (7)$$

where C_H is a constant parameter to be estimated and H_{max} is the entropy of the uniform distribution. We then fix q 's entropy to the target entropy H_{target} by searching for a temperature r such that $H_{target} = H(q) = H(\text{softmax}(l/r))$ with binary search, where l are the logits of the neural network. Note that temperature is only used for the generator q and not for the critic model p .

3.4 Qualitative Evaluation

We conducted an online user study to investigate if the IIC curves computed on generated and real music correspond to users' experience of being musically surprised.

Firstly, we present the participant with a musical section generated by our method using one of five target curves. The participant is then tasked to select the IIC curve that best describes their perceived surprise when listening to the section. Secondly, we present the user with a segment of real music and IIC curves extracted from real music, one of which corresponds to the music segment. The user's task is to identify the corresponding curve.

The experiment is conducted on a website that, after an initial experiment description, asks the user for their years of musical training (more or less than five years). Then, it shows an example of a generated piano music section and the surprisal curve used as a target for the generation (together with a textual explanation).

The participant is then presented with five pages, like the one in fig. 2. Each presents a musical section generated using one of five simple target curves. The participant is asked to identify which of the five curves they think has been used to generate the section. The final page contains a 10-second segment of real piano music from the evaluation set and two IIC curves, one corresponding to the piano

music and the other to a randomly selected 10-second segment from the evaluation dataset.

The samples for the first five pages are generated as follows: As contexts for the model, we select the first 13 measures of Mozart K.331, 1st mvt. and the first 16 measures of K.332, 2nd mvt. from the evaluation dataset and generate 200 samples for every combination of the two musical contexts and the five IIC curves shown on the page, with $C_H = 50$, $t' = 0.3s$ and $k = 128$ (i.e., the optimal beam search parameters, as shown in table 1). For each combination, we then select the 25 samples with the lowest IC deviation for the user study. For the final page of the user study related to real performances, we select 300 different 10-second segments from the evaluation dataset and compute the IIC curves. The results of the user study will be presented and discussed in section 4.2

3.5 Analysis of IIC

As discussed in the introduction, IC and surprisal might be related to aspects of musical complexity, but learning effects may lead to a decrease in surprisal in passages with repeated musical content. To investigate these relationships, we designed an experiment to determine if the IIC correlates with harmonic complexity, as quantified by *tonal tension (cloud diameter)* [20], where the IIC is calculated using progressively larger segments of musical context. Tonal tension is calculated for a segment of music by considering its most dissonant pitch class interval, where an interval dissonance is measured as the distance between the interval pitches embedded in a specific Euclidian space where the position is based on the circle of fifths [21].

We extracted one-second segments centered on the onsets of notes in the evaluation dataset. For $i = 1, \dots, 1000$, we then compute the Pearson correlation coefficient between the tonal tension and the segment surprisal (see eq. (3)) of the first i segments within every performance.

In addition, we investigate complexity in terms of note density, i.e., the number of notes per segment. To do so, we use the same setup as for tonal tension but count the number of notes within one-second segments.

Finally, we investigate rhythmical complexity using the *IOI histogram entropy* of measures [22]. We choose this measure over other structural rhythmical complexity measures [23–28] since it does not assume the rhythm to be cyclic. We follow the same procedure as mentioned above, but instead of selecting fixed-sized segments centered around note-onsets, we select segments of one measure based on the measure annotations [18]. More specifically, we match the notes of the performance with its score notes and extract for each measure: 1) the normalized entropy of the score notes IOI histogram and 2) the segment IIC of the measure normalized with the length of the measure. The segment boundaries are estimated by the mean onset time of the first and last note in subsequent measures.

⁵ Entropy is the expectation of IC.

Figure 2. Example page of the user study with a generated musical section and five target curves to choose from.

t'	0.1s	0.2s	0.3s	0.4s	0.5s	0.6s	0.7s	0.8s	1.0s	2.0s
IC dev.	3.63	2.71	2.61	2.72	2.69	2.93	3.03	3.11	3.31	3.90
k	1	2	4	16	32	64	96	128		
IC dev.	8.41	5.90	4.36	2.61	2.14	1.89	1.76	1.69

IC dev.	8.33	4.11	2.67	2.21	2.15	2.15	2.25	2.45	3.12	2.61

Table 1. IC deviation between target curves IC* extracted from real music, and IIC curves from continuations generated with different beam search parameters.

4. RESULTS

4.1 Beam Search Parameter Study

In table 1, we report the mean IC deviation of samples generated with different beam search step sizes t' , numbers of continuations generated in parallel k and C_H , constants used for setting the softmax temperature dynamically. Bigger step sizes create longer continuations with high IC deviation variance, resulting in worse performance. The lowest values ($t' = 0.1s, 0.2s$) also worsen IC deviation, likely because sampled notes exceed the timestep, causing inaccuracies in the next beam search iteration. For the number of continuations generated in parallel k , we find that the IC deviation always decreases with higher k . This is not surprising as the model has more candidate continuations to choose from. The decrease flattens out as seen by the small IC deviation differences when $k \geq 64$. For the dynamic temperature, we find that $C_H = 50, 60$ reduces the IC deviation compared to using no temperature scaling (marked with "No" in table 1).

4.2 Qualitative Results

The user study results reported as a binary classification of finding the correct curve, among the curves described

in section 3.4, are presented in Table 2. 29 users participated, 23 participants had more than 5 years of musical training, and 6 participants had less than 5 years of experience. 152 generated samples and 21 samples of real music were classified in total. Due to the imbalance in the number of untrained and trained participants and since we found little difference in the classification performance between the groups, we combined their results in the table.

The overall F_1 -score was reported as 0.52 for generated data and 0.71 for real data, which is reasonably above the proportions 0.2 and 0.5, being the F_1 scores of random classifiers, with 5 and 2 classes respectively. The results for the individual curves show difficulty differences in classifying the different curve types, with RAMP_DOWN having the lowest F_1 -score of 0.41 and STEP_UP having the highest F_1 -score of 0.71. We therefore investigate the confusion of curves in Figure 3. We find that the confusion of CONSTANT is evenly distributed on all curves, except for STEP_UP, which is reasonable since CONSTANT does not share any characteristics with the other curves. We furthermore find that generations that start with the same IIC value, either high or low, are confused. This is seen by the confusion of RAMP_DOWN with STEP_DOWN and the confusion of STEP_UP and RAMP_UP.

	IIC Curves					Gen. all curves	Real
	CONSTANT	RAMP_DOWN	STEP_UP	RAMP_UP	STEP_DOWN		
F_1	0.53	0.41	0.71	0.48	0.49	0.52	0.71
#True	36	34	29	29	24	152	21
#Pred	36	33	31	30	22	152	21

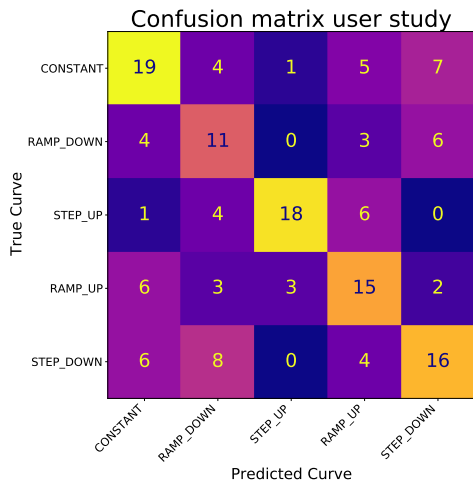

Figure 3. The confusion matrix for users identifying the IIC* curves used to generate the music examples.

4.3 Analysis of IIC

The correlations between IIC and the tonal tension tt , note density d , and the IOI histogram entropy he were calculated on the first n segments of the 36 evaluation data performances as described in section 3.5 and reported in fig. 4. We report the results for IIC calculated using *Pitch* only, *Timeshift* only, or both token types. For tt , d , and $he_{Timeshift}$, the correlations reported were found significant using a significance level of 0.05, whereas for he_{Pitch} and he_{Both} , the correlations are not significant.

The results show a moderate to high correlation of IIC with all metrics at the beginning of the performances (when n is small). However, these correlations decrease in later parts of the performances (when n is high), likely due to “learning” (simulated by longer context) over time.

The highest correlations are found for note density d . This may be explained by the definition of IIC (see eq. (2)) as a weighted sum of token ICs since more tokens per segment simply lead to higher sums.

Considering the different token type combinations, we find that tt is most correlated with IIC calculated using only *Pitch* tokens and he using only *Timeshift* tokens. This is reasonable, considering that very dissonant segments and very complex rhythms tend to be associated with *Pitch* and *Timeshift* tokens, respectively, which are infrequent in the training dataset, resulting in a high token IC. Interestingly, tt is also correlated with IIC calculated using only *Timeshift* tokens (encoding IOIs), which

Figure 4. Correlation between IIC and tonal tension tt , note density d , and IOI histogram entropy (he).

might stem from the critic model facing greater uncertainty in predicting any token type when confronted with a highly harmonic complex context that is infrequent in the dataset.

The curves of *Both* and *Pitch* follow each other closely for total tension and note density, indicating that using both *Timeshift* and *Pitch* tokens does not significantly reduce the complexity correlations. For rhythmical complexity, using *Both* tokens instead of *Timeshift* tokens alone decreases the correlation more.

5. CONCLUSION

In this study, we introduced a novel framework for controlling musical surprisal through Instantaneous Information Content (IIC), which maps token-based surprisal to a continuous time-domain function. Using a beam search algorithm, we demonstrated that our approach can generate music that closely follows predefined IIC curves, effectively aligning generated and target surprisal curves.

Our user study confirmed that participants could reasonably identify target IIC curves from generated music, indicating that our method captures perceptible aspects of musical surprise. Furthermore, our analysis showed that IIC correlates with measures of musical complexity such as tonal tension and note density.

Future work will explore alternative critic models, like personalized models, trained on music that is familiar to the user or models with smaller context windows to more directly control local musical complexity.

ABSTRACT

Optical music recognition (OMR) aims to convert music notation into digital formats. One approach to tackle OMR is through a multi-stage pipeline, where the system first detects visual music notation elements in the image (object detection) and then assembles them into a music notation (notation assembly). Most previous work on notation assembly unrealistically assumes perfect object detection. In this study, we focus on the MUSCIMA++ v2.0 dataset, which represents musical notation as a graph with pairwise relationships among detected music objects, and we consider both stages together. First, we introduce a music object detector based on YOLOv8, which improves detection performance. Second, we introduce a supervised training pipeline that completes the notation assembly stage based on detection output. We find that this model is able to outperform existing models trained on perfect detection output, showing the benefit of considering the detection and assembly stages in a more holistic way. These findings, together with our novel evaluation metric, are important steps toward a more complete OMR solution.

1. INTRODUCTION

Optical music recognition (OMR) focuses on converting music notation into digital formats amenable to playback and editing. OMR systems are generally divided into two categories: end-to-end systems (which directly convert the image into music notation) and multi-stage systems. Proposed and refined by [1–3], a standard multi-stage system consists of four stages: preprocessing, music object detection, notation assembly, and encoding. In this study, we focus on the object detection and notation assembly stages.

MUSCIMA++ [4] suggests representing music notation as a graph where each pair of musical symbols is linked by a binary relationship, allowing for clear notation reconstruction. The authors created a dataset of handwritten scores with a bounding box for each music object and a human-annotated graph of object relationships in each image. Notation assembly on MUSCIMA++ can be framed

as a set of binary classification decisions to predict the pairwise relationships between music symbols. Most prior research has explored notation assembly with the assumption of perfect detection output [5], but such assumptions can introduce unwanted biases that deteriorate the performance of the notation assembly system when applied as part of a pipeline. Pacha et al. [6] evaluate a notation assembler on realistic detector output, finding some degradation relative to gold-standard objects, but they do not seek to mitigate the problem.

To improve notation assembly robustness, we propose a training method to complete notation assembly on top of (imperfect) object detection output directly. To have a strong detector to start with, we train YOLOv8 [7] and perform a set of preprocessing steps to adapt the model to the MUSCIMA++ v2.0 dataset. Our detector outperforms previous detectors on MUSCIMA++ v2.0 [8] by 2.4%, establishing a solid foundation for notation assembly.

Traditional evaluation methods, which perform notation assembly over all pairs of ground-truth objects and report an F1 score or a precision-recall curve, become inadequate when the input objects come from imperfect detection. We propose an end-to-end evaluation metric, called Match+AUC, that accounts for both detection errors and assembly errors by first matching detected objects with their ground-truth counterparts before assessing notation assembly accuracy. It complements metrics that evaluate pipeline components individually.

Our code for reproducing all of the experiments is publicly available at <https://github.com/guang-yng/completeOMR>.

2. MULTI-STAGE OMR

We focus on the MUSCIMA++ v2.0 dataset [4] and follow its multi-stage pipeline for the OMR system. This dataset includes 140 high-resolution annotated images out of 1000 images from the CVC-MUSCIMA dataset [9]. It contains 91,254 symbol-level annotations and 82,247 relationship annotations between symbol pairs by human annotators. These annotations span 163 distinct classes of music symbols. Figure 2 shows an example from this dataset.

As the MUSCIMA++ dataset provides symbol-level pairwise relationships, it allows study of two stages of the pipeline: (i) detection and (ii) assembly. In (i), given an image as input, an object detector is used to extract all music symbols in the image, denoted as the set $V = \{v_i\}_i$,

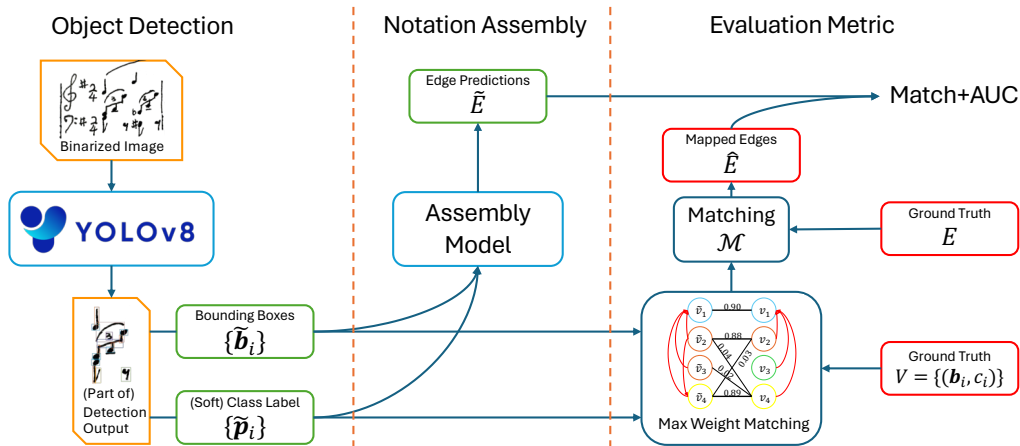

Figure 1. An overview of our OMR pipeline, highlighting key components: object detection, notation assembly, and evaluation metric. Detailed explanations of each component can be found in Subsections 3.1, 3.2, and 3.3 respectively.

Figure 2. Example of a music image (binarized) extracted from the MUSCIMA++ dataset.

where $v_i = (b_i, c_i)$ is a tuple of a bounding box and a class label. Each pair of music symbols (v_i, v_j) is then fed into (ii) the notation assembly model to predict whether or not there exists a relationship between them. The notation assembly stage can be framed as an edge prediction problem where the model needs to output a set of edges E to get a directed graph $G = (V, E)$. MUSCIMA++ defines a grammar over all possible music symbol classes so that the direction of an edge is uniquely determined by the class labels (c_i, c_j) of the vertices (v_i, v_j) . Consequently, the edge prediction problem can be reduced to predicting an undirected graph. The authors of [4] argue that such a graph G enables straightforward reconstruction of the full symbolic music notation, so we do not consider the decoding process after (i) and (ii) in this work.

In previous works, the two stages are considered separately, either focusing on object detection, without fully analyzing its effect on downstream notation assembly [8, 10, 11]; or focusing on notation assembly and assuming perfect detection input during training [5, 6]. This raises the question of whether the best object detector is a good fit for the best notation assembly model. To investigate, we developed an end-to-end metric that evaluates the performance of the entire pipeline, as explained in Section 3.3. We found that, compared with our approach where both stages are considered together—specifically, where the notation assembly model is trained using the output of the object detector—treating the two stages separately leads to poorer results.

3. METHODOLOGY

We describe our method for each stage, and how we connect the two stages together and evaluate the entire pipeline. Figure 1 shows an overview of our methods.

3.1 Music Symbol Detection

A music object detection system analyzes an image to identify each music object it contains, providing both the bounding box and class label for every detected object [10]. Traditionally, this process would begin with an initial stage of image preprocessing, typically aimed at removing staff lines, followed by a second stage focusing on the segmentation and classification of symbols. Thanks to recent advances in computer vision, there are mature solutions for image preprocessing and staff line removal, allowing us to treat it as a largely solved problem [12–14]. In our case, MUSCIMA++ provides us with staff line removed images as input, so we directly build our detectors on top of these images.

Following the work of Zhang et al. [8], we adopted a convolutional neural network-based approach for page-level object detection of handwritten music notes, opting for this approach over segmentation-based methods, because segmentation-based methods often struggle with overlapping symbols. We choose YOLOv8 [7], which is the latest version of YOLO [15], due to its superior performance on traditional computer vision tasks. Compared to YOLOv4 [16], which is used by [8], YOLOv8 has a new loss function and a new anchor-free detection head, achieving higher performance on various detection tasks. YOLOv8 has not yet, to our knowledge, been applied to OMR. Furthermore, since the images of handwritten music notation in MUSCIMA++ have high resolution and music objects are drastically different from the objects considered in computer vision research, directly applying the training strategy of YOLOv8 doesn’t work well. We follow [2, 8, 17] to crop images into small snippets during the training stage to alleviate this issue. Specifically, we randomly crop the images during training and compactly segment the image during inference. More details are pre-

Figure 3. Frequencies of different classes in the dataset, from most- to least-frequent. A long-tailed distribution with 48 classes on the right of the red line that never appear. The y -axis shows the value of $\ln(\text{frequency} + 1)$. The top-5 classes are `stem`, `nodeheadFull`, `ledgerLine`, `beam`, and `staffSpace`.

sented in Section 4.1.2.

The MUSCIMA++ v2.0 dataset includes 163 object classes in total, covering a large variety of notation. However, most of the classes scarcely appear and barely affect the replayability of the OMR output (e.g., the construction of a MIDI file encoding the score). The distribution of classes is shown in Figure 3; 48 classes never appear in the entire dataset. Given this, we manually remove these 48 classes along with some other rare classes, leading to a subset of 73 attested “essential” classes that are observed in the dataset. To get a direct comparison with previous methods, while also keeping a focus on essential classes, we report results using both the full class set and essential classes only. Meanwhile, we also report results on the 20 “primitive” classes selected for evaluation by [8].

3.2 Notation Assembly

The notation assembly model takes a pair of nodes as input, and gives a binary output indicating whether there is a relationship between them. An intuitive method is to first concatenate the features of two nodes, and then pass the pair as a single feature vector through a series of layers of a multi-layer perceptron (MLP). A sigmoid function σ is applied at the end to output the probability that there exists a relationship.

$$\hat{e}_{ij} = \sigma(\phi_{\text{MLP}}([v_i, v_j])) \quad (1)$$

As notation assembly is essentially binary classification, we use binary cross-entropy as our loss function:

$$\mathcal{L}_{\text{BCE}}(\hat{e}_{ij}) = -e_{ij} \log(\hat{e}_{ij}) - (1 - e_{ij}) \log(1 - \hat{e}_{ij}).$$

We adopt the input feature design in [5], where each v_i is represented by its 4-dimensional bounding box and the class label. The class label is passed to an embedding layer with x dimensions. Therefore, the input to MLP will be a $(4 + x) \times 2$ dimensional vector.

Existing work assumes perfect detection output; therefore, the input bounding box and class label are the ground-truth information. While previous work has attempted to manually perturb the bounding box as a test of robustness, such perturbations don’t reflect the kind of errors that might arise in a practical object detector.

To ensure our notation assembly system can adapt to errors introduced in the detection stage, we propose a supervised training pipeline that directly trains the assembly model on detection output \tilde{V} . Since most of the time $\tilde{V} \neq V$, we can’t directly use the ground truth E as the supervision signal.

To deal with this issue, we construct a maximum weight matching M in the bipartite graph $G_M = (\tilde{V}, V)$ and build \hat{E} for supervising our notation assembly model. We describe the detail of our matching procedure in Section 3.3, where it is also employed in evaluation. We adopt the edges from the ground truth according to our matching. Given a pair $(\tilde{v}_i, v_k) \in M$ and an edge $(v_k, v_h) \in E$, we add $(\tilde{v}_i, \tilde{v}_j)$ to \hat{E} if $(\tilde{v}_j, v_h) \in M$. Our method essentially builds a training set for the detection output that is in the same format as the ground-truth, allowing seamless training and evaluation.

3.3 End-to-End Evaluation

The main challenge of OMR evaluation is finding the edit distance between two music scores under some particular representation (e.g., XML format [18]). Hajič [19] argued that intrinsic evaluation is needed to decouple research of OMR methods from individual downstream use-cases, since specific notation formats change much faster than music notation itself. Some works have taken steps to analyze the complexity of standard music notation [20] and propose common music representation formats [21].

As a general system consisting several modules, we seek to also evaluate our OMR pipeline holistically, without a specific focus on what the downstream processing will be. We therefore propose a novel matching-based evaluation metric to assess predictions that include errors from the detection stage. For the same reason we had to adapt ground-truth edges to create training data for the notation assembly model ($\tilde{V} \neq V$), we cannot straightforwardly use the ground-truth graph to evaluate notation assembly. Our metric finds a matching between a test instance’s predicted objects and those in the ground-truth object detection, and then uses this as a bridge to evaluate the edges returned by the notation assembly module.

The results reported by Pacha et al. [6] are the sole benchmark for assessing a notation assembly model using detected symbols. To address the matching issue between \tilde{V} and V , Pacha et al. employ a rule-based method, considering two objects identical if they belong to the same class and their intersection over union is at least 50%. However, this greedy matching approach is inadequate, as inaccuracies in symbol detection cannot be compensated for by the notation assembly model. Furthermore, Pacha et al. use conventional precision/recall metrics with a hard decision boundary, which fails to capture the overall performance

Figure 4. An example of detected objects and predicted graph, alongside ground truth. At the right is the constructed bipartite graph (zero-weight edges not shown). Thick edges represent the matching function \mathcal{M} induced by the matching algorithm. In our notation, $E = \{(v_2, v_1), (v_3, v_1), (v_4, v_1)\}$ and the matching function maps v_1 to \tilde{v}_1 , v_2 to \tilde{v}_2 and v_4 to \tilde{v}_4 . Therefore, $\hat{E} = \{(\tilde{v}_2, \tilde{v}_1), (\tilde{v}_4, \tilde{v}_1)\}$. Because $\tilde{E} = \{(\tilde{v}_2, \tilde{v}_1), (\tilde{v}_2, \tilde{v}_4), (\tilde{v}_3, \tilde{v}_1), (\tilde{v}_4, \tilde{v}_1)\}$, we get a precision of 0.5 and recall of 1.0.

of the model comprehensively. To resolve these issues, we propose a complementary metric based on a global optimal matching and area under the precision-recall curve.

Formally, we denote $\tilde{V} = \{\tilde{v}_1, \tilde{v}_2, \dots, \tilde{v}_n\}$ as the set of symbols obtained from an object detection model, where $\tilde{v}_i = (\tilde{\mathbf{b}}_i, \mathbf{p}_i)$ is a tuple of a bounding box $\tilde{\mathbf{b}}_i \in \mathbb{R}^4$ and a probability distribution vector $\mathbf{p}_i \in \mathbb{R}^C$ over all symbol classes. A notation assembly prediction on \tilde{V} would be an edge set $\tilde{E} = \{\tilde{e}_1, \tilde{e}_2, \dots, \tilde{e}_m\}$ where each edge \tilde{e}_i is a tuple of two vertices. Similarly, we denote the ground truth notation graph as $G = (V, E)$ with $V = \{v_1, v_2, \dots, v_n\}$, $v_i = (\mathbf{b}_i, c_i)$, $E = \{e_1, e_2, \dots, e_m\}$, where $\mathbf{b}_i \in \mathbb{R}^4$ is a bounding box and $c_i \in \{1, 2, \dots, C\}$ is a symbol class label.

We first construct a complete weighted bipartite (\tilde{V}, V) where the weight for edge (\tilde{v}_i, v_j) is $w_{ij} = \text{IoU}(\tilde{\mathbf{b}}_i, \mathbf{b}_j) \cdot \mathbf{p}_{i,c_j}$. Here, IoU is the intersection-over-union between the area occupied by the two boxes, defined as:

$$\text{IoU}(\mathbf{b}_i, \mathbf{b}_j) = \frac{\text{Area}(\mathbf{b}_i \cap \mathbf{b}_j)}{\text{Area}(\mathbf{b}_i \cup \mathbf{b}_j)}.$$

Based on this bipartite graph, we find the maximum weighted matching M using the implementation described in [22] and filter the “weak” matching edges with weight w_{ij} less than a threshold T_{match} to get the matching function $\mathcal{M} : V \rightarrow \tilde{V} \cup \{\emptyset\}$:

$$\mathcal{M}(v_j) = \begin{cases} \tilde{v}_i, & \text{if } (\tilde{v}_i, v_j) \in M \text{ and } w_{ij} > T_{\text{match}}, \\ \emptyset, & \text{otherwise.} \end{cases}$$

Here, T_{match} is a filtering threshold for matching and we set it to 0.05 without tuning.

After getting the matching function, the ground truth assembly edges are naturally mapped back to edges between predicted vertices. The mapped edge set $\hat{E} = \{(\mathcal{M}(v_i), \mathcal{M}(v_j)) \mid (v_i, v_j) \in E, \mathcal{M}(v_i) \neq \emptyset, \mathcal{M}(v_j) \neq \emptyset\}$ represents a ground truth edge set on detected vertices, which can be used to evaluate predictions \tilde{E} to get a precision and recall. An example is shown in Figure 4.

Most notation assembly models predict a probability of the existence of an edge (v_i, v_j) , and the probability is

further compared with a threshold T_{predict} to determine whether (v_i, v_j) belongs to the prediction set \tilde{E} . By adjusting the model prediction threshold T_{predict} , we can get a series of predictions $\{\tilde{E}_1, \tilde{E}_2, \dots\}$ and therefore derive a series of precision-recall pairs, which are used to estimate the area-under-the-curve (AUC) score. We refer to the full evaluation metric as “Match+AUC.”

“Match+AUC” is an end-to-end evaluation metric for the OMR pipeline with following advantages:

- “Match+AUC” accounts for model performance in both the object detection and notation assembly stages. To be specific, given an object detector’s output, a notation assembly model will achieve a higher score if it predicts no edges among redundant objects, since connecting redundant nodes into the assembly graph would greatly affect the final output music score. Also, for the same assembly model, a worse object detector would generate a large amount of redundant and inaccurate objects, making it very hard for the assembly model to distinguish them.
- Instead of a hard rule-based matching used in past methods, “Match+AUC” creates a comprehensive matching among detected symbols and ground truth symbols, making the final score more accurate and sensitive.
- “Match+AUC” evaluates the model using the area under the precision-recall curve, which summarizes performance across a range of threshold choices that could be made by a downstream module or a system user.

We believe that our novel “Match+AUC” is a compelling tool for analyzing OMR pipelines that is complementary to existing approaches.

4. IMPLEMENTATION DETAILS

4.1 Music Symbol Detection

4.1.1 Model Details

We finetune the “large” version of YOLOv8 (YOLOv8l), an object detection model pre-trained on the COCO dataset [23], on MUSCIMA++ v2.0 for music object detection. The model consists of 43.7M parameters and is capable of detecting object bounding boxes and generating corresponding class distributions. The input image size of our model is set to 640.

4.1.2 Training

We used the MUSCIMA++ v2.0 dataset to train and evaluate the music symbol detection model [4]. The images are binarized (pixels are 0/1-valued) and in a size of approximately 3500×2000 pixels. For simplicity, we use images with staff lines removed. Additionally, following the exact method described in [6], we split the dataset into 60% training data, 20% validation data, and 20% test data. To effectively train YOLOv8 on these dense images involving many small annotations, which include augmentation dots and piano pedal markings, we have to reduce the image size. Therefore, following the methods used by [8],

Figure 5. Example of music symbol detection segments for inference. The thick red line indicates the primary cropped area, while the thick blue line represents an extended cropped section designed to include partial symbols that may extend beyond the main cropped area. For better visualization, we only show the extended area of one image crop. Image crops on the right and bottom border of the page are padded to fit into YOLOv8.

given a large music score image, we randomly sample $14\ 1216 \times 1216$ crops and further resize them in to 640×640 to fit the YOLOv8 input requirement.

We fine-tune the YOLOv8 model for 500 epochs with a batch size of 8. We use the AdamW optimizer with a learning rate of 5.5×10^{-5} and a momentum of 0.9, which are automatically set by the YOLOv8 codebase [7]. During training, we use the early stopping strategy with a patience of 100 epochs. We keep the checkpoint with the highest validation performance as our final model.

4.1.3 Inference

Since our detector is trained on cropped data, during the inference stage, we also need to segment the large images into smaller segments. However, partial objects at the edges of these crops would be hard to detect since the model can't see the full object. To resolve this issue, we extend every crop with a margin, which serves as a context for each image. The cropping is visualized in an example in Figure 5. We then perform symbol detection on each extended crop and consolidate the detection results. To make sure the objects on the edges are only detected once, overlapping bounding boxes are filtered based on their Intersection over Union (IoU) overlap rate.

4.2 Notation Assembly

4.2.1 Model Details

We use a 4-layer MLP for ϕ_{MLP} , where the two hidden layers both have hidden dimension 32. The embedding dimension for the symbol class is also set to be 32. We use ReLU [24] as the activation function.

4.2.2 Training

Again we used the MUSCIMA++ v2.0 dataset to train and evaluate the notation assembly model [4]. Following previous work [5, 6], we balance the positive and negative pairs in the training set by filtering out the pairs of nodes that are too distant from each other since they are unlikely to

be connected. Before feeding the bounding box coordinates to the model, we normalize them by the image width while keeping the aspect ratio fixed, so that all of the x -coordinate values fit in the range of $[-1, 1]$.

We train our models for 200 epochs with batch size 256, and use Adam optimizer with a learning rate of 0.0001. We evaluate our model every 20 epochs and pick the checkpoint with highest validation Match+AUC as our final model. All of the experiments are conducted with three different random seeds.

In our experiments, we consider three methods for training the notation assembly model:

- A **baseline**, which uses the ground-truth object lists provided in the MUSCIMA++ dataset to train the notation assembly model. This is the setup used in [5].
- A **pipeline**, which runs the music object detection model on the images to construct the training set for the notation assembly model, as discussed in Section 3.2.
- A “soft” variant of the pipeline, where we replace the embedding layer for the symbol class with a linear layer that maps the symbol class probabilities outputted from the music object detection model to a 32-dimensional vector. Note that this linear layer will have the same parameter count (number of classes multiplied by the hidden dimension) as the replaced embedding layer.

4.2.3 Inference

Since we consider both stages together, the input to the notation assembly stage should correspond to the output of the object detection stage. As described in Section 3.2, the detection output is converted into (V', E') . We then pass each pair of nodes to the notation assembly model, and feed the result into our evaluation function. We hypothesize that this realistic setup introduces a distribution shift to the model that was trained on the ground-truth objects and we will make the comparison in Section 5.

5. EXPERIMENTS

In this section, we first report the performance of our music symbol detection model. Then, we compare the performance of different notation assembly training pipelines using the evaluation metric described in Section 3.3.

5.1 Music Symbol Detection

Following the evaluation protocols of the Pascal VOC challenge [25], which is used by previous methods [8, 10, 11], we present both the mean average precision (mAP) and the weighted mean average precision, as detailed in Table 1. To elaborate, a predicted bounding box $\tilde{\mathbf{b}}_i$ is thought to be a true positive only if $\text{IoU}(\tilde{\mathbf{b}}_i, \mathbf{b}_j) > 0.5$ for some ground truth box \mathbf{b}_j . Then, average precision (AP) computes the area under the precision-recall curve, providing a single value that encapsulates the model's precision and recall performance. The weighted/unweighted mean Average Precision (mAP) extends the concept of AP by calculating the average AP values across multiple object classes,

Models	# Classes		mAP (%)	Weighted mAP (%)
YOLOv8 + cropping (ours)	163	(all)	84.79	92.67
YOLOv8 + cropping (ours)	73	(essential)	85.67	89.96
YOLOv8 + cropping (ours)	20		94.22	95.72
YOLOv4 + CBAM [8]	20		91.8	94.56 [†]
PP-YOLO-V2 [8]	20		91.1	–
YOLO-X [8]	20		90.4	–
YOLOv4 [8]	20		89.1	–
Faster R-CNN [8]	20		86.2	–

Table 1. Object detection results on test set. “mAP” is mean average precision. We compared it with results reported by [8]. The lower block is included for comparability with the 20-class setting from past work. †: Value computed from average precision per class reported in [8].

Models	# Classes	Match+AUC	
		Average	S.D.
MLP baseline (train on ground truth objects)	73	92.44 ± 0.24	
+ pipelined training (ours)	73	93.09 ± 0.16	
+ pipelined training + soft label (ours)	73	95.00 ± 0.18	
MLP baseline (train on ground truth objects)	163	83.97 ± 3.04	
+ pipelined training (ours)	163	85.76 ± 0.42	
+ pipelined training + soft label (ours)	163	87.10 ± 1.19	

Table 2. Multi-stage system results (test set) using our Match+AUC metric.

taking into account the number of occurrences of each class in a weighted or unweighted manner. Our experiments are conducted with the MUSCIMA++ v2.0 dataset, while the authors of most previous methods [10, 11] have only tested their models on MUSCIMA++ v1.0. This introduces a misalignment between our results. Thanks to Zhang et al. [8], who provided reproduced results of most previous methods on MUSCIMA++ v2.0, we directly report their reproduced results in the table.

Our model outperforms Zhang et al.’s method on their selected 20 classes by 2.4% (mAP, absolute), likely due to the improvements in YOLOv8 compared to v4.

5.2 Notation Assembly

In this section, we complete the multi-stage OMR system by chaining different notation assembly models to the best music object detection model we trained in Section 5.1. We use the metric we designed in Section 3.3 to report the end-to-end performance of the OMR system.

In Table 2, we compare the notation assembly systems trained with baseline training, pipelined training, and soft pipelined training as described in Section 4.2. We found that pipelined training improves the Match+AUC score by 0.65% (essential) and 1.79% (all), absolute, and incorporating the soft class label further increases the performance by 1.91% (essential) and 1.34% (all), absolute. Training the notation assembly model on the detection model output and using the soft label probability to represent the class information, we are able to improve the Match+AUC of the OMR system by 3.13%. We hypothesize that pipelined training helps the assembly model adapt to any inaccuracies our object detector has, and incorporating the soft class labels enables the assembly model to consider alternative class labels, not just those chosen by the object de-

tector.

6. CONCLUSION AND FUTURE WORK

In our study, we reconsider a multi-stage OMR pipeline built and evaluated using the MUSCIMA++ dataset. We first propose a state-of-the-art music symbol detector, serving as a strong preprocessor for the notation assembly stage. We then propose a training pipeline in which notation assembly is learned from imperfect object detection outputs (rather than ground-truth objects), which leads to higher performance. Finally, we introduce an evaluation score, Match+AUC, which can jointly consider the error in both detection and assembly stages, allowing evaluation of the two stages together.

Match+AUC is not restricted to being an evaluation metric. Future research could explore the application of Match+AUC within a joint training objective function for both the object detection and notation assembly stages. This approach would enable the entire model to be optimized for retrieving a globally optimal music notation graph.

In this study, we focused on the object detection and notation assembly stages in the OMR pipeline. Progress on the encoding stage is also required for a complete OMR solution; while the music notation graph arguably contains the essential information for recovering a score [4], conversion of such graphs into standard formats remains unsolved.

7. ACKNOWLEDGMENTS

The authors wish to express our deepest gratitude to all creators of the public OMR datasets for their dedication

and generosity in collecting and sharing these invaluable resources. We extend our sincere thanks to Carlos Peñarubia for his assistance in clarifying questions regarding the reproduction of their method. We are also grateful to Tim Althoff for his insightful comments on our evaluation metric. Special thanks go to Victoria Ebert and Teerapat Jenrungrot for providing us with essential materials in the OMR field. Finally, we sincerely appreciate the constructive reviews, which have significantly enhanced the rigor and completeness of this paper.

ABSTRACT

Audio-text contrastive models have become a powerful approach in music representation learning. Despite their empirical success, however, little is known about the influence of key design choices on the quality of music-text representations learnt through this framework. In this work, we expose these design choices within the constraints of limited data and computation budgets, and establish a more solid understanding of their impact grounded in empirical observations along three axes: the choice of base encoders, the level of curation in training data, and the use of text augmentation. We find that data curation is the single most important factor for music-text contrastive training in resource-constrained scenarios. Motivated by this insight, we introduce two novel techniques, Augmented View Dropout and TextSwap, which increase the diversity and descriptiveness of text inputs seen in training. Through our experiments we demonstrate that these are effective at boosting performance across different pre-training regimes, model architectures, and downstream data distributions, without incurring higher computational costs or requiring additional training data.

1. INTRODUCTION

Music-text embedding models have become a cornerstone of music information retrieval (MIR), facilitating core tasks that underpin music organisation and search, such as music tagging and cross-modal retrieval [8, 11, 14, 26, 27]. At a high level, these are multimodal models that produce aligned audio-text representations by learning to project high-dimensional data from the audio and text modalities onto a lower-dimensional joint representation space whose structure encodes semantic similarity. The canonical learning framework to obtain such embeddings is dual-encoder multimodal contrastive learning, first popularised by CLIP [20] in the image domain, and soon after adopted in most areas of machine perception, including audio [9, 29] and music processing [8, 11, 14].

Driven by the empirical success of this framework, a recent line of research has attempted to analyse its inner workings from a theoretical perspective [18, 36] or elucidate which aspects are most responsible for its effectiveness in visual models [34, 35]. However, within the audio domain, our understanding of multimodal contrastive learning remains limited [8], with sparse effort into ablating design choices, or training data- and compute-efficient models. Among prior work that takes a step in this direction, the focus is mostly on comparing backbone models [8, 11, 29], but without considering other important factors such as model initialisation or training data. Additionally, audio-text learning poses specific challenges in the context of music, as the amount of data with aligned audio and text is typically orders of magnitude smaller than in other domains, where large-scale web-crawled data is commonplace. This makes transferring insights from other areas of representation learning particularly challenging.

In this paper we present a deep dive into music-text contrastive learning and its use in text-based music retrieval, adopting a practical perspective and thoroughly investigating the impact of major design choices. In particular, we study the problem of how to train this family of models under different resource-constrained scenarios (with respect to data and compute), and how to meaningfully evaluate them for real-world use. In brief, our contributions are as follows: (i) we systematically compare backbone encoders in parameter-efficient settings, and demonstrate that we can leverage this to enable multilingual support for the first time and without additional training data (Section 3); (ii) we study the trade-off between training dataset size and quality, showing that the impact of data curation outweighs that of scale (Section 4); (iii) building upon these findings, we propose a training recipe, *Augment, Drop & Swap* to construct more effective contrastive views (via *Augmented View Dropout*) and improve model robustness (via *TextSwap*) with no extra computational overhead (Section 5). Incorporating the proposed pipeline within variants of the music-text contrastive framework under different computational constraints, we show that this consistently improves over prior work, establishing a new state-of-the-art on three benchmark datasets. Finally, we conduct the first listening study to evaluate text-based music retrieval, further corroborating our automatic evaluations and underscoring the importance of accounting for distribution gaps when measuring performance.

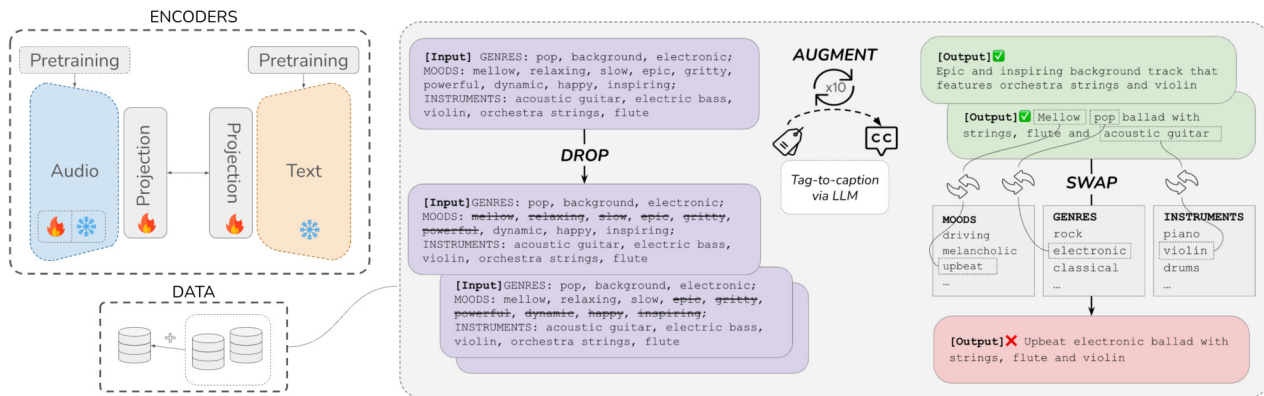

Figure 1: Overview of our approach. We study the role of encoders and data in music-text learning and propose a text augmentation pipeline, *Augment, Drop & Swap*, to increase data diversity and introduce hard negatives during training.

2. STUDYING THE DESIGN SPACE OF MUSIC-TEXT EMBEDDING MODELS

We explore two major factors in the design of music-text embedding models: architecture and data. While we acknowledge that there are others, such as training procedure, and alternative designs, we choose to restrict our focus exclusively to these two axes and to dual-encoder models, due to their predominance in the field. In the rest of the paper, we always refer to this family of models when discussing *music-text embeddings* or *music-text models*, and interchangeably use the terms *text* and *language*.

The typical design of a music-text embedding model consists of the following components: two modality-specific base encoders which separately process inputs of the text and audio modality to an intermediate representation space; a fusion or projection module responsible for mapping the intermediate representations to the shared embedding space; and a contrastive loss, through which the model parameters are optimised to encode semantically related audio and text inputs within the same neighbourhood of the embedding space, while pushing apart unrelated items. We provide an overview of this design in Figure 1. While prior works have converged towards standard choices for the last two components, it remains unclear how to reliably choose unimodal encoders among several existing options. We look at this in Section 3, before discussing the role of training data in Section 4.

2.1 Our experimental approach

Before delineating our areas of focus, we outline here the standard experimental setup used in our experiments.

Projection module We design our experiments to compare variations of the dual-encoder contrastive architecture described above, varying several components, but keeping two fixed throughout: the projection module and the loss. Similarly to [16, 24], we adopt a two-head, two-layer Transformer as our projection module. From a sequence of 256-dimensional embeddings produced by each projection head, we employ the [CLS] token embedding as the global representation for each branch. For ease of

reference, we denote this model architecture by DuET-MC (**D**ual-**E**ncoder **T**ext-**M**usic **C**ontrastive).

Training We optimise our network via the multimodal formulation of the InfoNCE loss [19], using cosine similarity between the l_2 -normalised projection embeddings from the audio and text branch as our scoring function, and a temperature parameter of 0.03. As part of our training procedure, we use the Adam optimizer with decoupled weight decay of 0.05, varying our learning rate through a cosine decay schedule from its peak value of $1e-3$, after a linear warm-up of 5 epochs. We train on 8 A100 NVIDIA GPUs, with an effective batch size of 1024 or 2048 based on memory requirements, for a maximum of 100 epochs, with early stopping based on the validation loss. Unless otherwise specified, our default training data is a corpus of licensed instrumental music with high-quality, manually curated genre, mood, and instrument tags, which we refer to as MusicTextHQ. For training, we select a subset totalling a duration of 100 hours, and augment tags into captions following our data augmentation strategy described in Section 4.

2.2 Evaluation

We evaluate all our models on text-based music retrieval, as this represents the most prominent task for music-text embedding models and has been shown to correlate to performance on other tasks [11, 14]. Retrieval is performed by ranking all audio clips in the dataset by decreasing cosine similarity of their embedding with the embedding of a text query. From this, we compute $\text{Recall}@k$ ($R@k$), the average number of times the target appears within the top- k retrieved items, and Median Rank (MR). To normalise performance scores by the different dataset sizes, we repeat this procedure on random subsets of 500 items, and report the average value for each metric. When reporting a single metric, we always refer to $R@10$.

Datasets In order to robustly measure performance across our experiments, we adopt a multi-dataset evaluation suite comprising three public datasets containing audio tracks paired with human-written captions: YT8M-MusicTextClips (MTC) [16], MusicCaps [2] and Song De-

Dataset	Hours*	Tags	Captions
<i>Training</i>

CLIP-T [20]	151M	clip-vit-base-patch32
T5 [21]	11.3B	flan-t5-xx
mT5 [30]	13B	mt5-xx

Table 2: Audio and text encoders we compare in our experiments on the impact of encoder backbones (Section 3).

scriber (SDD) [15]. These all represent out-of-distribution data (see Table 1), with different degrees and types of distribution shifts in both the audio and text modality. For example, MTC and MC both contain 10-second audio clips from YouTube videos, but they differ significantly in their captions, with respect to content, descriptiveness and even text length [15]. Audio in the SDD consists instead of music recordings from the music platform Jamendo [3], while captions describe much longer audio segments.

3. THE ROLE OF ENCODER BACKBONES

We experiment with two audio encoders, HTS-AT [5] and MERT [33], and three text encoders, RoBERTa [13], the text encoder from CLIP [20] (CLIP-T), T5 [21] and mT5 [30]. We choose these either because they represent the state of the art in their respective tasks, or because they have been previously used in contrastive audio-text learning, thus allowing for direct comparison with prior work.

3.1 Encoders: initialization and freezing

In this set of experiments, our goal is to study parameter-efficient configurations of existing audio and text encoders, training only a subset of the model weights. The motivation for exploring this setting is threefold: freezing part of the model lowers the memory budget and training time, it avoids catastrophic forgetting [17], and it reduces the risk of overfitting in data-constrained scenarios. To fulfil these requirements, we do not consider end-to-end finetuning, and instead focus on leveraging pre-training, locking the audio and text encoders based on their parameter size.

¹ We use the HTSAT_AudioSet_Saved_6 checkpoint of HTS-AT trained on AudioSet from the official repository.

Figure 2: Retrieval performance (R@10) of different combinations of audio and text encoders compared through the lens of our DuET-MC framework.

Specifically, we keep all text encoders frozen, as these all count over 100M parameters, as shown in Table 2, and only train the full audio encoder, both with and without general-audio pre-training when using HTS-AS, due to its smaller size. When using MERT, we keep the encoder frozen but train a learnable aggregator over the hidden states of each layer, implemented as a 1D convolutional layer, to obtain audio representations that capture the different levels of abstraction encoded at different depths of the network [33].

Results From Figure 2 we first observe that, under the constraints described above, the overall best configuration is given by MERT and CLIP-T. We attribute this to two main reasons: with regards to the audio branch, the superior performance exhibited by MERT suggests that a larger model capacity and stronger music prior may be beneficial to music-text alignment; with regards to the text branch, while all encoders are characterised by large-scale pre-training, CLIP-T stands out as the only model with multimodal capabilities. Although this is somewhat surprising, as CLIP is pre-trained on image-text pairs, we note that prior work has also shown that it can be successfully transferred to the audio and music domains [6, 16, 28, 32]. Secondly, when using MERT with any of the text encoders considered, we find that we can train less than 1% of the total amount of weights (~ 3M making up the projection and aggregation layers) without loss of performance compared to current state-of-the-art models (shown later in Table 4). This demonstrates that we can successfully align locked text representations to the audio modality through lightweight music-text contrastive learning, confirming that our encoder locking strategy is effective when leveraging powerful music-specific pre-training, in line with similar findings in the visual domain [35]. With regards to the audio branch initialization, comparing the two variants of HTS-AT, we find that general-purpose audio pre-training can give a slight advantage over training from scratch, but this benefit is not consistent across the different text encoders HTS-AT is paired with. In the rest of the paper we fix the encoder configuration to locked MERT + locked CLIP-T in all experiments, unless otherwise specified.

Language	R@10		
	YT8M-MTC	MusicCaps	Song Describer
English	10.43	16.00	19.00
German	9.90	13.28	18.00
French	11.71	12.32	15.40
Italian	10.43	13.68	15.80
Spanish	11.60	13.48	18.40

Table 3: Multilingual retrieval performance.

3.2 Supporting retrieval in multiple languages

Due to a lack of data in different languages, music-text modelling has so far exclusively focussed on English. Real-world applications for music-text embeddings, however, can greatly benefit from the support of multiple languages. To address this limitation, we explore the use of pre-trained locked encoders, similarly to Section 3.1, this time adopting mT5 [30], a multilingual text-to-text Transformer model, as our text encoder. To evaluate multilingual performance, we choose a subset of four languages, German, French, Italian and English, and translate our evaluation datasets via GPT3.5-turbo [4]. In Table 3, we show that this approach provides a viable solution to text-based retrieval in multiple languages while using only English text paired with music in training and with only a minor drop in performance compared to English.

4. THE ROLE OF TRAINING DATA

Having established best practices with respect to choosing audio and text backbones, we now shift our attention to the training data. As widely acknowledged in the literature [7, 8, 14], a major limitation in training music-language models is the lack of large public datasets with paired audio-text data. To circumvent this issue, a number of works have proposed to employ large language models to augment text data more commonly found in music datasets, such as categorical labels, metadata and tags, into full natural language sentences, corresponding to *pseudo-captions* [7, 10, 16]. In the next section we present our investigation of the impact of tag-to-caption augmentation.

4.1 Tag-to-caption augmentation via LLMs

Following [16], we leverage the in-context learning ability of LLMs via few-shot prompting, and adopt a similar approach to augment tags into captions for our training dataset MusicTextHQ. For this, we use BLOOM-176B [23], a competitive open-access LLM trained on responsibly sourced data. Differently from [16], we do not employ synthetic tags, but use tags provided by expert annotators. We compare this to training on LP-MusicCaps-MTT [7] (LP-MusicCaps for short), a dataset obtained via a similar approach, where tags from the MagnaTagATune [12] dataset are augmented into captions via GPT3.5-turbo. To measure the impact of tag-to-caption augmentation, we train three variants of our model on each dataset, varying p_{cap} , the probability of selecting captions over tags as the text input for each training pair.

Figure 3: The effect of varying p_{cap} , the probability of swapping tags with captions. On the y-axis, we show the relative change in performance compared to $p_{cap} = 0$.

Results Results are shown in Figure 3, where we compare the effect of gradually shifting from tags to captions in the two training datasets considered. We first note that introducing tag-to-caption augmentation for at least a portion of the training data ($p_{cap} = 0.5$) leads to an improvement regardless of training dataset. Interestingly, unlike in MusicTextHQ, this trend does not extend to the scenario where we replace all text inputs with pseudo-captions ($p_{cap} = 1$) in LP-MusicCaps. In this case, we observe instead a slight degradation in performance on two of the evaluation datasets, compared to using only tags, or using captions half of the time. We posit that this divergence may be due to a gap in label quality between the two training sets, as pseudo-captions in LP-MusicCaps are generated based on sparse labels, with 50% of the items in the dataset paired to only three tags or less, and in many cases without being balanced across categories. Intuitively, this is likely to result in non-descript, or even inaccurate captions, as the LLM generation will be more prone to hallucinations and may therefore deviate substantially from the audio content. In contrast, MusicTextHQ provides strong grounding to the audio content, with multiple expert-provided tags per category (often three or more for *each* tag category). From this, we conclude that, while LLM-enabled text augmentation can provide a valuable strategy for enriching training data, it is not a substitute for adequate data curation, but rather a supplement. This is an important observation, as prior work has also found that specificity in captions is instrumental to effective multimodal contrastive learning [22, 31]. Since LLM-based augmentation, being bounded by the information content in the source data, cannot increase specificity, our results highlight an often overlooked shortcoming of synthetic text.

4.2 Training data: size vs quality

Next, we ask whether simply increasing dataset size can emphasise the benefits of tag-to-caption augmentation. To scale up the size of our training data, we include YT8M-MV, a subset of the YouTube8M dataset [1] tagged as *music video*, as an additional dataset to our training pool. For this, we follow [16] and employ tags from an automatic

music tagger and pseudo-captions generated following the same procedure described in Section 4.1. For simplicity, we refer to LP-MusicCaps, MusicTextHQ and YT8M-MV as Dataset_A (or simply A), Dataset_B (B) and Dataset_C (C), ordered by size as shown in Table 1. We also consider combining the two biggest datasets (B + C) and all three together (A + B + C). We note that each dataset differs not only in size, but also in audio and label quality.

Results In Figure 4 we showcase results from training on the datasets described above. Notably, we find that scaling dataset size does not consistently result in an improvement, signalling that the gap in quality between datasets can eclipse their size difference. Although we observe that combining all datasets yields better performance, likely due to overall increased diversity in the training data, the difference is not proportionate to the rise in training cost necessary to scale up. Instead, our results underscore the importance of data curation as a more efficient way of boosting performance, confirming that constructing a subset of highly curated examples, with descriptive and accurate captions, more positively contributes to learning in the contrastive setting [22].

5. IMPROVING DIVERSITY VIA TEXT AUGMENTATIONS

Having established that augmenting high-quality tags into captions offers a useful and inexpensive strategy to enrich training data, we explore this further and propose two augmentation-based techniques aimed at increasing data diversity and model robustness.

5.1 Augment, Drop & Swap

Augmented View Dropout First, building upon the tag-to-caption strategy described in Section 4.1, we explore text augmentation with the goal of constructing more effective views for contrastive learning, following the principle that optimal views should minimise mutual information between paired items while retaining a high degree of semantic alignment [25]. To this end, we propose *Augmented View Dropout*, where, for each item in our dataset, we randomly sample a subset of the tags, balanced by category (genre, mood, instrumentation) and produce a set of 10 different captions. Each can be thought of as a complementary, but partial view of the associated music track, as we mask a subset of all the ground-truth tags to produce each view. At training time, views are randomly sampled, effectively resulting in a further form of data augmentation.

Hard negatives via TextSwap Finally, we tackle another important challenge in contrastive learning, hard negative sampling, and propose to also address this through the lens of text augmentation, via a technique which we call TextSwap. In order to increase the rate of hard negatives beyond the natural rate found in the dataset, we create partially perturbed versions of the captions by stochastically swapping genre, mood or instrument keywords with alternative descriptors from a predefined dictionary (e.g. “a mellow *pop* track” becomes “a mellow *hip-hop* track”).

Figure 4: Retrieval performance across models trained on datasets that differ in size and annotation quality.

During training, for each positive pair, we then select a random subset of the negative captions in a batch and replace them with hard negatives by applying TextSwap once per descriptor category. This is illustrated in Figure 1, where we provide a visual guide for the full *Augment, Drop & Swap* pipeline. We hypothesise that the presence of hard negatives is particularly critical in later stages of training, once the model has already acquired basic features, and learning on “easy” negatives has saturated. Based on this, we follow a curriculum learning approach and linearly increase the probability of applying TextSwap from 0 to 15% over the course of 20 epochs, after a warm-up period of 5.

5.2 Experiments

Ablations In this set of experiments we examine the effect of each of the three components in our augmentation pipeline: tag-to-caption augmentation, Augmented View Dropout and TextSwap. We look at two scenarios: one where we want to measure their contribution in training two variants of our parameter-efficient DuET-MC framework, each with different degrees of audio pre-training and finetuning and locked text encoders, and one where we relax our computational requirements and explore whether our proposed method can be usefully applied in finetuning a general purpose audio-text embedding model (CLAP [29]), with limited paired music data.

Results We present our ablations on the proposed pipeline in Table 4, where we also compare to two audio-text contrastive baselines, CLAP [29] and TTMR [8], trained on general-purpose audio and music respectively. The table displays three different settings to which we apply our proposed pipeline: (1) training the audio encoder from scratch (shown in the HTS-AT + CLIP-T configuration), (2) training only 1% of the parameters in our locked audio-text encoder (MERT + CLIP-T), and (3) fine-tuning the full model on music, following general audio-text pre-training (CLAP-FT). From this, we observe that, while the vanilla version of DuET-MC (trained only on tags) exhibits at best comparable performance to the baselines, each additional component in our pipeline lifts performance across all model configurations, pre-training regimes and finetuning strategies. Among these, tag-to-caption augmentation

Model	Tag-to-caption	Augmented View Dropout	TextSwap	YT8M-MTC		MusicCaps		Song Describer		Avg R@10 ↑

	✓	✓	✓	15.7	57	43.5*	14*	26.3	<u>31</u>	28.5*

Table 4: Ablations. For each model, subsequent rows show the effect of introducing an additional step in our proposed *Augment, Drop & Swap* pipeline. We highlight best results for each model (underlined) and amongst all models (bold). * denotes values that may be inflated due to in-distribution bias.

and Augmented View Dropout emerge as the most influential, while the benefits of TextSwap are more prominent for model configurations where encoders have higher levels of pre-training, hinting at the necessity to increase the complexity of negatives later in training. This suggests that our *Augment, Drop & Swap* recipe provides a data-efficient strategy to improve music-text modelling under a variety of model configurations, at no additional computational cost. Importantly, this trend generalises across evaluation datasets, suggesting that it is beneficial to model robustness, and demonstrates that the lack of large-scale paired data in the music domain can be alleviated through augmentation-based techniques which enhance data quality instead of quantity. Finally, comparing retrieval scores of different family of models (TTMR, CLAP and DuET-MC), we note consistent differences between datasets, with CLAP-based models invariably showing a significant jump in performance on the MusicCaps dataset compared to MTC and SDD. We hypothesise that this may be a result of in-distribution bias, since there are several instances of non-music or noisy, low-quality recordings in MC. Since CLAP is trained to recognise everyday sounds, this points at a smaller shift from its training distribution, compared to SDD and MTC, which are exclusively composed of music recordings. We posit that further mismatches in the training and test distributions exist along the text dimension and investigate this through human evaluation.

Are metrics aligned with human preference? We recruit 35 participants to evaluate DuET-MC, CLAP and TTMR in a head-to-head pairwise comparison. Participants are presented with up to 24 text prompts, where each is a caption taken from one of the three evaluation datasets, and are asked to choose which one of two music tracks best aligns to the description. Through this qualitative evaluation, we find that DuET-MC does substantially better than TTMR, losing against it only 30.9% of the times, and largely mirroring our findings from Section

5.2. Surprisingly, the win and tie rate vs CLAP drops instead to 37.3% and 38.5% respectively. Looking at the breakdown of scores by dataset, this advantage in CLAP is predominantly observed on MC and MTC, while DuET-MC outperforms CLAP on SDD. Interestingly, DuET-MC is preferred or considered equivalent to the ground truth 38.9% of the times on MTC compared to 15.4 and 17.9% on the other two datasets. This points to significant differences in the level of alignment between caption and audio in the different datasets, signalling that evaluating on several datasets is paramount to understanding real-world performance. Additionally, it leads to an observation that complements our automatic evaluation in Table 4: the discrepancy between DuET-MC’s performance on MTC compared to MC and SDD may be ascribed to a higher degree of *vagueness* in MTC captions, which, as revealed through our qualitative evaluation, admit instead alternative matching tracks to those in the ground truth.

6. CONCLUSIONS

In this work we presented *Augment, Drop & Swap*, a training recipe for efficient music-text representation learning informed by our findings on training music-text contrastive models in resource-constrained scenarios. Through our experiments, we provide a practical guide to this family of models, and foreground their real-world use by focusing on multilingual support, computationally efficient techniques, and cross-dataset evaluation. Showing that data curation has a significant effect at modest data scales, we design each step in our pipeline to tackle specific aspects of the text used in training, such as descriptiveness and specificity, via data augmentations, leading to views that are more effective in multimodal contrastive learning. Through automatic and qualitative evaluations, we show the usefulness of our approach and reveal insights on the relation between measured performance and distribution shifts in the test data.

ABSTRACT

A conversational music retrieval system can help users discover music that matches their preferences through dialogue. To achieve this, a conversational music retrieval system should seamlessly engage in multi-turn conversation by 1) understanding user queries and 2) responding with natural language and retrieved music. A straightforward solution would be a data-driven approach utilizing such conversation logs. However, few datasets are available for the research and are limited in terms of volume and quality. In this paper, we present a data generation framework for rich music discovery dialogue using a large language model (LLM) and user intents, system actions, and musical attributes. This is done by i) dialogue intent analysis using grounded theory, ii) generating attribute sequences via cascading database filtering, and iii) generating utterances using large language models. By applying this framework to the Million Song dataset, we create – **LP-MusicDialog**, a Large Language Model based Pseudo Music Dialogue dataset, containing over 288k music conversations using more than 319k music items. Our evaluation shows that the synthetic dataset is competitive with an existing, small human dialogue dataset in terms of dialogue consistency, item relevance, and naturalness. Furthermore, using the dataset, we train a conversational music retrieval model and show promising results.¹

1. INTRODUCTION

In recent years, conversational systems have emerged as a promising solution to enhance user experience in various domains [1–4], including conversational music retrieval and recommendation [5, 6]. The goal of a conversational

¹ Our code is available at <https://github.com/seungheondoh/lp-music-dialog/>

Step1. Intent Analysis from Human Dialogue

Step2. Cascading Music Database Filtering

Step3. Music Discovery Dialogue Generation

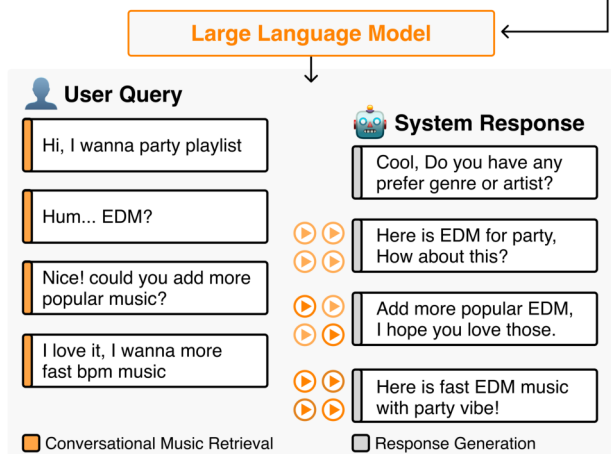

Figure 1. The generation process of pseudo musical dialogue.

music system is to assist users in finding their desired music through dialogues. Such a system should possess three key capabilities: i) to understand the *intents* and *musical needs* of users from their queries expressed in natural language, ii) to generate responses and facilitate human-like interaction, iii) to find music that aligns with the user’s preferences by taking previous dialogues into account.

Currently, the primary challenge of developing a conversational music retrieval system is the scarcity of large-scale public datasets. Chaganty et al. [5] introduce the Conversational Playlist Curation Dataset (CPCD). This crowd-sourced dataset comprises human-to-human dialogues that simulate the process of music discovery. How-

ever, as it relies on a manual process, the dataset is small and exhibits biases from the music streaming platforms used by the recommenders. To address this problem, Leszczynsk et al. [6] propose a dialogue generation framework through random walks in the music-text joint embedding space and dialogue inpainting [7]. However, this approach requires a high-quality music-text joint embedding and needs to use template-based system responses as input. As a result, the system’s responses are always composed of limited format utterances, leading to low naturalness in human evaluation.

In this paper, we introduce a framework for generating *human-like* music discovery dialogues using intent and a large language model (LLM). The proposed framework is based on the existing method [6], but we address their limitations by employing *cascading music database filtering* instead of a joint embedding and extensive *intent analysis* for naturalness. Using the grounded theory approach [8], we analyze a dataset of human music discovery dialogues and develop taxonomies for user intents, system actions, and musical attributes relevant to the task of music discovery. Furthermore, we introduce a model-free attribute sequence generation by applying cascading filtering to a multi-label music annotation database. Finally, we synthesize music discovery dialogues through an LLM using the created attribute sequences and human intents/actions.

Our contributions are threefold: First, we analyze music discovery dialogues and propose a taxonomy. Second, we introduce the LP-MusicDialog dataset, a large-scale synthetic dialogue dataset created using human intent and an LLM. Third, we present extensive objective and subjective evaluations to demonstrate the effectiveness of LLM-based pseudo-music dialogues.

2. RELATED WORK

Recently, there has been some progress in conversational music systems including language-based music retrieval [9–11]. However, existing systems are often limited to single-turn tasks. This means users are not able to refine their queries to obtain a highly satisfactory outcome. Towards multi-turn dialogues, Chaganty et al. [5] released the Conversational Playlist Curation Dataset (CPCD), which comprises 917 dialogues averaging 5.7 turns each. Unlike single-turn retrieval, conversational retrieval takes into account previous chat history to find relevant items. The model in [5] aggregates the context of history embedding and the current query embedding using average pooling, then uses contrastive loss to maximize the similarity between them. However, their model showed limited performance due to the small size of CPCD.

A solution to the data scale issue is synthesizing data using existing datasets and language models. Recently, synthetic datasets that bridge natural languages and music have been proposed to enhance music understanding [12, 13], captioning [13, 14], reasoning [13], and retrieval [11]. For the conversational music retrieval, Leszczynski et al. [6] proposed a two-stage data synthesis framework: musical attribute sequence generation via

random walk and utterance generation through dialogue inpainting [7]. The musical attribute sequence represents the evolution of user queries over turns (e.g., ask for workout music in the first turn, then refine the results to be also pop music). During utterance generation, a language model creates user queries using system responses as input, which include sampled musical attributes and a static template.² As a result, they created one million multi-turn music discovery dialogues: TtW Music, leveraging a private playlist dataset. However, this approach encounters issues with model errors in the music-text joint embedding space used for the random walk method and faces challenges with response consistency due to the reliance on manually created templates for system responses.

Deep understanding in music query has to be preceded aforementioned data generation. So far, query understanding has primarily focused on describing musical needs. Downie and Cunningham [15] analyzed 161 music queries and categorized them into 1) information needs, 2) desired outcomes, 3) intended uses for the information, and 4) social and contextual elements. Bainbridge et al. [16] utilized the grounded theory approach to analyze 502 real-world music queries, expanding upon prior research with 10 types of need descriptions. Lee [17] analyzed 1,705 Google Answers queries to propose a refined taxonomy for information needs and searching behavior. Despite these efforts, previous studies have been limited to the information needs (musical attributes) contained in queries, and intent in multi-turn queries has not received significant attention.

3. DIALOGUE INTENT ANALYSIS

3.1 Taxonomy Development

For the dialogue-specific music discovery taxonomy, we analyze the existing human-to-human music dialogue dataset (CPCD [5]) using the grounded theory approach [8]. Grounded theory is a qualitative approach that creates refined theory from unstructured real-world data. In detail, (1) we adopt the taxonomy from previous research as our initial taxonomy. For user intent and system action, we use the *conversational movie intent* taxonomy [18], and for musical needs, we use *music feature* taxonomy [17] as the initial taxonomy. (2) Three authors annotate ten dialogues using the initial taxonomy and discuss the limitations of the existing taxonomy. (3) We update the taxonomy and annotate a new randomly sampled five dialogues. This cycle of proposing, refining, and annotating was completed three times to ensure our taxonomy could capture the full range of scenarios present in the dialogue samples.

3.2 Analysis Results

3.2.1 Taxonomy for User Intents

In Table 1, we categorize user intents into four main categories, with eight detailed sub-intents. The **Initial Query**

² For example, “Of course! Let me add some songs described as <musical attributes>. What else?”

User Intent	Description	Example	%
<i>Start Dialogue</i>			
Initial Query	User initiates the inquiry with a specific request.	"Hi, I want to create a playlist for hiking."	18.5
Greeting	User initiates the dialog, often with greeting words.	"Hello, I would like... / "Good Morning! Let's start..."	12.7
<i>Item Discovery Query (Retrieval / Recommendation)</i>			
Positive Filter	User requests to include an additional criterion.	"I would like to add a bit of Rihanna."	76.7
Negative Filter	User requests to negative criterion in this turn.	"I do prefer them to not have any lyrics"	3.7
Continue	User requests for more songs with the current criteria.	"Those are good songs. More like these would be great."	6.8
<i>Item Understanding Query (Question Answering)</i>			
Item Attribute Question	User questions attributes of music.	"Do you know where Samer (Artist) is from?"	0.2
<i>Feedback Response</i>			
Accept Response	User responds positively to the recommendations.	"Thank you, they are perfect"	44.4
Reject Response	User responds negatively to the recommendations.	"I still didn't get any song suggestions..."	4.8

Table 1. Taxonomy for user intents. % represents the percentage of occurrences within the user query.

System Action	Description	Example	%
<i>Request</i>			
Feedback Request	System requests the user to evaluate recommendations.	"What about these ones?"	12.8
Detail Attribute Request	System requests for the user's needs or desires for recommendations.	"Are there any particular artists you want to see?"	20.8
<i>Item Discovery Response (Retrieval / Recommendation)</i>			
Passive Recommendation	System recommends music based on user's preferences.	"Here are some pop songs for kids."	71.4
Active Recommendation	System proactively recommends music without being explicitly asked.	"Nice! I added a couple more."	14.9
<i>Item Understanding Response (Question Answering)</i>			
Item Attribute Answer	System answers to user's question with musical attributes.	"Frederic Chopin was a Polish composer..."	0.1
<i>General Response</i>			
Parroting Response	System responds to the user's inquiry by mirroring.	"Here's some picks from The Who."	25.4
Sympathetic Response	System responds to the user's inquiry with human-like sympathy.	"Excellent! Looks like a great Kickstart!"	57.2

Table 2. Taxonomy for system actions. % represents the percentage of occurrences within the system response.

is part of the 'start-dialogue' category, serving as the kick-off point for recommendation dialogues. At times, users start interactions with **Greetings** to initiate the system into a more engaging mode of communication. The 'item-discovery-query' captures user preferences for music retrieval and recommendations, subdivided into **Positive Filter** for add preferences, **Negative Filter** for discarding existing ones, or **Continue** to sustain the current preferences. **Item Attribute Question**, where users inquire about the precise attributes of music tracks, such as their genre, mood, tempo, and key/mode. Feedback responses are outlined, with users either expressing satisfaction (**Accept Response**) or dissatisfaction (**Reject Response**) to the recommended music.

3.2.2 Taxonomy for System Actions

Table 2 shows the system action taxonomy, structured into four primary categories, and seven specific intents. The 'request' category enhances the search experience, either through post-recommendation **Feedback Request** to gauge satisfaction or **Detail Attribute Request** to clarify vague or incomplete user queries. To address user queries for music discovery, the system can adopt a **Passive Recommendation** approach to comply with user requests. This approach is similar to a retrieval task because there is an explicit query from the user. The system also proactively engage through **Active Recommendation**. It is similar to a recommendation task because it implicitly uses the context of the dialogue even without an explicit query from the user.

In **Item Attribute Answer**, the system responds to users' inquiries about specific musical attribute questions

such as genre, mood, tempo, and key/mode. For general responses, the system mimics user requests in its recommendations (**Parroting Response**) to affirm that user preferences are being considered, or it may adopt a more empathetic stance (**Sympathetic Response**) to foster a more human-like interaction.

3.2.3 Taxonomy for Musical Attribute

Musical attributes such as genre, mood, and artist are closely related to user preferences. They are categorized into (1) objective metadata produced when a track is registered on the platform, (2) subjective similarity with music entities, (3) user & listening context, and (4) music content information (Table 3). Metadata is mainly associated with entity recognition [19], where **Track** refers to requests for a single music recording entity, **Artist** denotes user requests for tracks released by a specific artist, **Year** reflects the era/year in which a piece of music was released, and **Popularity** indicates the level of attention a piece of music has received. **Culture** is related to the national or regional style of the music, often linked to the artist's nationality. Unlike objective metadata, **Similar Track** and **Similar Artist** are subjective musical attributes, representing connections to other track or artist entities. The user % listening context consist of **User**, which is related to the demographics of the listener, and **Theme**, which encompasses the location, time, usage, and activities associated with listening. **Mood** refers to the emotional tone conveyed by the music or the listener's emotional state. Lastly, the categories tied closely to music content itself include **Genre**, which relates to high-level music form and style, and aspects associated with timbre such as **Instru-**

Musical Attribute	Description	Example	%
<i>Metadata</i>			
Track	A single musical work, recording, performance	Can you add montero from lil nas?	4.5
Artist	A creator or performer of music.	How about some more Justin Timberlake?	43.1
Year	The time of music’s creation or release	Could you throw in some 90s hip hop?	6.6
Popularity	The widespread acclaim of music.	Awesome! How about more male disco hits?	0.7
Culture	The national or regional influences on music.	i like Nigerian songs	0.9
<i>Similar with Music Entity</i>			
Similar Track	The song is similar to the specific track.	Can I have more songs similar to Jessie’s Girl?	1.1
Similar Artist	The song is similar to the specific artist.	Adele and Sia type of music	5.0
<i>User & Listening Context</i>			
User	The listeners characterized by demographics.	I want to create a fun playlist for the kids	1.9
Theme	A context for music listening related to location, time, usage, and activity.	hi please i need a playlist to workout with	15.2
Mood	The emotional tone conveyed by music, or the emotional state of user.	I want to create playlist for when I’m sad	6.7
<i>Music Content Information</i>			
Genre	A category of music characterized in form, style, or subject matter.	I would love to start with classical music	17.2
Instrument	A tool or device designed to produce musical sounds	What other quartet music do you suggest?	1.1
Vocal	The singing voice in music, including styles, techniques, and expressions	try some female vocalists too	1.2
Tempo	The speed or pace at which a piece of music is played	Add me some slow slow songs from juice wrld	1.3
Key / Mode	The tonal information of music	(Not appear)	0.0

Table 3. Taxonomy for musical attributes. % represents the percentage of occurrences within the user query.

ment and **Vocal**, as well as **Tempo** related to rhythm, and **Key/Mode** for tonal information.

3.2.4 Dialogue intent annotation

After the development of the taxonomy, the three annotating authors proceeded to annotate user intent, system action, and musical attributes according to the proposed taxonomy within a new sampled 30 CPCD [5] dialogues. To measure the level of agreement among the annotators for the degree of concurrence, we employed Krippendorff’s alpha [20]. The results showed high agreement levels, with Krippendorff’s alpha scores of 0.83 for user intent, 0.85 for system action, and 0.71 for musical attributes. Following this agreement phase, each annotator independently annotated a portion of the total 888 CPCD dialogues, excluding 29 error samples out of the total 917 dialogues.

3.3 Intent Analysis and Findings

The proportion of categories in each taxonomy is on the rightmost columns of Tables 1 – 3. For user intent (in Table 1), the majority of item discovery queries progress through the *Positive Filter* (76.7%), whereas the opposite, *Negative Filter*, constitute a smaller portion (3.7%). *Item Attribute Questions* are almost non-existent (0.2%). The majority of recommendation are accepted (44.4% of *Accept Response* vs 4.8% of *Reject Response*). Regarding system actions, a notable observation is that the system predominantly provides recommendations passively, rather than actively offering suggestions (71.4% vs 14.9%). In the case of general responses, the system favors eliciting human-like conversations through sympathetic responses over merely parroting back information (57.2% vs 25.4%). In the case of music, categories such as artist (43.1%), genre (17.2%), and theme (15.2%) occupy a significant portion of the user queries. This may suggest that in a *Wizard of Oz* setting [21], where the recommender utilizes music streaming platforms, the platform’s search support may be limited to these categories. Conversely, similarity queries or music content queries beyond genre are rarely employed.

4. MUSIC DISCOVERY DIALOGUE GENERATION

In this section, we describe the framework for generating music discovery dialogue consisting (1) attribute sequence generation and (2) utterance generation. This two-step approach is an improved version of previous research [6] with model-free attribute sequence generation by *Cascading music database filtering*, and utterance generation by a LLM and *Intent Analysis*.

4.1 Musical Attribute Sequence Generation

For attribute sequence generation, we employ a series of cascading filters on a multi-label annotated dataset to extract samples with overlapping semantics. Inspired by [22], which utilized *functional programs* to construct a visual reasoning dataset, we apply this approach to the domain of music discovery dialogue using user intents such as add filter, remove filter, and continue. Figure 2 illustrates an example of a cascading data filter. For example, a user may initially request songs in the *EDM* genre, narrow it down to a *party* theme, and finally specify a need for *fast tempo* music. This sequence can be represented by a series of connected functional program filters: *filter(tempo:fast, filter(theme:party, filter(genre:edm, database)))*. This method requires the types of filters and musical attributes. We derive filter types from the annotated intents (Section 3.2). For musical attributes, we initially conducted random sampling. Subsequently, to ensure diverse sampling with high co-occurrence with previous attributes, we employed top-*k* sampling ($k=20$), which involves randomly selecting a word from the top *k* words with the highest frequency. During top-*k* sampling, we include attributes from the *metadata* and *similar with music entity* categories.

4.2 Utterance Generation via Language Model

The sequence of musical attributes and annotated intent becomes prompts for LLMs to generate user and system

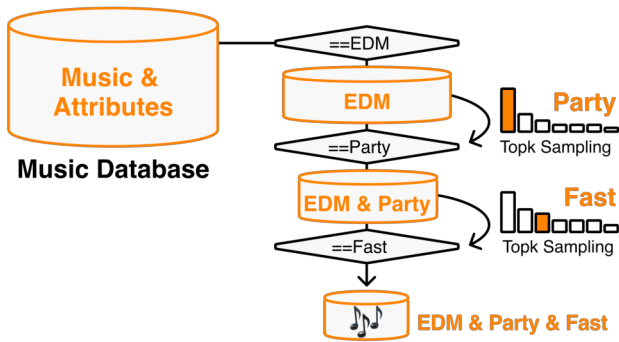

Figure 2. Cascading database filtering.

utterances. Our proposed utterance generation follows the formulation: $x_{text} = f_{LLM}(\mathcal{P}, y_{intent}, y_{music})$, where y_{intent} and y_{music} refer to the annotated intent/action (Sec 3.2) and the sampled musical attribute (Sec 4.1), respectively, and \mathcal{P} is the prompt for dialogue generation. We assumed that dialogue intent and musical attribute can serve as effective conditions for human-like dialogue generation.

5. DATASET: LP-MusicDialog

5.1 Data Source

To construct our synthetic dialogue dataset, we utilize the Million Song Dataset (MSD) [23], which has rich metadata including track details, artist information, release year, and artist familiarity. We quantize year and artist familiarity into decades and popularity, respectively.³ To cover a wide range of musical attributes as listed in Table 3, we interlink multiple annotation datasets using track IDs. For culture, mood, theme, genre, instrument, and vocals, we utilize tags from Tagtraum [24], Last.fm [25, 26], and AllMusic [27].⁴ For similar track attribute, we incorporate merged data from the Art of the Mix playlist [28] and EchoNest taste profiles. We utilize a weighted matrix factorization technique [29] to create a similarity matrix of item vectors. We then annotate the top- k similar tracks for each track ($k=128$). For artist similarity, we use cultural similarity annotation from the OLGA [30] dataset. Finally, for key/mode and tempo, we extract beats per minute (BPM), 24 key/mode using the pretrained classifier [31, 32].⁵

5.2 Creation Process

Based on the proposed pseudo dialogue generation method, we created LP-MusicDialog, an LLM-based Pseudo Music Dialogue dataset. We integrate user intents and system actions annotated in CPCD dialogues (Sec.3.2) with musical attributes obtained through cascading music database filtering (Sec.4.1) as inputs for GPT 3.5-turbo. At each cascading filtering step, we randomly sample 10

³ We categorize the top 10% of artist familiarity as high popularity, 10-30% as mid popularity, and the lower 30% as low popularity.

⁴ As the ‘style’ category in AllMusic is structured as sub-genres, we merged it with ‘genre’ category.

⁵ BPM was quantized into three text label: songs below 70 BPM were classified as slow, those between 70 BPM and 130 BPM as moderate, and those above 130 BPM as fast.

Data Source	# of Track	Musical Attributes
Million Song Dataset [23]	1,000,000	Track, Artist, Year, Popularity
TagTraum [24]	280,831	Genre, Instrument, Vocal, Mood, Theme, Culture
Last.fm [25, 26]	344,865	
AllMusic [27]	507,435	
Art of the Mix [28]	119,686	Similar Track
TasteProfile [23]	380,462	
OLGA [30]	542,364	Similar Artist
Madmom Key/Mode [32]	992,525	Key/Mode
Madmom Tempo [31]	978,759	Tempo

Table 4. Data sources for the dialogue generation

	CPCD [5]	TtW [6]	LPMD (Ours)
# of Dialog	917	1,037,701	287,675
# of Tracks	106,736	332,594	391,465
# of Vocab	9872	N/A	105,832
Avg.# of turns	5.7	5.6	4.97
Avg. query len.	54.4	80.3	63.8
Avg. response len.	45.8	N/A	87.8
Public Available	Yes	No	Yes

Table 5. Statistics of conversational music retrieval datasets. LPMD stands for LP-MusicDialog.

tracks to link with the dialogue turn. As a result, we acquire 287,675 user query, system response, music item triplets for each turn of the dialogue.

As detailed in Table 5, LP-MusicDialog is significantly larger and more diverse than existing datasets. Compared to the human dialogue dataset CPCD [5], it contains $\times 313$ larger dialogues, a more than $\times 10$ diverse vocabulary, and nearly four times more tracks. While remaining open to the public, our dataset is on par with a private dataset, TtW [6], in many aspects, with plans to expand further upon confirming active usage. In contrast, LP-MusicDialog is not only publicly available but also offers an extensive collection of connected tracks. Figure 3 shows the musical attribute ratio in dialogue. Unlike CPCD [5], where a significant portion is occupied by artist and genre due to platform bias, LP-MusicDialog shows a higher proportion of dialogues concerning music content and user listening context. Although the proportion of queries for entity recognition such as track and artist has decreased, the percentage of similarity queries has increased.

5.3 Human Evaluation

Following previous work [6], we assess the quality of our generated data through human evaluation, focusing on three key aspects: 1) Consistency - evaluating if the user preferences are coherent across dialogue turns; 2) Relevance - determining the alignment between the retrieved music items and the user query; 3) Naturalness - assessing the likelihood of such a conversation occurring in real life. Unlike previous work, we adhere to mean opinion score (MOS) that uses a 5-point Likert scale instead of a 3-point scale. A total of 26 raters evaluated 10 randomly sampled dialogues each. Within 260 total ratings, we only reported dialogues assessed by three or more raters.

Table 6 presents the MOS evaluations for dialogues from CPCD [5] and LP-MusicDialog. To understand the

Figure 3. The ratios of musical attributes in music discovery dialogues.

	Consistency	Relevance	Naturalness
LP-MusicDialog	3.79 ± 0.56	4.04 ± 0.74	3.87 ± 0.57
+ Intent / Action	3.88 ± 0.87	4.05 ± 0.53	4.24 ± 0.38
Human Dialogue [5]	3.90 ± 0.70	4.16 ± 0.68	4.29 ± 0.43

Table 6. Mean opinion scores of the generated dialogues (LP-MusicDialog) and human dialogues (CPCD [5])

impact of user intent and system action, we conducted an ablation study synthesizing dialogues with only musical attributes and prompts. Comparing the first and second rows, we find minimal differences in consistency and relevance, as both sets of generated dialogues utilize identical musical attributes. However, a notable distinction arises in naturalness, suggesting that LLMs can foster more human-like dialogue synthesis by incorporating intents and actions. In comparing human dialogues with our generated dialogues, we found that the generated dialogues perform comparably to the human dataset across all three metrics, within the standard deviation.

6. CONVERSATIONAL MUSIC RETRIEVAL

In this section, we present a benchmark of conversational music retrieval models. Unlike prior studies [5, 6] that have music embeddings solely relying on metadata-based text modality,⁶ we expand it to include audio modality. We use a pre-train audio-text joint embedding model (TTMR++ [11]), that consists of a text encoder that handles user queries and system responses and an audio encoder that takes music tracks. We freeze TTMR++ and add a trainable MLP layer for both text and audio encoder. To handle chat history, we use a chat embedding created by average-pooling the current query, previous queries, responses, and music embeddings. Two encoders are trained to maximize the cosine similarity between the chat embedding and target music embedding using the InfoNCE [33] loss. In the inference stage, we extract chat embeddings for each turn in the same way as in the training stage and measure the similarity score with all music embeddings in the train and test splits. Based on the similarity score, we retrieve the most similar k items by nearest neighbor search.

We chose the CPCD dataset as the compared dataset and report Hit@ K as evaluation metric ($k=\{10,20,100\}$).⁷ Our baseline models are as follows: (1) BM25 [34], as a sparse retrieval baseline; (2) Contriever [35], an unsu-

⁶ {title} by {artist} from {album}

⁷ Excluding the lost audio due to YouTube crawling, we use 98,738 out of 106,736 tracks for evaluation. We use the official evaluation codebase: <https://github.com/google-research-datasets/cpcd>

Model	Type	Hit@10	Hit@20	Hit@100
BM25 [34]	-	0.180	0.251	0.433
Contriever [35]	Zeroshot	0.176	0.255	0.344
TTMR++ [11]	Zeroshot	0.201	0.275	0.505
+ LPMD only	Finetune _{OD}	0.173	0.253	0.479
+ CPCD only	Finetune _{ID}	0.209	0.295	0.530
+ LPMD & CPCD	Finetune _{OD+ID}	0.219	0.304	0.533

Table 7. Conversational music retrieval performance on CPCD Dataset. **OD** stands for out of domain. **ID** stands for in domain.

pervised dense retrieval baseline; and (3) TTMR++ [11], an audio-text joint embedding baseline. Table 7 shows the performance of conversational retrieval. Among the baselines, TTMR++ shows superior performance over BM25 and Contriever, highlighting the importance of the audio modality in the music domain. Furthermore, training TTMR++ with only LP-MusicDialog (i.e., inter-dataset evaluation) somewhat leads to a performance decrease. This is presumably due to the musical entity difference between the two datasets. Specifically, the LP-MusicDialog dataset derives from the MSD, which contains music up to the year 2010, while the CPCD dataset includes music extending up to the year 2023. Nonetheless, training with both LP-MusicDialog and CPCD results in performance improvement over training only with CPCD, suggesting the usefulness of the proposed dataset.

7. CONCLUSION

We proposed a musical dialogue generation approach with i) dialogue intent analysis using the grounded theory, ii) generating attribute sequences via cascading database filtering, and iii) generating utterances using a large language model. Our intent analysis underpins the synthesis of human-like conversations, demonstrating strengths in naturalness. Cascading filtering allows us to utilize music attributes from external music databases to generate new dialogues. The outcome, the proposed **LP-MusicDialog** covers a broader range of musical attributes and aids in the conversational music retrieval task.

However, the proposed methods have several limitations. The first is that cascading filtering is sensitive to annotation errors [36]. The second is that top-k sampling, by following the tag distribution, inevitably leads to a data imbalance problem. We hope that these limitations of cascading filtering will be addressed in future research by incorporating balanced sampling.

ABSTRACT

Although deep neural networks can estimate the key of a musical piece, their supervision incurs a massive annotation effort. Against this shortcoming, we present STONE, the first self-supervised tonality estimator. The architecture behind STONE, named ChromaNet, is a convnet with octave equivalence which outputs a “key signature profile” (KSP) of 12 structured logits. First, we train ChromaNet to regress artificial pitch transpositions between any two unlabeled musical excerpts from the same audio track, as measured as cross-power spectral density (CPSD) within the circle of fifths (CoF). We observe that this self-supervised pretext task leads KSP to correlate with tonal key signature. Based on this observation, we extend STONE to output a structured KSP of 24 logits, and introduce supervision so as to disambiguate major versus minor keys sharing the same key signature. Applying different amounts of supervision yields semi-supervised and fully supervised tonality estimators: i.e., Semi-TONEs and Sup-TONEs. We evaluate these estimators on FMAK, a new dataset of 5489 real-world musical recordings with expert annotation of 24 major and minor keys. We find that Semi-TONE matches the classification accuracy of Sup-TONE with reduced supervision and outperforms it with equal supervision.

1. INTRODUCTION

Self-taught musicians can tell whether two pieces go “in tune” or “out of tune”. To do so, they do not need to know the name of every key [1]. Meanwhile, in music information retrieval (MIR), current tonality estimators depend on a vocabulary of labels such as $C : \text{maj}$ or $F : \text{min}$.

In this context, we aim to develop models which “learn by ear” like humans; i.e., from little or no annotated data. This goal is justified in practice by the fact that online digital music corpora are larger and more musically diverse than established MIR datasets, yet often lack expert metadata.

To overcome the need for large amount of labeled data, self-supervised learning (SSL) has emerged as an alternative paradigm to supervised learning, with numerous applications in speech and music processing [2–5].

The design of pretext tasks is a long-standing issue in SSL for audio. On one hand, some of them are meant as pretraining step for general-purpose representation learning: contrastive predictive coding [6], deep metric learning [7], and self-distillation [8], to name a few. On the other hand, another family of pretext tasks is designed to suit a particular downstream task, such as tempo and pitch estimation [9, 10]. In this context, the concept of *equivariance* plays a central role. Loosely speaking, equivariance means that a certain parametric transformation of the input data forms a simple trajectory in the space of learned representations. Yet, equivariant SSL has never been used to study tonality, for lack of an adequate pretext task.

The main idea of our paper is that, even so *absolute* key labels are unknown, we can construct paired samples in which *relative* harmonic progressions serve as a learning signal for tonality estimation. Our contributions are:

STONE. To our knowledge, the first SSL framework whose model predictions correlates with key signatures. It comprises a new equivariant neural network named ChromaNet and a noncontrastive loss function based on cross-power spectral density (CPSD).

Downstream task. We extend STONE into Semi-TONE, a semi-supervised model that is tailored for 24-way key estimation. Semi-TONE performs on par with a supervised counterpart (Sup-TONE) while reducing dependency on annotated data by 90%¹.

FMAK. A new large dataset of 5489 real-world music recordings, collected from the Free Music Archive (FMA) and annotated by an expert for 24 major and minor keys, is available for free download².

variability: e.g., variations in pitch or tempo [10–12]. In particular, PESTO is a monophonic pitch estimator trained by learning the pitch shift of the same sample [9]. However, its extension to multipitch tracking is an open problem [13].

2.2 Computational models of tonality

Tonality estimation remains a relatively under-researched field, due to the scarcity of labeled data available for both training and evaluation purposes. The earliest methods were based on template matching [14–17]. Later, convolutional neural networks (convnets) and transformers appeared, treating the task as a supervised 24-class classification problem [18–20]. Among studies employing the same dataset, the convnet of Korzeniowski *et al.* [21] achieves the best performance. Against the lack of annotated data, prior work proposed to integrate key estimation with unsupervised autoencoding [18, 19]. However, their approach is computationally intensive and its evaluation is limited.

2.3 Annotated datasets for key estimation

Key detection datasets face a conundrum between diversity and reproducibility. The Million Song Dataset [22] offers key labels for diverse commercial music but lacks public audio. GiantSteps MTG Key (GSMK)³, GiantSteps Key (GSK) [23] and McGill Billboard datasets [24] offer public data, yet they are restricted in terms of genres and quantity. In particular, GSMK and GSK serve in the training and evaluation of supervised SOTA [21].

3. METHODS

Figure 1 illustrates our proposed method for STONE.

3.1 Artificial pitch transpositions of the CQT

We compute a constant- Q transform (CQT) with $Q = 12$ bins per octave and center frequencies ranging between $\xi_{\min} = 27.5$ Hz and $\xi_{\max} = 2^{99/12}\xi_{\min} = 8.37$ kHz.

Given a CQT matrix \mathbf{x} and an integer $c \leq 15$, we reduce the number of rows from 99 down to 84 (7 octaves) by trimming the c lowest-frequency bins and $(15 - c)$ highest-frequency bins. This is tantamount by a pitch transposition by c semitones [9]. We denote the result by $T_c\mathbf{x}$ where $T_c\mathbf{x}[p, t] = \mathbf{x}[p - c, t]$ for each frequency $p < 84$ and time t .

3.2 ChromaNet: a convnet with octave equivalence

The cropped CQT matrix $T_c\mathbf{x}$ has a frequency range of $QJ = 84$ semitones with $Q = 12$ and $J = 7$ octaves. We define a 2-D fully convolutional network f_{θ} with trainable parameters θ , operating on $T_c\mathbf{x}$ with no pooling over the frequency dimension. The last layer has a single channel and performs global average pooling over the time dimension.

The architecture f_{θ} composes seven blocks, each of them composing a ConvNeXT block [25] and a time downsampling block, and layer normalization. It returns a vector in dimension QJ . While ConvNeXT blocks leaves the input

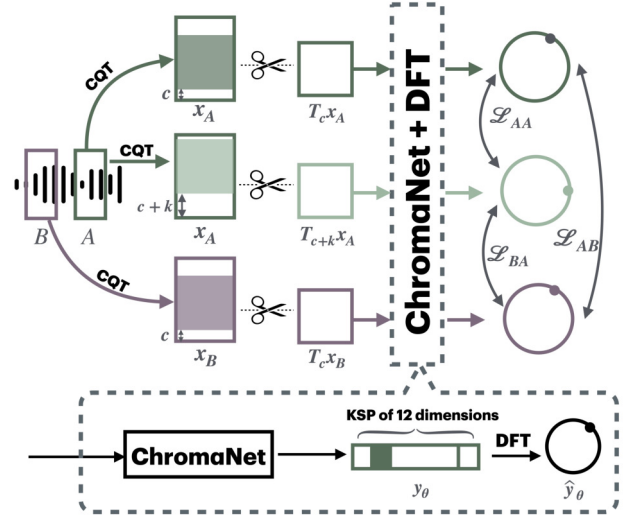

Figure 1. Overview of the equivariant pretext task in STONE. Given two segments A and B from an unlabeled musical recording, we compute their constant- Q transforms (CQT) and apply random crops by c and $(c + k)$ to simulate pitch transpositions. We feed them to ChromaNet, an equivariant neural network with octave equivalence, yielding a learned key signature profile (KSP) of 12 chromas. We compute the discrete Fourier transform (DFT) of each KSP and derive pairwise cross-power spectral densities (CPSD). Self-supervised losses \mathcal{L}_{AA} , \mathcal{L}_{AB} , and \mathcal{L}_{BA} are formulated as CPSD regression residuals in the complex domain.

resolution unchanged, time downsampling blocks decrease time resolution while preserving frequency resolution.

We compose the convnet f_{θ} with a non-trainable operator g whose role is to guarantee octave equivalence. We roll the log-frequency axis into a spiral which makes a full turn at every octave, thus aligning coefficients in $f_{\theta}(T_c\mathbf{x})$ of the form $(p \pm Qj)$ for integer j . The operator g sums these coefficients across octaves j for each pitch class q and applies a softmax transformation. We obtain a Q -dimensional vector \mathbf{y}_{θ} whose entries are nonnegative and sum to one. We propose to call this vector a “key signature profile” (KSP):

$$\begin{aligned} \mathbf{y}_{\theta}[q] &= (g \circ f_{\theta})(T_c\mathbf{x})[q] \\ &= \frac{\exp\left(\sum_{j=0}^{J-1} f_{\theta}(T_c\mathbf{x})[Qj + q]\right)}{\sum_{q'=0}^{Q-1} \exp\left(\sum_{j=0}^{J-1} f_{\theta}(T_c\mathbf{x})[Qj + q']\right)}. \end{aligned} \quad (1)$$

For brevity, we do not recall the dependency of \mathbf{y}_{θ} upon \mathbf{x} nor c . Equation 1 resembles the extraction of chroma features [26], hence the proposed name of ChromaNet.

3.3 DFT over key signature profiles

With $Q = 12$, the discrete Fourier transform (DFT) of the KSP \mathbf{y}_{θ} is

$$\hat{\mathbf{y}}_{\theta}[\omega] = \mathcal{F}\{\mathbf{y}_{\theta}\}[\omega] = \sum_{q=0}^{11} \mathbf{y}_{\theta}[q] e^{-2\pi i \omega q / 12}, \quad (2)$$

where ω is an integer between 0 and 11 that is coprime to 12 for a full circular distribution over all 12 pitches. With

³ <https://github.com/GiantSteps/giantsteps-mtg-key-dataset>

$\omega = 7$, a circular shift of \mathbf{y}_θ by seven chromas corresponds to a multiplication of $\hat{\mathbf{y}}_\theta[\omega]$ by $e^{2\pi i 49/12} = e^{2\pi i/12}$. Hence, the phase of the complex number $\hat{\mathbf{y}}_\theta[\omega]$ denotes a key modulation in the circle of fifths (CoF). Alternatively, $\omega = 1$ would correspond to a circle of semitones. Our paper evaluates both settings but only describes the CoF setting ($\omega = 7$) for the sake of conciseness.

3.4 Cross-power spectral density (CPSD)

Let us split the CQT matrix \mathbf{x} into two disjoint time segments of equal length: $\mathbf{x} = (\mathbf{x}_A, \mathbf{x}_B)$. We denote the ChromaNet response for A by $\mathbf{y}_{\theta,A} = (g \circ f_\theta)(T_c \mathbf{x})$ idem for B. The circular cross-correlation between $\mathbf{y}_{\theta,A}$ and $\mathbf{y}_{\theta,B}$ is

$$\mathbf{R}_{\mathbf{y}_{\theta,A}, \mathbf{y}_{\theta,B}}[k] = \sum_{q=0}^{Q-1} \mathbf{y}_{\theta,A}[q] \mathbf{y}_{\theta,B}[(q+k) \bmod Q] \quad (3)$$

for $0 \leq k < 12$. Taking the DFT of the equation above yields the circular cross-power spectral density (CPSD)

$$\hat{\mathbf{R}}_{\mathbf{y}_{\theta,A}, \mathbf{y}_{\theta,B}}[\omega] = \mathcal{F}\{\mathbf{R}_{\mathbf{y}_{\theta,A}, \mathbf{y}_{\theta,B}}\}[\omega] = \hat{\mathbf{y}}_{\theta,A}[\omega] \hat{\mathbf{y}}_{\theta,B}^*[\omega], \quad (4)$$

where the asterisk denotes complex conjugation.

3.5 Differentiable distance over the circle of fifths

Given a constant DFT frequency $\omega = 7$ and an arbitrary musical interval k in semitones, we compute the CPSD associated to the pair $(\mathbf{y}_{\theta,A}, \mathbf{y}_{\theta,B})$ and measure its half squared Euclidean distance to $e^{-2\pi i \omega k / Q}$ in the complex domain:

$$\mathcal{D}_{\theta,k}(\mathbf{x}_A, \mathbf{x}_B) = \frac{1}{2} \left| e^{-2\pi i \omega k / Q} - \hat{\mathbf{R}}_{\mathbf{y}_{\theta,A}, \mathbf{y}_{\theta,B}}[\omega] \right|^2. \quad (5)$$

Intuitively, in the case where $\hat{\mathbf{y}}_{\theta,A}[\omega]$ and $\hat{\mathbf{y}}_{\theta,B}[\omega]$ are both one-hot-encoding of 12 dimensions, they will be mapped as complex numbers of module 1 on the border of the CoF, $\hat{\mathbf{R}}_{\mathbf{y}_{\theta,A}, \mathbf{y}_{\theta,B}}[\omega]$ measures the difference of phases on the CoF. Then, $\mathcal{D}_{\theta,k}(\mathbf{x}_A, \mathbf{x}_B)$ measures its deviation from the DFT basis vector $e^{-2\pi i \omega k / Q}$, which corresponds to the actual pitch shift k on the CoF. This distance is differentiable with respect to the weight vector θ .

3.6 Invariance loss

Although the contents of \mathbf{x}_A versus \mathbf{x}_B may differ in terms of melody, rhythm, and instrumentation, we assume them to be in the same key. This implies that ChromaNet responses $\mathbf{y}_{\theta,A}$ and $\mathbf{y}_{\theta,B}$ should be maximally correlated at the unison interval $k = 0$ and decorrelated for $k \neq 0$. In other words, the CPSD at the frequency ω should be maximal; i.e., equal to one. Thus, given an arbitrary pitch interval c , we define an *invariance loss* \mathcal{L}_{AB} , defined as the distance between $T_c \mathbf{x}_A$ and $T_c \mathbf{x}_B$ on the CoF. We obtain⁴:

$$\mathcal{L}_{AB}(\theta | \mathbf{x}, c) = \mathcal{D}_{\theta,0}(T_c \mathbf{x}_A, T_c \mathbf{x}_B) \quad (6)$$

⁴ In this paper, we use the vertical bar notation so as to clearly separate neural network parameters on the left versus data on the right.

3.7 Equivariance loss

We want the model f_θ to be equivariant to pitch transpositions. Hence, we define an *equivariance loss* $\mathcal{L}_{c,k}^{AA}$ as the distance between $T_c \mathbf{x}_A$ and $T_{(c+k)} \mathbf{x}_A$ on the CoF:

$$\mathcal{L}_{AA}(\theta | \mathbf{x}, c, k) = \mathcal{D}_{\theta,k}(T_c \mathbf{x}_A, T_{c+k} \mathbf{x}_A). \quad (7)$$

In theory, setting the architecture of f_θ to a ChromaNet should lead to equivariance by design, for any value of the weight vector θ . Yet, in practice, we observed that some values of θ break this property of equivariance, likely due to boundary artifacts in 2-D convolutions—a similar observation to PESTO [9]. For STONE, only minimizing the invariance loss \mathcal{L}_c^{AB} causes the ChromaNet to collapse and predict a constant one-hot vector regardless of audio input \mathbf{x} under certain hyperparameter choices, particularly for $\omega = 1$. To prevent this collapse, we penalize f_θ with the equivariance loss in Equation 7.

3.8 Combined invariance and equivariance loss

In addition, we penalize f_θ according to the following loss:

$$\mathcal{L}_{BA}(\theta | \mathbf{x}, c, k) = \mathcal{D}_{\theta,k}(T_c \mathbf{x}_B, T_{c+k} \mathbf{x}_A), \quad (8)$$

i.e., the distance between ChromaNet responses $T_c \mathbf{x}_B$ and $T_{(c+k)} \mathbf{x}_A$ on the CoF. Observe that both these responses are already available after Equations 6 and 7. Therefore, the inclusion of Equation 8 in the loss comes at almost no extra computational cost during gradient backpropagation.

4. SELF-SUPERVISED KEY SIGNATURE PROFILES

4.1 Training on real-world unlabeled data

We collect 60k songs from the catalog of a music streaming service, with due permission. For each of them, we extract two disjoint segments \mathbf{x}_A and \mathbf{x}_B of duration equal to 15 seconds each. Following prior knowledge in music cognition [27], we set this duration to be as large as possible, considering the memory constraints of GPU hardware.

We implement ChromaNet and CPSD in PyTorch. The interval c (see Section 3.1) varies between zero and 15 semitones while the interval k (see Section 3.7) varies between -12 and 12 semitones. We define a CPSD-based stochastic loss function by combining Equations 6, 7, and 8:

$$\mathcal{L}^{\text{CPSD}}(\theta | \mathbf{x}, k, c) = \mathcal{L}_{AB}(\theta | \mathbf{x}, c) + \mathcal{L}_{AA}(\theta | \mathbf{x}, k, c) + \mathcal{L}_{BA}(\theta | \mathbf{x}, k, c), \quad (9)$$

where CQT samples \mathbf{x} and intervals c and k are drawn independently and uniformly at random. We train the ChromaNet for 50 epochs using a cosine learning rate schedule with a linear warm-up. We use an AdamW optimizer with a learning rate of 10^{-3} and a batch size of 128.

The self-supervised procedure above learns an approximately equivariant mapping from CQT to key signature profiles (KSP). After training, we observe informally that for each input \mathbf{x} , most of the softmax activation in the KSP \mathbf{y}_θ is concentrated on a single pitch class. In other words, the loss $\mathcal{L}^{\text{CPSD}}$ (Equation 9) is sparsity-promoting.

4.2 Calibration on a C major scale

By learning to predict pitch transpositions between segments, STONE learns the notion of relative tonality, just like the relative pitch of musicians; however, it lacks a notion of absolute tonality. Thanks to the equivariant property of ChromaNet, we only need to introduce this notion via a single recording of a C major scale paired with C major chords. This calibration procedure resembles previous work in self-supervised fundamental frequency estimation [9, 11].

Denoting the C:maj calibration sample by \mathbf{x}_{cal} , we look up the index of its highest KSP coefficient in STONE:

$$q_{\text{cal}}(\boldsymbol{\theta}) = \arg \max_{0 \leq q < Q} (g \circ f_{\boldsymbol{\theta}})(\mathbf{x}_{\text{cal}})[q]. \quad (10)$$

Then, given a CQT matrix \mathbf{x} from the test set, we realign its ChromaNet response $\mathbf{y} = (g \circ f_{\boldsymbol{\theta}})(\mathbf{x})$ via a pitch transposition of the learned KSP by $q_{\text{cal}}(\boldsymbol{\theta})$ semitones:

$$h_{\boldsymbol{\theta}}(\mathbf{y})[q] = \mathbf{y}[(q - q_{\text{cal}}(\boldsymbol{\theta})) \bmod Q]. \quad (11)$$

4.3 Evaluation on real-world labeled data (FMAK)

FMAK is a subset of Free Music Archive dataset [28] containing 5489 songs that present a clear key and are in major or minor modes. We label these songs by ear. Each of the 24 keys is represented in FMAK by at least 89 songs. C:maj and A:min are the best represented, while G#:maj and G#:min are the least represented. Songs are distributed in major and minor modes evenly. Rock and electronic dance music are the best represented genres; jazz and blues are the least represented. To our knowledge, FMAK stands as the largest and most diverse MIR dataset with key annotation.

4.4 Key signature estimation accuracy (KSEA)

In compliance with MIREX [29], we propose the following figure of merit for key signature estimation:

$$\text{KSEA}(\boldsymbol{\theta}) = \frac{1}{N} \sum_{n=0}^{N-1} \left(\boldsymbol{\delta}[s_n(\boldsymbol{\theta}) - s_n^{\text{ref}}] + \frac{1}{2} \boldsymbol{\delta}[|s_n(\boldsymbol{\theta}) - s_n^{\text{ref}}| - 6| - 1] \right), \quad (12)$$

where $s_n(\boldsymbol{\theta}) = \arg \max_{0 \leq q < Q} (h_{\boldsymbol{\theta}} \circ g \circ f_{\boldsymbol{\theta}})(\mathbf{x}_n)[q]$ and $\boldsymbol{\delta}$ is the Kronecker symbol. KSEA assigns a full point to the prediction if it matches the reference and a half point if the prediction is one perfect fifth above or below the reference.

4.5 Results on key signature estimation

We evaluate two variants of STONE on FMAK, all other things being equal: $\omega = 7$ (CoF) and $\omega = 1$. For comparison, we also evaluate the work of Korzeniowski *et al.*, the supervised state of the art (SOTA) for this task [21], a convnet trained on GSMK. Lastly, we evaluate a feature engineering pipeline, requiring no supervision: i.e., we take the global average of the chromagram representation and extract the pitch class with highest energy.

Table 1 summarizes our results. We observe that, for both values of the CPSD frequency ω , STONE outperforms the feature engineering baseline. Furthermore, for $\omega = 1$, the KSEA approaches that of the supervised SOTA.

Table 1. Evaluation of self-supervised models on FMAK. KSEA denotes key signature estimation accuracy. We also report the supervised state of the art (SOTA) for comparison.

	Correct	Fifth	KSEA
Feature engineering	1599	981	38%
STONE ($\omega = 7$)	3587	1225	77%
STONE ($\omega = 1$)	3883	920	79%
Supervised SOTA [21]	4090	741	81%

Table 2. Ablation study of STONE ($\omega = 7$) on FMAK. CPSD denotes cross-power spectral density. KSEA denotes key signature estimation accuracy. We report a naive baseline (i.e., predict the key signature of C:maj and A:min for every sample) for comparison.

	Correct	Fifth	KSEA
STONE ($\omega = 7$)	3587	1225	77%
w/o octave equivalence	1052	1267	31%
w/o CPSD	1049	1267	31%
Baseline (predict C)	1049	1267	31%

4.6 Ablation study

The two main novel components of STONE are the ChromaNet (Section 3.2) on one hand and cross-power spectral density (CPSD) over learned key signature profiles (KSP) on the other hand. In order to evaluate their relative performance, we conduct an ablation study: i.e., we substitute them by more conventional alternatives.

First, we replace the non-learned octave equivalence layer g (Equation 1) by a fully connected layer with same output size. Secondly, we replace the three CPSD-based losses (Equation 9) by 12-class cross-entropy losses. Intuitively, the first ablation disables equivariance in $f_{\boldsymbol{\theta}}$ while the second disables equivariance in \mathcal{L} . We observe that both ablations cause a collapse of SSL, leading it to predict the majority class (i.e., C:maj) on almost every sample. This suggests that both octave equivalence and CPSD are essential to the success of STONE.

5. SELF-SUPERVISED TONALITY ESTIMATION

5.1 Structured prediction

After having established that STONE learns to represent key signatures without any supervision, we turn to study its transferability to the well-known MIR problem of key estimation. For this purpose, we must accommodate the distinction between major and minor keys, thus doubling the output dimension of the ChromaNet from 12 to 24.

We note that key signature and mode are orthogonal concepts: each major key has exactly one relative minor and vice versa. These considerations suggest that the downstream task of key estimation may be formulated as structured prediction: i.e., in a 2-D label space. We encode structured labels in a matrix \mathbf{Y} with 12 rows and two columns.

Figure 2. We modify the ChromaNet architecture of Figure 1 to accommodate structured prediction key signature and mode. We apply batch normalization per mode m and softmax over all coefficients, yielding a 12×2 matrix $\mathbf{Y}_\theta(\mathbf{x})$. Summing $\mathbf{Y}_\theta(\mathbf{x})$ over modes m yields a learned key signature profile $\lambda_\theta(\mathbf{x})$ in dimension 12; summing $\mathbf{Y}_\theta(\mathbf{x})$ over chromas q yields a pitch-invariant 2-dimensional vector $\mu_\theta(\mathbf{x})$.

5.2 Batch normalization across key signatures

We modify the last layer of the ChromaNet f_θ to output two channels instead of one. We also redefine the non-learnable operator g for octave equivalence to accommodate two channels, apply batch normalization with non-learnable parameters on each channel, and a softmax nonlinearity over all batch-normalized coefficients. This procedure normalizes each channel to null mean and unit variance over the training set, thus ensuring that both channels are activated and thus prevents a form of collapse during self-supervision.

The composition of g and f_θ , under their new definitions, yields a matrix $\mathbf{Y}_\theta(\mathbf{x})$ with $Q = 12$ rows and two columns. By property of the softmax in g , all 24 coefficients in $\mathbf{Y}_\theta(\mathbf{x})$ are positive and sum to one. As illustrated in Figure 2, we take advantage of this property to derive a key signature estimator λ_θ and a mode estimator μ_θ , respectively defined as row-wise and column-wise partial sums of $\mathbf{Y}_\theta(\mathbf{x})$:

$$\lambda_\theta(\mathbf{x})[q] = \sum_{m=0}^1 \mathbf{Y}_\theta(\mathbf{x})[q, m] \quad (13)$$

$$\mu_\theta(\mathbf{x})[m] = \sum_{q=0}^{11} \mathbf{Y}_\theta(\mathbf{x})[q, m]. \quad (14)$$

We verify that the 12-dimensional vector $\lambda_\theta(\mathbf{x})$ is positive, sums to one, and is *equivariant* to pitch transpositions in $\mathbf{Y}_\theta(\mathbf{x})$. Conversely, the 2-dimensional vector $\mu_\theta(\mathbf{x})$ is positive, sums to one, and is *invariant* to pitch transpositions in $\mathbf{Y}_\theta(\mathbf{x})$. We use λ_θ as a substitute for $(g \circ f_\theta)$ in $\mathcal{L}^{\text{CPSD}}$.

5.3 Self-supervised mode estimation

We now introduce a loss for self-supervised mode estimation. To this aim, we posit that mode is not only constant throughout the musical piece, but also remains invariant by pitch transposition. Therefore, going back to the notations from Section 4: $T_c \mathbf{x}_A$, $T_c \mathbf{x}_B$, and $T_{c+k} \mathbf{x}_B$ should elicit the same value of the mode estimator μ_θ .

We recall the definition of binary cross-entropy (BCE) for 2-D vectors whose entries are positive and sum to one:

$$\text{BCE}(\boldsymbol{\mu}, \boldsymbol{\mu}') = -\boldsymbol{\mu}[0] \log \boldsymbol{\mu}'[0] - \boldsymbol{\mu}[1] \log \boldsymbol{\mu}'[1]. \quad (15)$$

We compute the pairwise BCE between mode estimator responses associated to the three predictions of the self-supervised ChromaNet (see Figure 1)⁵:

$$\begin{aligned} \mathcal{L}^{\text{BCE}}(\boldsymbol{\theta} | \mathbf{x}, c, k) &= \text{BCE}(\mu_\theta(T_c \mathbf{x}_B), \mu_\theta(T_c \mathbf{x}_A)) \\ &\quad + \text{BCE}(\mu_\theta(T_c \mathbf{x}_A), \mu_\theta(T_{c+k} \mathbf{x}_A)) \\ &\quad + \text{BCE}(\mu_\theta(T_c \mathbf{x}_B), \mu_\theta(T_{c+k} \mathbf{x}_A)). \end{aligned} \quad (16)$$

We add the BCE-based loss in Equation 16 to the CPSD-based loss in Equation 9, thus yielding a full-fledged loss for self-supervised tonality estimation (STONE):

$$\mathcal{L}(\boldsymbol{\theta} | \mathbf{x}, c, k) = \mathcal{L}^{\text{CPSD}}(\boldsymbol{\theta} | \mathbf{x}, c, k) + \mathcal{L}^{\text{BCE}}(\boldsymbol{\theta} | \mathbf{x}, c, k). \quad (17)$$

We train the modified ChromaNet to minimize \mathcal{L} with the same optimization hyperparameters as in Section 4.1. The resulting model, named 24-STONE, performs key signature estimation with λ_θ and mode estimation with μ_θ . However these estimators are uncalibrated: i.e., λ_θ only contains information of relative tonalities and μ_θ may swap relative major and minor. We calibrate them by means of a C:maj scale, via the same procedure as in Section 4.2.

5.4 Results on key and mode classification

We evaluate two variants of 24-STONE on FMAK: $\omega = 1$ and $\omega = 7$; as well as the supervised SOTA. We also evaluate the template matching algorithm of [17], requiring behavioral data but no supervision.

Table 3 summarizes our results. The 24-STONE model with $\omega = 7$ is best in the unsupervised category, although well below the supervised SOTA. However, setting ω to 1 dramatically hurts the MIREX score of 24-STONE, placing it below the naive baseline. Thus, formulating CPSD regression over the CoF (see Section 3.5) seems necessary for STONE to transfer to key and mode estimation, even so it is outperformed by $\omega = 1$ in KSEA (see Section 4.4). With this result in mind, we set $\omega = 7$ in the rest of this paper.

6. SEMI-SUPERVISED TONALITY ESTIMATION

6.1 Supervising the ChromaNet

Thanks to structured prediction, the ChromaNet accommodates supervised training in the same label space as self-supervised training. Note that the 24-STONE losses $\mathcal{L}^{\text{CPSD}}$ and \mathcal{L}^{BCE} involves pairwise comparisons between three items belonging to the same \mathbf{x} : i.e., two transposed versions of the same segment \mathbf{x}_A and one from another segment \mathbf{x}_B . In this context, a simple way to introduce supervision is to replace the responses $\lambda_{\theta, B}$ and $\mu_{\theta, B}$ by “oracles” λ_{ref} and μ_{ref} which are informed by the ground truth.

Given the ground truth key signature q_{ref} and mode m_{ref} , one-hot encoding yields the sparse vectors $\lambda_{\text{ref}, c}(\mathbf{x})[q] = \boldsymbol{\delta}[(q - q_{\text{ref}} - c) \bmod 12]$ and $\mu_{\text{ref}}(\mathbf{x})[m] = \boldsymbol{\delta}[m - m_{\text{ref}}]$, where c is a pitch interval in semitones (see Section 3.1). We use these oracles to write supervised variants of losses

⁵ Compared to $\mathcal{L}^{\text{CPSD}}$, we have swapped \mathbf{x}_A with \mathbf{x}_B in the first term. This is for compatibility with the supervised setting, as described in Section 6.1, so as to avoid an undefined BCE due to a logarithm of zero.

	Correct	Fifth	Relative	Parallel	Wrong	MIREX
Template matching [17]	2398	631	390	506	1564	53.4%
24-STONE ($\omega = 1$)	421	535	399	253	3881	15.6%
24-STONE ($\omega = 7$)	2443	628	1320	115	983	57.9%
Supervised SOTA [21]	3586	482	504	165	752	73.1%
Baseline (predict C : ma j)	551	568	498	286	3586	19.0%

Table 3. Evaluation of self-supervised models for key and mode estimation on FMAK. We also report the supervised state of the art (SOTA) [21] and a naive baseline (i.e., predict C : ma j for every sample) for comparison. See Section 5.4 for details.

\mathcal{L}^{CPSD} and \mathcal{L}^{BCE} . This seamless switch from SSL to supervised learning requires no change of architecture nor optimizer. Thus, instead of using supervision as fine-tuning, we propose an alternated scheme: one epoch of SSL followed by one epoch of supervised learning, and so on.

6.2 Semi-TONE and Sup-TONE

Introducing supervision into 24-STONE yields a semi-supervised tonality estimator, or Semi-TONE for short. We alternate between self-supervised epochs on 60k unlabeled recordings (see Section 4.1) and supervised epochs on the 1159 songs in GSMK in which annotators agree. For the sake of comparison, we experiment with disabling SSL and training the ChromaNet directly on GSMK: hence a fully supervised tonality estimator, or Sup-TONE for short.

To compare their ability to learn from limited labeled data, we retrain Semi-TONE and Sup-TONE after subsampling GSMK at random by factors of 10 and 100.

Figure 3. Evaluation of self-supervised (dashed blue), semi-supervised (solid blue), and supervised models (orange) on FMAK. All models use $\omega = 7$. We also report the supervised state of the art (SOTA) [21] in dashed green.

6.3 Results on key and mode classification

Figure 3 summarizes our results. We observe that Semi-TONE systematically outperforms Sup-TONE at any amount of training data. In particular, training Semi-TONE with 10% of GSMK leads to a comparable MIREX score as training Sup-TONE with 100% of GSMK. This result

Figure 4. Confusion matrices of STONE (left, 12 classes) and Semi-TONE (right, 24 classes) on FMAK, both using $\omega = 7$. The axis correspond to model prediction and reference respectively, keys arranged by proximity in the CoF and relative modes. Deeper colors indicate more frequent occurrences per relative occurrence per reference key.

confirms the interest of our proposed pretext tasks towards the overarching goal of reducing human annotation effort.

Training Semi-TONE on the full GSMK dataset yields a MIREX score of 72.6%; i.e., roughly on par with the supervised SOTA (73.1%). Figure 4 shows the confusion matrix of calibrated STONE and Semi-TONE on FMAK. Although our methods do not outperform the SOTA on key estimation, it brings insights into a novel framework that does not require high supervision for training. Moreover, we note that self-supervision remains beneficial even when the full GSMK dataset is available for training. Therefore, a promising avenue of research is to scale up the dataset of unlabeled recordings (see Section 4.1), thus widening the gap between Semi-TONE and Sup-TONE on FMAK.

7. CONCLUSION

STONE learns key signature profiles (KSP) via equivariant self-supervised learning in the time–frequency domain. We have seen that a semi-supervised extension of STONE (semi-TONE) reduces expert annotation by 90% less at no loss of MIREX score compared to the fully supervised variant (sup-TONE). The primary limitation of our work resides in the inability of the STONE objective (CPSD, i.e., cross-power spectral density) to distinguish major keys from minor keys. Future work will study how STONE can be adapted to other pitch-relative MIR tasks.

BEAT THIS!

ACCURATE BEAT TRACKING WITHOUT DBN POSTPROCESSING

ABSTRACT

We propose a system for tracking beats and downbeats with two objectives: generality across a diverse music range, and high accuracy. We achieve generality by training on multiple datasets – including solo instrument recordings, pieces with time signature changes, and classical music with high tempo variations – and by removing the commonly used Dynamic Bayesian Network (DBN) postprocessing, which introduces constraints on the meter and tempo. For high accuracy, among other improvements, we develop a loss function tolerant to small time shifts of annotations, and an architecture alternating convolutions with transformers either over frequency or time. Our system surpasses the current state of the art in F1 score despite using no DBN. However, it can still fail, especially for difficult and underrepresented genres, and performs worse on continuity metrics, so we publish our model, code, and preprocessed datasets, and invite others to beat this.

1. INTRODUCTION

Beat tracking is the task of estimating the temporal locations of musical beats in an audio signal. It is often combined with the downbeat tracking task, which targets a higher metrical level: tracking the beginning of each measure. Despite being one of the long-standing problems in the Music Information Retrieval (MIR) field, it still attracts attention and several approaches were proposed in recent years [1–8]. Most recent work follows a common pipeline: the audio files are transformed into some spectrogram-like representation, then a deep neural network predicts frame-wise beat and downbeat probabilities, which are postprocessed to obtain the final predictions. The most widely used postprocessing technique is the Dynamic Bayesian Network (DBN) in the form proposed by Böck et al. [9]. It addresses four tasks: variable threshold peak-picking, forcing the tempo to stay in a certain range (i.e., limiting the allowed distance

between beats), limiting sudden tempo changes, and (for downbeat tracking) ensuring that the downbeat falls every n beats, where n is constant for a piece of music and is selected from a limited list of values.

We argue that the DBN is a problematic component because it is inherently bound to fail for several music pieces: pieces with time signature changes, pieces whose tempo falls outside of the tempo range (or that slow down/speed up outside the tempo range), and pieces whose number of beats per measure are not included in the list of supported values. Moreover, it has a fixed parameter controlling allowed tempo variations, although we can expect, for example, classical music to have bigger tempo variability than rock music. Finally, even the hypotheses of having periodic beats and downbeats may be invalid, for example, for songs where the players make mistakes or audio tracks containing multiple concatenated songs.

Still, the DBN performs well on most pieces commonly used to train and evaluate beat tracking systems: music with a constant time signature of 3/4 or 4/4 and a stable, medium tempo. This can be seen from the default DBN parameters which most systems use,¹ i.e., tempo range [55, 215] BPM, beats per measure [3, 4], and a tempo variability optimised on pop, rock and dance datasets. Pieces outside these specifications are likely to be mispredicted by the system, but form a minority in typical datasets. Therefore, in terms of evaluation metrics, it usually does not pay to remove the DBN. However, working in these “simplified” conditions blocks research from solving corner cases in existing datasets and targeting more challenging or diverse data.

Our first goal is thus to replace the DBN with minimal postprocessing, free of the aforementioned musical assumptions. A recent attempt to remove the DBN was made by Chen and Su [2]. However, their system may not look appealing to practitioners requiring beat tracking for downstream tasks, or researchers seeking a system to improve, as its accuracy falls clearly behind DBN-based ones.

Our second goal is to provide a powerful basis for practitioners and researchers. The current best-performing system (which uses a DBN) from Hung et al. [10] falls short in this regard, as its code or a pretrained model is not public, its architecture is very complex, and (to the best of our knowledge) the results could not be reproduced by others.

* Equal contribution.

¹ We could verify that [3, 4, 8] use these parameters, since their code is publicly available, and we assume [1, 10] do as well, since they do not mention any details in their paper.

In this paper, we present an open-source system that obtains new state-of-the-art F1 scores without a DBN. It is based on a rotary transformer [11] applied on spectrograms, with the following novelties: (1) We design a frontend alternating convolutions with a transformer variant by Lu et al. [12] that attends alternatively over frequency bins or time frames. (2) We train with a shift-tolerant binary cross-entropy (BCE) that can cope with small deviations in the beat/downbeat annotations, and with weights on beat/downbeat frames to balance their relative scarcity. (3) We propose an approach that encourages downbeat predictions to be a subset of beat predictions, and (4) a data augmentation masking input segments to encourage the network to consider a longer context. Our code, pretrained models, and preprocessed datasets are openly available.²

2. RELATED WORK

The currently best-performing model (on the GTZAN dataset [13] commonly used for evaluation) is by Hung et al. [10] and serves as a point of comparison. It uses a complex neural network architecture named SpecTNT which alternates computing frequency-related features with a frequency-oriented transformer, and processing a virtual extra frequency band with a time-oriented transformer. This runs in parallel with a more widely used Temporal Convolutional Network (TCN, a fully convolutional network with dilated convolutions), and the outputs of the two networks are merged for the final predictions. Unfortunately, the approach is not open source, and to the best of our knowledge, no other research group has managed to reproduce its results. Moreover, it still uses the DBN, which, as argued in the introduction, limits the system’s generality.

Although no other work could reach the accuracy reported by Hung et al., two other recent beat tracking papers brought new interesting ideas [3, 4]. Both perform instrument separation (with a pretrained network) and feed the separate stems (bass, drums, vocals, other, for [3] also piano) into the model, mixing their information in cross-instrument attention blocks. While this approach is very reasonable from a music perception standpoint, it reduces the generality of the system, since it assumes that the input pieces will contain such instruments, at least to some extent. Another proposal of [3, 4] is the use of dilated attention, following the successful use of dilated convolutions in beat-tracking architectures to increase the receptive field without adding computations. We find that flash attention [14] enables us to train with dense attention over a satisfactorily large input size, and leave experiments with dilated attention for future work.

Chen and Su [2] try to remove the DBN and propose a set of improvements. The most impactful is to replace the BCE with the Dice [15] and Focal [16] loss, inspired by their common usage for medical image segmentation. While these losses improve results, possibly due to their inherent ability to handle unbalanced classes, we found that a BCE with weights on the positive (beat and downbeat)

classes outperforms them. We suspect this is because, in contrast to medical image segmentation, our positive examples are single frames, and the Dice and Focal loss perform better when the area of positive predictions is larger [17]. Another proposal by Chen and Su is to predict the phase of the beat/downbeat instead of a single binary value, following [18]. Although this seems promising, the results on both papers (and ours) do not show any consistent improvement.

Many recent approaches [2, 3, 18, 19] use the additional task of tempo prediction (a single tempo target for each input excerpt) in a multi-task setting. While this improves their results, it goes against our goals of generality, since it assumes an (almost) constant tempo in the file excerpt, which is not the case for many kinds of music.

Other recent papers do not align with the goal of this paper: [1] explores the usage of different time resolutions between the input audio and output predictions (only addressing beats); [8] performs unsupervised beat tracking; [20] focuses on online beat tracking; [5] notices the problems of the DBN for music with tempo changes, and proposes a different postprocessing method targeted specifically to classical music; [7] focuses on fine-tuning existing systems, and changing the DBN parameters for targeting specific underrepresented genres.

3. METHOD

Our beat tracker is based on a neural network with ~ 20 M parameters. It starts from 30 seconds of mono audio sampled at 22.05 kHz and converts it to a 128-bin mel spectrogram from 30 Hz to 10 kHz, with a window size of 1024 and hop size of 441 samples (yielding 50 frames per second), and magnitudes scaled via $\ln(1 + 1000x)$ (similar to $\ln(\max(10^{-3}, x))$, but maps silence to zero). These hyperparameters were optimised in preliminary experiments. Our model processes this into frame-wise beat and downbeat probabilities, followed by minimal post-processing to derive beat and downbeat locations.

3.1 Model

Our model (Figure 1) processes a $T \times 128$ spectrogram into $T \times 2$ probabilities; T being the number of input frames (1500 in case of 30 s). It consists of three components: a frontend converting the spectrogram into a sequence of feature vectors, a transformer processing these vectors, and two task heads computing the output probabilities.

3.1.1 Frontend

The frontend’s role is to integrate information across the 128 frequency bands into feature vectors. Typically, this is done via 2d convolutions gradually reducing the number of bands to 1 while increasing the number of channels [3, 10]. We adopt this, but found it helps to interleave convolutions with *Partial Transformers*, which treat the time and frequency axis independently. Overall, our frontend consists of a stem, three identical blocks, and a linear projection.

The stem (Figure 1, top right) starts with a batch normalisation that processes each frequency band separately

²https://github.com/CPJKU/beat_this

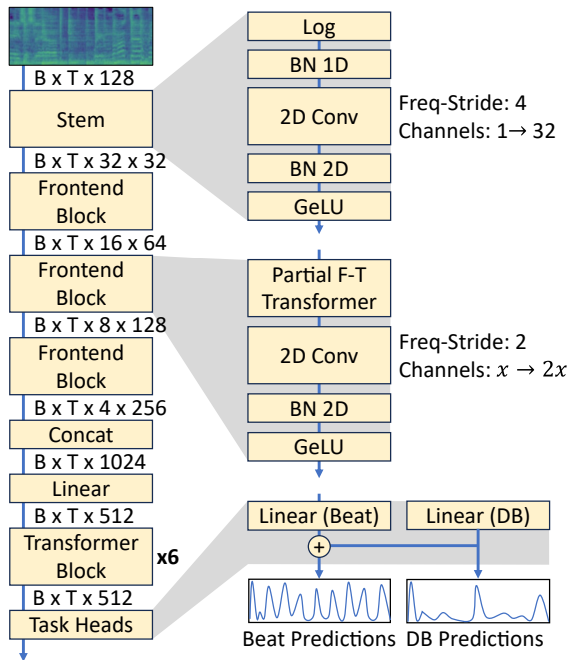

Figure 1: Full model architecture.

to homogenise them, followed by a 2d convolution of 3×4 kernels, regular batch normalisation, and GeLU nonlinearity. The convolution is strided to reduce the number of frequency bands to a fourth and creates 32 channels.

Each block (Figure 1, middle right) consists of two partial transformers, a strided 2d convolution halving the number of bands while doubling the number of channels, batch normalisation and GeLU. The first partial transformer is *frequency-directed*, i.e., it processes the $T \times F \times C$ tensor by treating each time frame as a sequence of length F (the number of bands), the second one is *time directed* and treats each frequency band as a sequence of length T (the number of frames), an idea adopted from the Band Split RoFormer [12]. Each transformer has a head size of 32 (one head in the first frontend block, two in the second, four in the third), rotary positional embedding [11], a sigmoid gate per head [21, Sec. 4.2], and includes a usual pointwise feedforward network with a hidden size of four times the channel count.

After three frontend blocks, the resulting $T \times 4 \times 256$ tensor (4 bands, 256 channels) is reshaped to a $T \times 1024$ tensor and linearly projected to 512 features.

3.1.2 Transformer

The transformer makes up the bulk of our model’s parameters and compute. It consists of 6 stacked transformer blocks processing the 512-dimensional vectors with 16 heads of size 32, rotary positional embedding, sigmoid gating, and a pointwise feedforward network of 2048 hidden units. This matches the configuration in the frontend transformer blocks, but as it processes a single sequence of 512-dimensional feature vectors, it is a regular transformer over time without separately considering a frequency dimension. Its goal is to map the 512 input features to a space that relates to beats and downbeats. Due to the attention

mechanism, the transformer’s receptive field covers the full sequence, and it could therefore produce an output that has characteristics that we want in the beat predictions, for example, regularity.

3.1.3 Task Heads

The output of the final transformer block is processed by two linear layers, one for beats and one for downbeats. Initially, we used the common approach of passing their output into 2 sigmoid functions to produce a probability for each input frame, and then threshold this probability at 0.5 to obtain "hard" beat predictions. However, we observe that this sometimes produces downbeat predictions not coinciding with a beat prediction, which is allowed under the evaluation metrics but is a musically invalid and unusable output. This problem is solved when using a DBN to jointly process beats and downbeats. However, we noticed that several works, e.g., [3,6], use two independent DBNs to predict beats and downbeats (and others [2,10] do not specify). To our surprise, this leads to better metrics, but it severely limits practical use.

To mitigate this problem, we propose a *Sum Head* that sums the output of the beat and downbeat layers, and treats this as the beat logits (for prediction and training). This is a very simple way of helping the network produce a beat when there is a downbeat (though it does not enforce that; a highly negative output of the beat layer can still counter the downbeat layer). We explored other ways of aggregating the beat and downbeat logits, like taking their maximum, but this hampered training due to the sparser gradients. On the GTZAN dataset, the sum head almost halves the percentage of downbeats that are more than 70 ms away from the closest beat, from 1.1% to 0.62%, compared to directly using the output of the linear layers. We observe that the remaining unmatched downbeats are in pieces with very erratic predictions that would be incorrect anyway.

Some systems circumvent the problem by using a 3-way classifier (beat vs. downbeat vs. none) instead of the two binary classifiers (beat vs. none, and downbeat vs. none). However, to be able to train on datasets that do not include downbeat annotations, we stick to binary classifiers.

3.2 Postprocessing

To obtain beat/downbeat locations, we pick all frames assigned the highest beat/downbeat probability within a neighborhood of ± 3 frames (± 70 ms), and probability > 0.5 . In case adjacent frames are assigned the same probability, we report their center. Finally, we move all downbeat predictions to the closest beat prediction to correct the remaining mismatches described in the previous section. For music pieces longer than 30 s, we concatenate predictions over non-overlapping 30-second excerpts.

3.3 Loss

The model is trained by gradient descent on a loss function that compares the frame-wise beat and downbeat predictions with frame-wise binary annotations. The usual loss for binary classification is Binary Cross-Entropy,

Figure 2: The standard binary cross-entropy loss (left plot) encourages high network outputs (upward arrow) at beat annotations (vertical line), and low outputs for all other frames (downward arrows). Max-pooling the predictions over time redistributes gradients to local maxima (right plot). This way, slightly shifted annotations do not affect learning, and the network produces confident sharp peaks.

$L_{\text{bce}}(\mathbf{y}, \hat{\mathbf{y}}) = -\sum_t y_t \log(\hat{y}_t) + (1 - y_t) \log(1 - \hat{y}_t)$. Training with BCE leads to unconfident predictions since the problem is heavily imbalanced. To counter this, we can weight positive examples by a factor w as $L_{\text{wbce}}(\mathbf{y}, \hat{\mathbf{y}}, w) = -\sum_t w y_t \log(\hat{y}_t) + (1 - y_t) \log(1 - \hat{y}_t)$. We found that setting w to the number of negative examples divided by the number of positive examples (over the training set) yields the best result and is crucial when not using a DBN.

Another problem persists: annotations are not precise down to our spectrogram resolution, due to annotators’ imprecision, players’ asynchronicity, or simply the limits of human perception. This is taken into account during the evaluation, e.g., the typically used F1 score accepts predictions in a ± 70 ms window around labels. During training, the BCE loss punishes close positive predictions (Figure 2, left) even though they may be correct, thus creating two problems: training is slower and the network learns to predict wide “blurred” peaks. This is commonly addressed by adding two extra positive labels around each annotation weighted by 0.5, but this only mitigates the former problem without helping with the latter. Instead, we max-pool predictions over time (7 frames, stride 1) before comparing them to the labels. In this way, only the largest positive prediction ± 3 frames from each label is considered (Figure 2, right). The loss for negative examples is ignored ± 6 frames from each label, as this is how far a max-pooled prediction 3 frames away from a label spreads. Denoting max-pooling of k frames with $m_k(\cdot)$, we can formalise our *Shift-tolerant weighted BCE* as: $L_{\text{st}}(\mathbf{y}, \hat{\mathbf{y}}, w) = -\sum_t w y_t \log(m_7(\hat{\mathbf{y}})_t) + (1 - m_{13}(\mathbf{y})_t) \log(1 - m_7(\hat{\mathbf{y}})_t)$.

3.4 Data Augmentation

Masking. To encourage the model to not only rely on local information for its predictions, we mask 0 to 6 areas of 0.5 to 2 s. Each masked area is randomly divided into 5 to 10 parts which are randomly reordered. This destroys local correspondence between audio and beats without changing local input statistics, and works better than zero masking as employed in SpecAugment [22]. We assume our approach makes it harder for the network to learn a dedicated behaviour for masked areas.

Pitch and time. We speed up and slow down every song by 20, 16, 12, 8, and 4%, and transpose by at most +6 and -5 semitones. We precompute these augmentations (us-

ing Pedalboard [23]) so experiments become reproducible without access to the original audio. To limit storage use, tempo and pitch augmentations are not combined, giving 22 variations for each song. We verified that our limited tempo augmentation gives comparable results to the commonly used approach by Böck and Davies [19] of performing on-the-fly augmentations by randomly changing the hop size of the STFT, at the advantage of not requiring audio access.

4. EXPERIMENTS

We perform 8-fold cross-validation experiments on multiple datasets, compute results on the test-only GTZAN dataset, and do an ablation study.

We use the standard beat-tracking metrics: F1, CMLt, and AMLt and compute them using the `mir_eval` package [24] with default parameters.³ CMLt and AMLt are called continuity metrics, and only consider a beat/downbeat as correct if both it and the previous beat/downbeat are correct; AMLt also accepts different metrical levels such as half or double time, and offbeats [25]. The metrics and their settings match those used by Hung et al. [10]; this enables a comparison with their reported results, though it is unclear which 8-fold dataspit they use, and we cannot run any statistical significance tests since their code is not reproducible. Therefore, any comparison needs to be taken only as an indication.

4.1 Datasets

We train and validate with several datasets: Simac [26], SMC [27], Hainsworth [28], Ballroom [26, 29], HJDB [30], Beatles [31], Harmonix [32], RWC [33, 34] (classical, pop, royalty-free, and jazz), TapCorrect [35], JAAH [36], Filosax [37], ASAP [38], Groove MIDI [39], GuitarSet [40], Candombe [41]. The first two datasets contain only beat annotations, all others both beat and downbeats. We discard one Beatles piece which does not contain downbeat annotations and one with empty beat annotations, resulting in a total of 4556 tracks. For comparison, Hung et al. [10] train with only the first 7 datasets reported above (Simac to Harmonix), plus RWC pop, for a total of 3144 pieces (when assuming the same handling of missing annotations). We use the GTZAN [13] dataset (993 pieces discarding one unannotated track and 6 tracks that miss downbeat annotations) for testing only.

We use only the backing tracks of Filosax without the saxophone solos. For ASAP, we discard the tracks that contain the “rubato” beat annotations. In Groove MIDI, we keep all pieces that are longer than 20 seconds and use the provided audio renderings. We only use the comping tracks of GuitarSet, discarding the solos.

We employ the *8-fold cross-validation splits* published by Böck and Davies [19] for the datasets they used and produce new ones for our added datasets, ensuring different versions of the same piece are not spread across folds, and

³This includes “trim_beats” of 5s that discards the first 5 seconds during the evaluation, which is a choice we do not necessarily approve of, but we use it to be consistent with what seems the standard way of evaluating.

stratifying by metadata when possible. We also produce a new *single split* with $\sim 15\%$ of the pieces on each dataset as validation (again taking care of different versions of the same piece).

4.2 Training

We train for 100 epochs with gradient accumulation over 8 batches of size 8,⁴ AdamW optimizer [42], weight decay of 0.01 (excluding biases and learned norms), learning rate warm-up [43] of 1000 steps to a maximum of 0.0008, and cosine annealing. During each epoch, we randomly sample 30 seconds of each piece, and pad if the total piece duration l is less than 30 seconds. We draw k samples from pieces that are longer than 30 seconds, following the equation $k = \text{round}(\alpha \cdot l/30)$ with $\alpha = 0.65$, since we observe it leads to faster convergence than using one random sample per piece, or $l/30$ non-overlapping samples. On average, this yields ~ 3 samples per piece. During training, every time a sample is drawn, we randomly select a precomputed augmentation described in Section 3.4, and apply masking. The full training takes around 8 hours on a single NVIDIA RTX 2080 Ti, 6 hours on A40, and 4 hours on A100.

During our experimentation, we found that to achieve good results without a DBN, we need our network to be overconfident in its predictions. This may seem to violate usual deep learning practice, but can be explained by a closer look at the beat tracker’s desirable output. We do not want our network to produce probabilities close to 0.5 when unsure, since this will lead to random oscillations between positive and negative predictions, and thus erratic beats. Instead, we want it to give steady, high-probability predictions even when unsure, exactly like the DBN would. To achieve this, we keep training even after the validation loss starts increasing, which would typically indicate overfitting. Indeed, we see that the validation F1 score continues to improve even with increasing validation loss. This means that even with our modifications, the BCE loss is not a good indicator of the F1 score, and further research into alternative losses may be valuable.

The reader may wonder why, once we obtain our well-performing network, we do not use the DBN to increase the metrics even more. By having overconfident predictions, we reduce the benefits of such a postprocessing method. With a degree of simplification, we can imagine the DBN as using a model’s most high-confident predictions to infer beats in low-confidence areas. By avoiding the low-confidence predictions, we are disrupting this mechanism.

4.3 Main Results

We report the results on our 18 datasets in the commonly used 8-fold cross-validation setting: each dataset is split into 8 parts, we jointly train on $18 \cdot 7$ parts (all but one per dataset) and predict on the remaining 18, after 8 such runs we covered all pieces and average metrics over pieces by dataset. We observe that our model outperforms Hung et al. [10], except for Harmonix and RWC Pop (downbeat). In

	Beat F1		Downbeat F1	
	Our	Hung	Our	Hung
ASAP	76.3	-	61.2	-
Ballroom	97.5	96.2	95.3	93.7
Beatles	94.5	94.3	88.8	87.0
Candombe	99.7	-	99.7	-
Filosax	99.5	-	98.5	-
Groove MIDI	93.7	-	82.1	-
GuitarSet	92.0	-	88.1	-
Hainsworth	91.9	87.7	80.0	74.8
Harmonix	95.8	95.3	90.7	90.8

RWC RF	94.5	-	91.9	-
Simac	77.9	-	-	-
SMC	62.7	60.5	-	-
TapCorrect	93.0	-	86.4	-

Table 1: Results with 8-fold cross-validation.

our results, the lowest downbeat performance is obtained in the ASAP and RWC Classical datasets, confirming the well-known difficulty of beat-tracking classical music [2, 5]. Performance on SMC (where only beat annotations are accessible) is also very low, consistent with the outcomes of other systems, highlighting the substantial room for improvement that beat tracking systems continue to hold.

We also report the results on the GTZAN dataset in Table 2. We compute these results with a single model trained on the entirety of our training-val dataset (note that we do not perform any early stopping or other techniques for which the validation dataset may still be necessary). All our runs are computed 3 times with different random seeds, and we report the means and standard deviations of the computed metrics over the 3 seeds. We notice that even when training on the reduced collection of datasets by Hung et al. (third row in the table), we still outperform their F1 score without a DBN, proving the effectiveness of our design choices. Our main model has ~ 20 M parameters, 5 times more than Hung et al. with 4 M, so we also show the results for a smaller model with the hidden dimension of the main transformer blocks reduced from 512 to 128, and the number of heads from 16 to 4. This small model has ~ 2 M parameters and still gives SOTA F1 scores.

Disappointingly, we notice that the continuity metrics (CMLt and AMLt) are lower than those of Hung et al. From qualitative inspections of the results, we notice that for complex or underrepresented pieces, our network introduces non-periodic beats, which drastically lower the continuity metrics. We are then brought to wonder why our network cannot learn a supposedly obvious behaviour, such as only producing periodic-like output, and we can propose two explanations. Firstly, our loss does not specifically penalise non-periodic predictions, but treats each beat individually.

⁴ This enables training with under 8 GiB of GPU memory.

	Beat			Downbeat		
	F1	CMLt	AMLt	F1	CMLt	AMLt
Hung et al. [10]	88.7	81.2	92.0	75.6	71.5	88.1

Table 2: Evaluation on the test dataset (GTZAN). The results for Hung et al. [10] are taken from their paper.

	Beat F1	Downbeat F1
Our system	92.6 ± 0.1	85.4 ± 0.1
No sum head	92.6 ± 0.1	85.0 ± 0.1
No tempo augmentation	92.5 ± 0.1	84.9 ± 0.1
No mask augmentation	92.2 ± 0.0	84.5 ± 0.3
No partial transformers	92.2 ± 0.1	83.9 ± 0.2
No shift tolerance	91.2 ± 0.2	82.2 ± 0.4
No pitch augmentation	88.3 ± 0.4	80.8 ± 0.5
No shift tol., no weights	79.5 ± 0.7	68.7 ± 0.8

Table 3: Ablation studies on the single split validation dataset, ordered by decreasing downbeat F1.

This results in a discrepancy between what is preferred by continuity metrics and what the network learns to predict in difficult parts to minimise the loss. Secondly, our datasets contain several non-periodic annotations, some due to quality issues (see Section 4.5), some in correctly annotated pieces such as tapcorrect_10 or beatles_Wild-Honey-Pie, where a 2/4 measure in the middle of a 4/4 piece disrupts the assumption of periodicity for downbeats. Finally, one could also question the generality of the AMLt metric as a tool to quantify double/half-time errors, since the computations of different metrical levels assume that the time signature and the tempo do not change and that a measure can always be divided into 2 or 3 parts.

Using a DBN increases our CMLt downbeat performance by correcting some of the (wrongly) non-periodic outputs, but it reduces our F1 performance, by changing other otherwise correct predictions that fall outside the DBN assumptions. The AMLt score does not increase since our network is overconfident in its predictions, and the DBN cannot easily switch to another metrical level.

4.4 Ablation Studies

We ablate multiple components of our model on the single split described in Section 4.1. We perform every experiment 3 times with different seeds and report the mean and standard deviation on the validation set in Table 3. The usage of our Sum Head shows little impact, but we use it to have a musically valid output, rather than to increase the F1 score. Pitch, mask, and tempo augmentations help, in this order of importance. The usage of partial transformers in our front-end proves more effective than only having convolutions. Our most impactful design choice is the weighted shift-

tolerant loss. Using a normal BCE with positive example weights results in decreased performance, which decreases even further when the weights are removed.

4.5 Notes on Dataset Quality

While exploring the datasets, we found multiple problems in the annotations, and we think this hinders the development of better models, especially for downbeat predictions. Even the GTZAN dataset, which is commonly used for evaluation, is not immune to quality problems. Some of them are evident and not debatable, like jazz_00000, jazz_00002, jazz_00083, blues_00015, reggae_00095, classical_00077, rock_00067. Furthermore, there are pieces where even for experts it would be hard to agree on a unique beat and downbeat annotation, like metal_00081 or classical_00056, and multiple annotations would be necessary. Finally, some pieces question the primary assumption of beat tracking, i.e., that there is a beat/downbeat to track, like pop_00064, and jazz_00003.

5. CONCLUSIONS AND OUTLOOK

In this paper, we presented a new beat tracking system which obtained a state-of-the-art F1 score on a very diverse set of music, with minimal assumptions about the tempo, time signature, and their changes over time. Remarkably, we do not use the DBN postprocessing, which was employed by all recent high-accuracy models. However, removing the DBN hurts the CMLt and AMLt metrics. A study on how this trade-off affects human perception, alternative metrics, and a direct comparison with DBN-based models on complex pieces is left for future work.

We emphasise that beat tracking is not a solved problem, even for commonly targeted genres such as rock or electronic music, especially for the downbeat tracking task. We provide an open-sourced model that can be used as a starting point, and we invite future researchers to improve it. Potential directions are: reducing the model parameters, developing new losses that enforce periodicity during training, using other data augmentation techniques to make the system more robust to multiple sound conditions, fine-tuning it on specific genres, and training on larger datasets. The contribution of people with musical expertise will also be essential, as we think that correcting the existing commonly used datasets, and producing new annotated data for under-represented genres is a crucial step for further development.

6. ACKNOWLEDGEMENTS

This work was supported by the European Research Council (ERC) under the EU’s Horizon 2020 research & innovation programme, grant agreement No. 101019375 (*Whither Music?*), and the Federal State of Upper Austria (LIT AI Lab). The computational results presented were achieved in part using the Vienna Scientific Cluster (VSC).

Papers – Session VII

SCORING TIME INTERVALS USING NON-HIERARCHICAL TRANSFORMER FOR AUTOMATIC PIANO TRANSCRIPTION

Yujia Yan, Zhiyao Duan

University of Rochester, Rochester, New York, USA,
yujia.yan@rochester.edu, zhiyao.duan@rochester.edu

ABSTRACT

The neural semi-Markov Conditional Random Field (semi-CRF) framework has demonstrated promise for event-based piano transcription. In this framework, all events (notes or pedals) are represented as closed time intervals tied to specific event types. The neural semi-CRF approach requires an interval scoring matrix that assigns a score for every candidate interval. However, designing an efficient and expressive architecture for scoring intervals is not trivial. This paper introduces a simple method for scoring intervals using scaled inner product operations that resemble how attention scoring is done in transformers. We show theoretically that, due to the special structure from encoding the non-overlapping intervals, under a mild condition, the inner product operations are expressive enough to represent an ideal scoring matrix that can yield the correct transcription result. We then demonstrate that an encoder-only non-hierarchical transformer backbone, operating only on a low-time-resolution feature map, is capable of transcribing piano notes and pedals with high accuracy and time precision. The experiment shows that our approach achieves the new state-of-the-art performance across all subtasks in terms of the F1 measure on the Maestro dataset. **See appendix for post-camera-ready updates.**

1 Introduction

Automatic Music Transcription (AMT) transforms the audio signal of music performances into symbolic representations [1]. In this work, we focus on transcribing piano performance audio into its piano roll representation.¹ The piano roll representation, as formulated in [2], can be abstracted as consisting of sets of non-overlapping time intervals of the form [onset, offset], with each set corresponding to one particular event type, e.g., a specific note or pedal.

Recent strategies to handle the problem of outputting this structured representation fall into three main categories: 1) Keypoint detection and assembly: This approach involves identifying the onsets, offsets, and frame-wise activations of notes and then assembling these elements together with a handcrafted post-processing step. Examples include [3–5];

Duan, “Scoring Time Intervals using Non-Hierarchical Transformer for Automatic Piano Transcription”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

2) Structured prediction with a probabilistic model: Models in this category use a probabilistic model to ensure the structure of the output to be sets of non-overlapping intervals, e.g., [2, 6, 7]; 3) Sequence-to-sequence (Seq2Seq) methods²: These methods, such as [8], treat music transcription as a machine translation problem, which translates audio to tokens that encode the target symbolic representation.

Our study focuses on the neural semi-Markov Conditional Random Field (semi-CRF) framework [2] from the second category, which directly models each music event (note or pedal) as a closed time interval associated with a specific event type. The approach employs a neural network to score interval candidates and uses dynamic programming to decode non-overlapping intervals. This framework eliminates the need for separate keypoint detection and assembly steps in the first category but outputs the events (intervals) in a single stage. Compared to other methods in the second category, e.g. [6, 7], it does not need hand-crafted state definitions and state transitions. Additionally, it benefits from optimal decoding in a non-autoregressive fashion as opposed to the slow autoregressive and suboptimal decoding in Seq2Seq methods (the third category).

This paper builds upon, simplifies, and improves the neural semi-CRF framework [2] for piano transcription. Our major contributions are as follows. First, we replace the original scoring module that assigns a score for every possible interval with a simpler and more efficient pairwise inner product operation. Specifically, we prove that due to the special structure of encoding non-overlapping intervals, under a mild condition, the inner product operation is expressive enough to represent an ideal scoring matrix that can yield the correct transcription decoding. Second, inspired by the resemblance between the proposed inner product operation and the attention mechanism in the transformer [9], we use the transformer architecture to produce the interval representation for inner product scoring. We demonstrate that an encoder-only non-hierarchical transformer backbone, operating only on a low-time-resolution feature map, is capable of transcribing notes with high accuracy and time precision. Third, we compare our method against state-of-the-art piano transcription systems on the Maestro v3 dataset, showing that our method establishes the new state of the art across all subtasks in terms of the F1 score.

² Strictly speaking, the Seq2Seq approach can also be categorized as a probabilistic model for structured prediction. We isolate it here for simplifying the discussion.

2 Related Work

2.1 Neural Semi-CRF for Piano Transcription

Previous work of [2] introduced a neural semi-Markov Conditional Random Field (semi-CRF) framework for event-based piano transcription, where each event (note or pedal) is represented as a closed interval associated with a specific event type. The approach employs a neural network to score interval candidates and uses dynamic programming to decode non-overlapping intervals. After interval decoding, interval-based features are used to estimate event attributes, such as *MIDI velocity* and *refined onset/offset positions*³.

The neural semi-CRF can be viewed as a general output layer, similar to a softmax layer, but tailored for handling non-overlapping intervals. For a sequence of T frames, let \mathcal{Y} denote a set of non-overlapping closed intervals. The semi-CRF layer for \mathcal{Y} takes two inputs for each event type:

1. $score(i, j)$: A $T \times T$ triangular matrix that scores every candidate interval $[i, j]$ for inclusion in \mathcal{Y} . The diagonal values $score(i, i)$ represent single-frame events.
2. $score_\epsilon(i - 1, i)$: A $(T - 1)$ -dimensional vector that assigns a score to every interval $[i - 1, i]$ not covered by any interval in \mathcal{Y} , serving as an inactivity score.

Both $score(i, j)$ and $score_\epsilon(i - 1, i)$ are computed using a neural network from the audio input \mathcal{X} . The total score for \mathcal{Y} , given \mathcal{X} , is:

$$\Phi(\mathcal{Y}|\mathcal{X}) = \sum_{[i,j] \in \mathcal{Y}} score(i, j) + \sum_{\substack{[i-1,i] \\ \text{not covered} \\ \text{in } \mathcal{Y}}} score_\epsilon(i - 1, i). \quad (1)$$

For inference, maximum a posteriori (MAP) is used to infer the optimal set of non-overlapping intervals \mathcal{Y}^* :

$$\mathcal{Y}^* = \arg \max_{\mathcal{Y}} \Phi(\mathcal{Y}|\mathcal{X}). \quad (2)$$

For training, the maximum likelihood approach is used, with the conditional log-likelihood defined as:

$$\log p(\mathcal{Y}|\mathcal{X}) = \Phi(\mathcal{Y}|\mathcal{X}) - \log \sum_{\mathcal{Y}'} \exp \Phi(\mathcal{Y}'|\mathcal{X}). \quad (3)$$

Here, $\arg \max$ in Eq. (2), and the summation in the second term in Eq. (3) are over all possible sets of non-overlapping intervals. We refer the readers to [2] for algorithmic details.

To make predictions for all event types (88 keys + pedals), multiple instances of semi-CRF are used in parallel, each corresponding to a specific event type.

2.2 Vision Transformer and YOLOs

The Vision Transformer (ViT) [10] introduced a significant shift in computer vision, offering an alternative to traditional CNN models. ViT processes images as sequences of fixed-size patches using transformer layers [9], proving successful across various tasks. For end-to-end object detection, YOLOs [11] demonstrated a minimal, non-hierarchical encoder-only design that appends [DET] tokens (representing object slots) directly to image patch tokens as input to the transformer encoder. Our architecture adopts a similar encoder-only design for event-based music transcription.

³ For dequantizing onset/offset positions from quantized positions.

3 Revisiting Interval Scoring for Semi-CRFs

The neural semi-CRF framework crucially relies on modeling the interval scoring matrix, $score(i, j)$, which assigns a score to each candidate interval. The size of the matrix, which grows quadratically with the sequence length, poses a challenge to designing an efficient and expressive model architecture. For this discussion, $score_\epsilon$ will be excluded due to its minimal impact on model performance from our observation and negligible modeling challenges.

3.1 Interval Scoring in [2]

In [2], a backbone model first transforms the input sequence $\mathcal{X} = [\mathbf{x}_0, \dots, \mathbf{x}_{T-1}]$ into a sequence of feature vectors $[\mathbf{h}_0, \dots, \mathbf{h}_{T-1}]$. Each interval $[i, j]$ is scored by applying an MLP to features computed from the interval, with the output dimension being the number of event types. For simplicity, assuming only one event type to predict, the score is computed as

$$score(i, j) = MLP([\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_i \odot \mathbf{h}_j, \mathbf{m}_1, \mathbf{m}_2, \mathbf{m}_3]), \quad (4)$$

where \mathbf{h}_i and \mathbf{h}_j are feature vectors corresponding to the interval's onset and offset, \odot denotes element-wise multiplication, and $\mathbf{m}_1, \mathbf{m}_2, \mathbf{m}_3$ are the first, second, and third statistical moments over the interval $[i, j]$.

After producing the initial interval scoring matrices for all event types, a shallow CNN is applied, treating the interval endpoints as spatial coordinates and event types as channels. This refinement step slightly improves the result.

Directly computing Eq. (4) and the subsequent refinement step are memory intensive. The official implementation processes the scoring matrix in segments and applies gradient checkpointing during training, reducing peak memory usage at the cost of increased computational time. Consequently, the MLP and CNN layers' depth and width are constrained, potentially limiting the model's capacity and increasing susceptibility to local pattern overfitting.

3.2 Interval Scoring with Inner Product

We propose to use the following method for interval scoring:

$$score(i, j) = \frac{|j - i|}{\sqrt{D}} \langle \mathbf{q}_i, \mathbf{k}_j \rangle + b_i \delta(i, j), \quad (5)$$

where $\delta(i, j)$ is the Kronecker delta, which is 1 if $i = j$ and 0 otherwise. $\mathbf{q}_i \in \mathbb{R}^D$, $\mathbf{k}_i \in \mathbb{R}^D$ and $b_i \in \mathbb{R}$ are computed from the embedding vector \mathbf{h}_i using a linear layer f :

$$[\mathbf{q}_i, \mathbf{k}_i, b_i] = f(\mathbf{h}_i). \quad (6)$$

The interval scoring matrix computed from Eq. (5) takes a low-rank plus diagonal structure. This method, termed **Scaled Inner Product Interval Scoring**, computes the score of an event as the scaled inner product between vectors \mathbf{q}_i and \mathbf{k}_j representing the start and the end of the interval.

Despite its simplicity and resemblance to the attention mechanism in transformers, one question arises about the expressiveness of the inner product for capturing the transcription result. We answer this question by constructing a family of interval scoring matrices that can yield the correct decoded result, and then show that this family of matrices can be represented in the form of pairwise inner product under certain conditions.

Without loss of generality, we ignore the intervals of form $[i, i]$, which correspond to the diagonal values in the interval scoring matrix; they can be added back as diagonals as in Eq. (5). Additionally, since only the upper triangular part of the interval scoring matrix is used, we use the notation for a full matrix to simplify the derivation. We begin by defining a set of nonoverlapping closed intervals.

Definition 3.1. Let \mathcal{Y} be a set of closed intervals defined on $\mathbb{N} \cap [0, T - 1]$, i.e., T steps. It is a set of *non-overlapping* intervals if for any two intervals $[i_0, j_0] \in \mathcal{Y}$ and $[i_1, j_1] \in \mathcal{Y}$, $i_0 \geq j_1$ or $i_1 \geq j_0$, and, additionally, $\forall [i, j] \in \mathcal{Y}, i < j$.

Definition 3.2. An ideal interval scoring matrix for \mathcal{Y} over T steps, i.e., $\mathbf{S}_Y \in \mathbb{R}^{T \times T}$, is a matrix such that

$$\begin{aligned} \mathbf{S}_Y(i, j) &> 0, & \forall [i, j] \in \mathcal{Y}, \\ \mathbf{S}_Y(i, j) &= -\epsilon, & \text{otherwise} \end{aligned}$$

where $\epsilon > 0$.

With an ideal scoring matrix \mathbf{S}_Y , it is clear that the MAP decoding will yield \mathcal{Y} , since the exclusion of $\forall [i, j] \in \mathcal{Y}$ or the inclusion of $\forall [i, j] \notin \mathcal{Y}$ will decrease the total score.

Lemma 3.1. *The rank of an ideal interval scoring matrix \mathbf{S}_Y for a set of non-overlapping intervals, \mathcal{Y} , is $M + 1$, where $M = |\mathcal{Y}|$, which is the number of intervals.*

Proof. By definition, the first column is $-\epsilon \mathbf{1}$, that is, $\forall i, \mathbf{S}_Y(i, 0) = -\epsilon$. Subtracting the first column from all columns gives \mathbf{S}'_Y such that

$$\begin{aligned} \mathbf{S}'_Y(i, j) &> \epsilon, & \forall [i, j] \in \mathcal{Y}, \\ \mathbf{S}'_Y(i, j) &= 0, & \text{otherwise} \end{aligned}$$

Given that no two non-zero entries in \mathbf{S}'_Y share a row or column (as per the definition of set of non-overlapping intervals), and there are M non-zero entries, the rank of \mathbf{S}'_Y is M . Since there are at most $T - 1$ non-overlapping intervals across T frames, we have $M \leq T - 1$, and the number of nonzero entries in \mathbf{S}'_Y is smaller than or equal to $T - 1$. As a result, $-\epsilon \mathbf{1}$ (T non-zeros) cannot be represented by a linear combination of other nonzero columns in \mathbf{S}'_Y , therefore $\text{rank}(\mathbf{S}_Y) = \text{rank}(\mathbf{S}'_Y) + 1 = M + 1$. \square

Theorem 3.2. *Let \mathcal{Y} be a set of non-overlapping closed intervals over T steps, with cardinality M . An ideal interval scoring matrix \mathbf{S}_Y can be represented as pairwise inner products between two 1d sequences $(\mathbf{k}_i)_i$ and $(\mathbf{q}_i)_i$ of vectors:*

$$\mathbf{S}_Y(i, j) = \langle \mathbf{q}_i, \mathbf{k}_j \rangle, \quad (7)$$

provided that $\text{rank}(\mathbf{Q}_Y) > M$ and $\text{rank}(\mathbf{K}_Y) > M$ where $\mathbf{Q}_Y = [\mathbf{q}_0, \dots, \mathbf{q}_{T-1}]$, and $\mathbf{K}_Y = [\mathbf{k}_0, \dots, \mathbf{k}_{T-1}]$.

Proof. By Lemma 3.1, the rank of \mathbf{S}_Y is $M + 1$. Then it directly follows the rank factorization of a matrix. \square

Theorem 3.2 establishes a minimum rank requirement for \mathbf{Q}_Y and \mathbf{K}_Y to represent an ideal scoring matrix. This leads to two key observations:

1. The vector dimensions D of \mathbf{k}_i and \mathbf{q}_i must exceed the total number of intervals, $|\mathcal{Y}|$.

2. Consider a linear upsampling operator u_c , which is a special case of a 1-d transposed convolutional layer. It works by dividing each step of a vector sequence into c equal parts when the sequence is upsampled c times. Suppose we want to represent \mathbf{Q}_Y and \mathbf{K}_Y using low-resolution 1-d vector sequences: $\mathbf{Q}'_Y = [\mathbf{q}'_0, \dots, \mathbf{q}'_{T'-1}]$ and $\mathbf{K}'_Y = [\mathbf{k}'_0, \dots, \mathbf{k}'_{T'-1}]$ where $T' < T$, and this representation is achieved by applying u_c to \mathbf{Q}'_Y and \mathbf{K}'_Y , resulting in $\mathbf{Q}_Y = u_c(\mathbf{Q}'_Y)$, and $\mathbf{K}_Y = u_c(\mathbf{K}'_Y)$, where $c = T/T'$ represents the upsampling factor. For this representation to be valid, the vector dimension D' for the low-resolution sequence, i.e., \mathbf{q}'_i and \mathbf{k}'_i should exceed $c|\mathcal{Y}|$.

These observations highlight that the dimensionality requirement depends solely on the count of intervals in \mathcal{Y} and the downsampling (upsampling) factor $c = T/T'$ along the time axis. This analysis reveals sufficient conditions to guarantee the expressiveness of the inner product interval scoring method. From Theorem 3.2, by applying a scaling factor⁴ and reintegrating diagonal terms, we can recover Eq. (5).

3.3 Comparison with Attention Mechanism

Comparing the neural semi-CRF with the inner product scoring to the attention mechanism reveals interesting parallels. Both of them have quadratic time complexity in the length of the input. The original score module, as in [2], resembles an additive attention mechanism, as introduced by [12]. However, attention mechanisms based on inner products [13] have become preferred for their simplicity and computational efficiency. Similarly, the proposed inner product scoring for neural semi-CRFs efficiently scores intervals. However, in contrast to attention mechanisms that score sequence positions and normalize posteriors for each position, neural semi-CRFs score intervals and normalize posteriors globally over sets of non-overlapping intervals.

The Transformer architecture can be viewed as inherently refining a sequential representation for inner product scoring. Inspired by these similarities, we utilize the transformer architecture to produce the 1-d sequence representations $(\mathbf{h}_i^{\text{eventType}})$ for each event type, termed **event tracks**, which will be used for inner product interval scoring.

4 Proposed System

Figure 1 summarizes the proposed system. The input is an oversampled log-mel spectrogram, as in [2]. The spectrogram is downsampled using 2-d strided convolutional layers, followed by the addition of spatial position embeddings (Section 4.2). Event tracks for all event types (notes and pedals) are initialized with their own spatial position embeddings and concatenated with the downsampled spectrogram representations. The concatenated features are processed by a transformer encoder. Subsequently, only the event track embeddings are upsampled using one 1-d transposed convolutional layer. The upsampled event tracks are used for inner product interval scoring (Eq. (5)) to generate

⁴Note that applying a length-dependent scaling on the ideal scoring matrix does not change the decoded result.

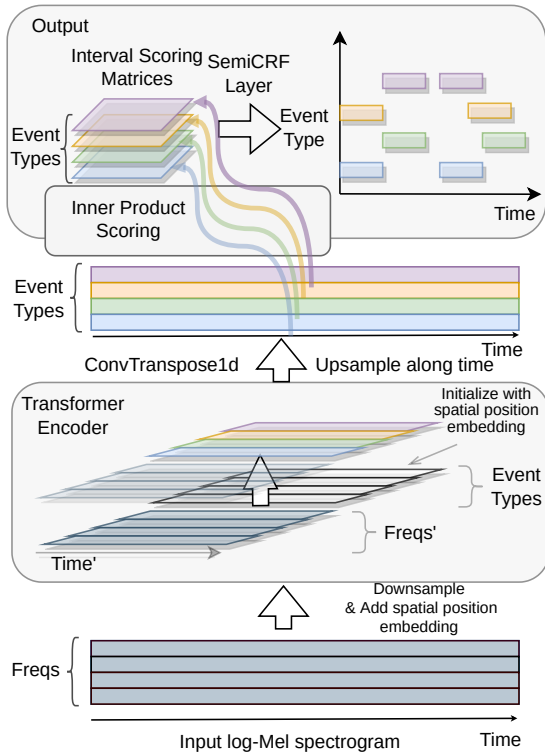

Figure 1: Overview of the proposed system. Inner product scoring follows Eq. (5).

interval scoring matrices, which are then fed to the neural semi-CRF layer for log-likelihood calculation or inference.

4.1 Rethinking Downsampling

Existing studies on Vision Transformers (ViTs) demonstrate the effectiveness of a non-hierarchical design that uses highly downsampled, low-resolution feature maps even for tasks requiring dense predictions, e.g., [14], challenging the dominance of hierarchical models like UNET [15]. However, state-of-the-art (SOTA) piano transcription systems, including [2, 4, 5, 8], retain full resolution along the time axis. These approaches preserve the temporal detail of the input frames, but at the cost of increased training time and reduced model scalability.

This choice might be explained by concerns over losing temporal precision when locating events. However, we argue that the high dimensionality of the embeddings makes the low temporal resolution feature map still capable of processing with enough information.

In our approach, we use strided convolutional layers to downsample the input spectrogram, along both the time and frequency axes, transforming it from its original spatial dimensions (T, F) to a low-resolution feature map with dimensions $(T', F') = (\frac{T}{c_T}, \frac{F}{c_F})$. In line with the ViT literature, we refer to this reduced feature map as *patch embeddings* for $c_T \times c_F$ patches. The choice of patch size (c_T, c_F) may present a trade-off between computational efficiency and the model’s capacity to capture dense events in the input spectrogram. As an initial exploration, we use a patch size of 8×4 to keep the training time within our expected range.

To upsample event tracks to the original temporal res-

olution of frames, we utilize a single transposed 1-d convolutional layer. We found that this simple upsampling layer efficiently prepares representations for inner product scoring at the desired resolution.

4.2 Transformer Encoder Architecture

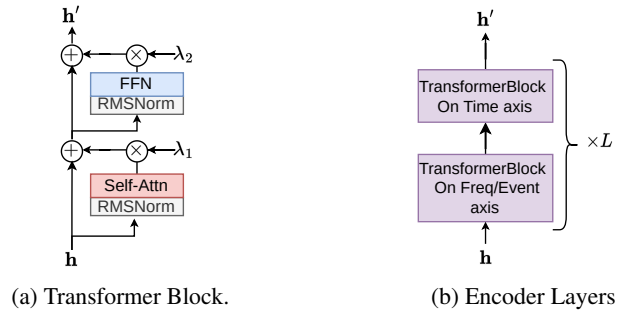

Figure 2: Building Blocks for the Transformer Encoder **Spatial Position Embedding.** We use learnable Fourier features for spatial position embeddings [16] for both time-frequency representations with coordinates $(frameIdx, freqIdx)$, and event tracks with coordinates $(frameIdx, eventTypeIdx)$. This position embedding is chosen for its simplicity and broad compatibility with transformer architectures. Our formula differs slightly from [16] as we follow the formula in the original random Fourier features paper [17]. We compute the position embedding $\mathbf{y} \in \mathbb{R}^E$ from a multidimensional coordinate $\mathbf{x} \in \mathbb{R}^C$ as:

$$\mathbf{y} = g\left(\sqrt{\frac{2}{B}} \cos(\mathbf{W}_r \mathbf{x} + \mathbf{b})\right), \quad (8)$$

where \mathbf{W}_r is a learnable matrix $\mathbb{R}^{B \times C}$, initialized from $\mathcal{N}(0, \gamma^{-2})$; B is the dimension for the Fourier features; γ is a hyperparameter; $\mathbf{b} \in \mathbb{R}^B$ is the learnable bias term, initialized from $\mathcal{U}(-\pi, +\pi)$; $g: \mathbb{R}^B \rightarrow \mathbb{R}^E$ is a two-layer perceptron. This position embedding functions like an MLP that takes coordinates as input, with the first nonlinearity being a scaled cosine function.

The Transformer Encoder Layer. Figure 2a illustrates the basic transformer block. This block first applies *RMSNorm* [18] before the self-attention and feed-forward layers. To enhance training stability, we use ReZero [19] which applies a learnable scaling factor λ , initially set to 0.01, before adding to the skip connection. As in Figure 2b, for reducing computational cost, we alternate attention within each transformer block along the time and frequency/eventType axes; similar ideas are often used for efficient transformer architectures [20–22].

4.3 Segment-Wise Processing

Longer audio is transcribed using segments with 50% overlap. Unlike [2], which discards events that exceed the segment boundary during training, we truncate such events to fit within the segment. We introduce two binary attributes, *hasOnset* and *hasOffset*, to indicate whether an event’s onset or offset has been truncated.

For each event type within a segment, decoding starts from either: (1) the current segment’s boundary, or (2) the offset of the last event in the result set with *hasOffset = true*, whichever is later. Events decoded in the current

segment are then processed as follows: (1) non-overlapping events with $hasOnset = true$ are directly added to the result set; (2) for events overlapping with the last event of the same type in the result set: if the current event has $hasOnset = true$, it replaces the last event⁵; otherwise, the two events are merged.

4.4 Attribute Prediction

Attributes associated with each event include *velocity*, *refined onset/offset positions* (for dequantizing frame positions), and the binary flags *hasOnset* and *hasOffset*. To predict these attributes for an event extracted from the event track $(\mathbf{h}_i^{\text{eventType}})_{i=0}^{T-1}$, e.g., $[a, b]$, we use a two-layer MLP that takes $\mathbf{h}_a^{\text{eventType}}$ and $\mathbf{h}_b^{\text{eventType}}$ as input. The MLP outputs the parameters of the probability distributions for each attribute. Specifically, $velocity \in \{0 \dots, 127\}$ is modeled as a categorical distribution, $refined\ onset/offset\ positions \in (-0.5, 0.5)$ are modeled as continuous Bernoulli distributions [23] shifted by -0.5 , and $hasOnset/hasOffset \in \{0, 1\}$ are modeled as Bernoulli distributions.

5 Experiment

5.1 Dataset

Maestro v3.0.0 [24]. This dataset contains about 200 hours of piano performances, including audio recordings and corresponding MIDI files captured using Yamaha Disklavier pianos. We use the standard train/validation/test splits.

MAPS [25]. The MAPS dataset includes both synthesized and real piano recordings, with the real recordings captured by MIDI playback on Yamaha Disklavier. We evaluate our model on the Disklavier subset (ENSTDkAm/MUS and ENSTDkCl/MUS) of the MAPS dataset, which consists of 60 recordings and is commonly used for cross-dataset evaluation. However, we discovered systematic alignment issues in the ground-truth annotations for both notes and pedals, affecting both onset and offset locations. Onset alignment issues have been previously reported in [26] but are not widely known in the community⁶.

SMD [27]. Similar to Maestro dataset, the SMD dataset was created by recording human performance on a Yamaha Disklavier. We use SMD version 2. The dataset contains 50 recordings. We found that both the onset and offset annotations in SMD are better aligned compared to MAPS.

5.2 Model Specification

The key model specifications are summarized in Table 1. Training takes about 6 days on 2 *NVIDIA RTX 4090*.

Input Mel Spectrogram	sr: 44100 Hz, hop: 1024, window size: 4096, subwindows:5, mels: 229, freq: 30-8000 Hz, segment: 16s,
Patch	shape: 8×4 , embedding size: 256
Strided Conv. Layers for Downsampling	initial proj. size: 64, added with freq. embeddings. out channels: [128, 256, 256, 256], kernel size: 3, strides: [(2,1), (2,2), (2,2), (1,1)]. Each followed by GroupNorm, groups = 4, and GELU (except for the last conv.)
Position Embedding	$\gamma = 1$, $ B = 256$, MLP hidden size 1024
Transformer Encoder	8 heads, 6 layers (=12 blocks), FNN size: 1024
Upsampling	1d. transposed conv, out: 128, kernel size:8, stride:8
Attribute Prediction	two layer MLP, hidden size: 512, dropout 0.1
Batch Size	12
Optimizer	Adabelief [28], maximum learning rate: $4e-4$
Weight Decay	$1e-2$, excluding bias, norm., and pos. embedding
Learning Rate Schedule	500k iterations, 5% warm-up phase, cosine anneal.
Gradient Clipping	Clipping norms at 80% quantile of past 10,000 iterations

Table 1: Model Specification.

5.3 Evaluation Metrics

We compute precision, recall, and f1 score averaged over recordings for both activation level (from [2], equivalent to frame level with infinitesimal hop size), and note level metrics (*Note Onset*, *Note w/Offset*, and *Note w/Offset & Vel.*, using *mir_eval* [29], default settings). All metrics are directly computed from transcribed MIDIs. For details on these metrics, readers can refer to the supplementary material of [2], and the documentation of *mir_eval* [30].

Due to the ground-truth alignment issues discussed in Section 5.1 and space constraints, we only report activation-level and onset-only note-level metrics for MAPS and SMD.

5.4 Results

Our results on the Maestro v3 test set are presented in Table 2. The proposed model achieves state-of-the-art performance across all metrics in terms of f1 score, surpassing previous methods by a significant margin. We also report results for soft pedal transcription which has not been previously explored. The low event-level metrics suggest that accurately determining soft pedal onset and offset times is more challenging than for notes and sustain pedals. We conjecture this is because soft pedals are typically engaged for longer durations and appear significantly less frequently in the dataset than sustain pedals.

Scoring Methods Comparison. We conducted an ablation study to compare our proposed inner product scoring with the more complex scoring method from [2]. We trained a model with an identical architecture but replaced the inner product scoring with the scoring module from [2]. To ensure a fair comparison, we adjusted the hidden sizes of the scoring module to keep the training time for a single iteration within a factor of two of our proposed system. Specifically, all event tracks were projected to a single sequence with a dimension of 512, and the hidden size of the scoring module was set to 512. As shown in Table 2, our inner product scoring outperforms the more complex scoring method, demonstrating its effectiveness and efficiency.

Furthermore, we compared two variants of the inner product scoring: a linear layer and an MLP for computing the $k/q/b$ vectors (f in Eq. (6)). The results demonstrate that the linear layer yields better performance than the MLP.

⁵ For overlapping events between segments: (1) The first event must have $hasOffset = false$. (2) A continuing second event must have $hasOnset = false$. (3) If the second event’s $hasOnset = true$, the first event is replaced by the second event as it’s not supported by the second.

⁶ A piece-dependent onset latency around 15 ms has been previously discussed in [26]. Due to the electro-mechanical playback mechanism, this latency could also be note/pedal dependent. Offset deviation (up to approximately 70 ms) appears more complex and may be influenced by pedal-/note-dependent mechanical latency or undocumented specific piano model’s response to non-binary pedal values.

Table 2: Transcription Result on Maestro v3.0.0 Dataset Test Split.

Interestingly, this aligns with how k and q are computed in transformers.

Effect of omitting incomplete events. We found that omitting steps of handling incomplete events at segment boundaries (Section 4.3) only cause noticeable performance impact for pedals, particularly the soft pedal (Table 2). This can be explained by the fact that pedal events, especially soft pedals, can often exceed the segment length, while notes are normally shorter than the segment length we choose.

Results on MAPS/SMD. We evaluated our model on the MAPS dataset using three different ground-truth annotations: (1) Original, (2) Ad hoc Align, where the median deviation from the initial evaluation is subtracted from all notes for each piece and then re-evaluated, and (3) Cogliati, which subtracted a latency value per recording for ENST-DkCL as provided by [26]. For the SMD dataset, only the original annotation is used. Table 3 presents the results.

All methods exhibit low activation-level F1 scores on MAPS. Using the onset-corrected annotation (Cogliati) on MAPS increases the onset F1 score but degrades the activation-level F1 score due to the uncorrected offset biases. In fact, the Cogliati annotation achieves similar or lower activation-level F1 scores compared to all listed methods when evaluated against the original annotation.

All methods achieve F1 scores on SMD that are more comparable to those evaluated on Maestro. However, performance decreases significantly on MAPS, even with corrected annotations. This suggests that the dataset issue may be more complex than a simple piece-dependent timing shift.

Notably, the corrected annotations can lead to different conclusions compared to the original annotation. For example, while the data-augmented Onsets&Frames model achieves a higher note onset F1 score than hFT using the original annotation, it scores lower than hFT when evaluated using the ad hoc correction and the Cogliati annotation.

These observations highlight the need for caution when evaluating models on datasets created using mechanisms that may involve systematic biases, e.g., electromechanical playback. Despite these complications, our proposed system, with or without data augmentation⁷, achieves the highest note onset F1 score among the compared methods on both SMD and MAPS with Ad hoc/Cogliati correction.

⁷ Data augmentation: pitch shifting ± 20 cents, adding noise from [31],

6 Conclusion

This paper introduces a simple and efficient method for scoring time intervals using scaled inner product operations for the neural semi-CRF framework for piano transcription. We demonstrate that the proposed scoring method is not only simple and efficient but also theoretically expressive for yielding the correct transcription result. Inspired by the similarity between the proposed scoring method and the attention mechanism, we employ a non-hierarchical, encoder-only transformer backbone to produce event track representations. Our method achieves state-of-the-art performance on the Maestro dataset across all subtasks. Due to resource constraints, we have not evaluated the effect of patch and embedding sizes, which is left for future work. Additionally, future research could explore more advanced transformer architectures, investigate the interaction between transformer architecture and the neural semi-CRF layer, and extend the approach to other instruments and multi-instrument music transcription tasks.

applying randomized 8 band EQ and impulse response from [32].

⁸ Use their provided code and pretrained weights. Recomputed from transcribed MIDIs.

⁹ Previous SOTA for sustain pedals. Their released code indicates a 200 ms onset tolerance for pedal evaluation, contrary to the reported 50 ms in their paper. Here, we use a 50 ms onset tolerance, which explains the large discrepancy between the numbers here and their reported results.

PERTOK: EXPRESSIVE ENCODING AND MODELING OF SYMBOLIC MUSICAL IDEAS AND VARIATIONS

Julian Lenz
Lemonaide Research
Barcelona, ES

Anirudh Mani
Lemonaide Research
Boston, US

ABSTRACT

We introduce *Cadenza*, a new multi-stage generative framework for predicting expressive variations of symbolic musical ideas as well as unconditional generations. To accomplish this we propose a novel MIDI encoding method, *PerTok* (Performance Tokenizer) that captures minute expressive details whilst reducing sequence length up to 59% and vocabulary size up to 95% for polyphonic, monophonic and rhythmic tasks. The proposed framework comprises of two sequential stages: 1) *Composer* and 2) *Performer*. The Composer model is a transformer-based Variational Autoencoder (VAE), with Rotary Positional Embeddings (RoPE) [1] and an autoregressive decoder modified to more effectively integrate the latent codes of the input musical idea. The Performer model is a bidirectional transformer encoder that is separately trained to predict velocities and microtimings on MIDI sequences. Objective and human evaluations demonstrate *Cadenza*'s versatile capability in 1) matching other unconditional state-of-the-art symbolic models in musical quality whilst sounding more expressive, and 2) composing new, expressive ideas that are both stylistically related to the input whilst providing novel ideas to the user. Our framework is designed, researched and implemented with the objective of ethically providing inspiration for musicians.

1. INTRODUCTION

The creative endeavor in present-day music production is inherently complex and multifaceted. However, it can be broadly categorized into distinct phases that include 1) initiation, 2) evolution and development, and 3) completion of musical ideas into a finished musical outcome. Modern generative models have had a major impact in every creative domain, none the least in music creation. MIDI, and therefore Symbolic AI research approaches for single-track MIDI generation are especially applicable to the contemporary music producer. The motivation behind our investigation arises from a gap in this current landscape to facilitate the crucial middle phase of the creative pro-

cess: absence of a comprehensive, adaptable modeling framework specifically engineered for generating expression variations from a given MIDI file input. Our proposed solution, *Cadenza*, addresses this by focusing on the 'development' phase of music creation while unveiling a framework that is designed for flexibility and efficiency. *Cadenza* utilises a multi-stage generative process, the *composer* and the *performer*, to create novel ideas and variations while emulating the nuanced performance characteristics that can define a given musical style. We choose to call our framework 'Cadenza', inspired by the improvised musical passage played by soloists, creating new and exciting variations of the original motifs of the piece being performed.

1.1 Encoding Symbolic Music

Alongside transformer-based architectures a number of methods have been proposed to encode, or *tokenize* MIDI files into a discrete sequence of tokens. As transformers suffer from quadratic memory complexity in relation to sequence lengths [2], particular focus is placed on capturing relevant MIDI information whilst minimizing the total number of tokens. Popular tokenizers include REMI [3], TSD [4] and Structured [5], amongst many others. However, these approaches suffer from a common drawback: they rely on singular tokens to denote the position of each note event on an evenly-spaced temporal grid. In comparison to MIDI files, which typically utilise a time resolution of 220 or 440 *ticks-per-quarter* [note], these tokenizers are typically employed with just four intervals per quarter note. This has two negative effects: first, note-values outside this range are immediately *quantized*, such as quarter-triplets, eighth-triplets, quintuplets, and thirty-second notes. In addition, any rhythmic performance attributes, expressed as subtle deviations from the fixed-grid, are immediately lost. As a result, the current state-of-the-art in MIDI tokenizers are unable to accurately capture the full range of rhythmic values and expressive performances.

1.2 Expressive Modeling

In both digital and physical contexts, it is common to divide the act of *composing* music and *performing* it. The composition (or score) contains the raw musical idea, whereas the performance will typically embellish it with additional details, such as varying volumes (velocities in MIDI) and subtle timing deviations. Symbolic datasets can

be categorized broadly as:

- **Score:** The sequences contain quantized rhythmic values and minimal/no volume information.
- **Time-Performance:** Dynamics and expressive timing are captured. The performer(s) play without a fixed tempo, resulting in a *time*-based encoding (typically milliseconds), such as [6].
- **Beat-Performance:** Dynamics and expressive timing are captured. The notes are recorded in relation to a fixed tempo, with rhythmic expressivity occurring as deviations from the quantized beats.

Although a substantial quantity of **score** datasets exist, there are significantly fewer in both **performance** categories. As a result, systems such as that proposed in [7], wherein both composition and performance elements are jointly trained and predicted, are limited by this inequality.

A number of recent models have been proposed to exclusively add performance elements, such as RenderingRNN [8] and ScorePerformer [9]. However, they rely on the prediction of *tempo* tokens in alignment with the **Time-Performance** standard. This results in MIDI files that are still rhythmically *quantized*, albeit with varying tempos. We posit that this approach is incompatible with the common production standards of many modern genres that instead rely on fixed tempos.

The framework in Compose & Embellish [10] proposed a system of jointly training Lead-Sheet (score) and Performance models. With a modified REMI [3] tokenization they demonstrated that the lead-sheet model could be pre-trained on a greater quantity of **score** data, and subsequently fine-tuned with the performer, on a smaller **performance** dataset. Similar to prior systems, they quantize rhythms to the nearest 16th position, and instead predict [Tempo] for expressive timing. Furthermore, due to the joint-conditioning training method, the compose model can lose certain capabilities from the fine-tuning process as it fits to the smaller performance dataset.

1.3 Generating Variations

A number of models have been proposed to solve variations-adjacent tasks. ThemeTransformer [11] utilises contrastive representation learning in a sequence-to-sequence framework to generate a melody and accompaniment that recurrently incorporates the original theme. The authors of Music FaderNets [12] instead propose a *style-transfer* task, wherein a number of high-level attributes can be applied to transform a polyphonic sequence. Our work most notably builds off of the model proposed in MuseMorphose [13], which uses a novel *in-attention* mechanism in a transformer-based VAE for generating attribute-controlled variations on symbolic data. However, these models are designed to predict long-form sequences (16+ bars) that do not contain any expressive information.

Overall, our key contributions to the field through this work are two-fold. Firstly, in section 2.2 we introduce

PerTok, a novel MIDI encoding method that captures expressive details with required granularity while maintaining compact sequence lengths and manageable vocabulary sizes. PerTok is implemented with the MidiTok [4] library, released open source and is compatible with any token-based sequential generation model. Secondly, the *Cadenza* framework itself represents a significant leap forward as presented in section 3, integrating the 'Composer' and 'Performer' models into a cohesive architecture that is researched and designed for the domain of AI-assisted music creation. Our framework offers a natural and intuitive way for musicians to create and modify music, which can be tailored to specific stylistic goals. Human evaluations showcase how Cadenza matches other state-of-the-art MIDI models in unconditional score generation quality, creates dynamic variations on input ideas, and sets a new standard for human-like expressive articulations.

2. SYMBOLIC DATA ENCODING

We aim to encode MIDI data in a manner that is both 1) aligned with common audio production use-cases and 2) efficient in the context of transformer-based generative models. While a number of state-of-the-art models such as Anticipatory Music Transformer (AMT) [14], Figaro [15] and Multi-Track Music Machine (MMM) [16] have focused on long-form, multi-track generation, we have observed from our experiences in designing products for contemporary music producers that they more commonly interact with short, single-track files. Furthermore, we observe that a number of tokenization methods such as [9] rely on *tempo* tokens to create a sense of expressive performance, whereas music producers often keep a singular, consistent tempo throughout their composition. Thus, our proposed encoding method is focused on single-track MIDI files in which the expressivity is calculated in relation to a fixed tempo.

2.1 Score & Performance Encoding

To address this, we create separate tokens to model the composition and performance timing elements. More specifically, the macro *timeshift* tokens represent the quantized note locations within a score. Separately, the *microshift* events denote a small adjustment from the quantized location, similar to the subtle timing deviations used by human performers. By separating these events, we are able to maintain reasonable balance between vocabulary size and total sequence length. Furthermore, the differentiation allows for models to be separately trained on the composition and performance tasks respectively. As there is a significant difference in the availability between quantized and performed symbolic datasets, this enables us to feed a far greater quantity of data into the composition-only model.

Initial tests revealed that the common convention of quantizing the composition-level timeshift tokens to 16th notes was leading to a number of musical issues. For example, when quarter- or eighth-note triplets were present

Figure 1. Example of PerTok tokenization on a 2-bar excerpt of a MIDI file. Composition tokens are highlighted in yellow, and performance tokens in blue.

in the input MIDI file, the quantization process was considering them to be 16th notes with large degrees of *microshift*. We addressed this by providing the ability to specify multiple, overlapping quantization grids, such as 16th, quarter-triplets, and 8th-triplets. Thus, the PerTok tokenizer is more adept at capturing the wide variety of rhythmic values that are commonly found in genres such as hip-hop, jazz and salsa (among many others).

2.2 PerTok

Score Tokens: Similar to the MIDI-Like [7] and Structured [5] encoding methods we represent *macro* time changes between notes with **Timeshift** tokens. As MIDI time data is typically expressed as ticks-per-quarter, PerTok allows for multiple overlapping granularities to model a variety of rhythmic values. When encoding the MIDI data, PerTok matches each note’s position to the closest possible timeshift value. **Pitch** is denoted as a MIDI pitch value between 0-127, with the capability to limit this range when musically appropriate. **Duration** tokens are used after each new note, to indicate the length of time before a MIDI note-off message is triggered. Notably, PerTok allows for the removal of duration tokens altogether, which helps further reduce sequence lengths when modeling rhythmic instruments.

Performance Tokens: With the addition of performance tokens, we aim to capture the musical subtleties that transform a written score into an expressive performance. **Velocity** tokens denote the strength of the note’s attack, a property that is typically used in DAWs to augment timbre and volume characteristics. Although MIDI provides a range of 0 - 127 for velocity values, we allow for a bucketing approach to reduce a given velocity into one of n possible values. **Microshift** tokens provide a granular shift from the quantized rhythmic note value. PerTok is provided a maximum microshift value (e.g. 30 MIDI ticks) and a discrete number of possible microshift buckets. For example, *Microshift 15* represents a placement of 15 ticks after the quantized note position, and *Microshift 0* results in the initial quantized value.

In **Table 1** we provide a benchmark of our proposed PerTok encoding against a number of popular MIDI tokenizers. We sampled from 2,000 polyphonic 4- and 8-bar

Tokenizer	Vocab. Size	Seq. Length
REMI	273	195
REMI-p	5505	199
Structured	289	216
Structured-p	7265	216
TSD	288	188
TSD-p	7264	192
PerTok	196	134
PerTok-p	259	243
PerTok no-duration	164	80

Table 1. Vocabulary sizes and average sequence lengths for popular tokenizers and our proposed PerTok encoding.

MIDI files that are used in modern audio production environments. For each tokenizer, we use 32 possible velocity buckets. To demonstrate the tradeoff between composition and performance, we initialize one version with 16th-note quantization (thus removing any performance characteristics), and a second (denoted with a -p) version with 440 timeshifts per quarter note. REMI and Structured methodologies use evenly spaced temporal grids to encode the location of each event, whereas PerTok uses a mixture of macro and micro timeshift tokens leading to a 95% reduction in vocabulary size when encoding expressive rhythmic details. We additionally provide a visualization of our encoding method with a sample 2-bar melody in **Figure 1**.

3. MODEL

With the objective of generating expressive, beat-structured variations on an input MIDI file, we present *Cadenza*, a multi-stage VAE with transformer-based components. The framework is designed upon a principle that the *composition* task requires a significant quantity of data and benefits from auto-regressive generation, whereas the patterns of expressive *performance* tokens can be learned with smaller datasets and predicted in a bi-directional manner.

3.1 The Composer

Given an input sequence of tokens $\{x_1, x_2, \dots, x_t\}$ in which x_t represents a single token x at index t the **composer** model is designed to auto-regressively predict $\{y_1, y_2, \dots, y_t\}$, an output sequence that is musically related yet distinct from the input. We utilise a sequence-to-

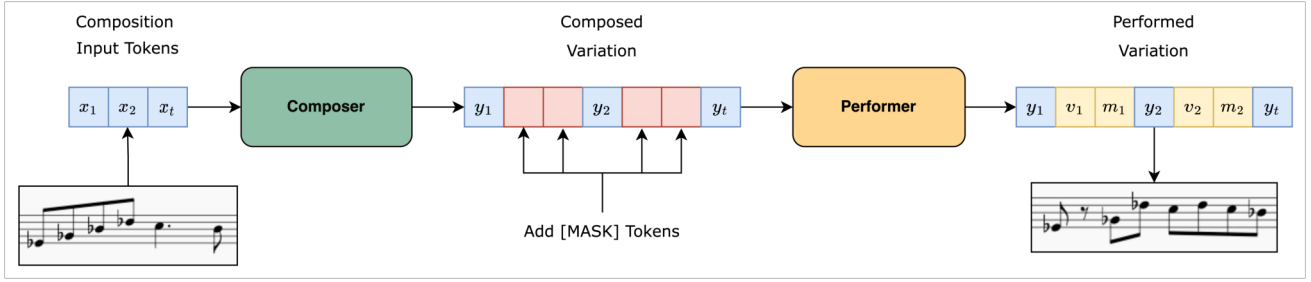

Figure 2. An overview of the multi-stage *Cadenza* architecture.

sequence VAE architecture with in-attention conditioning similar to MuseMorphose [13], enabling the model to learn a compressed, latent representation of short musical ideas within a regularized space. Within each attention mechanism, the query q and key k vectors at timesteps m, n are obtained with RoPE [1] for enhanced positional context:

$$q_m^\top k_n = (R_{\Theta, m}^d W^q x_m)^\top (R_{\Theta, n}^d W^k x_n) \quad (1)$$

Wherein $R_{\Theta, m}^d$ and $R_{\Theta, n}^d$ are the rotary matrices for positions for embedding positional information, W^q and W^k are learnable weight matrices transforming inputs x_m and x_n into the query and key vectors. For additional context we encourage readers to refer the original paper. As music is a deeply temporal phenomenon, the composer benefits from the increased token spatial modelling that is provided by the rotary embeddings.

The encoder is designed to create a latent vector z of the input musical idea which serves as an anchor throughout the decoding process. In alignment with the original transformer [2] we first project the input sequence with a learned embedding space, transforming it into $X \in \mathbb{R}^{d \times t}$ where d is the hidden dimension size. This is then processed through several multi-head self-attention layers. Following a similar approach to [13] we extract the first timestep of the final attention layer output to obtain hidden vector $h \in \mathbb{R}^d$, a contextual representation of the full input sequence.

Following standard VAE methodology [17], the output vector is then processed through two learnable weight matrices $W_\mu \in \mathbb{R}^{d \times d_z}$ and $W_\sigma \in \mathbb{R}^{d \times d_z}$, wherein d_z denotes the size of the latent dimension. This process yields the mean μ and standard deviation σ vectors, encapsulating the latent space distribution parameters. Using the reparameterization trick, we sample ϵ from the Gaussian distribution to obtain $z \in \mathbb{R}^{d_z}$ from our encoder:

$$z = hW_\mu + hW_\sigma \odot \epsilon \quad (2)$$

The encoder’s output distribution $q(z|X)$ is aligned to a Gaussian prior $\mathcal{N}(0, 1)$ by the traditional Kullback-Leibler (KL) divergence loss term:

$$D_{KL}(q(z|X)||p(z)) = -\frac{1}{2} \sum_{k=1}^{d_z} (1 + \log(\sigma_k^2) - \mu_k^2 - \sigma_k^2) \quad (3)$$

We further modify the equation utilising free bits as proposed by [18], allowing the encoder a degree of unpenalized space defined by λ to learn musical attributes without regularization.

$$\mathcal{L}_{KL} = \sum_{k=1}^{d_z} \max(\lambda, D_{KL}(q(z_k|X)||p(z_k))) \quad (4)$$

The decoder is trained to autoregressively predict an output sequence of tokens whilst maintaining a recognizable connection with the input musical idea. Initially, the latent vector z is expanded to the decoder’s hidden dimension d via a learnable matrix $W_{\text{pre}} \in \mathbb{R}^{d_z \times d}$. We separately expand the input tokens v_1, v_2, \dots, v_k with the same embedding layer used by the encoder.

In the context of the autoregressive VAEs it has been noted that *posterior collapse* is a common issue [19–21], in which a sufficiently powerful decoder can simply ignore the encoder’s regularized information, instead relying purely on the previous tokens. We utilise the methodology of Skip-VAE [22] and MuseMorphose [13], integrating the proposed *in-attention* mechanism. Prior to each attention layer, we sum expanded latent vector z_{pre} with every timestep of the previous hidden state, thus reinforcing its information throughout every stage of the decoding process. Therefor hidden state $H \in \mathbb{R}^{t \times d}$ at layer i is calculated as:

$$H_i = \text{SelfAttention}(H_{i-1} + x_{\text{pre}}) \quad (5)$$

The final hidden state is then passed through a feed-forward layer, which has weights tied to the embedding layers as first proposed in [23]. The decoder minimizes the negative log likelihood (NLL) of the output sequence y_t when given prior tokens:

$$\mathcal{L}_{\text{recon}} = \sum_{t=1}^T \log p_\theta(y_t | y_{<t}, z) \quad (6)$$

Thus, the composer is optimized with the NLL reconstruction loss as well as the β -scaled regularization KL loss:

$$\mathcal{L}_{\text{composer}} = \mathcal{L}_{\text{recon}} + \beta \mathcal{L}_{KL} \quad (7)$$

3.2 The Performer

The Performer is separately tasked with computing tokens for **velocity** and **microshift** time values. Thus, it is able to transform a quantized MIDI score into one with expressive characteristics, rendering it more suitable for a variety of music production tasks. Whereas the composition task generally benefits from an autoregressive setup wherein each token is predicted sequentially, it has been demonstrated in [24, 25] that performance attributes can be predicted in a bi-directional manner.

We utilise a framework comparable to the masked token prediction task of BERT [26]. During training and inference, we replace the input performance tokens denoting velocity and microtiming with a single [MASK] token. The tokens related to pitch, timeshift, and duration are left unmodified. The model is a standard transformer encoder as per [2], with sinusoidal positional embeddings, layer normalization and a final feedforward layer that has weights tied to the initial embedding layer.

During training the model is tasked to replace each [MASK] token with an appropriate velocity and microshift value, with cross-entropy loss used exclusively on the masked tokens. We perform the masking operation on 100% of performance tokens. At inference time, we manually mix tokens between the original source and model predictions, thus ensuring the original pitch, timeshift and duration values are maintained.

4. EXPERIMENTAL SETUP

4.1 Composer Ablations

By training several composer models, we aim to understand the relationship between various degrees of KL regularization and the decoded sequence’s similarity to the input. Each model is trained on 4-bar segments of the full Lakh-MIDI dataset [27]. The models all have 12 layers and 8 heads in both the encoder and decoder, with a latent dimensionality d_z of 128 and hidden dimension d of 512. The *Full-KL* model was trained with a KL regularizer $\beta = 1.0$ and free bit $\lambda = 0.15$. The *Balanced-KL* model was trained with $\beta = 0.3$ and $\lambda = 0.25$. In both instances the KL regularization was applied with cosine cyclical annealing [28] every 10,000 steps. We initially keep $\beta = 0.0$ for the first 25,000 steps, and then linearly raise it to the maximum value over the proceeding 25,000 steps. Finally, the *No-KL* model had a $\beta = 0.0$ (no regularization), thus allowing the encoder to exclusively optimize against reconstruction quality.

Objective Evaluations : We generate a single variation for 500 files from the test set for each model, utilising greedy decoding to remove any sampling logic from the evaluation framework. For each sample, we calculate the similarity in **pitch distribution**, **onset locations** and **durations**:

$$\text{similarity}(x^a, x^b) = 100 \frac{\langle x^a, x^b \rangle}{\|x^a\| \|x^b\|} \quad (8)$$

wherein $x \in \mathbb{Z}^t$ is a discrete vector of t attributes; in the case of **pitch** we set $t = 128$ to capture the full MIDI note range, and for both **onset location** and **duration** $t = 64$, representing the nearest 16th value in a 4-bar pattern. Finally, we report **Absolute Similarity**, the percentage of notes that have *identical* characteristics (pitch, onset, duration) between both sequences.

4.2 Performer Fidelity

Two performer models are trained with separate datasets to measure their capacity to model the unique expressive characteristics of a given training set. Both models are trained with 12 layers and heads, a hidden dimensionality of 768, and a dropout of 10%. One model is trained on the classical MusicNet dataset [29], and the other (referred to as *HipHop*) is trained on a proprietary hip-hop dataset. In both cases, we train on approximately 10,000 4-bar excerpts. Each dataset contains polyphonic data with differing expressive patterns of velocities and microtiming.

We randomly extract 2,000 polyphonic 4-bar patterns from the Lakh-MIDI dataset [27] and generate expressive tokens from both models. We subsequently measure the velocity and microtiming distributions of both the generations as well as the two original training datasets. **Velocity** distribution is represented as $v \in \mathbb{Z}^{128}$, a vector representing the number of occurrences of each velocity value. For each note, **microtiming** is calculated as a percentage deviation from the nearest 16th note, with +/-50% denoting the halfway point to/from the adjacent 16th time index. The total distribution of **microtiming** deviations in a given sequence is thus represented with vector $mt \in \mathbb{Z}^{100}$.

For both velocity and microtiming, we compare the distributions of both model’s predictions against the MusicNet and HipHop datasets. In **Table 4** we report the KL divergence, as well as the absolute difference in the mean and standard deviation for these distributions. In each metric, a lower value indicates higher degree of similarity between the model’s predictions and the original dataset’s expressive characteristics.

4.3 User Study

We conduct a thorough user study to achieve a qualitative understanding of our model’s performance, comparing to different external baselines and versions due to hyperparameter settings. All the audio samples that users heard were 4 bar MIDI files voiced through the same Piano VST. In Part A of the user study, 25 human evaluators listened to 5 seed melodies and 4 alternative variations for each of them, coming from the *No-KL*, *Balanced-KL* and *Full-KL* versions of our proposed model, and additionally a *Placebo* melody which was randomly selected to be in the same key and scale as the input but had no relation to it. This was done to confidently ground the musical understanding of our human evaluators. Overall, 44% of our evaluators identified themselves as "Novice : I have little to no experience making music", 32% as "Amateur : I love making music for fun", and 24% as "Professional : I regularly make music in a professional capacity".

Model	Pitch Sim.(%)	Onset Sim.(%)	Duration Sim.(%)	Absolute Sim.(%)	Human Eval(1-5)
Full-KL	71.01	77.99	88.65	9.44	1.94
No-KL	95.64	83.04	98.40	20.05	2.84
Balanced-KL	92.06	80.80	96.95	16.46	2.71
Placebo	-	-	-	-	1.22

Table 2. Objective and human-evaluation results from the ablation studies. Higher values indicate more similarity to the input’s musical characteristics.

In Part B, the same 25 human evaluators also rated 3 unconditional generations from Cadenza, Anticipatory Music Transformer (AMT) [14]¹ and Figaro [15] models, which broadly represent the state-of-the-art in symbolic polyphonic generation. We randomly sampled 3 generations from publicly-available checkpoints of each model, all of which were trained on identical versions of the Lakh MIDI dataset [27], and present the results in **Table 3**. As Cadenza’s composer requires a latent vector, we randomly sample from a Gaussian distribution for unconditional generations. For each sample, the evaluator was asked to rate between how musically appealing it sounded to them with 1 being the lowest and 4 being the highest score. In addition, they were also asked to select, in a binary choice, whether they thought the performance was generated by a human or computer.

Model (Params)	Musical Appeal Score ↑ (1-4)	‘Human-like’ Score ↑ (1-2)
AMT (360M)	3.33	1.57 (57.3%)
Figaro (87M)	2.73	1.57 (57.3%)
Cadenza (142M)	2.91	1.72 (72.0%)

Table 3. Human Evaluation Results for Model Quality. Percentages represent the fraction of modeling outputs that were selected by human evaluators when asked if it could have been created by a human.

5. RESULTS AND DISCUSSION

We discuss our experimental results to answer three high level questions - 1) provided an input MIDI sequence, how *musically related* are the Cadenza variations; 2) can the performer model tangibly improve expressivity; and 3) how appealing are the novel generations. We analyze our proposed scientific approach through quantitative and qualitative measures.

Both human and objective evaluations demonstrate in **Table 2** that training the composer with varying degrees of KL regularization has noticeable impacts on the balance between between recall and variety. Provided a musical idea as input, the *No-KL* model will produce outputs nearly identical to the input melody. Alternatively, the *Balanced-KL* model will produce outputs that are related, yet altered enough to provide new sources of inspiration. In many cases, the *Full-KL* model will produce entirely unrelated outputs, as a result of the encoder’s heavy focus on regularizing the latent vectors. Since a score of 4.0 for a generation would be considered identical we can infer that the

¹ Specifically, the music-medium-800k checkpoint

Model (Metric)	KL		Mean Δ		Std Dev Δ	
	Train	Opposite	Train	Opposite	Train	Opposite
HipHop (Velocity)	1.68	3.63	1.81	16.83	1.74	9.04
HipHop (Microtiming)	0.66	2.64	0.05	0.05	0.00	0.14
MusicNet (Velocity)	3.17	11.57	1.95	13.06	1.20	12.00
MusicNet (Microtiming)	0.07	3.17	0.02	0.13	0.01	0.15

Table 4. Objective results on the Performer fidelity evaluations.

ideas generated by *No-KL* and *Balanced-KL* are roughly 70% related to the input. This aligns with the quantitative results, which consistently show a negative correlation between the KL regularization and input/generation similarity metrics. As such, our framework is demonstrated to consistently generate variations that are perceptually relevant to, yet distinct from, the input musical idea.

In **Table 4**, we report results from the Performer Fidelity quantitative study. In both MusicNet and HipHop models, the distributions of predicted velocities and microtimings are consistently closer to that of their respective training datasets. We can therefore infer that the performer model, in conjunction with our newly proposed PerTok tokenizer, is capable of accurately learning the patterns of expressive characteristics from a comparatively small dataset.

In **Table 3** we compare Cadenza to AMT [14] and Figaro [15] on the task of novel generations. Our model, although comparable to its competitors on musical appeal, comes in second to the AMT. However, Cadenza comprehensively outperforms other models by 14.7% in the *human-like* expressivity ratings. We note that our framework is highly adaptable, in that both composer and performer models could be replaced with any type of sequential network. Theoretically, one could further improve the unconditional generation quality by replacing our VAE-based composer model with a decoder-only model, similar to that of AMT.

6. CONCLUSION

We introduced a multi-stage generative framework which allows for both variation and novel generation tasks, maintaining a competitive quality of composition and setting a new state-of-the-art of expressive characteristics. Our proposed tokenizer is used to create expressive symbolic sequences while effectively reducing vocabulary size and sequence length. We invite readers to our model page ² where we showcase its fidelity in generating outputs for polyphonic, monophonic, bass and drum instruments.

In particular, our performer model in conjunction with the new tokenization method led to a quantifiable increase in listener’s perceptions of the expressivity in the generations. These results were achieved with relatively tiny datasets, paving the way for further collaborations with artistic communities. Future research directions include exploring *controllability*, as well as further improvements in the domain of novel generation.

² Access code and demonstrations on our model page here. PerTok tokenizer is available as part of MidiTok library here.

7. ETHICS STATEMENT

As generative AI technology advances rapidly, it is crucial to address the implications of these developments in the generative domain. Concerns such as perpetuating cultural biases, undermining artists' financial opportunities, and using data without proper consent require urgent attention and dialogue within research communities. When developing new models, we must carefully consider both their intended applications and potential impacts.

Our research involves deep collaboration with artists to understand their motivations and needs, ensuring our efforts benefit the creative communities we serve. For instance, our new framework, designed for the MIDI symbolic domain, focuses on enhancing artists' tools with features that inspire creativity rather than replacing the artists. We also deliberately chose to work with smaller models, which helps minimize data requirements. This strategy promotes fair data agreements and increases the chances of fairly compensating musicians, thus fostering sustainability in creative industries and prioritizing ethical responsibility, especially in creative domains.

LOOKING FOR TACTUS IN ALL THE WRONG PLACES: STATISTICAL INFERENCE OF METRIC ALIGNMENT IN RAP FLOW

Nathaniel Condit-Schultz

natcs@gatech.edu

ABSTRACT

Musical rhythm and meter are characterized by simple proportional relationships between event durations within pieces, making comparison of rhythms between *different* musical pieces a nebulous practice, especially at different tempos. Though the “main tempo,” or tactus, of a piece serves as an important cognitive reference point, it is difficult to identify objectively. In this paper, I investigate how statistical regularities in rhythmic patterns can be used to determine how to compare pieces at different tempos, speculating that these regularities could relate to the perception of tactus. Using a Bayesian statistical approach, I model first-order (two-gram) rhythmic event transitions in a symbolic dataset of rap transcriptions (MCFlow), allowing the model to renotate the rhythmic values of each transcription as needed to optimize fit. The resulting model predicts makes “renotations” which match a priori predictions from the original dataset’s transcriber. I then demonstrate that the model can be used to rhythmically align new data, giving an objective basis for rhythmic annotation decisions.

1. INTRODUCTION

Symbolic representations of music generally encode rhythm using integer-related *note-value* categories—whether expressed as durations or inter-onset-intervals (ioi). Absolute timing is encoded indirectly (if at all) as the *tempo* of a reference note-value, conventionally the quarter-note. The musical and psychological validity of this approach is well established, as the schematic syntax of musical rhythm is primarily determined by proportional relationships, not absolute (clock-time) durations [1].¹ However, this approach also presents a problem: If only proportional relationships *within* a piece are rhythmically relevant, on what basis can relationships or comparisons be made across pieces? Can we be confident that a “quarter-note” in one piece is the same as a “quarter-note” in another? For example, consider three expert transcriptions of

¹ In fact, human perception tends to normalize ioi ratios that are *not* simple ratios to the nearest simple-ratio category [2].

songs by Johnny Cash from the *RS200* dataset [3]: “Folsom Prison Blues” (1955) and “Ring Of Fire” (1963) are transcribed with quarter-notes at 110_{bpm} and 104_{bpm} respectively, while “I Walk The Line” (1956) is transcribed at 210_{bpm} .² These three songs share many idiomatic musical features, including *backbeat* strikes in between bass-notes at a $105\text{--}110_{bpm}$ pulse. Given these similarities, perhaps the quarter-notes in “I Walk the Line” ought to be compared to the eighth-notes in “Ring of Fire.”

The quarter-note is more than a default reference unit for rhythmic encoding: It is also associated with the cognitive phenomenon of the “main beat” or *tactus*, and thus the “true” tempo of metric music [1, 4–6]. Other metric *levels* may be related to the tactus, both in notation and in human perception [1, 5, 6]. Thus, rhythmic comparison (in metric music) might be, essentially, a question of tactus comparison between two or more pieces. Which metric level in, for example, “Ring of Fire” or “I Walk the Line” is the tactus? This is essentially another perspective on the classic issue of “tempo octaves” in tempo-estimation research.

1.1 Background

Listeners must infer metric structure from music as they hear it [7], including the tactus level [5]. Though listeners’ metric interpretations often agree [8], disagreement is also common, especially regarding tactus [4, 5, 8–11]. This suggests that tactus inference is constrained, but not determined, by features of music’s objective organization. Which features constrain our perception of tactus? The obvious feature to consider is absolute (clock) time. Indeed, listeners tend to subdivide slower pulses or group faster pulses into beats in a preferred timing range, approximately corresponding to a tempo octave ($2/1$ ratio) of $160\text{--}80_{bpm}$ [5, 10, 12]. However, empirical measures of optimal tempo ranges have often covered larger ratios—from $2.25/1$ [12] to $2.5/1$ [13]—and a non-trivial number of observations spread across even more extreme tempos [4, 10]. Tempos from $200\text{--}60_{bpm}$ will feel somewhat familiar to most musicians, creating an “apparent contradiction between the narrow range of preferred tempi and the wide range of (absolute) tempi found in real music” [14]. These findings demonstrate that tactus perception is not determined by absolute timing in a trivial manner. Even if a strict tempo-octave were used for comparison, this still requires an arbitrary choice of the cutoff between tempo-octaves [10].

² “Ring of Fire” was transcribed by Temperley, the other two songs by de Clercq.

Relative rhythmic features also contribute to tactus perception [4, 13–15]. In particular, the density and consistency of attacks at particular metric levels—what Martens [4] calls “pulse consistency”—serve as an important cue [6, 10]. Music theorists have also noted specific rhythmic patterns or aspects of the music’s feel³ that relate to tactus. A notable example is the backbeat pattern evident in the Johnny Cash examples above, which is often regarded as tactus defining [5, 17, 18]. However, De Clercq [17] has argued that absolute speed overwhelms the backbeat norm in many cases, and musical features must be balanced with absolute speed when inferring the tactus.

In traditions that rely on notated music, composers’ explicit choice of note values and time signature might be regarded as the “correct” tactus; However, many scholars have noted that classical time signatures leave room for ambiguity regarding the true tactus [4, 10, 17, 19, 20]. Music from vernacular traditions pose an even more acute problem for research, as rhythm values must be chosen by a scribe [17]. If theory, convention, and intuition serve, we might hope that homogeneous collections of scores are coherently aligned. Unfortunately, representing metric alignment across pieces is not necessarily an important goal in traditions of music notation, and there are no clear standards for composers, transcribers, or arrangers to follow.

1.2 Hypothesis

If metric orientation is essential to the syntactic organization of music, then proper metric alignment of pieces is necessary to reveal structural similarities and generalize about rhythmic syntax in a body of music [17]. Conversely, any “misaligned” pieces—like “I Walk the Line,” perhaps—add noise to empirical distributions and hinder musicological analysis. In this paper, I explore a novel statistical approach to aligning and comparing rhythmic patterns across pieces within stylistically homogeneous musical corpora. I hypothesize that regularities in proportionally-encoded rhythmic patterns can serve as consistent cues of metric alignment of pieces, independent of absolute speed. In other words, that specific rhythmic patterns or features (notably, pulse saliency) will be statistically associated with particular metric levels, and that these patterns can then be used as the basis to align and compare pieces. To achieve this, we can systematically rescale note values of transcriptions—either in *augmentation* (longer values) or *diminution* (shorter values)—so as to optimize the fit of statistics related to syntactic rhythm relationships. For example, we could renotate “I Walk the Line” in diminution, and then confirm if the resulting tabulation of the overall RS200 collection is less noisy, “expos[ing] connections that would be otherwise hidden or obscured” [17]. My argument is that these connections, should they be revealed, may relate to listeners’ perceptual

³ Another plausible area where musical organization might influence metric alignment is sub-syntactic *micro-timing*: small discrepancies between actual rhythmic timing and their perceived rational categories. Micro-timing is often related to the “feel” of music, and can be used to emphasize particular beat levels [16].

experience of the tactus, though I cannot directly demonstrate that here.

A central premise of my hypothesis, is that metric alignment can be done based on proportional rhythmic data, without absolute timing information. This does not preclude that absolute timing plays an important role in musical alignment, but if the hypothesis is supported, it would demonstrate that rhythmic syntax is at least partly independent of tempo, and help explain why tempos are used outside a preferred tempo octave.

2. METHODOLOGY

With no ground truth available, I can only attempt to optimize fit to my data in an unsupervised way. My approach is to characterize empirical probability distributions of rhythmic data conditioned on different interpretations of the metric alignment of pieces.

2.1 Data

For this project, I use my own Musical Corpus of Flow (MCFlow) [18], in which I transcribed the rapped part of 124 popular hip-hop songs, all in $\frac{4}{4}$ time. Rap flow is suitable for this task for several reasons: Rap flow is saturated with the rhythmic features of American popular music more broadly, with lots of rhythmic variation within songs. Rap also tends to exhibit a rhythmically dense, fast pace, with few long iois, which makes relatively simple ngram-like analyses (described below) more plausible. I parsed the MCFlow dataset using humdrumR [21]—a R package for analyzing data encoded in the humdrum syntax (as MCFlow is). I restrict my analysis to inter-stress-intervals because rap scholars agree that most useful rhythmic information is in the stressed syllables of rap [18, 22].

MCFlow divides each of its 124 songs into verses. In some cases, different artists perform different verses, occasionally even at different tempos. I thus regard each verse as a separate rhythmic passage to analyze. To isolate only “pure” duple rhythmic data, I remove 155 measures of music, in 44 unique verses, which contain at least one triplet. I then removed 16 verses with fewer than eight measures remaining. This leaves a total of 376 verses, containing 36,553 stressed syllables; the shortest remaining verse has only 21 stressed syllables, with the longest containing 314 and a median length of 98.

In my MCFlow transcriptions, I used the backbeat in the rap’s accompaniment to determine the quarter-note value [18]. However, one of the most important reasons I use MCFlow is because I [23] originally noted thirty-five verses (in eleven⁴ songs) which are clear outliers in tempo annotation (Table 1), and speculated that they might be better notated at a different tempo. This gives us a set of *a priori* predictions about metric alignment in the data. Figure 1 illustrates the distribution of quarter- and eighth-note iois in MCFlow, as notated (above) and incorporating my speculated renotations (below). Interestingly, the

⁴ I also identified two other outlier verses which I exclude because they contained fewer than eight measures of non-triplet bars.

Song	Verse(s)	BPM
Dead and Gone (T.I., 2009)	1–2	68
Niggas in Paris (Jay Z and Kanye West, 2011)	1–3	70
Mercy (Kanye West, at al., 2012)	1,2,4	70
What’s Your Fantasy (Ludacris, 2000)	1–3	70
Holy Grail (Jay Z, 2013)	1–2	72
How Low (Ludacris, 2009)	1–2	72
Woof (Snoop Dogg, 1998)	1–3	83
Pray (M.C. Hammer, 1990)	1–5	122
It’s Tricky (Run-D.M.C., 1987)	1–4	128
You Be Illin’ (Run-D.M.C., 1986)	1–4	128
Fight for Your Right (the Beastie Boys, 1987)	1–3	134
Mercy (Kanye West, at al., 2012)	3	140

Table 1. List of verses in MCFlow which Condit-Schultz [18] identified as tempo outliers. BPM = quarter-notes per minute.

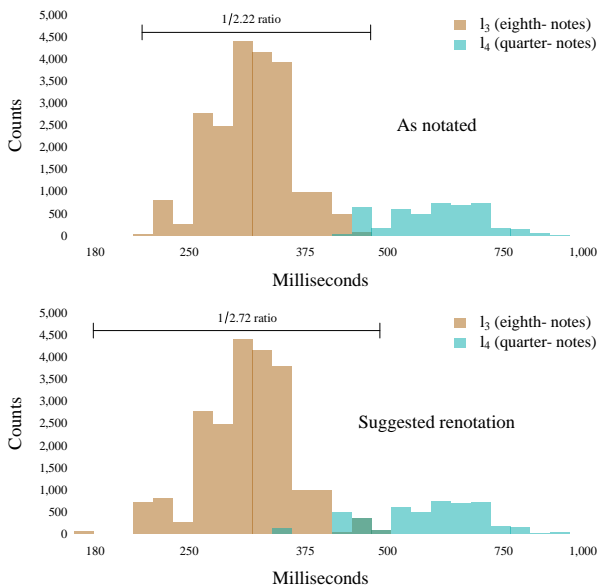

Figure 1. Distribution of notated quarter- and eighth-note inter-stress-intervals in MCFlow, by absolute duration.

raw, backbeat-based notation covers an tempo range only slightly greater than one tempo octave, similar to observed listener preferences [12, 13]. In contrast, following my speculated renotations results in a few verses being moved into more extreme absolute tempos.

2.2 Meter

Meter is an organizational structure in music, wherein multiple phase-aligned beats with integer-related periods form a nested hierarchical pattern [5]. These beats can be sorted from fastest (“lowest”) to slowest (“highest”), each considered one *metric level*, notated here as $[l_1, \dots, l_k]$. The highest metric level (l_k) defines the overall period of the meter, a *measure*; the lowest metric level (l_1) is known as the *tatum*. In a musical passage, each note onset is associated with a tatum pulse [24], and thus a unique *metric position* within each measure—e.g., “beat 4.” Metric positions may also coincide with one or more higher-metric levels, with the highest level defining the “level” of that position. For example, the downbeat of each measure is the unique position at level l_k .

In this paper, I consider only simple duple meter, with each metric level having twice the period of the level below it [1]: essentially a $\frac{4}{4}$ meter with strictly no triplets. The standard $\frac{4}{4}$ generally presumes at least three central levels [5, 20]. However, music often evinces hyper-metric pulses above the measure level [20] and, conversely, faster levels well below the ostensible tatum (e.g., 16th- and 32nd-notes). Thus, I proceed with a slightly expansive $k = 6$: six metric levels with 32 metric positions. This could be interpreted as one measure of 32nd-notes, two measures of sixteenth-notes, or four measures of eighth-notes. Throughout this paper, I will take l_1 as 32nd-notes, putting quarter-notes in l_4 .

Regardless of notation, the fastest metric level (tatum) can always be identified in any transcription. However, some musical passages may have *implicit* subdivisions, that would be felt by a listener, but are never articulated in the music. Thus, the *true* tatum l_1 may be different than the observed tatum l_1 . For any given musical transcription, we can postulate one or more implicit subdivisions, effectively “shifting” the observed metric positions up one level—equivalent to renotating the music in augmentation.

2.2.1 Modeling Meter

To characterize the rhythms of music in metric terms, I use a first-order (two-gram) model, considering the joint probability of the metric positions of sequential pairs (antecedent-consequent) of note events. Given 32 positions, a full transition matrix would require 1,024 parameters, many of which would be close to zero or simply redundant, as rhythmic patterns in different parts of the measure can be closely related. To work with less sparse and more interpretable parameters, I explored ways of reducing the full 32x32 parameters space to a smaller number of parameters while maintaining predictive power. My final approach is to bin each antecedent note according to its metric level l_k and each consequent into one of nine categories defined relative to the antecedent position. My nine *metric consequent types*, illustrated in Figure 2, are able to differentiate between shorter and longer iois, weak-to-strong versus strong-to-weak beat transitions, and different sorts of syncopations. These forty-seven parameters are represented in a vector \mathbf{p} , with components $p_{l,m}$ corresponding to the probability of each metric transition (Table 2). In the raw MCFlow data, the full 32X32 metric transition matrix has a joint entropy of 6.19 bits (10 being the maximum theoretical value). My antecedent-consequent parameterization, with only 47 parameters, achieves a cross-entropy with the same data of 7.44 bits, gaining only 1.25 bits⁵ by removing 977 parameters. Figure 3 illustrates the distribution of my antecedent-consequent parameters, using the raw MCFlow note-values.

2.3 Statistical Model

The statistical model I employ mirrors the thought process we explored with Johnny Cash songs above, “renotating”

⁵ This difference in bits is equivalent to the Kullback–Leibler divergence.

Figure 2. Illustration of nine metric consequent types at the l_4 level. Arrows point to exact points; shaded areas indicate points binned together.

	Drop	Step	Dot	Straight	Drop sync.	Straight sync.	Dot sync.	Up sync.	Long
l_6	$p_{6.1}$	$p_{6.2}$	$p_{6.3}$	$p_{6.4}$	$p_{6.5}$		$p_{6.7}$		$p_{6.9}$
l_5	$p_{5.1}$	$p_{5.2}$	$p_{5.3}$	$p_{5.4}$	$p_{5.5}$	$p_{5.6}$	$p_{5.7}$	$p_{5.8}$	$p_{5.9}$
l_4	$p_{4.1}$	$p_{4.2}$	$p_{4.3}$	$p_{4.4}$	$p_{4.5}$	$p_{4.6}$	$p_{4.7}$	$p_{4.8}$	$p_{4.9}$
l_3	$p_{3.1}$	$p_{3.2}$	$p_{3.3}$	$p_{3.4}$	$p_{3.5}$	$p_{3.6}$	$p_{3.7}$	$p_{3.8}$	$p_{3.9}$
l_2	$p_{2.1}$	$p_{2.2}$	$p_{2.3}$	$p_{2.4}$	$p_{2.5}$	$p_{2.6}$	$p_{2.7}$	$p_{2.8}$	$p_{2.9}$
l_1				$p_{1.4}$		$p_{1.6}$		$p_{1.8}$	$p_{1.9}$

Table 2. Forty-Seven metric coefficients (\mathbf{p}). Empty slots are logically impossible given the definitions. sync. = syncopation.

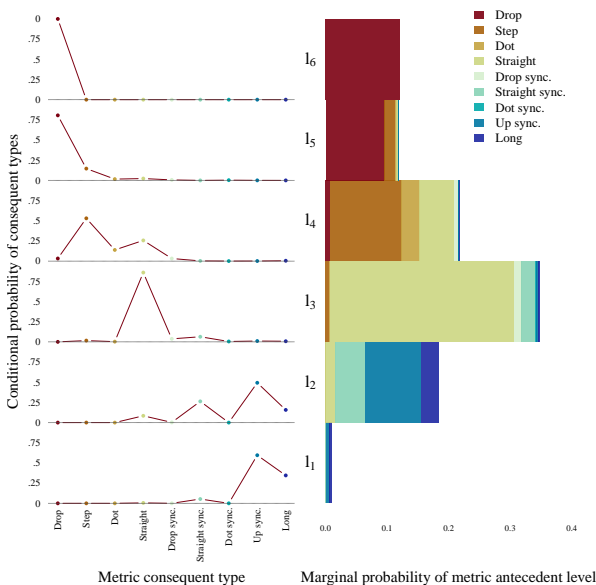

Figure 3. Raw empirical estimates for $p_{l,m}$. Both sides of the figure show the same information in two different formats: the left side shows the conditional probability of each metric consequent, given the metric level of an antecedent syllable; the right side shows the joint probability of the same antecedent-consequent pairings.

verses in the MCFlow corpus to find a good fit. With each iteration of the model’s Monte Carlo algorithm, the model finds estimates of the metric coefficients (explained below) using the dataset as currently encoded. The model then estimates parameters which represent the “scaling” of each individual verse, by retabulating the music assuming one or two unobserved sub-divisions—equivalent to renotating the music in augmentation. The process repeats, reestimating the meter parameters using the new scaling parameters, etc., until a complete picture of the posterior distribution emerges, as guaranteed by the Metropolis-Hasting algorithm [25]. Ultimately, I find the scalings of each verse that result in the best fit to the overall metric distribution.

In each verse, I count instances of 47 metric transition bins, indexed $l.m$ as defined above for \mathbf{p} . Let the counts in the n th verse be labeled $C^n = [c_{l,m}^n, \dots]$. I then model each set of counts as an independent draw from a multinomial distribution $C^n \sim \mathcal{M}(\sum C^n, \mathbf{p})$. The core purpose of the project, however, is to estimate a set of indicator, “shift,” parameters, one for each verse: $\mathbf{s} = [s^1, \dots, s^n]$, where $s^n \in \{0, 1, 2\}$. There are thus actually three different counts ($C^{n(s \in \{0,1,2\})}$) for each verse, one for each possible shift parameter: When $C^{n(s=0)}$, the metric parameters are counted assuming the observed tatum is the true tatum $l_{\bar{1}} = l_1$. When $C^{n(s=1)}$, count assuming that there is one implicit level of duple subdivision in the meter, $l_{\bar{1}} = l_2$, “shifting” the metric parameters up one level. When $C^{n(s=2)}$, counted assuming two subdivisions, $l_{bar1} = l_3$. I assume also that the values of $\mathbf{s} \sim \mathcal{M}(n, \mathbf{S})$, where $\mathbf{S} = [S_0, S_1, S_2]$ is another discrete probability distribution (though this ultimately had little impact on my results).

2.3.1 Model Estimation

Given the assumed distributions above, I use a Bayesian Markov Chain Monte Carlo (MCMC) algorithm to calculate posterior distributions for \mathbf{p} , \mathbf{s} , and \mathbf{S} . Since objective estimates for the \mathbf{s} shifting parameters are my main goal, I specify no prior distribution for \mathbf{s} , letting the model believe (initially) that all values of \mathbf{s} are equally probable. For \mathbf{p} and \mathbf{S} , I specify minimally informed Dirichlet prior distributions: $prior(\mathbf{p}) \sim Dir(\alpha_{l,m} = 5)$ and $prior(\mathbf{S}) \sim Dir(\alpha_S = 5)$. These minimal priors—equivalent to observing 235 prior note transitions and 15 prior verse shifts respectively—mainly serve to (weakly) discourage the model from assigning values close to zero. Note that the Bayesian approach here does not only find the optimal point-estimate for each parameter, but a complete prior distribution of belief regarding each parameter. This will allow the model to express degrees of certainty about each s^n , rather than finding only one optimal choice.

I estimate the posterior distribution using a custom MCMC implementation in R, with three Gibbs-sampler steps (for \mathbf{s} , \mathbf{S} , and \mathbf{p}) in each iteration, i . In each Gibbs step, I sample new parameter estimates for one parameter from the conditional distribution of that parameter given the current values of the other parameters. The result is a sequence of estimates for each parameter, forming a

Figure 4. MCMC trace for four selected parameters. Dashed lines indicate boundaries between independent chains.

Markov chain which converges on the true posterior distribution.

For the \mathbf{s} scaling parameters, new estimates for all $[s^1 \dots s^n]$ parameters are sampled in a single step. For each verse, the probability of observing $C^{n(s)}$ for all three values of s , conditioned on \mathbf{p}_i and \mathbf{S}_i , is computed.

$$s_{i+1}^n \sim P(C^{n(s)} | \mathcal{M}(\sum_1^n C_i^{n(s)}, \mathbf{p}_i)) * \mathbf{S}_i$$

For the \mathbf{p} metric coefficient parameters, new estimates for all parameters were sampled in a single step, conditional only on \mathbf{s}_i . Taking advantage of the conjugate relationship between the multinomial and Dirichlet distributions, I can sample from the conditional distribution of \mathbf{p} directly using the Dirichlet distribution:

$$\mathbf{p}_{i+1} \sim Dir(\alpha = \sum_{n=1}^N C^{n(s_i)} + prior_\alpha(\mathbf{p}))$$

Updates for \mathbf{S} are similar but even simpler, using only the current (estimated) counts of \mathbf{s} : $\mathbf{S}_{i+1} \sim Dir(\alpha = counts(\mathbf{s}_i) + prior_\alpha(\mathbf{S}))$.

To minimize the effect of initial values, I initialized forty independent markov chains on different random draws from the prior distributions of \mathbf{p} and \mathbf{S} , and a uniform random sample of \mathbf{s} parameters. Each chain ran for 11,000 samples, with an initial “burn in” of 1,000 iterations removed from each chain, though each chain appeared to reach its stationary distribution well before the 1,000th iteration. All forty chains converged on the same final distributions for all parameters (see Figure 4 for a few examples). As is usually the case with MCMC models, several parameter chains evinced moderate autocorrelation values (the largest being 0.287), so I thinned the chain by taking every tenth sample, cutting the absolute autocorrelation values down to $r \leq 0.115$. The result is a chain of 40,000 samples for each parameter. Figure 4 shows the MCMC traces for four of the \mathbf{p} parameters; the other parameter traces look essentially identical.

3. RESULTS

The main parameters I am interested in are the estimates of \mathbf{s} , the “shift” parameters for each verse. Despite the fairly long MCMC trace (40,000 samples), in 372 of 376 verses the model selected the same shift parameter in every sample; evidently, most verses fit in one, and only one, interpretation. In only three verses—none of which were *a priori* tempo outliers—did the model find significant uncertainty, with the non-modal choice sampled between 12.6% and 43.9% of the time (these appear midway between shift levels in Figure 5). The important question is whether these highly confident shift parameters match my *a priori* expectations. If we take the posterior modal value for each s^n , we observe 37 shifts of 0, 318 of 1, and 21 of 2. Figure 5 shows these average posterior \mathbf{s} values normalized relative to the original empirical l_1 of each verse, such that 0 indicates the original notated quarter-note. The model correctly identifies the predicted renotation for 27 of the 35 *a priori* outliers. The model also identifies four unanticipated verses that need shifting, and fails to shift eight verses—if we view this as a binary classification task, the model achieves an F-score of .818. Note that the model was not provided any information about absolute timing, so this accuracy is achieved purely by looking at metric transitions. Close investigation of the false positives reveals that, though I didn’t originally identify these verses as outliers [18], each features flow that could make sense renoted. The false negatives are not as easy to interpret; However, in no case did the model falsely reject all outlier verses in a song: for example, the model correctly shifts four of the five verses in MC Hammer’s “Pray,” but fails to shift the fourth verse (for no obvious reason).

To visualize the posterior distribution of \mathbf{p} , the metric coefficients, I show the average posterior value for each $p_{l.m}$ parameter in Figure 6. If we compare this to Figure 3, there are no dramatic differences, except at l_1 , where the model places considerably less probability mass. The average entropy of the \mathbf{p} posterior is 3.339 bits, slightly lower than the joint distribution of the raw-notation counts at 3.409 bits, demonstrating that model has improved the overall fit of the data. Finally, I can also use the posterior parameters to evaluate unseen data. For example, if I apply the posterior \mathbf{p} to our three Johnny Cash songs, we find that the model shows (with total confidence) that the three songs *should* be aligned at the same backbeat level, as I speculated at the outset.

4. DISCUSSION AND CONCLUSION

Though it appears that my statistical approach both improves fit and matches (my) expert judgments [18], this initial foray is not a decisive demonstration that this approach can help us generalize about metric syntax. It appears that my model is learning, or at least observing, *something* about the organization of metric syntax across metric levels, but future work is needed to elucidate what is going on, and determine how robust this methodology can be.

It may seem that my full Bayesian treatment is overkill:

Figure 5. Average posterior s estimates for each verse, sorted by raw quarter-note bpm. Blue marks indicate the predicted tempo outliers. The shifts have been "normalized" such that 0 indicates the original notated quarter-note, rather than the fastest metric level.

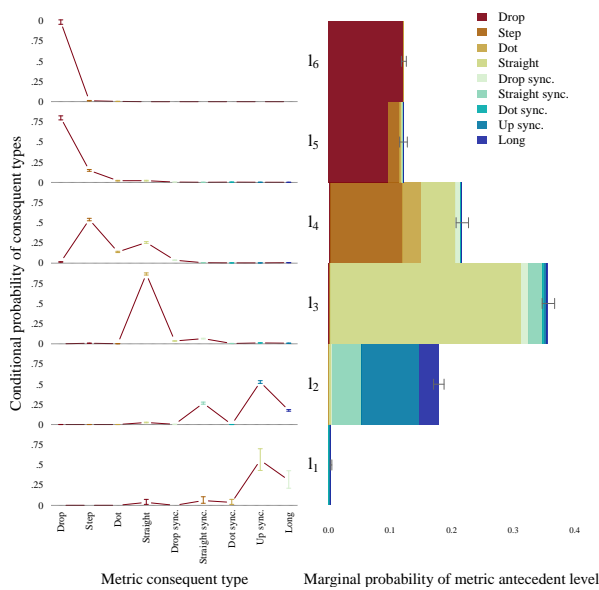

Figure 6. Mean posterior parameter estimates for $p_{l,m}$. Both sides of the figure show the same information in two different formats: the left side shows the conditional probability of each metric consequent, given the metric level of an antecedent syllable; the right side shows the joint probability of the same antecedent-consequent pairings. Bars indicate the Bayesian 95% credible interval for each parameter.

My parameter estimates are tightly packed around their mean and not dramatically different than the simple counts derived from the raw data; my posterior estimates of s also show little variability. This suggests that a simpler approach could probably achieve similar results on this dataset. My results are also strongly fitted to this particular dataset—for this initial attempt I specified uninformative priors on all parameters, allowing the model to fit the data at hand very closely. However, I believe this full Bayesian approach will prove robust if extended to other datasets which might be less rhythmically uniform than MCFlow, and the results here could be used as the basis for more informative priors for future work.

Finally, though I have argued that this task is theoretically connected to perceptual and musicological ideas of tactus and tempo, future work with human participants will be necessary to establish direct connections between my findings and human perception. For example, my p estimates could be used to generate rhythmic stimuli with different (predicted) tactus interpretations. For course, as discussed above, there is plenty of evidence that tactus is never fully determined by musical features [4, 5, 8–11]. Listeners’ perception might be shaped previous context, personal experience, their own personal state, or by conscious effort. My analysis of “syntactic regularities,” even if valid, isn’t necessarily connected to tactus at all: indeed, at least one prominent psychomusicological theory of rhythm, London’s [20] (p. 95) *tempo-metrical types*, “is [explicitly not] defined in terms of the level heard as the tactus.” It’s possible that the statistical regularities found by my model represent tempo-metrical types, or other rhythmic structural principles, but *not* tactus.

Basing psychological conclusions on statistical evidence requires a match between the musical corpora and the listening experience of people. Different musical exposure (and thus statistical experience) might explain disagreements about tactus. Stepping back further, it is possible that syntactic relationships in music involve relationships between various rhythms and beats *without* assuming any privileged reference level at all. My results here make this final possibility appear unlikely, but much work remains to be done.

ABSTRACT

Recent progress in text-based Large Language Models (LLMs) and their extended ability to process multi-modal sensory data have led us to explore their applicability in addressing music information retrieval (MIR) challenges. In this paper, we use a systematic *prompt engineering* approach for LLMs to solve MIR problems. We convert the music data to symbolic inputs and evaluate LLMs’ ability in detecting annotation errors in three key MIR tasks: beat tracking, chord extraction, and key estimation. A *concept augmentation* method is proposed to evaluate LLMs’ music reasoning consistency with the provided music concepts in the prompts. Our experiments tested the MIR capabilities of Generative Pre-trained Transformers (GPT). Results show that GPT has an error detection accuracy of 65.20%, 64.80%, and 59.72% in beat tracking, chord extraction, and key estimation tasks, respectively, all exceeding the random baseline. Moreover, we observe a positive correlation between GPT’s error finding accuracy and the amount of concept information provided. The current findings based on symbolic music input provide a solid ground for future LLM-based MIR research.¹

1. INTRODUCTION

Recent advancements in text-based Large Language Models (LLMs) have showcased their significant reasoning and knowledge retrieval capabilities across various domains, including music understanding. For instance, the standard GPT-4 model performs better than random on music theory questions [1]. This success raises the question of whether such text-based reasoning abilities could enhance Music Information Retrieval (MIR) tasks. From a psychological perspective, we are interested in how a *cognition module*, typically represented by a text-based LLM, can possibly

interplay with a *perception module*, typically represented by an MIR network, to improve music understanding.

A key challenge in achieving this goal is the inherent difference between music and text modality, which typically requires aligning data in other modalities to text. Common strategies include either transforming all inputs into a unified modality [1, 2], or developing adapters tailored to other domains, such as MiniGPT-5 [3] and NextGPT [4]. Given the substantial data requirements and training costs involved in addressing cross-modality issues, we believe a practical initial step for LLM-based MIR research is to translate sensory inputs into symbolic representations and investigate the performance of text-based LLMs in a training-free way (e.g., prompt engineering [5]). This methodology allows us to assess how much cognition alone, without additional auditory perception, can enhance MIR tasks.

To this end, we propose a systematic prompt engineering method to assess the music understanding capabilities of text-based LLMs, focusing specifically on their ability to *detect errors* in MIR annotations. Each task input includes: 1) a music segment converted into MIDI or higher-level musical features, 2) a corresponding MIR annotation with deliberately inserted errors, and 3) a text prompt that introduces the MIR problem and outlines relevant musical concepts. The LLM’s role is to pinpoint errors within the musical annotations, effectively acting as an MIR judge. In all the tasks, annotation errors are randomly applied at controlled rates, and prompts are crafted using common prompt engineering techniques. Additionally, we propose a *concept augmentation* strategy to evaluate the LLM’s behavioral consistency in response to the musical concepts provided. This involves adjusting the occurrence of certain musical concepts in the prompt, such as replacing a musical term (e.g., pitch sequence) with a more general term (e.g., time series) to obscure a concept, or vice versa, to explore whether these changes influence the LLM’s performance in predictable ways.

We carried out experiments using the GPT-3.5 model (hereafter, GPT), targeting three MIR tasks: beat tracking, chord extraction, and key estimation. The experiment results indicate that the error detection rates are higher than random, achieving scores of 65.20%, 64.80%, and 59.72%, respectively. Furthermore, the concept augmentation experiments show that GPT’s performance broadly

¹ Code repository: <https://github.com/kunfang98927/gpt-eval-mir>

correlates with the amount of musical concepts introduced in the prompts. These findings suggest that GPT exhibits measurable music understanding capability, which sets a foundational baseline for future LLM-based MIR research. In sum, the contributions of the paper are as follows:

1. **We pioneer the integration of MIR problems with text-based LLMs.** Our approach utilizes prompt-engineering techniques for MIR error detection and adopts the symbolic music format to unify music and text modality, which does not require additional training.
2. **We perform a systematic study on GPT’s abilities as a judge** in beat tracking, chord extraction, and key estimation tasks, demonstrating GPT’s capability in solving MIR problems.
3. **We provide a solid ground for LLM-based MIR research.** The proposed methodology sets a baseline for future studies.

2. RELATED WORK

Recently, the advancements of text-based LLMs [6–8] have expanded beyond textual data, incorporating capabilities to interpret information from various other modalities. In the computer music domain, the research to combine text and audio LLMs is also popular. For example, Chat-Musician is a text-based LLM, which focuses mainly on generating symbolic music in ABC notation [1]; Music-Gen [9] and Coco-Mulla [10] are audio-based LLMs allowing text and symbolic music control; and MU-LLaMA is an audio-to-text model for caption generation [11]. Despite all these achievements, the current cross-modal research of text-based LLMs is restricted to generative tasks; and their ability to reason about cross-domain data is still under-researched. The focus of this paper is to evaluate whether LLMs can be used for music understanding and solving MIR problems.

In most cross-modal LLM studies, extensive training is required to align cross-modal information. These approaches involve training separate adapters to align the pre-trained model with other-domain data [3,4,12], fine-tuning an LLM on symbolic cross-domain data [1], or learning a trainable autoencoder to convert other-domain data to text tokens [2]. In the music domain, since music can be naturally represented as readable symbolic representations, we propose using prompt engineering methods to connect the music and text domains to avoid extra training.

The cross-domain prompt engineering methods used in this paper originate from the text domain. These strategies involve chain-of-thought [5], few-shot prompting [13], least-to-most prompting [14], and many others [15–17]. These methods show that the more organized the prompt is, the better the LLM will be able to reason. To the best of our knowledge, we present the first attempt of using prompt engineering to teach LLMs to reason about music. We aim to explore to what extent music reasoning alone can help MIR.

3. METHODOLOGY

In this study, we use prompt engineering to evaluate the capabilities of text-based LLMs through three MIR error detection tasks: beat tracking, chord extraction, and key estimation (as shown in Figure 1). In Section 3.1, we introduce the task definition and data representations for each task. In Section 3.2, we discuss the structure and main components of the prompts. Finally, Section 3.3 introduces the proposed concept augmentation methods to test the LLMs’ music reasoning ability with respect to the music concepts included in prompts.

3.1 Task Definition and Data Representation

For symbolic MIR tasks, beat tracking determines the precise timing of beats in a MIDI-like music representation, chord extraction assigns a chord label to each segment, and key estimation identifies the musical key of each segment. Building on these tasks, we introduce a novel task: MIR error detection. This task involves identifying errors specific to each of the three traditional MIR tasks. The following subsections define the error detection tasks for beat tracking, chord extraction, and key estimation.

3.1.1 Beat Tracking Error Detection

We deliberately introduce a certain proportion of errors to the ground-truth beat annotations and ask the LLM to output the *beat index range* containing beat errors based on the music performance data in the symbolic music format. We introduce three types of error on beat annotations: 1) insert an extra beat between adjacent beats; 2) delete a beat; and 3) offset the timing of one beat, where the offset should be greater than a 70ms tolerance [18]. In beat tracking tasks, error detection is not a binary classification problem per detected beat, because there are false negative predictions (i.e., missed beats error). Therefore, it is crucial to return the beat index range so that both false positive beats and missed beats can be captured.

As shown in Figure 1 (left), the music segment and the beat annotations with errors are provided in the JSON format. The notes and beats are sorted by the temporal positions (i.e., onsets or beat locations).

3.1.2 Chord Extraction Error Detection

We deliberately introduce chord annotation errors and ask the LLM to output the *indices of incorrect chords* based on the music performance data in the symbolic music format. The chord errors are applied to the root, chord quality, and chord inversion attributes independently at a controlled rate.

As shown in Figure 1 (middle), we use the JSON format to represent the music segment and the chord annotations. The notes and chords are sorted by their temporal positions, and chords are notated as chord symbols in the conventional format [19].

3.1.3 Key Estimation Error Detection

We deliberately introduce key annotation errors and ask the LLM to output “correct” or “incorrect” based on the

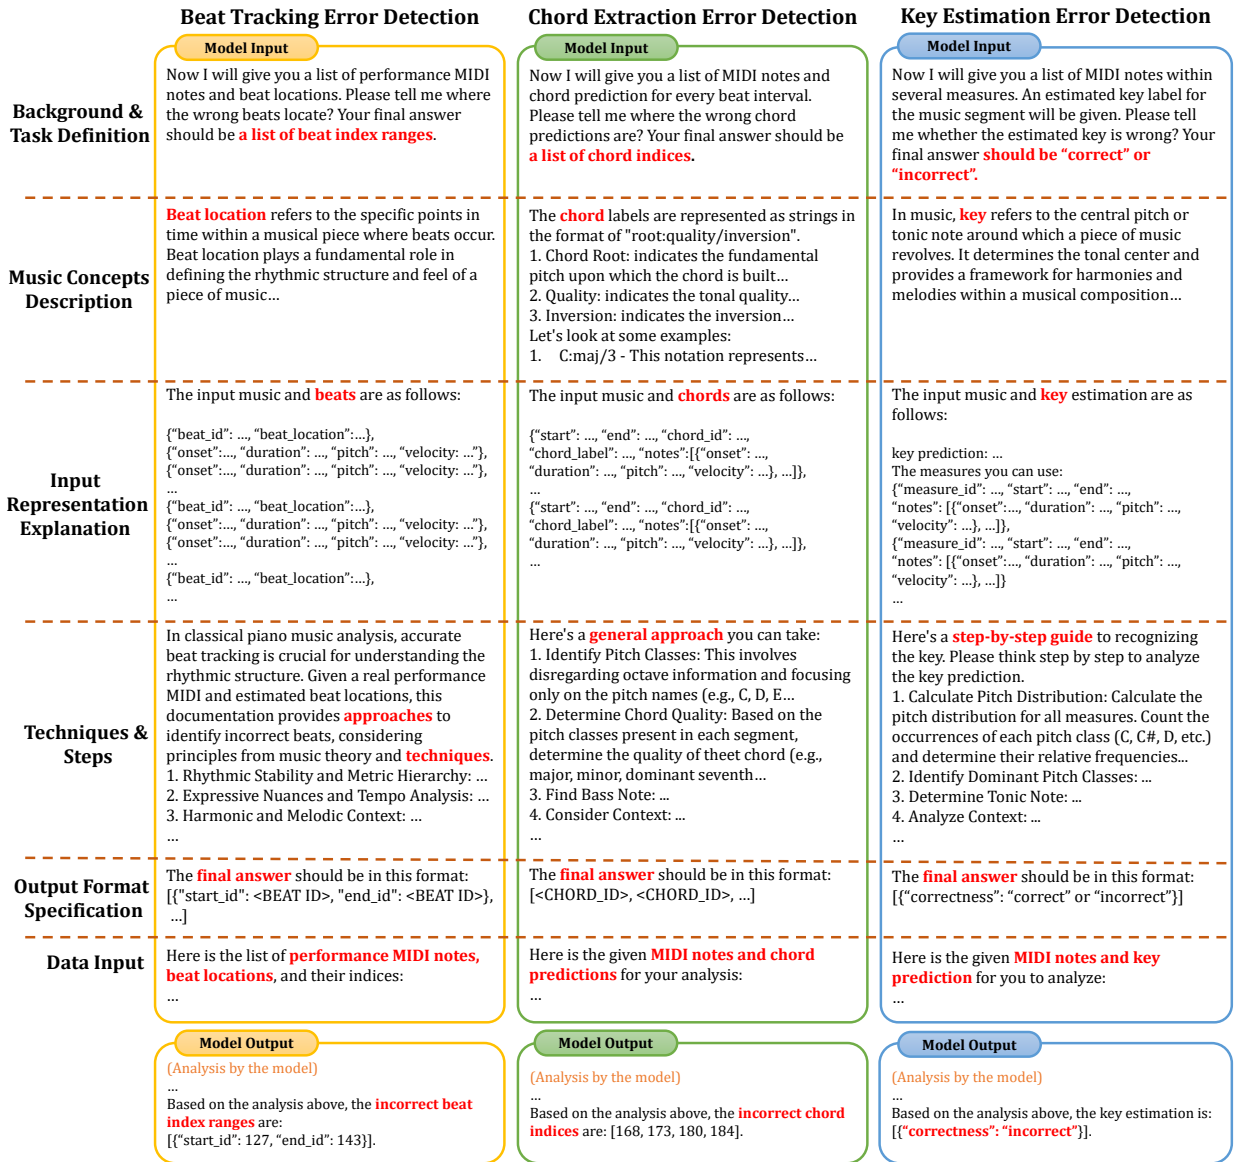

Figure 1: The example prompts and model outputs for the three error detection MIR tasks: beat tracking, chord extraction, and key estimation. Some keywords are highlighted in red in this figure for better readability. Orange texts indicate omitted content. The prompt structure is shown on the left.

music performance data in symbolic format. The errors are introduced by selecting an incorrect key out of the other 23 major and minor keys randomly at a controlled rate.

As shown in Figure 1 (right), we use the JSON format to represent the music segment and key annotations, where the key annotation is given at the beginning. The predicted key is represented by a formatted string of tonic and mode (e.g., "A:min").

3.2 Prompt Structure

Our investigation of prompt engineering methods indicates that a well-organized prompt structure is essential for successful MIR error detection. As shown in Figure 1, the prompt of the three MIR tasks all consists of six components as follows:

- **Background and Task Definition** introduces the MIR task and music domain background, and specifies the

role of the LLM as a judge in assessing the correctness of MIR results.

- **Music Concepts Description** introduces relevant music concepts about beat, chord, or key, together with examples of those concepts. For example, we show examples of chord root, quality, and inversion for chord extraction, to guide the LLM to better parse the chord labels such as C:maj/3.
- **Input Representation Explanation** specifies the data structure and format of the input music data.
- **Techniques and Steps** provides reference steps to encourage the LLM to apply "chain-of-thought" in the error detection process. For example, we provide clear steps in the chord extraction task: 1) Identify Pitch Classes; 2) Determine Chord Quality; 3) Find Bass Note; 4) Consider Music Context; and etc.
- **Output Format Specification** defines the JSON-like output format, ensuring consistency for post-processing.

- **Data Input** provides the subject music piece and the MIR results to be judged, following the format defined in input representation explanation section.

3.3 Concept Augmentation

The prompts defined in Section 3.2 contain extensive music concepts for each of the three tasks, which we regard as *Basic Concepts*. Based on these, we apply *concept augmentation* by either introducing new concepts or masking basic concepts in order to compare the LLM performance under varying amounts of music knowledge provided.

In *Concept Introduction*, we add new concepts that are supposedly helpful for doing MIR tasks. For example, for beat tracking, we introduce “rhythm” to the LLM: we provide a brief description of on-beat notes and off-beat notes, and how to compute their density percentages. We explain how such concepts contribute to better judgments.

Conversely, we also define the *Concept Masking* operation, which eliminates or blurs music concepts at different levels. Such operations are used to examine the *innate* reasoning ability of LLMs as a reference:

- **Music Attribute Masking:** removes explanations about music concepts pertaining to the musical objects under operations. For example, in chord extraction, “root note”, “chord quality”, and “inversion” are replaced by an abstract generic expression, “a chord feature”.
- **Task Masking:** on top of Music Attribute Masking, removes explanations about all concepts related to the MIR task, so that the LLM is required to reason about the correctness for a novel abstract task. For example, for beat tracking, the task becomes “Please read a sequence of MIDI notes and music labels to determine the correctness of each label.” All expressions that imply beat tracking will be deleted, including “tempo”, “fast”, “slow”, etc., to ensure that the task information is not implied in any form.
- **Domain Masking:** on top of Task Masking, eliminates explanations about all concepts related to the *music* domain to the greatest extent, leaving the LLM with an abstract logic-domain reasoning problem. For example, the LLM is told: “You will be given some labels and the corresponding raw data. Your task is to tell me where the wrong labels are located?”

4. EXPERIMENTS

We conduct our LLM-based MIR tasks with GPT-3.5. We introduce the datasets in Section 4.1 and the evaluation metrics in Section 4.2. The evaluation results are provided in Section 4.3.

4.1 Datasets

We use symbolic performance MIDI dataset for the three proposed tasks. For beat tracking error detection, we use classical piano recordings from the MAPS database [20], specifically from the “ENSTDkCI” subset (29 pieces) which has been commonly used as a beat tracking test

set. We also use the corresponding metrical annotations from [21]. We randomly create beat errors by inserting (9%), deleting (12%), or offsetting (9%) beats, resulting in an emulated MIR prediction with an F-score of 0.8370.

For both chord extraction and key estimation error detection, we use MIDI for Chinese pop songs on a subset of the POP909 dataset [22]. For chord extraction, we randomly introduce errors in root, quality, or inversion with a ratio of 30%, resulting in an “MIR” accuracy of 0.7327. We choose 50 songs and divide each song into segments with 32 chord labels. For key estimation, we test on 757 songs in the dataset whose ground-truth key is unchanged throughout the piece. We randomly select three four-measure segments for each song and modify 30% of the key labels at random. A summary of the data statistics is shown in Table 1.

	Beat Tracking	Chord Extraction	Key Estimation
#Notes	70,607	48,919	177,535
#Labels	14,194	9,200	2,271
#Tokens (per call)	6065.31	9256.80	3214.63

Table 1: Statistics of the music data used for evaluation. The row #Notes represents the total number of MIDI notes processed for each task. The row #Labels indicates the number of labels used in the evaluation of each task. The row #Tokens (per call) shows the average number of tokens per call fed into the GPT-3.5 model for each task.

4.2 Evaluation Metrics

We design metrics to evaluate the performance of LLMs in identifying errors in MIR annotations. Since our approach does not directly predict MIR annotations, our metrics differ from existing MIR evaluation metrics. For chord extraction and key estimation tasks, we regard error detection as a binary classification task in which each chord or key label is classified as correct or incorrect. We use weighted precision, recall, and F1-score to evaluate GPT’s performance on both correct and incorrect classes [23].

In beat tracking error detection, the beat sequence with potential errors is typically not one-to-one aligned with the ground truth beats. We consider three types of beat locations: 1) correctly identified beats, 2) additional beats, and 3) missing beats, which are also referred to as true positives, false positives, and false negatives, respectively, in conventional beat tracking tasks [18]. We use TP, FP, and FN to denote these sets of beat positions and I to denote the union of time intervals predicted by an LLM error detector. We consider the following metrics:

- **CPR (Correct Pass Rate on TP)** is defined as $\frac{|TP-I|}{|TP|}$, which measures the proportion of true positives that are correctly identified (by GPT) as “correct beats”.
- **EDR_P (Error Detection Rate on FP)** is defined as $\frac{|I \cap FP|}{|FP|}$, which evaluates the proportion of false positives that are correctly identified (by GPT) as “incorrect beats”.
- **EDR_N (Error Detection Rate on FN)** is defined as: $\frac{|I \cap FN|}{|FN|}$, which evaluates the proportion of false negatives that are correctly identified (by GPT) as “incorrect beats”.

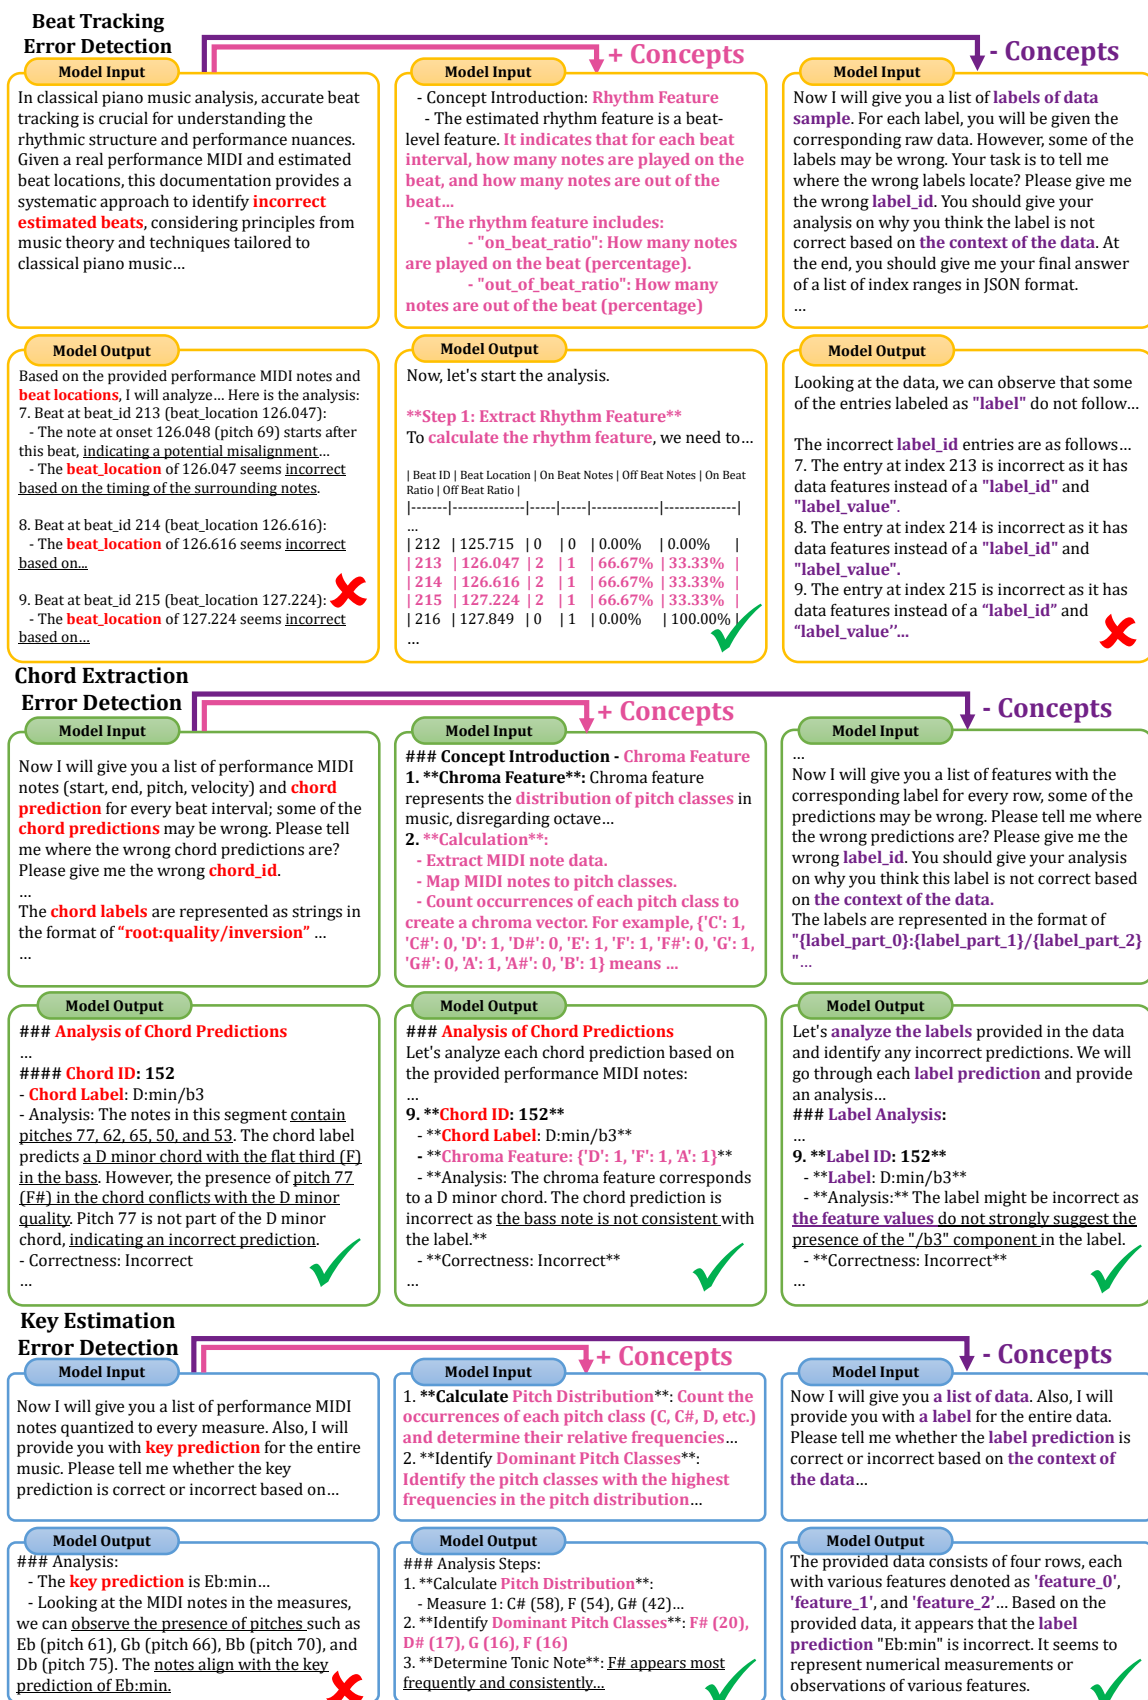

Figure 2: The impact of concept augmentation on GPT's behavior in three MIR error detection tasks: 1) *Basic Concepts* (left), 2) *Concept Introduction* (middle), and 3) *Concept Masking*: all music domain concepts removed (right). Red color indicates the basic concepts. Pink color indicates the introduced concepts. Purple color represents the expression after masking all music-related concepts. Underlines denote reasoning process. The checkmark indicates a correct judgment made by GPT, while the cross indicates an incorrect judgment by GPT.

Concept Augmentation	CPR \uparrow	EDR $_P$ \uparrow	EDR $_N$ \uparrow	WS \uparrow
Basic Concepts	0.6681	0.3728	0.1794	0.5607

- "Music"(Domain Masking)	0.5927	0.4161	0.4085
Random	0.5779 \pm 0.0086	0.4977 \pm 0.0093	0.5186 \pm 0.0089

(c) Evaluation results on key estimation error detection

Table 2: The evaluation results of GPT on three MIR error detection tasks: beat tracking, chord extraction, and key estimation. Each task is assessed under different concept augmentation. "+" denotes *Concept Introduction*. "-" denotes *Concept Masking*. \uparrow indicates that higher values are better. p , r , and f stand for precision, recall, and F-score, respectively.

Finally, we compute a weighted average of these metrics, denoted by WS:

$$WS = \frac{CPR \times |TP| + EDR_P \times |FP| + EDR_N \times |FN|}{|TP| + |FP| + |FN|} \tag{1}$$

4.3 Evaluation Results

We evaluate the performance of GPT on three MIR error detection tasks. We first use the prompt with Basic Concepts and compare it with a random baseline, as well as prompts under different concept augmentation methods (see Section 3.3). The results are summarized in Table 2.

The results of beat tracking error detection task are shown in Table 2a. The random baseline is implemented by first randomly selecting k beat labels and joining consecutively selected beats into time intervals serving as detected error ranges. In Concept Introduction, we guide the GPT to compute the number of on-beat and off-beat note percentages, and in Concept Masking, we apply music attribute, task, and domain masking incrementally. Results show the basic prompt outperforms the random baseline in all prompt settings. Moreover, as the number of concepts decreases, the performance of GPT in judging the correctness of beat labels shows an overall downward trend.

The results of chord extraction error detection task are shown in Table 2b. The random baseline detects incorrectness with a probability of 50%. In Concept Introduction, we show GPT the chord chroma concept and encourage GPT to deduce the pitch distribution from input music. Results show that all GPT settings far exceed the random baseline. There remains a downward trend as the number concepts decreases except in the Domain Masking setting.

The results of key estimation error detection task are shown in Table 2c. The random baseline and concept aug-

mentation are implemented similarly to those of chord extraction. In Concept Introduction, we show GPT the scale concept. Results show that GPT performs slightly better than the random baseline in F-score and recall, and similar to the baseline in precision. The downward trend of concept augmentation is less salient.

Finally, we provide a case study (Figure 2) to illustrate GPT’s behavior under different settings of concept augmentation. In all tasks, GPT exhibits general time series analysis abilities even when music concepts are all masked, and the introduced music concepts help GPT to reason in a more musical fashion, particularly in beat tracking. However, we also observe limitations, including high randomness in output, sensitivity to prompts, and hallucination [24]. These issues make it challenging to empirically summarize or conjecture GPT’s reasoning abilities in solving MIR problems in general.

5. CONCLUSION AND FUTURE WORK

In conclusion, we have proposed a methodology to solve MIR problems with text-based LLMs with prompt engineering. We evaluate the performance of GPT-3.5 in error detection across three MIR tasks and find out that GPT’s music reasoning ability in MIR tasks can be enhanced when provided with well-structured prompts with music concepts. Across all three MIR error detection tasks, GPT consistently outperforms random baseline methods and demonstrates improved performance when prompted with additional music knowledge. In this study, we establish a baseline for assessing LLMs’ ability to understand music solely through reasoning, paving the way for future LLM-based MIR research. In the future, we will consider evaluating LLMs’ judging ability on real MIR errors instead of synthetic ones and using fine-tuning techniques to better explore LLM-based MIR study.

ABSTRACT

Recent advancements in music generation are raising multiple concerns about the implications of AI in creative music processes, current business models and impacts related to intellectual property management. A relevant discussion and related technical challenge is the potential replication and plagiarism of the training set in AI-generated music, which could lead to misuse of data and intellectual property rights violations. To tackle this issue, we present the Music Replication Assessment (MiRA) tool: a model-independent open evaluation method based on diverse audio music similarity metrics to assess data replication. We evaluate the ability of five metrics to identify exact replication by conducting a controlled replication experiment in different music genres using synthetic samples. Our results show that the proposed methodology can estimate exact data replication with a proportion higher than 10%. By introducing the MiRA tool, we intend to encourage the open evaluation of music-generative models by researchers, developers, and users concerning data replication, highlighting the importance of the ethical, social, legal, and economic consequences. Code and examples are available for reproducibility purposes.¹

1. INTRODUCTION

Significant advancements in generative algorithms for digital art creation are challenging the role of artificial intelligence (AI) in artistic practices. Regarding generative AI in the music domain, there is an increasing discussion related to the use of computational tools in music creative processes [1], the effects on artists' work, existing listening experiences and business models, and the impacts on intellectual property (IP) management [2,3]. A key point is the potential replication and plagiarism of the training set in AI-generated music [3,4], which can lead to data misuse and IP violations.

Serra, Y. Mitsufuji and E. Gómez, "Towards Assessing Data Replication in Music Generation with Music Similarity Metrics on Raw Audio", in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

The inherent opaque nature of music generation models complicates tracing replications or references to training set samples in AI-generated music, limiting the interpretation of whether generated samples contain replicated fragments. In addition, diffusion models, one of the most popular generative AI architectures, tend to memorise and replicate training data [5–7]. Understanding the behaviour of these models has become critical to address legal issues [8], especially when dealing with data protected by IP rights. This is significant in the music domain as the vast majority of music is protected by authorship and copyright.

Despite multiple claims emphasising the importance of assessing music-generative algorithms, there is a lack of evaluation tools directly focused on detecting data replication based on raw audio. Considering this research gap, the present investigation is motivated by two main questions:

- Are audio-based music similarity metrics suitable to assess data replication in AI-generated music?
- Can we propose an open model-agnostic evaluation method and tool found on diverse audio-based music similarity metrics?

Thus, this work proposes assessing the effectiveness of five music similarity metrics² (four state-of-the-art widely-used and a novel one) in estimating exact data replication in music. We review the implications of potential data replication in AI-generated music (Section 2) and present our experimental setup, including the selected music similarity metrics and specific methodology to control and estimate exact data replication (Section 3). We analyse metrics' behaviour in different music materials (Section 4.1), aiming to assess later their data replication detection sensitivity (Section 4.2). The proposed methodology is implemented in tool MiRA (Music Replication Assessment), which computes music similarity between reference and target samples to obtain global and per-pair distances (Section 5). Finally, we discuss our research's insights, limitations and future perspectives (Section 6).

By introducing MiRA tool, we advance towards the assessment of data replication in AI-generated music using similarity metrics, contributing to open evaluation methods for accessibility for researchers, developers and users. We strive to raise awareness, detect and prevent misappropriation of training sets, and hope to motivate research on these issues.

² Hereafter, music similarity metrics refer to audio-based metrics.

2. BACKGROUND AND RELATED WORK

2.1 Implications of potential data replication in AI-generated music

Music-generative AI is advancing rapidly with novel high-quality models driven by a strong push from the industry, which is encouraging a suitable environment for real-world deployment. Yet, music generation algorithms bring significant concerns regarding their ethical, social, legal and economic implications. A key challenge is the potential data replication in AI-generated music—inquiring whether a generative model extracts and copies fragments from the training data and whether AI-generated music can be considered novel and original [3, 4]. This issue is further complicated by the implications derived concerning data misuse and IP violations such as copyright infringement. Moreover, diffusion models, one of the most popular architectures for generative AI, present high risks of data replication as they have shown a tendency to memorise their training data [5–7]. In the image generation domain, Somepalli et al. [9] demonstrate instances where generated images with diffusion models contain object-level copies of their training data. Based on image retrieval frameworks, they compare generated images with training samples and detect when content has been replicated. Similarly, Carlini et al. [5] demonstrate that diffusion models memorize and reproduce images from their training data.

Memorising training data and potential IP violations is highly under-discussed in music generative models literature, despite being one of generative AI’s main negative ethical implications in the music domain [10]. However, the recently proposed music generative model *MusicLM* [11] has been refrained from releasing due to the ethical risks and potential work replication. In addition, *MusicLDM* [12] acknowledges potential issues linked to data replication and plagiarism and, to address them, proposes two beat-synchronous mix-up strategies for data augmentation. The exemplified initiatives underscore the relevance of considering and addressing the ethical implications of these algorithms.

2.2 Evaluation methodologies in music generation

Xiong et al. [13] present a survey on music generation evaluation methodologies divided into objective, subjective and combined approaches. They highlight a current claim in finding a standardised proper method that aligns with all stakeholders, from developers to musicians and music listeners. However, even if multiple evaluation methodologies exist for music generation models, the literature highlights a lack of evaluation methodologies focused on assessing data replication and the originality of AI-generated music [4, 14]. In the symbolic domain, Yin et al. [4] introduce the *originality score* to measure the extent to which an algorithm might be copying from the training set. Nonetheless, there is a growing interest in models outputting directly audio music instead of symbolic representations. Thus, a research gap exists in detecting data replication in AI-generated music based on raw audio.

A recent work by Barnett et al. [15] proposes a framework based on two music audio embeddings to assess the similarity between the training data and AI-generated samples for understanding training data attribution. Their approach, based on VampNet [16], computes cosine distance on embeddings obtained from CLMR (Contrastive Learning of Musical Representations) [17] and CLAP (Contrastive Language-Audio Pretraining) [18].

Our perspective is that combining metrics based on audio embeddings, acoustic qualities, and features capturing music characteristics, such as chord progression or tonal similarity, provides a comprehensive assessment of potential data replication in AI-generated music. In this study, we aim to validate the effectiveness of five music similarity metrics and build an open tool to assess exact data replication in AI-generated music using these metrics.

3. FORCED-REPLICATION EXPERIMENT

3.1 Audio Music Similarity Metrics

For this study, we consider five music similarity metrics: four state-of-the-art approaches and a novel one, covering a diversity of characteristics. We here describe the metrics (summarised in Table 1) and methods used to implement them.³

Cover Song Identification (CoverID) [19–21]: Cover song identification is a task aiming to detect whether two music recordings are based on the same composition, accounting for variations in tempo, structure, and instrumentation while keeping a similar melodic or harmonic line. CoverID relies on pitch-content features and local alignment. To obtain CoverID distance, we use the implementation available in Essentia.⁴ A low CoverID value suggests substantial composition similarity between the two analysed music samples.

Kullback-Leibler (KL) divergence: This metric provides a non-symmetric statistical measurement between reference and target probability distributions relative to their entropy. KL divergence has been employed in the literature to estimate similarity in music (e.g. [22, 23]), and more recently, to assess automatic music generation prompt adherence (e.g. [24]). We aim to explore its capabilities to estimate data replication in music samples. To obtain probability distributions, we use the PaSST audio classifier proposed in Koutini et al. [25], trained on Audioset. This methodology aligns with common practice in the literature, such as in *AudioGen* [26] and *MusicGen* [27] to obtain the probabilities of the labels in their audio and music samples. To avoid the non-symmetry of KL divergence, we compute reference to target and target to reference KL divergence and, subsequently, average both results to obtain symmetric KL divergence. Low KL divergence indicates a closer similarity between distributions.

³ Two of the metrics rely on Essentia implementation. Essentia is an open-source library and tools for audio and music analysis, description and synthesis, developed in the Music Technology Group at Universitat Pompeu Fabra: <https://essentia.upf.edu>.

⁴ https://essentia.upf.edu/reference/std_CoverSongSimilarity.html

Table 1: Summary of the considered music similarity metrics, indicating whether values correspond to higher or lower similarity (↓/↑).

Metric	Description
CoverID (↓)	Musical composition similarity based on music-specific characteristics.
KL divergence (↓)	Differences in distributions from an audio classifier.
CLAP (↑)	Distance between embeddings from a music pre-trained model.
DEfNet (↑)	Novel metric based on distance between embeddings from a contrastive learning model for music similarity.
FAD (↓)	Distance between embeddings based on CLAP music model.

Contrastive Language-Audio Pretraining (CLAP) score [18]: CLAP embeddings⁵ allow to obtain latent representations of audio or text by conditioning information. For instance, *MusicLDM* [12] uses this metric to assess the novelty in text-to-music generations. To compute the CLAP score between two music samples, we extract the audio embeddings from the pre-trained music model⁶ for each one and compute the cosine distance between them. A high CLAP score indicates a high similarity between the two music samples.

Discogs-EffNet (DEfNet) score: In addition to state-of-the-art distances between audio embeddings, we incorporate a novel approach based on Essentia models [28]. Essentia’s Discogs-EffNet model⁷ provides music audio embeddings trained on Discogs metadata with contrastive learning purposes for music similarity. We consider DEfNet score to observe the effectiveness of embeddings of a model trained for a music-related task on estimating data replication. Embeddings are extracted based on track self-supervised annotations⁸ and compute the cosine distance between reference and target samples. A high DEfNet score reveals high track similarity.

Fréchet Audio Distance (FAD) [29, 30]: FAD is an adaptation of Fréchet Inception Distance (FID) for music, comparing embedding distributions of a reference and a target set, based on the ViGGish model [31]. Nonetheless, a recent study by Gui et al. [30] questions whether ViGGish is the optimal model for FAD computation for music generation evaluation. They propose a tool kit⁹ with multiple models to obtain more accurate embeddings to assess AI-generated music when calculating FAD. Consequently, we implement the adapted version of FAD using the CLAP audio music pre-trained model. A low FAD score indicates a high resemblance between the compared music samples.

3.2 Experimental Approach

To validate the effectiveness of the selected music similarity metrics in detecting exact data replication, we carried out a controlled forced-replication experiment with synthetic data, i.e. replicating music excerpts into another song under controlled conditions. Synthetic data guaranteed that the analysed music samples contained copied instances, limiting our scope to exact data replication.

For this experiment, we use an in-house dataset of 30-second audio previews from the Spotify API¹⁰, composed of over 18,000 samples and 24 music genre classes. We focus on six music genre classes defined by Spotify API internal class labels: *heavy metal*, *afrobeats*, *techno*, *dub*, *cumbia* and *bolero*. These genres were chosen for their diverse musical compositions and elements, allowing us to examine the metrics across multiple scenarios. This selection was supported using ChatGPT, which affirmed that these genres have distinct musical characteristics.

We divide data into three groups: (1) **reference set:** acting as training data, (2) **target set:** composed of synthetic data, representing AI-generated music, and (3) **mixture set:** containing different songs from the reference set but from the same music genre to build synthetic data. Synthetic data with replication contains a controlled percentage of copy from a song in our reference set: 5% (1.5s), 10% (3s), 15% (4.5s), 25% (7.5s) and 50% (15s). A synthetic sample is created by introducing the copied proportion at a random point of a music sample in the mixture set. We create 10 samples with a proportion of replication per song in the reference set. Figure 1 illustrates the procedure to build synthetic data with 5% of replication. For each music genre, the reference and mixture sets are composed of 400 songs each. Thus, the target set comprises 4,000 (400 x 10) songs per percentage of replication for each genre. Music samples are 30 seconds long as currently it is the common length in full song composition music generative models.

We assess each metric for all the songs within the reference set against themselves to establish a baseline (400 x 400 = 160,000 per-pair evaluations). Then, we compute them for each reference song and its copied instances to only consider cases with exact data replication (4,000 per-pair evaluations). Our experiment considers 120,000 samples of synthetic data (approximately 167h of music with a proportion of data replication).

Figure 1: Synthetic data procedure with 5% of replication.

4. RESULTS

4.1 Analysing metric behaviour

Figures 2, 3, 4, 5 and 6 depict the average μ and standard deviations σ of the different metrics per degree of replication and music genre. We observe a steady and similar behaviour by three metrics (CoverID, CLAP and DEfNet) through all studied music genres, showing higher similarity values for cases with higher replication levels (i.e., 50%). Standard deviation decreases with increasing replication level, which suggests less disparity within the analysed pairs. These three metrics show the sensitivity¹¹ to estimate data replication.

Instead, KL divergence presents a different behaviour with very similar values of μ and σ for all degrees of replication. Some sensitivity is observed in all music genres, except for *dub*, where the baseline mean μ_b is smaller than in replication cases μ_r , despite the standard deviation being higher ($\mu_b=0.757$, $\sigma_b=0.511$; $\mu_r=0.862$, $\sigma_r=0.462$). Thus, KL divergence demonstrates the capability of detecting replication but is ineffective in distinguishing between degrees of replication.

Contrasting with the other metrics, FAD based on CLAP music embeddings completely differs from them. On the one side, its behaviour is inconsistent as it exhibits fluctuating trends for the different examined cases. On the other side, it fails to detect data replication. A higher similarity value (low FAD) is always obtained for the baseline. Instead, for the different degrees of replication, higher FAD is achieved. Consequently, FAD based on CLAP music embeddings does not appear to be a suitable metric to assess exact data replication in music samples.

By analysing the metrics' behaviour, we could directly conclude that CoverID, KL divergence, CLAP and DEfNet are suitable for our posed research aim. However, further exploration is required before determining their ability to detect replication and degree of replication. We delve into this analysis in the next subsection.

4.2 Assessing data replication detection sensitivity

In this section, we complement the previous analysis with an assessment of statistical differences. Because our data is not normally distributed and variance is heterogeneous, the Kruskal-Wallis test [32] is the most adequate statistical analysis to examine our results, as is non-parametric, does not rely on normality and handles unequal sample sizes. We perform the Kruskal-Wallis test on CoverID, KL divergence, CLAP and DEfNet. Significant statistical differences ($p < 0.05$) are observed across all music genres and degrees of replication, consistent with our earlier findings.

Nonetheless, the insight of this analysis relies on the pairwise comparisons between the baseline and different degrees of replication. CoverID pairwise comparison reveals a statistically significant difference between the baseline and the 5% replication degree for *afrobeat*, *cumbia* and *techno*. For the three other music genres, this happens

Figure 2: CoverID (↓)

Figure 3: KL divergence (↓)

Figure 4: CLAP (↑)

¹¹ *Sensitivity* is understood as the capability to differentiate between degrees of replication.

Figure 5: DEfNet (↑)

Figure 6: FAD (↓)

for a 10% replication degree. Then, statistical significance also appears in pairwise comparisons of different degrees of replication. We can derive that CoverID is sensible for 10% of replication, and in some cases at 5%. When considering KL divergence, pairwise comparison depicts a statistically significant difference between the baseline and the 5% replication degree. Between degrees of replication, no statistical significance is revealed for any pairwise comparison, except for *heavy metal* between 5% and the other replication degrees. Regarding the CLAP and DEfNet, a significant difference already appears when comparing the baseline against the samples with 5% replication, indicating that these metrics are sensitive to 1.5 seconds of replication. In all cases, a notable difference emerges among the levels of replication, enhancing the sensitivity of these metrics’ detection capabilities. They demonstrate sensitivity to varying replication degrees.

Withal, this statistical analysis sustains the validity of these four metrics to assess exact data replication in the training set and determines their degree of sensitivity.

5. MUSIC REPLICATION ASSESSMENT TOOL

Derived from the presented experiment, we implement the proposed methodology into an evaluation tool. We introduce the Music Replication Assessment (MiRA) tool: an open evaluation method based on four diverse raw audio music similarity metrics.

MiRA computes music similarity between reference and target samples to obtain global and per-pair distances, based on CoverID, KL divergence, CLAP and DEfNet. It can estimate data replication with a proportion higher than 10% (3 seconds), but in most of the examined scenarios, it is sensible to 5% of replication. Per-pair distances are highly beneficial for detecting close pairs, outliers and suspicious cases with potential data replication. Considering that replication detection requirements may vary depending on the evaluation, users are left to set their replication threshold. In addition, MiRA is model-independent as no information about the model architecture or its characteristics is necessary. The evaluation is conducted directly with the training (**reference**) and generated samples (**target**) of the analysed generative model.

However, designating a baseline value is encouraged to accurately interpret the music similarity between the reference and target samples. We propose a third comparison group of samples (**control**) based on songs related to the reference songs but unseen by the model (e.g. shared music genre). Again, this is a decision for the users conditioned to their evaluation scope. Note that using a control group allows us to understand and interpret the results obtained by acting as the baseline similarity level of independent songs with a shared characteristic.

The complete structure of the implemented system is depicted in Figure 7. We release MiRA as an open-source tool, built into a PyPI package¹². Together with the code, we provide examples and best practice recommendations for using this methodology. With the release of MiRA, we hope to enhance transparency in music generation models and data replication assessment.

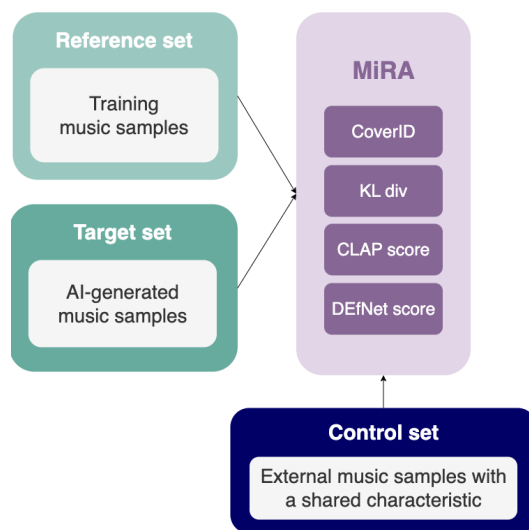

Figure 7: MiRA’s structure scheme.

6. DISCUSSION AND CONCLUSIONS

This work focused on validating the use of music similarity metrics for assessing data replication in AI-generated music. We hypothesise that similarity metrics are effective in estimating data replication. Therefore, we framed the scope of our study to exact data replication in music samples, while conducting a controlled forced-replication experiment with synthetic data.

We examined five diverse audio-based metrics: four standard metrics (CoverID, KL divergence, CLAP and FAD) and a novel one (DEfNet). Our results indicate that four of the five studied metrics can detect data replication to a certain extent. Instead, FAD based on CLAP music embeddings presented an opposite behaviour compared to the other metrics. Higher similarity is obtained for the baseline group and FAD shows unstable trends throughout the diverse music genres. Thus, we do not find it suitable for our case study. However, it must be acknowledged that the recent publication by Gui et al. [30] offered multiple classifiers to compute FAD. There is the possibility that we did not consider the appropriate classifier for our task. Thus, we should consider exploring other classifiers before determining the validity of FAD in detecting replication in music.

Regarding the other four metrics, our results show interesting insights. First, we find CoverID to be sensible to different replication degrees, establishing a robust threshold level at 10% of replication. Furthermore, in some of the studied cases, replication sensitivity is lowered to 5% of replication. This is a substantial finding to validate the suitability of metrics oriented to specific music characteristics, such as tempo, structure and composition.

Next, we observe that KL divergence can be sensitive to replication as pairwise comparison between baseline and degrees of replication is statistically significant. Nevertheless, the other pairwise results reveal that KL divergence is ineffective for differentiating between replication degrees. We consider this an unexpected turnout in our analysis.

Considering CLAP and DEfNet scores, both embedding-based metrics, our experiment validates their suitability to detect data replication. Not only do they show robustness by increasing their similarity value parallel to the replication degrees (i.e. higher similarity for higher level of replication), but they also show high sensitivity for different degrees of replication. All results suggest their sensitivity might be higher than we envisioned and might be able to detect replication in smaller samples (i.e. < 1.5 seconds).

As a result of these findings, we achieve our second goal within the scope of this research: to build an open model-agnostic tool based on music similarity metrics on raw audio. In this article, we have introduced the MiRA tool, leveraging the four validated similarity metrics, which can be used to evaluate any music-generative model with audio output. MiRA does not require any information about the model architecture or its characteristics. Instead, similarity evaluation relies on comparing reference and target samples.

By introducing the MiRA tool, we are contributing to the research gap of lack of evaluation methodologies directly assessing potential data replication in AI-generated music. Our study validates the use of similarity metrics to estimate training data replication. We intend to encourage the open evaluation of music generation models by researchers, developers and users concerning data replication. In addition, our research strives for the importance of ethical, social, legal and economic consequences of generative AI in the music domain, together with the need to address their risks and issues.

6.1 Limitations and Future Work

Despite our contribution to advance towards data replication assessment with music similarity metrics, there are multiple opportunities to complement our investigation.

First, we limited the scope of our experimental approach to assessing the use of different music similarity metrics for exact data replication, consequently reducing the definition of plagiarism to exact replication of fragments in the training set. We followed such an approach to validate our hypothesis and ensure an attainable method to address this issue. While this reduced scope could potentially be solved using audio fingerprinting strategies [33], we believe that by employing a diverse range of metrics we can provide a more comprehensive assessment of data replication.

Framing our aim to exact data replication also introduced a limitation in considering typical perturbations that music samples experience when training the model or during the model procedure to generate a music sample. Thus, it would be a key point for future work to validate the robustness of these metrics towards typical data augmentation techniques, such as pitch shifting and reverberation. Proving them to be robust would also enhance the capabilities of MiRA for detecting potential replication in AI-generated music. At the same time, we intend to expand the abilities of MiRA for data replication by incorporating complementary metrics, if necessary.

In addition, our experimental process was limited to the high computational costs of some of the metrics. In particular, we faced significantly large amounts of time to compute FAD and KL divergence. This is a relevant concern as we want MiRA to be an open tool that can be used by any researcher or user. Thus, considering the computational capacity required to compute the integrated metrics within is a relevant issue in our research.

Another limitation is the type of data that we use. We base our experiment on synthetic data despite our goal being oriented to AI-generated music. We must use synthetic data with a controlled percentage of replication to guarantee and assess the capabilities of detection and sensitivity of music similarity metrics. However, we would like to test the validity of the introduced tool when used in a generation context. To do so, we require not only a generative model but its details on training data and generation samples. We plan to expand our research in with AI-generated content in upcoming studies.

7. ACKNOWLEDGMENTS

8. ETHICS STATEMENT

The late rapid popularity growth of generative AI in the music domain brings significant ethical implications. The main challenges are linked to the role of AI within music creative processes, such as composition, potential misappropriation of data in AI-generated music, inquiries on the novelty of generations, derived authorship attribution, effects on intellectual property rights and sustainability of current business models. In addition, there are notable concerns about the cultural bias in these systems and their environmental impact.

Our research focused on the issue of assessing potential data replication in AI-generated music. We observed a lack of evaluation methodologies to examine replication in raw audio. We contributed to this issue by proposing a methodology based on audio-based music similarity metrics. We demonstrated its effectiveness and provided an open tool to evaluate AI-generated music. Our introduced approach is contributing to the transparency of music generation algorithms.

Despite the positive contribution of our investigation, we must be critical of some methodological aspects of our work. Our principal ethical concern falls under the type of data used to conduct our forced-replication experiment. In particular, we employ an internal dataset created with Spotify previews (30-second samples of music). Even if these practices are common in the ISMIR community, we see the need for guidelines for the legal assessment of MIR data included in datasets, incorporating country dependencies, origin and intended use, personal data involved (from artists and listeners) and potential future consequences¹³.

GENERATING SAMPLE-BASED MUSICAL INSTRUMENTS USING NEURAL AUDIO CODEC LANGUAGE MODELS

*Equal contribution

ABSTRACT

In this paper, we propose and investigate the use of neural audio codec language models for the automatic generation of sample-based musical instruments based on text or reference audio prompts. Our approach extends a generative audio framework to condition on pitch across an 88-key spectrum, velocity, and a combined text/audio embedding. We identify maintaining timbral consistency within the generated instruments as a major challenge. To tackle this issue, we introduce three distinct conditioning schemes. We analyze our methods through objective metrics and human listening tests, demonstrating that our approach can produce compelling musical instruments. Specifically, we introduce a new objective metric to evaluate the timbral consistency of the generated instruments and adapt the average Contrastive Language-Audio Pretraining (CLAP) score for the text-to-instrument case, noting that its naive application is unsuitable for assessing this task. Our findings reveal a complex interplay between timbral consistency, the quality of generated samples, and their correspondence to the input prompt.

1. INTRODUCTION

The exploration of sound synthesis and the development of interfaces to manipulate timbre are fundamental topics in audio research [1]. With the evolution of sound synthesis in the digital realm, musicians have unprecedented means to manifest their artistic visions. Meanwhile, generative models for images and text have shown disruptive abilities in creating novel samples from learned distributions [2]. It becomes only natural to consider implications of such technologies when applied to a music production context.

Several generative models for neural audio synthesis have been put forth, including NSynth [3], which uses a WaveNet [4] autoencoder to create samples of pitched instruments, and GANSynth [5], which models signal phase through an instantaneous frequency representation. Furthermore, Differentiable Digital Signal Processing (DDSP)

[6] and its related works [7] introduce autoencoders with differentiable synthesizers for improved controllability, while a novel approach via a real-time variational autoencoder is presented in [8]. Additionally, GANstrument [1] leverages a feature descriptor obtained through adversarial domain confusion, highlighting the diverse methodologies employed to advance the field of audio synthesis. These models lack an interface for controlling audio generation via text input. Accordingly, we have witnessed a surge in text-to-audio systems generating convincing audio examples from text prompts [9]. One family of approaches rely on neural audio codecs [10, 11] representing audio as a set of discrete codes whose sequence can be learned using transformer-based language models. While initial approaches targeted speech [12, 13] and ambient sounds [14], follow-on works adapt methods for text-to-music generating full musical passages from text [15, 16].

Though compelling, seminal text-to-music works target generation of entire musical arrangements or otherwise lack fine-grained control over their outputs, and might not integrate well into musicians' workflows. Consequently, efforts have been made to adapt these models to sit closer in the creative process. These include StemGen [17], predicting instrument track layers from a given musical context, and VampNet [18], generating musical variations via generative filling. We align with this philosophy, intending to enable new sounds to inspire musical creativity.

In this paper, we introduce the application of neural audio codec language models for the automated creation of sample-based musical instruments using both text and audio prompts as input, building upon our preliminary work in progress in [19]. We model a musical instrument as a set of waveforms sampling the instrument's time-domain response across the dimensions of pitch (the fundamental frequency of a note) and velocity (the intensity with which a note is played). Under this paradigm, we move beyond the constraints of any one parametric synthesizer, avoiding expressivity limitations tied to its implementation. As in [1], we note that injecting inductive bias into the generative process via DDSP is interesting but complementary to our work, as such methods constrain the manifold that outputs can live on [20]. Unlike text-to-music systems, which typically generate a single audio example for a given text prompt during inference, prompt-to-instrument systems must generate an ensemble of audio samples from a fixed prompt, which must be pitch-accurate and timbrally

Blang, "Generating Sample-Based Musical Instruments Using Neural Audio Codec Language Models", in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

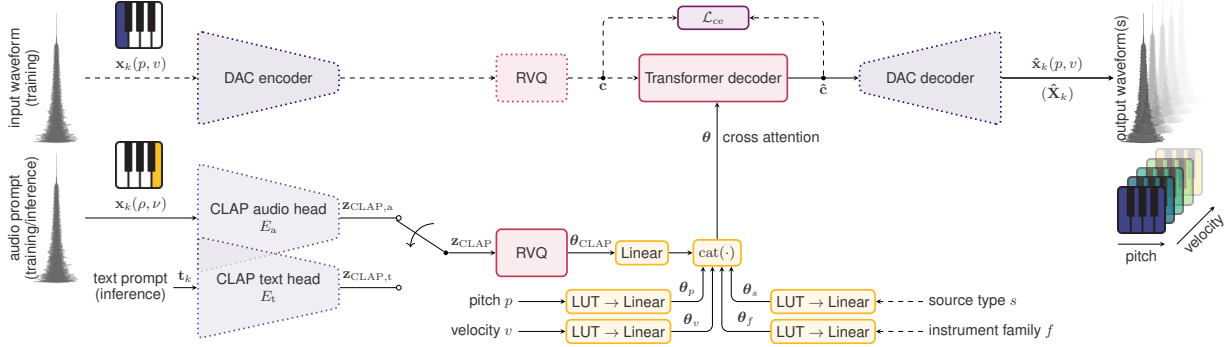

Figure 1. Overview of our proposed system. Dotted lines represent frozen pretrained modules. Dashed lines denote steps exclusive to training. CLAP’s audio or text head can be used at inference, disregarding source type and instrument family. Training operates on individual samples \mathbf{x} , while inference creates a set of samples $\hat{\mathbf{X}}$ from a consistent CLAP prompt and varied pitch/velocity cues to create a full instrument. Different piano keys/colors denote different pitches/velocities.

consistent with one another to allow for the assembly of a playable instrument. Our contributions are as follows:

- We introduce the text-to-instrument (T2I) task, in which waveforms comprising a sample-based musical instrument are generated from a user text prompt.
- We propose neural audio codec language models as solutions for both text- and audio-prompted sample-based instrument generation, expanding on a state-of-the-art generative audio model that is conditioned on a Contrastive Language-Audio Pretraining (CLAP) embedding [21], as well as pitch across the 88-key range of a standard full-length piano keyboard, velocity, instrument family and source type.
- We develop an objective metric to assess the timbral consistency (TC) of sample-based instruments.
- We propose an adaptation to the average CLAP score to be suitable for objectively assessing T2I.
- We propose and analyze three CLAP conditioning schemes through qualitative and quantitative means.
- We demonstrate the compatibility of our approach with both autoregressive (AR) and non-AR audio transformers like MAGNeT [22].

The remainder of this paper is organized as follows: Section 2 describes our proposed method, Section 3 outlines quantitative metrics for assessing performance, including the ones that we have developed, Section 4 reports our experimental results, and Section 5 draws conclusions.

2. PROPOSED METHOD

Figure 1 illustrates our proposed method, which is based on MusicGen [16] as a foundation, consisting of a neural audio codec and a language model to predict acoustic tokens from conditioning signals. We replace EnCodec [23] used in MusicGen with the Descript Audio Codec (DAC) [11], addressing codebook collapse in previous models while achieving higher audio fidelity. We also introduce a set of new conditioning signals including pitch and velocity, alongside a CLAP embedding [21]. Our conditioning signals reflect global cues θ for steering generation, which are fused with the language model via cross-attention. Using CLAP allows instrument samples to be inferred from

either audio or text prompts, and we denote their tasks as sample-to-instrument (S2I) and T2I, respectively. The aim of S2I may be considered one of pitch/velocity shifting, whereby the model transforms an audio prompt in ways transcending conventional signal processing. In T2I, text acts as a semantic interface to generate instruments whose timbres may otherwise not exist. To ensure the reproducibility of our findings, we use pretrained sub-networks without modification, training our core language models from random initialization on the standard research dataset NSynth [3]. We acknowledge that fine-tuning sub-modules within a generative model can improve a composite system, but consider this to be outside the scope of this work.

2.1 Compressed audio representation

We use the DAC encoder to create an intermediate representation of a monophonic waveform \mathbf{x} , resulting in the discrete codes \mathbf{c} , while the DAC decoder synthesizes an audio waveform $\hat{\mathbf{x}}$ from a predicted code sequence $\hat{\mathbf{c}}$. The DAC is trained on a broad spectrum of audio types, so we deem it suitable for generating tonal one-shot instrumental sounds. We model our task at a sample rate of 44.1 kHz, as this would be a minimum requirement for real-world music production use cases. We employ the corresponding pretrained model with fixed weights during training.

2.2 Language model

To model the discrete audio tokens of single-shot samples, we consider a smaller, 60M parameter variant of the transformer decoder in [16], in order to prevent overfitting, speed up inference, and conceptually demonstrate our approach. The model consists of 12 layers with 16 attention heads per layer and a transformer dimension $d = 512$. We consider scaling our models to larger sizes to be out of scope for this work. As in MusicGen [16], we predict audio from tokens of the 4 most significant [11] codebooks at each frame (of the 9 supported by DAC), selecting tokens from codebooks of size 1024. At inference time, we consider next-token prediction using AR sampling with delayed pattern interleaving [16], as well as the iterative decoding scheme proposed in [22] reporting a $7\times$ inference

speed-up. For MAGNeT-style inference, we use 20 decoding steps for the first codebook, and 10 for the remaining codebooks, respectively (compared to 345 steps for the AR scheme). As is customary, we can leverage classifier-free guidance at inference time in both cases [16, 17]. We expect AR priors to provide higher fidelity, considering the importance of onsets to perception [24] for the single-shot samples that we generate: earlier audio token predictions are likely to be perceptually more relevant than later ones.

2.3 Categorical conditioning

We use a categorical conditioning scheme for pitch p , velocity v , broad instrument family f , and source type s , that consists of a lookup table (LUT) and a fully connected layer that maps the dimension of the categorical feature space to the dimension d of the language model. For pitch, we model the $d_p = 88$ range of notes spanned by a full-length keyboard, corresponding to Musical Instrument Digital Interface (MIDI) note numbers 21-108, and note this to be a significant expansion relative to the chroma feature used in [16]. We consider $d_v = 5$ velocity layers, according to MIDI velocities 25, 50, 75, 100, and 127 within our training dataset. The instrument family (i.e. bass, brass, etc.) and source type (i.e., acoustic, electronic, etc.) attributes in our dataset serve as metadata-driven timbral cues that could optionally guide training [25], but we do not expect them to be specified at inference. We choose to include them for models trained in this work, subjecting them to dropout with 30% probability, noting that dropout can generalize their complete inclusion or exclusion.

2.4 Joint text and audio conditioning

We use the CLAP model [21], employing encoders to generate a common fixed-dimensional representation for audio/text pairs of size $d_z = 512$. This model was pretrained on musical signals, utilizing a contrastive loss to align respective audio and text embeddings, ultimately enabling the use of either modality as input to our system. The audio encoder E_a uses HTS-AT [26], while the text encoder E_t is based on RoBERTa [27]. Given an audio dataset of instrumental samples, this strategy allows for leveraging only the audio head during language model training, without requiring rich text captions in the dataset. We quantize resulting CLAP embeddings through Residual Vector Quantization (RVQ) with learned codes [16], yielding θ_{CLAP} .

A distinction between generating music and creating sample-based instruments from prompts is that the inference scenario for instrument generation utilizes a single fixed representation as input for generating a cohesive set of waveforms comprising an instrument. Consequently, we present three CLAP conditioning schemes specifically to train language models for sample-based instrument creation. These techniques amount to assigning pairs of $\mathbf{z}_{\text{CLAP},a}$ and codes \mathbf{c} as input and target training examples in various ways, where $\mathbf{z}_{\text{CLAP},a}$ is the output of the CLAP audio encoder E_a . Hence, the target codes and CLAP embedding within a training example need not be derived from the same waveform, so long as they come

from the same instrument. Excluding θ_f and θ_s for clarity, the forward pass observed during the training of a language model Θ is

$$\hat{\mathbf{c}} = \Theta(\mathbf{z}_{\text{CLAP},a}, \theta_p, \theta_v), \quad (1)$$

where $\mathbf{z}_{\text{CLAP},a} = E_a(\mathbf{x}_k(\rho, \nu))$. Here, k , ρ , and ν denote the timbre (i.e. instrument), pitch, and velocity exhibited in an underlying audio example, respectively, which we assume to be readily selectable from our training set. This $\mathbf{x}_k(\rho, \nu)$ is the input to E_a , and need not be identical to $\mathbf{x}_k(p, v)$ which is used to derive the target codes \mathbf{c} .

2.4.1 Baseline CLAP

By design, the CLAP audio encoder E_a will inevitably yield distinct numerical representations for instrumental samples of the same instrument but varying in pitch or velocity. During training, the following equation applies:

$$\mathbf{z}_{\text{CLAP},a} = E_a(\mathbf{x}_k(p, v)), \quad (2)$$

While this suffices for creating a music track from a singular representation, the scenario diverges significantly for sample-based instrument creation. Specifically, pitch and velocity are represented through both the CLAP representation as well as their respective categorical conditioners, which can reduce the overall effectiveness of the latter. We consider this adaptation of existing prompt-to-audio methodologies to serve as a baseline in this work, noting its application to this task is still novel.

2.4.2 Random CLAP

In order to disentangle the aforementioned pitch/velocity effect, we consider a randomization technique defined by

$$\mathbf{z}_{\text{CLAP},a} = E_a(\mathbf{x}_k(\tilde{\rho}, \tilde{\nu})), \quad (3)$$

with $\tilde{\rho} \sim \mathcal{U}\{21, \dots, 108\}$, and $\tilde{\nu} \sim \mathcal{U}\{25, 50, 75, 100, 127\}$. Random selection with replacement is performed throughout training. This method resembles the nearest neighbor data augmentation in [1], where we consider samples to be neighbors if they originate from the same instrument.

2.4.3 Fixed CLAP

Lastly, we consider a conditioning scheme where we use a fixed, predefined CLAP embedding for each instrument as

$$\mathbf{z}_{\text{CLAP},a} = E_a(\mathbf{x}_k(\rho_{0,f}, \nu_0)), \quad (4)$$

where $\rho_{0,f}$ is defined for each instrument family f (see Table 1) such that fixed representations are sampled within the natural range of each instrument (i.e. we make

Instrument families	Note name
Bass	C2
Brass, String, Synth lead	C3
Guitar, Keyboard, Organ, Reed, Vocal	C4
Flute, Mallet	C5

Table 1. Pitch values used for fixed CLAP conditioning.

lower-pitched selections for bass sounds). The categorical velocity ν_0 is fixed across the training set at velocity 100, conveying an instrument’s timbre played with a medium/strong intensity. If a sample matching a $\rho_{0,f}$ and ν_0 query is not available within an instrument, we opt for its nearest available pitch, followed by its nearest velocity.

Other fixed CLAP conditioning forms could also have been devised, e.g. using average per-instrument CLAP embeddings. We opt for our described approach as it ensures that each CLAP embedding used in model training originates from exactly one audio example. We assert that this fixed variant most closely aligns training to the scenario at inference. In fact, we posit that both the baseline and random CLAP approaches are data augmentation alternatives relative to this method, that increase the number of conditioning signal/target code pairs observed during training, while potentially introducing domain mismatches.

3. OBJECTIVE EVALUATION CRITERIA

We assess models across several objective criteria for S2I and T2I. Alongside the widely used Fréchet audio distance (FAD) [28] score, we introduce a novel metric to evaluate the TC of generated sample-based instruments. We also propose an adaptation of the average CLAP score to fairly evaluate text correspondence for T2I. Unless otherwise specified, we base instrument generation-specific metrics on the assumption that they are represented by $N_k = d_p d_v = 440$ audio samples. In practice, care is taken to properly aggregate/mask instrument statistics based on which samples are present.

3.1 FAD score

The FAD score allows a common framework for evaluating generative audio models using almost any audio feature descriptor [28]. We utilize a FAD metric formulated using VGGish, as in related works [15, 17]. We also report FAD scores using CLAP (audio) embeddings, since they form a pivotal component to our system, allow analysis for higher-sample rate audio (48 kHz), and have been shown to have increased correlation to perception relative to VGGish [29]. The FAD score is generically defined as

$$\text{FAD}(\mathbf{Z}_1, \mathbf{Z}_2) = \|\mu_1 - \mu_2\|_2^2 + \text{Tr}\left(\mathbf{A}_1 + \mathbf{A}_2 + (\mathbf{A}_1 \mathbf{A}_2)^{\frac{1}{2}}\right), \quad (5)$$

where $\mathbf{Z}_i \in \mathbb{R}^{d_z \times TN}$ is a collection of T d_z -dimensional embeddings extracted by a given audio descriptor, across N samples from a population $i \in [1, 2]$. Considering the 4-second long audio segments generated in this work and the strides of various models, $T = 4$ and 1 when using VGGish and CLAP, respectively. We reserve subscripts 1 and 2 to denote ground truth/test populations, respectively. Accordingly, each \mathbf{Z}_i has mean $\mu_i \in \mathbb{R}^{d_z}$ and covariance $\mathbf{A}_i \propto \mathbf{Z}_i \mathbf{Z}_i^\top \in \mathbb{R}^{d_z \times d_z}$. The first and second terms in Equation 5 quantify mean correspondence and similarities in the spread between distributions, respectively. The FAD score possesses a property allowing unpaired populations

to be compared, which we use as a criterion to assess "in-the-wild" T2I in lieu of ground truth audio.

3.2 TC score

Our system should generate timbrally consistent samples in order for them to triggered harmoniously as a sample-based instrument, and we aim to characterize this quantitatively. An apt definition for TC may seem ill-posed, since we want instrument samples to be fundamentally consistent with one another, but also expect them to exhibit some timbral variations as functions of pitch/velocity. This is particularly sought-after in high-quality virtual instruments, motivating the modeling approach in [6]. To contend with these potentially conflicting aspirations, we learn statistics from existing sample-based instruments serving as prototypes for realistic TC, and build metrics around them. We use CLAP embeddings as a basis to create an elegant embodiment in this work. To do so, we forego the mean subtraction step standard to covariance matrix computations, noting that samples are practically close to zero-mean in this respect. Hereafter, we use the terms covariance, affinity, and cosine similarity interchangeably.

We define per-instrument covariance matrices as

$$\mathbf{A}_{ij,k} = \frac{1}{N_k} \mathbf{Z}_{i,k}^\top \mathbf{Z}_{j,k}, \quad (6)$$

where $\mathbf{A}_{ij,k} \in \mathbb{R}^{N_k \times N_k}$ is the affinity between embeddings $\mathbf{Z}_{i,k}$ and $\mathbf{Z}_{j,k} \in \mathbb{R}^{d_z \times N_k}$ representing the subset of CLAP embeddings of the k th instrument within each population. Here, we compute statistics emphasizing variations across samples instead of feature dimensions. Referring to Equation 5, the L_2 -normalized quality CLAP embeddings will ensure us that $\text{Tr}(\mathbf{A}_{ii,k}) = 1 \forall i \in [1, 2]$ and $k \in [1, \dots, K]$. Accordingly, we can define

$$\text{TC}_{\text{CLAP}}(\mathbf{Z}_1, \mathbf{Z}_2) = \frac{1}{K} \sum_k \text{Tr}\left((\mathbf{A}_{11,k} \mathbf{A}_{22,k})^{\frac{1}{2}}\right), \quad (7)$$

which is bounded in $[0, 1]$ and aggregates the similarity in covariations across instruments within each population. Instead of using $\mathbf{A}_{11,k}$ for making comparisons between populations on a per-instrument basis, we consider $\mathbf{A}_{11,*} = \frac{1}{K} \sum_k \mathbf{A}_{11,k}$, averaging per-instrument affinity matrices across a ground truth evaluation set. This provides richer statistics for improved stability, and a unified method to assess TC for S2I and T2I. The TC score is then

$$\text{TC}_{\text{CLAP}^*}(\mathbf{Z}_1, \mathbf{Z}_2) = \frac{1}{K} \sum_k \text{Tr}\left((\mathbf{A}_{11,*} \mathbf{A}_{22,k})^{\frac{1}{2}}\right). \quad (8)$$

We compute $\mathbf{A}_{11,*}$ using all of the samples from the NSynth validation and test sets that are within our desired 88-key pitch range, reflecting a total of 53 instruments. The resulting covariance matrix is illustrated in Figure 2c, in which samples are ordered primarily by pitch and secondarily by velocity. Note how $\mathbf{A}_{11,*}$ deviates from "ideal TC," whereby all embeddings would be correlated with unity similarity (see Figure 2a). Moreover, a 5×5 texture

Figure 2. Covariance matrices for the text prompt $\mathbf{t}_k = \text{aggressive synth lead}$, computed using (a) naive replication, (b) translation, (c) coloration (matching the ground truth covariance $\mathbf{A}_{11,*}$ learned over the 53 instruments reflected in the NSynth validation/test sets), (d) cosine similarities relative to estimated $\hat{\rho}_k/\hat{\nu}_k$, corresponding to note E5/velocity 100.

emerges in $\mathbf{A}_{11,*}$, indicative of variations in cosine similarity amongst samples of the same pitch but differing velocities. Lastly, one may question the suitability of CLAP as a feature descriptor within this context, given its variability concerning pitch/velocity discussed in Section 2.4. Its improved correlation to perception aside [29], we assert that learning statistics over data effectively embeds potential measurement deficiencies that effectively neutralizes when we compare new population statistics against it.

3.3 Average CLAP score

3.3.1 Sample-to-instrument (S2I)

Given $N = \sum_k N_k$ and a cross-population covariance $\mathbf{A}_{ij} = \frac{1}{N} \mathbf{Z}_i^\top \mathbf{Z}_j \in \mathbb{R}^{N \times N}$, the average CLAP score computed on a per-sample basis can be expressed concisely as

$$s_{\text{CLAP}}(\mathbf{Z}_1, \mathbf{Z}_2) = \text{Tr}(\mathbf{A}_{12}) = \frac{1}{N} \sum_k N_k \text{Tr}(\mathbf{A}_{12,k}). \quad (9)$$

It can also be computed on a per-instrument basis by

$$s_{\text{CLAP}*}(\mathbf{Z}_1, \mathbf{Z}_2) = \frac{1}{K} \sum_k \text{Tr}(\mathbf{A}_{12,k}). \quad (10)$$

We opt for this version in our work, noting that the two measures are equivalent when $N_1 = N_2 = \dots = N_K$.

3.3.2 Text-to-instrument (T2I)

The average CLAP score $s_{\text{CLAP}*}$ is suitable for cases with a one-to-one match between ground truth prompts and their corresponding audio examples. However, it can deteriorate for T2I, where a single CLAP text embedding must be related to an ensemble of CLAP audio embeddings $\mathbf{Z}_{2,k}$. A naive adaptation involves comparing each audio embedding within the generated instrument to the same target text embedding. This amounts to creating $\mathbf{Z}_{1,k}$ by replicating the CLAP text embedding N_k times (whose resulting covariance is the "ideal TC" one in Figure 2a), and using it as input to Equation 10. Hence, we set out to *synthesize* a realistic ensemble of CLAP embeddings $\mathbf{Z}_{1,k}$ from a single CLAP text embedding $\mathbf{z}_{\text{CLAP},t} = E_t(\mathbf{t}_k)$, derived from the k th text prompt \mathbf{t}_k . Again, we accomplish this by leveraging statistics from available instrument data.

We construct $\mathbf{M}_{1,*} \in \mathbb{R}^{d_z \times d_p d_v}$ as the mean CLAP audio embeddings at each pitch/velocity pair across all instruments in our evaluation data, re-normalizing them upon

averaging. We posit that a text prompt implies a specific pitch/velocity (e.g., "softly plucked upright bass" suggests a low pitch/velocity). To estimate the corresponding pitch $\hat{\rho}_k$ and velocity $\hat{\nu}_k$ for a given prompt, and to identify its closest template $\hat{\mu}_{1,k}$, we use $\mathbf{M}_{1,*}$ as a template matching-based classifier onto $\mathbf{z}_{\text{CLAP},t}$. Accordingly, we can define

$$\mathbf{M}_{1,k} = \mathbf{M}_{1,*} + (\hat{\mu}_{1,k} - \mathbf{z}_{\text{CLAP},t}) \quad (11)$$

such that $\mathbf{M}_{1,k}$ is aligned to $\mathbf{z}_{\text{CLAP},t}$ at $\hat{\rho}_k/\hat{\nu}_k$. Re-normalizing, we have $\mathbf{Z}_{1,k} = \mathbf{M}_{1,k}/\|\mathbf{M}_{1,k}\|$. Figure 2b illustrates a covariance matrix derived from this approach for a given text prompt. This *translation* method improves upon naive replication, but contains higher cross-correlations than in $\mathbf{A}_{11,*}$. Finally, we derive a *coloration* transformation $\mathbf{Z}_{1,k} \leftarrow Y(\mathbf{Z}_{1,k}, \mathbf{A}_{11,*})$ through standard Eigendecomposition techniques, resulting in a $\mathbf{Z}_{1,k}$ with covariance $\mathbf{A}_{11,*}$, as in Figure 2c.

4. EXPERIMENTAL RESULTS

We train models on the NSynth dataset [3], pruning it according to our specified 88-key pitch range. We re-sample the 16 kHz dataset to 44.1 kHz, viewing it as a proxy in lieu of an equally comprehensive full-band alternative. Models are trained to minimize the cross-entropy \mathcal{L}_{ce} between predicted codes $\hat{\mathbf{c}}$ and ground truth \mathbf{c} , over 1M training steps with AdamW optimizer, a batch size of 48, and a cosine-annealed schedule as in [16] with an initial learning rate of 10^{-3} . We primarily analyze the impact of the proposed CLAP conditioning training variants with AR inference. Additionally, we train a baseline CLAP model with MAGNeT-style iterative decoding to compare its relative performance. To promote consistency in generated samples used for evaluation, we fix the random seed of our categorical samplers, ensuring that generations undergo the same random sampling trajectory. We refer readers to our supplementary materials available at <https://gen-inst.netlify.app/>.

We evaluate and analyze the models through several means. We liken S2I to a reconstruction of the NSynth test set [1] adapted to our inference condition, as a user can provide a sample at any pitch/velocity available to them and models must render its timbre over all pitch/velocity queries. We simulate this by randomly selecting a single query CLAP audio embedding for each instrument, using it to generate all other samples within the instrument. For

Model	Inference	FAD _{VGGish} ↓	FAD _{CLAP} ↓	s _{CLAP*} ↑	TC _{CLAP*} ↑
Baseline CLAP	AR	1.781	0.214	0.626	0.937
Random CLAP	AR	1.558	0.196	0.656	0.929
Fixed CLAP	AR	1.951	0.225	0.637	0.951
Baseline CLAP	MAGNeT	1.974	0.263	0.561	0.931

T2I, we curate 25 text prompts of varying complexity, generating instruments accordingly.

4.1 Objective evaluation

We analyze generations across S2I and T2I, using FAD (for overall expressivity and fidelity), s_{CLAP*} (for prompt correspondence), and TC_{CLAP*} (for TC) to evaluate models quantitatively. To compute FAD scores for T2I, we relate generated instruments to the NSynth test set in the absence of the ground truth audio. Lastly, we compare the different s_{CLAP*} versions for T2I introduced in Section 3.3.2.

Quantitative results for S2I and T2I are summarized in Tables 2 and 3, respectively. For S2I, the random CLAP variant outperforms other models in terms of FAD and s_{CLAP*} at the expense of reduced TC. The converse is true for the fixed CLAP variant, which outperforms in TC. While we do not prescribe which factor is most crucial to overall instrument quality, we do assert that TC is an important element for overall playability. The baseline CLAP approach slots itself in the middle with regards to all criteria. Its MAGNeT variant exhibits degraded performance, but generates samples with 7× fewer inference steps. These findings are largely mirrored in the T2I case. Interestingly, the baseline CLAP variant seemingly outperforms models in terms of s_{CLAP*} using a naively adapted measure. The translation method increases scores across all models. Lastly, we see that the random CLAP model (marginally) outperforms other variants when using the coloration method, in line with S2I. Note that this version of the measure significantly bolsters s_{CLAP*} across all models relative to naive replication and translation, so we argue that it is best-suited for computing T2I s_{CLAP*}.

4.2 Subjective evaluation

We used the Multiple Stimuli with Hidden Reference and Anchor (MUSHRA) and Mean Opinion Scores (MOS) methods [30] to evaluate model variants subjectively. The MUSHRA test was catered to S2I, and involved participants rating the quality of individual samples generated by different models against a hidden reference (i.e. a ground truth sample) and an anchor (i.e. a sample generated by a

randomly initialized model). We performed a 1-5 Likert scale MOS test for T2I scenarios, where participants evaluated the audio outputs generated from text prompts based on overall playability and TC. Our accompanying website demonstrates the nature of trials used in our evaluation.

In total, 62 participants took part in our two-phase evaluation, with results summarized in Table 4. Note that most participants possess expert listening skills and have been involved in virtual instrument creation for several years, contributing to slightly lower absolute results than anticipated. Listening test results were consistent with our objective evaluation, confirming the two assertions of our work: (1) random CLAP improves expressivity over baseline CLAP by virtue of its data augmentation, and (2) fixed CLAP improves TC over baseline CLAP because its training more closely resembles the inference condition.

Model	MUSHRA	MOS
Baseline CLAP	56.08	2.290
Random CLAP	63.35	2.661
Fixed CLAP	57.96	2.820
Ground truth	98.45	–
Anchor	0.442	–

Table 4. Summary of our subjective listening tests.

5. CONCLUSIONS

In this work, we proposed methods for generating sample-based musical instruments from text or audio prompts using neural audio codec language models. We considered different CLAP conditioning variants based on the unique challenge of our task, whereby a set of samples that are timbrally consistent must be generated from a single prompt. We proposed metrics to assess sample-based instruments through various means. Extensive evaluations showcased the effectiveness of our methods, underscoring a compromise between expressivity and TC. Future work will enable deeper control for sample generation, where adapters could be used to augment a base model [31]. We would also like to improve system fidelity, scaling models to larger sizes with fine-tuned modules [9].

6. ETHICS STATEMENT

We have intentionally pursued this task as a topic for scientific research as an alternative to more conventional prompt-to-media systems. The spirit of this work is specifically to expand sound synthesis possibilities for music creators in order to realize their artistic visions. Moreover, we feel that our resulting system and its intents pose far less risk to personal attack/misrepresentation as well as the livelihood of creatives, and is less susceptible to incrimination/impersonation attempts relative to the forms of generative models that have caused increased levels of concern within the general population [32].

Beyond our primary ethical concerns, we also recognize the environmental implications of our computational practices. Our experiments were carried out using Amazon Web Services in the *us-gov-east-1* region, with a carbon efficiency of 0.57 kgCO₂eq per kilowatt-hour. One training of our model entailed approximately 96 hours of computation on Intel Xeon E5-2686 v4 (Broadwell) hardware using a single V100 GPU, culminating in an estimated total emission of 7.93 kgCO₂eq. This estimation was facilitated by the Machine Learning Impact calculator [33]. In acknowledging our environmental impact, we underscore the importance of integrating sustainability considerations into the research process, reflecting on the imperative to balance innovation with ecological responsibility.

ABSTRACT

Hindustani music is a performance-driven oral tradition that exhibits the rendition of rich melodic patterns. In this paper, we focus on generative modeling of singers’ vocal melodies extracted from audio recordings, as the voice is musically prominent within the tradition. Prior generative work in Hindustani music models melodies as coarse discrete symbols which fails to capture the rich expressive melodic intricacies of singing. Thus, we propose to use a finely quantized pitch contour, as an intermediate representation for hierarchical audio modeling. We propose GaMaDHaNi, a modular two-level hierarchy, consisting of a generative model on pitch contours, and a pitch contour to audio synthesis model. We compare our approach to non-hierarchical audio models and hierarchical models that use a self-supervised intermediate representation, through a listening test and qualitative analysis. We also evaluate audio model’s ability to faithfully represent the pitch contour input using Pearson correlation coefficient. By using pitch contours as an intermediate representation, we show that our model may be better equipped to listen and respond to musicians in a human-AI collaborative setting by highlighting two potential interaction use cases (1) primed generation, and (2) coarse pitch conditioning.

1. INTRODUCTION

Hindustani music is a performance-driven music tradition that has a high level of melodic intricacy [1]. Despite the recent advances in generative modeling for music [2, 3], this genre remains difficult to model for several reasons including (1) a lack of a readily available and widely accepted abstract representation reflecting the genre faithfully (like Western symbolic notation), (2) as a niche musical form, the scarcity of available datasets restricts the ability to model the raw waveform directly.

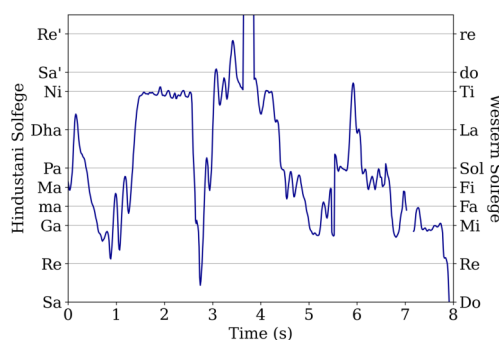

Figure 1. Extracted pitch from Hindustani vocal audio highlighting the melodic intricacies involved. Solfège notation is highlighted as a horizontal grid.

Symbolic notation is a well-defined discrete representation of music including lead sheet, MIDI, piano roll, text, and markup language. Musical notation used in Hindustani pedagogy uses a similar discrete representation by highlighting the prominent notes which fails to faithfully capture the fine melodic intricacies connecting these notes as seen in Fig. 1. Previous work on generative modeling for Hindustani music has side-stepped the lack of well-defined abstract representations with two methods: (1) using musical notation from textbooks or music theory [4–6], (2) leveraging MIDI extracted from audio [7, 8]. However, both methods ignore the rich melodic ornamentation present in this music. Computational analyses for the genre have addressed the difficulty in data representation by using the fundamental frequency contour, hereby referred to as ‘pitch’, as an intermediate representation for several melodic tasks including music style classification [9], motif discovery and matching [10–12] and *raga* recognition [13–15]. With evidence that pitch faithfully represents the melody for computational tasks, we are motivated to incorporate it in the context of generative modeling.

In this work, we present GaMaDHaNi¹ (Generative Modular Design of Hierarchical Networks), a modular hierarchical generative model for Hindustani singing. We employ a two-level hierarchy of data representation in-

Figure 2. The overall hierarchical generation structure of GaMaDHaNi comprising of the Pitch Generator, the Spectrogram Generator and a vocoder. During inference, given an optional short melodic input, i.e. ‘prime’, each of the generators produce a pitch continuation and a spectrogram conditioned on the resulting pitch respectively.

cluding pitch and spectrogram. The Pitch Generator and Spectrogram Generator are trained to generate these respectively, with the generated spectrogram converted to audio using a vocoder. Fig. 2 highlights the model’s high-level structure. We choose a finely quantized pitch contour as an intermediate representation due to its close relation to melodic content, strongly established in prior literature [9–15]. We model pitch under two paradigms: as discrete tokens using an autoregressive transformer and as continuous values using a diffusion model. In addition, with a relatively small dataset of 120 hours, we find that the pitch intermediate representation is effective at learning melodically diverse ideas (Sec. 4.4). As possible use cases for interaction, (1) we explore using the model to continue a given melodic prompt, termed ‘prime’, as seen in Fig. 2, and (2) we extend the hierarchy upwards to include a coarse pitch target, thereby enabling user-driven steering of the generation process.

We note that our current generation pipeline lacks incorporation of several key elements crucial to Hindustani music, specifically tonic frequency, and raga and tala, i.e. melodic and rhythmic frameworks. This work establishes a preliminary foundation for exploring the potential of generating music within this form while maintaining its characteristic melodic intricacies.

A summary of our core contributions include:

- We propose GaMaDHaNi, the first model capable of generating Hindustani vocal contours while maintaining the rich melodic complexity in the music.
- We present a hierarchical approach to modeling a waveform using an intermediate pitch representation

that works on a small dataset (120 hours).

- Through listening tests and qualitative observations, we show that our hierarchical approach performs better than baselines.

2. RELATED WORK

2.1 Music Representations in Indian Art Music

Past work on melody-based computational tasks for Indian Art Music include music style classification [9], motif discovery and matching [10–12], and raga recognition [14–16]. Previous work shows that fine quantization outperforms coarse quantization in pitch contours for tasks including raga recognition [16, 17] and motif matching [11]. Thus motivated by their ability to capture melodic information we use finely quantized pitch as an intermediate representation. Additionally, for Carnatic music, previous work on compact representations for Gamakas (type of note ornamentation) [18], and non-uniform pitch quantization schemes that can preserve raga-characteristics [19, 20] present forms of representation that are more condensed than the pitch contour while being adequately detailed which could be an interesting inclusion for future work.

2.2 Generative Modeling for Hindustani Music

Hindustani music is an improvised form of music where melodic movements are guided by a melodic framework (raga) [1]. Past work on the generation of this music is of two types: rule-based and data-driven models. AI-Raga [4] is a rule-based AI system developed to generate musical notation of compositions and improvisations that adhere to raga grammar based on an elaborate set of rules termed ‘generative theory of music’ [21]. Another work develops a Finite State Machine (FSM) to generate improvisations based on raga-specific melodic movements situated in theory [5]. An initial attempt at data-driven models learned from the musical notation of *alaps*, i.e. slow improvisation, in textbooks using bigrams in an FSM [6]. RMMM [7] explores the use of LSTM [22] and transformer-based [23] architectures to generate MIDI extracted from a corpus of Hindustani music. Other work also proposes generating MIDI with GANs [8, 24]. All models discussed in this section approach modeling data as solfege notation. While doing so, one gives up on the transitory melodic regions between notes of the melody, which is inherent to Hindustani music. AI-Raga [4] partially addresses this by using domain-informed tuning systems, and a simulation of transitory glides between notes. We propose to address this problem by incorporating a fine pitch data representation. Additionally, in contrast to previous work, we propose to generate audio waveform rather than symbolic data.

2.3 Hierarchical Audio Generation

Within the domain of music generation, hierarchical learning offers two distinct advantages: enhanced learning abilities on data-constrained tasks and multi-level controllability. MIDI-DDSP [25] takes advantage of the hierarchy in

the process of creating realistic audio of instrument performance given a sequence of MIDI data including notes, high-level performance attributes and low-level synthesis attributes. Our approach leverages a different hierarchy based on pitch as opposed to MIDI notes, and we generate pitch from scratch without relying on any symbolic input. Moreover, we choose to directly generate audio spectrograms instead of DDSP synthesis parameters since the latter is designed mainly for instrumental sound.

Another approach to hierarchical models for audio includes the generation of pre-trained compressed representations of audio, i.e. neural audio codecs [26, 27], framed as a language modeling task as seen in MusicLM [28] and MusicGen [3]. We study the effectiveness of this approach as a baseline in our experiments in Sec. 4.3, by comparing Encodec [26] and pitch as intermediate representations.

The use of fundamental frequency contours as an intermediate representation has been widely adopted in the context of Text To Speech synthesis (TTS) and Singing Voice Synthesis (SVS). Both fields follow a hierarchy including an input-conditioned acoustic model which mainly generates a subset of pitch, duration, and spectral features followed by a vocoder. The input could be text in the case of TTS [29–31] and musical score for SVS [32, 33]. CDAR [34] is a TTS model that seeks to control the prosody of generated speech by allowing users to edit parts of the spoken pitch contour while maintaining the realism of the prosody. We thus choose to adopt pitch as an intermediate representation with a strong precedence for its use and controllability in speech and singing applications.

3. METHOD

In this work, we seek a generative model for Hindustani vocal music by learning the joint distribution of amplitude mel-spectrograms s and pitch f following

$$p(s, f) = p_\phi(s|f)p_\theta(f), \quad (1)$$

where p_ϕ and p_θ are parameterized with neural networks called *Spectrogram* and *Pitch* Generators respectively. The generated spectrogram is converted to audio using a vocoder. Pitch conditioning f to p_ϕ is taken from our dataset for training and sampled from p_θ for inference.

3.1 Pitch Generator

We study the modeling of vocal pitch as the primary component in our hierarchical generation pipeline. Vocal pitch f are represented as integer-valued sequences sampled at 100Hz, with 90% of the values ranging from 86Hz to 899Hz, quantized with a fine resolution of 10 cents. To model such sequences, we investigate two distinct methods. The first employs an autoregressive, language-like model to predict the discrete pitch sequence, whereas the second leverages recent advancements in diffusion-based modeling for iterative generation of the entire sequence.

3.1.1 Discrete autoregressive model

We use a vanilla decoder-only transformer, to autoregressively predict the next token of a pitch sequence. In this

task, the pitch values f are considered to be discrete tokens in a vocabulary V , each mapped to an embedding vector of size d through an embedding matrix $E \in R^{|V| \times d}$. The model is trained with cross-entropy loss.

3.1.2 Continuous diffusion model

We use a simple yet effective diffusion variant, Iterative α -Deblending (IADB) [35] as the training objective of our model that generates finely quantized pitch f . IADB defines a simplified diffusion process that is a linear interpolation between noise $x_0 \sim X_0 = \mathcal{N}(0, 1)$ and data $x_1 \sim X_1 = X_{data}$:

$$x_\alpha = (1 - \alpha)x_0 + \alpha x_1. \quad (2)$$

We leverage a deterministic iterative deblending process proposed in [35] to sample a data point $x_1 \sim X_1$ from noise $x_0 \sim X_0$. With the total number of iterations in the process as T , and given a time step $t \in \{0, 1, 2, \dots, T\}$, we define the blending parameter $\alpha_t = \frac{t}{T}$ and an α -blended point x_{α_t} . Thus, the iterative deblending is defined as:

$$x_{\alpha_{t+1}} = (1 - \alpha_{t+1})\bar{x}_0 + \alpha_{t+1}\bar{x}_1, \quad (3)$$

where $(\bar{x}_0, \bar{x}_1) = E_{(X_0 \times X_1)|x_{\alpha_t}, \alpha_t}$ is the expected value of the posterior samples given x_{α_t}, α_t . Heitz et. al. [35] show that using expected posteriors \bar{x}_0, \bar{x}_1 in the deblending process (Eq. 3) instead of x_0, x_1 converges to the same point, while making the sampling process deterministic.

Taking the derivative of x_{α_t} with respect to the blending parameter α_t , the training objective becomes,

$$D_\theta(x_{\alpha_t}|\alpha_t) \approx \frac{dx_{\alpha_t}}{d\alpha_t} = (\bar{x}_1 - \bar{x}_0), \quad (4)$$

Taking a trained model D_θ , we perform an iterative sampling procedure to generate outputs:

$$x_{\alpha_{t+1}} = x_{\alpha_t} + (\alpha_{t+1} - \alpha_t)D_\theta(x_{\alpha_t}, \alpha_t), \quad (5)$$

3.2 Spectrogram Generator

On the next level of the hierarchy, we train a model to generate a spectrogram conditioned on pitch, which is then converted to an audio signal using a vocoder. This method uses IADB as described in Sec. 3.1.2, while additionally conditioned on singer and pitch. Each singer ID is embedded as a discrete vector, and the processed pitch is time-downsampled to match the spectrogram’s time axis. Both conditioning signals are concatenated as additional channels to the mel-spectrogram input. Thus given a conditioning signal c , the training objective $D_\phi(x_{\alpha_t}|\alpha_t, c)$ is similar to Eq. 4 but is additionally conditioned on c .

The singer and pitch values are conditioned using classifier-free guidance (CFG) [36]. Given a conditioning strength w , CFG is implemented such that $\overline{D_\phi}(x_{\alpha_t}|c)$ is used during the iterative sampling, defined as,

$$\overline{D_\phi}(x_{\alpha_t}|\alpha_t, c) = (1-w)D_\phi(x_{\alpha_t}|\alpha_t) + wD_\phi(x_{\alpha_t}|\alpha_t, c) \quad (6)$$

4. EXPERIMENTS

In this paper, we consider the Spectrogram Generator as a tool to convert melodic ideas from the Pitch Generator into perceivable audio. As a result, we evaluate both the Generators with a focus on quality of pitch generation and the spectrogram’s fidelity in representing that pitch.

Through our experiments, we aim to motivate our choices for (1) a hierarchical approach to generation, (2) the use of pitch as an intermediate representation, through listening tests. We also qualitatively evaluate the overall melodic quality of generations. Additionally, we assess the Spectrogram Generator by testing pitch adherence: the ability of the model to reliably reproduce the pitch conditioning through quantitative and qualitative analyses. We leave evaluation of other aspects of the Spectrogram Generator such as audio quality, singer adherence to future work. Readers are encouraged to listen to relevant supplementary audio samples on our project website while going through this and the following sections.

4.1 Dataset

We use a combination of the Saraga and Hindustani Raga Recognition datasets [37, 38]. Audio files in the combined dataset contain audio of vocal performances including the tanpura, i.e. a drone, along with the melodic and rhythmic accompaniment across 56 unique singers. It spans about 120 hours across 362 audio files, where the files range from 88 seconds (s) to 1.2 hours with a median duration of 20 minutes. The dataset is randomly split into training and validation sets at a 90:10 ratio. Furthermore, each audio file is split into 60 s segments resulting in 7174 and 719 segments in the training and validation sets respectively. Due to different inductive biases in the models used, they all have different receptive fields and are thus trained on sequences with lengths varying from 8.2 s-12 s, randomly sampled from the 60 s segments during training.

The vocals are isolated using 2-stem source separation with HT Demucs [39] and further, the pitch is extracted using CREPE [40] and is sampled at 100 Hz. We algorithmically reduce the number of pitch detection errors using a loudness-based pitch filtering approach; using a sliding window to calculate area under the loudness curve, we retain only corresponding pitch values exceeding an empirically set threshold. We normalize the pitch to a logarithmic scale such that an arbitrarily chosen frequency, 440Hz is 0 on this scale, and quantize it into 10-cent bins. Additionally, during training, the pitch is transposed by a random multiple of 10 cents within a range of $[-400, 400]$ cents.

Artifacts in the dataset Our source separation model, HT Demucs [39], allows some leakage from other instruments including mainly the *sarangi* (stringed melodic accompaniment) and the *tabla* (rhythmic accompaniment) as artifacts in the vocal stem due to the out of distribution nature of Hindustani music data for the model. These ‘leaked’ sounds are generated in our models too (both our proposed model and the baselines established). Additionally, instances of speech are found in some generated samples as it is present in our dataset. The Carnatic FTA-Net

[41], presents a domain-informed model trained to extract pitch contours from Carnatic vocal audio. Owing to the similarities between Carnatic and Hindustani music, an interesting direction for future work would be to adopt their methodologies in our data processing pipeline.

4.2 Model Architectures

Below we present model specific architectures and data preprocessing for the Pitch Generators (Autoregressive and Diffusion) and the Spectrogram Generator.

Pitch Generator (Discrete Autoregressive) This model was trained on 12s (1200 token) sequences. The quantized pitch f is converted into a sequence of discrete embedding vectors e , using an embedding space $E \in \mathbb{R}^{|V| \times d}$ where effective vocabulary size is $|V| = 796$ and embedding dimension is $d = 512$. The model is a decoder-only transformer [23] with 8 layers, with each layer having an output dimension of 512. AliBi positional method [42] is used to encode the position of tokens in the sequence. A cosine learning schedule with linear warm-up is used. Samples are generated with a temperature of 0.99 and using top k sampling with $k=40$.

Pitch Generator (Continuous Diffusion) This model was trained on 10.24s (1024 elements) sequences. The quantized pitch contour is limited to a range of 400 integers. This distribution is converted into a continuous Gaussian using the quantile function which maps a variable’s probability distribution to another probability distribution. This model is implemented as a U-Net with three down-sampling and up-sampling layers each with a stride of 4, 2 and 2 respectively. Each layer is made of four 1-D convolution layers with weight normalization [43] and Mish non-linearity [44]. The bottleneck involves 4 attention layers with 8 heads each.

Spectrogram Generator This model is trained on 8.2s (512 elements) of mel-spectrogram sequences. The relevant pitch conditioning is linearly interpolated and down-sampled to match the sequence length of the spectral data. The spectral data is produced with 192 mels and a hop size of 256 (0.016 s) given 16 kHz audio and is converted to a continuous Gaussian distribution using the quantile transform function as well. Apart from additional channels for singer and pitch conditioning, the architecture is the same as that used by the Pitch Generator (Continuous Diffusion) (Sec 4.2). For simplicity, spectrograms are converted to audio using the Griffin-Lim algorithm [45]. Future work could harness the power of recent developments in neural vocoders including HiFi-GAN [46].

4.2.1 Conditioning signals

In addition to pitch, the Spectrogram Generator utilizes singer conditioning to help maintain the consistency of the voice in generated audio as seen in the supplementary audio samples. Each singer is assigned a unique ID and mapped to an embedding vector of size $d_{singer} = 128$. Conditioning was implemented with CFG as discussed in Sec. 3.2 with a strength of $w = 3$ for pitch and singer conditioning. This value was determined based on empirical

studies as an optimal balance between fidelity to pitch and minimizing artifacts due to incorrect pitch extraction.

4.3 Baseline Models

Through our baseline models, we aim to motivate two major architectural choices: (1) hierarchy in the model and (2) an intermediate pitch representation. These models thus include a non-hierarchical baseline, a hierarchical baseline with a self-supervised intermediate representation (hierarchical Encodec baseline), and the ground truth.

Non-hierarchical Baseline In this baseline, we highlight a naive approach of modeling audio directly with no hierarchy. We train a diffusion model with the IADB objective directly on processed audio mel-spectrograms. The model architecture is similar to other diffusion models used in this paper (Sec. 4.2) and was trained on the same dataset as our model with sequences of length 8.2s.

Hierarchical Encodec Baseline We train a hierarchical autoregressive baseline on a self-supervised intermediate representation, Encodec [26]. Through this model, we aim to compare the effect of self-supervised and pitch intermediate representations. To this end, we train MSPrior [47, 48], a decoder-only transformer adapted for real-time use, on Encodec tokens [26] extracted using the 24 kHz Encodec model with a target bandwidth of 3 kbps (4 channels per token). This model was trained on only the Hindustani Raga Recognition Dataset (which constitutes about $\frac{5}{6}$ th of our dataset) with a sequence length of 900 (12 s). We use a temperature of 0.99 for sampling.

Ground Truth To set the gold standard of melodic quality, we use ground truth pitch for comparison. As the listening test focuses on evaluating the Pitch Generator, we standardize audio quality across all models (except the hierarchical Encodec baseline which already generates waveform) by synthesizing the ground truth pitch with our Spectrogram Generator. We use five singers (3 low and 2 high voice range) with reasonable representation in the dataset as singer conditioning. Depending on the range of the generated pitch, we randomly select from the appropriate set of singers to generate audio for the contour.

4.4 Human Evaluation on Melodic Quality

To evaluate the musical quality and characteristics of generated samples, we conduct a listening study and offer qualitative observations supported by audio examples in our supplementary material.

Listening study We compare five systems: non-hierarchical baseline, hierarchical Encodec baseline, autoregressive and diffusion variants of our method, and ground truth. Participants were presented with 8.2 s audio samples, from two random systems and asked to rate which one is more musically interesting, on a 5-point Likert scale. We recruited 15 participants who are trained in Hindustani or Carnatic music. Although Carnatic music is stylistically different from Hindustani music, the two share the context of raga and tala giving participants enough context to evaluate samples for this study. Participants' primary instruments were the voice or other melodic instruments includ-

Figure 3. Results from the listening study, showing how many times each system was preferred.

ing the harmonium, sarangi, sarod, sitar, flute, or violin. We collected 240 ratings, with each system involved in 96 comparisons.

Results Fig. 3 shows the number of wins in each system. We ran a Kruskal-Wallis H test and confirmed that there are statistically significant pairs among the combinations. According to a post-hoc analysis using the Wilcoxon signed-rank test with Bonferroni correction (with $p < 0.05/10$), we find that our hierarchical model with an autoregressive Pitch Generator outperforms the non-hierarchical baseline. Given the small sample size, we also compare all systems against each other by aggregating ratings and considering them as independent samples. Using the Independent (Mann-Whitney U) test with Bonferroni correction, we find that both our models, discrete autoregressive and continuous diffusion outperform the non-hierarchical baseline significantly. Through these experiments, we establish that our model outperforms the non-hierarchical baseline.

Diversity in Generation Participants did not prefer our methods significantly more than the hierarchical Encodec baseline. This baseline tends to hold a single note or move through a few stable notes without much dynamism. This understandably was preferred by participants as *vilambit alap* or slower improvisation, a common way to establish a raga in Hindustani music, involves the use of such long and stable notes. With only 8.2 s duration audio samples, the listeners do not have enough time to notice the lack of dynamic movement. In contrast, our proposed methods can render both slow and fast movements, resulting in more variety as seen in generated samples. We hypothesize that this could be due to the different intermediate representations of both models, i.e. due to the importance of intricate melodic movements, a model trained to explicitly generate fine pitch would be able to capture melodic complexity.

Consistency of vocal timbre We note that generations from the hierarchical model, which includes singer conditioning, display more consistency in the timbre of voice; the baseline models sometimes abruptly switch vocal timbre in the middle of generation.

4.5 Pitch Adherence in Spectrogram Generator

Although the Spectrogram Generator loss lacks an explicit term for pitch adherence, we evaluate it by calculating the

Figure 4. Examples of ground truth pitch (blue) and extracted pitch contour from the generated sample (orange) to highlight pitch adherence with low and high correlation, r (top to bottom). **Low correlation:** Audio 0 ($r = 0.1$) and 1 ($r = 0.11$) are examples of errors in pitch detection. **High correlation:** Audio 2 ($r = 0.94$) and 3 ($r = 0.99$)

Pearson correlation coefficient between the conditioning pitch and the pitch extracted from the generated audio. For this, we choose four singers (two male and two female) to generate audio conditioned on 32 random contours from the validation set resulting in a total of 128 contours to evaluate. We achieve a mean correlation of 0.71 between input and loudness-filtered extracted pitch.

Visual inspection reveals that differences between the input and extracted pitch sequences are pronounced when artifacts due to errors in pitch detection, source separation, or ground truth are present in either sequence. We present instances of samples with high and low correlation in Fig. 4. In addition, we note an inconsistent difference in timing between the ground truth and generated contour in Fig. 4. Future work could investigate pitch-specific training objectives and alternative conditioning representations to improve the precision of the generated audio’s pitch in time. Overall, based on visual analysis, we note that our model faithfully reconstructs the pitch conditioning shape.

5. INTERACTION USE CASES

We show two interactive use cases of GaMaDHaNi: (1) continuing an input melodic sequence or ‘prime’, and (2) guiding generation with coarse solfege-like notation.

5.1 Primed Generation

We investigate using our model for melodic sequence continuation. To this end, we input a four-second pitch sequence from our dataset termed ‘prime’ into our Pitch Generator, and ask the model to continue the sequence. The model can generate realistic-sounding continuations with

Figure 5. A staircase descending scale (in blue) as a coarse input. This input is then processed as described in Sec. 5.2 and fed into the model. The generated fine-grain contour (in orange) has glides (mindh) and fast jerky movement (gamak) characteristic to Hindustani music.

interesting patterns, as seen in Fig. 2 and in our audio samples. Future work could involve creating an interactive pipeline that would allow our model to directly take input from the user allowing a human-machine collaboration.

5.2 Coarse Pitch Conditioning

To explore further possibilities for interaction, we evaluate the model’s ability to adhere to solfege-like conditioning given to the Pitch Generator. To this end, a ‘coarse pitch’ signal is inferred by calculating a moving average of the pitch with a window size of 1s and a hop size of 0.01s. The Pearson correlation coefficient between the input and generated coarse pitch is 0.97, and between the ground truth and generated pitch is 0.79. Both values are averaged over 64 random samples from the validation set. Thus solfege input, once converted into a similar coarse pitch signal, can be used to guide the model’s generation as seen in Fig. 5, where the model renders a solfege-based descending scale into realistic-sounding audio. Although simple, this is an interesting avenue for interactive generation that we plan to explore in the future.

6. CONCLUSION

We present a modular hierarchical system to generate melodically rich Hindustani vocal audio using a relatively small dataset. Our model has comparable or better performance than established baselines while including an interpretable intermediate pitch representation. We present interesting forms of interaction including primed generations and coarse pitch conditioning that could be developed further to achieve interactive human-machine music making.

There are interesting future directions such as the use of tonic, raga and rhythmic aspects as conditioning for generation. Additionally, the Spectrogram Generator could adopt more advanced vocoders and conditioning signals such as loudness and phoneme features for better results.

7. ETHICS STATEMENT

This work, to our knowledge, is the first model trained to explicitly generate Hindustani vocal music and thus we find it important to emphasize that this work is intended to foster human-AI collaboration, creating a more accessible environment for creative exploration and is by no means intended to replace music teachers or musicians. While we acknowledge the ethical concerns involved in modeling singing voices, we include singer conditioning in our approach with the sole intention of maintaining voice consistency in the generated samples. Additionally, we note that this work utilizes datasets contributed by artists or institutes holding distribution rights to ensure responsible use with informed consent. These datasets were released with appropriate permissions to process audio recordings for research purposes. However, despite our current model's limited scope, future enhancements may pose a risk of mimicking the identities of existing singers, necessitating the establishment of protective guidelines for artists.

8. ACKNOWLEDGMENT

We thank all of our listening study participants for their invaluable contributions and insights. We also appreciate their promptness in completing the tests, which greatly facilitated this work.

ABSTRACT

Progress in the task of symbolic music generation may be lagging behind other tasks like audio and text generation, in part because of the scarcity of symbolic training data. In this paper, we leverage the greater scale of audio music data by applying pre-trained MIR models (for transcription, beat tracking, structure analysis, etc.) to extract symbolic events and encode them into token sequences. To the best of our knowledge, this work is the first to demonstrate the feasibility of training symbolic generation models solely from auto-transcribed audio data. Furthermore, to enhance the controllability of the trained model, we introduce SympAC (Symbolic Music Language Model with Prompting and Constrained Generation), which is distinguished by using (a) *prompt bars* in encoding and (b) a technique called *Constrained Generation via Finite State Machines (FSMs)* during inference time. We show the flexibility and controllability of this approach, which may be critical in making music AI useful to creators and users.

1. INTRODUCTION

The success of language models — especially large ones — has demonstrated that with more data and larger models, using a simple language model objective can endow a model with powerful natural language generation capabilities. On the other hand, although symbolic music and natural language share many similarities, no music model has yet seemed to match the capabilities of generative text models. One reason for this gap is the insufficient amount of symbolic music data.

To address this, previous efforts in symbolic music generation have involved combining limited manually annotated data with data obtained by automatic transcription [1], or collecting private symbolic training datasets [2]. By contrast, in this work, we demonstrate

that a high-quality, multi-track symbolic music generation model can be trained just using results from running Music Information Retrieval (MIR) models on audio music data. In this way, our framework eliminates the need for manually annotated symbolic music data, allowing for expansion purely through audio datasets.

On the other hand, there has been a recent surge of efforts that directly generate the auditory modality of music [3–5]. This is useful for some applications, but typically precludes fine-grained control and editing the outcome, which is crucial for composers who wish to shape their musical ideas precisely. In contrast, outputting symbolic data gives composers the ability to interactively shape and modify their musical ideas.

Considering such advantages, the problem of how to integrate user input to control the generation of symbolic music has been a popular research topic. In previous works, two methods for incorporating control signals are usually used. The first approach is based on a Variational Autoencoder (VAE) [6, 7], wherein the control is exerted within the VAE’s latent space. The second approach is to embed control information directly into the encoding of symbolic music and implant control inputs during inference [8–11].

In this work, we introduce the **SympAC** framework (**S**ymbolic Music Language Model with **P**rompting **A**nd **C**onstrained Generation), designed to work with decoder-only language models to enable user input controls. The SympAC framework consists of the following two parts. First, inspired by the prompting mechanism used in the natural language domain [12, 13], we introduce *prompt bars* in our symbolic music encoding, which consolidates all control signals into a separate prompt section before encoding the actual musical notes. This design is essential for a decoder-only language model to have the full context of control signals during the generation of music. Second, in the controlled symbolic music generation setting, the generated tokens should not only comply with the encoding grammar but also adhere to user inputs. Thus we propose to use *Constrained Generation via Finite State Machines (FSMs)*, which constrains the sampling of tokens at each time step to a subspace. We will discuss the advantages of SympAC over previous methods in Section 2, and provide more details of how SympAC can be used for various types of user inputs in Sections 3 and 4.

We collected roughly one million in-house audio samples and extracted MIR information for each, using pre-trained models for beat tracking [14], chord detection [15], section detection [16, 17], multi-track transcription [18], and music tagging [19]. The MIR results were transformed into various tokens, and then integrated into an extended REMI [10, 20] encoding to train a language model based on Llama [21] architecture. To summarize, our main contributions are:

Scalability: We demonstrate that a high-quality symbolic music generation model can be trained solely with transcribed data, without the need of manually annotated symbolic music, and can be scaled by amassing more audios.

Controllability: We propose the SympAC framework, which enables flexible user input controls on a decoder-only language model while retaining good quality.

2. RELATED WORK

2.1 Training Data For Symbolic Music

In Table 1, we summarize some popular music datasets in the symbolic and audio domains, together with our in-house audio dataset, and compare their sizes. The Lakh MIDI Dataset [24] is one of the biggest public datasets, containing 170K multitrack pieces in MIDI format. Many researchers use publicly available symbolic music datasets for training, but some collect and use large-scale ones that are not disclosed; e.g., MusicBERT [2] was trained on the Million-MIDI Dataset (MMD).

Although the combined size of the public datasets in Table 1 is large, combining them is not straightforward since they vary in format. For example, the Maestro dataset consists of transcriptions of piano performances where note timings reflect actual performance timings, whereas datasets like Lakh are quantized to metrical time with alignment to beats. The inclusion of instrument tracks and additional information (e.g., chords, sections) also differs between datasets. To expand the scale of training data by combining these datasets, it is necessary to unify their formats first, which may be tedious and introduce errors.

On the other hand, publicly available audio datasets are much larger in scale. The Million Song Dataset (MSD) [26], for example, contains 1M songs, or 709M notes in total after being run through a 5-track transcription model [18]. The recently published DISCO-10M [27] is of an even larger scale. Furthermore, by using a single set of MIR models to annotate all the audio data, we do not need to be concerned about the issue of inconsistent data formats. This makes it easier to scale up the training dataset.

2.2 Encoding For Symbolic Music

Since the introduction of the Music Transformer [28], language models based on the transformer architecture have become a popular choice for symbolic music generation. One of the most critical research questions has been how to encode symbolic music that is amenable to processing by such a model, which, in the context of language models, involves converting the piece into a sequence of tokens.

Early transformer-based models for symbolic music predominantly employed a MIDI-like encoding scheme, by treating MIDI event sequences almost identically as input token sequences [8, 9, 29]. Later, the Revamped MIDI (REMI) encoding [20] was proposed, which modified the MIDI encoding by replacing time shift events with duration events for each note and introducing bar and beat concepts to adopt metrical time instead of absolute time. These modifications facilitated the model’s learning of rhythmic patterns within the music, improving the quality of the output. Building upon REMI, several extensions have been proposed to support encoding multitrack [9] and various control tokens [10]. Our work is based on the multitrack REMI encoding, and given the MIR models we have, it incorporates control tokens such as genre, chord, and section tokens to the encoding.

2.3 Controllable Symbolic Music Generation

Previous methods for controlling symbolic music generation have typically fallen into two categories. The first is based on Variational Autoencoders (VAEs) [6, 7]. VAEs aim to find a latent space for representing music that encodes distinct musical attributes in independent dimensions. This disentanglement allows for specific attributes of generated music (e.g., rhythm, genre, or timbre) to be individually manipulated by altering corresponding dimensions in the latent space without affecting other attributes, thereby enhancing the controllability of music generation.

The second approach is to include control tokens in the encoding of symbolic music. For example, MMM [9] includes instruments and note density tokens in the encoding, which can be specified at inference. Similarly, FIGARO [10] uses “expert descriptions” indicating time signature, note density, mean pitch, mean velocity and mean duration as well as instruments and chords. It then uses an encoder-decoder model to learn a mapping from descriptions to sequences of a piece of music. Driven by the development of Large Language Models (LLMs), recent work has also explored using natural language to control symbolic music generation [30–33]. Natural language text can also be treated as control tokens, with the key distinction that it usually requires pre-training the LLM on text.

In our work, the proposed SympAC framework is designed to work with a decoder-only language model. In a controlled generation setting, prompt bars that conform with user input control signals are generated first. The generation of musical part comes after that, in which the model will have full context of control signals from prompt bars. These two generation stages are both controlled by an FSM, which takes into consideration the grammar of the encoding and user inputs. There are two main differences between SympAC and previous works

1. We encode control signals as tokens and use FSM to enforce input control signals during inference. In contrast, for VAE-based control methods, control signals are converted into latent embeddings, and the model is not guaranteed to follow these control signals.
2. Since we use a decoder-only language model, the to-

Dataset	#Songs	#Notes	Format	Multitrack	Public
Maestro [22]	1.1K	6M	MIDI	N	Y
GiantMIDI-Piano [23]	10.9K	39M	MIDI	N	Y
Lakh [24]	170K	910M	MIDI	Y	Y
MMD [2]	1.5M	2,075M	MIDI	Y	N
FMA [25]	100K	N/A *	Audio	Y	Y
MSD [26]	1M	709M	Audio	Y	Y
DISCO-10M [27]	15M	N/A *	Audio	Y	Y
In-House Dataset (IHD)	1M	3,688M	Audio	Y	N

Table 1: Comparison of different symbolic and audio music datasets. * Since we did not run transcription on FMA or DISCO-10M, we don’t have the number of notes information for them.

kens in prompt bars are also learned simultaneously. Consequently, the user is only required to input a portion of the control information, with the model being able to automatically generate missing controls. In contrast, an encoder-decoder framework like the one described in [10] would require a complete encoder input during inference, which lacks flexibility.

3. METHOD

3.1 Symbolic Music Encoding And Prompt Bars

Our data representation is based on the REMI+ [10] representation, an extension of REMI [20] that supports multitrack data. An illustration of our encoding is shown in Fig. 1. The fundamental unit of our encoding is a bar, of which there are two types: *prompt bar* and *song bar*. The token sequence of a song bar can be divided into four parts:

- The *meta* part includes four tokens for the bar, `genre`, `sec` (for section type name), and `bpm_level` (which indicates the tempo range).
- The *chord* part consists of alternating `position` and `chord` tokens.
- Each *instrument track* part consists of a `track` token, followed by one or more groups of `position`, `duration` and `pitch` tokens.
- The *drum track* part consists of a `track<drum>` token, followed by one or more groups of `position` and `drum` (drum MIDI) tokens.

Here are further explanations of `position`, `duration` and `track` tokens¹:

- `position`: Represents the starting position of subsequent `chord`, `pitch` or `drum` token within a bar. Each bar is divided into 16 steps, so that position ranges from 0/16 to 15/16.
- `duration`: Ranges from the minimum time division of 1/16 bar to a maximum of 2 bars, or 32/16.
- `track`: A track token will only exist if there is at least one note in the bar for the corresponding instrument. This allows the user to control which instruments are used within a bar.

¹ Details of all token types are provided in supplementary materials

Prompt bars contain a subset of tokens in song bars, retaining only tokens that represent *control signals*. In our case, these include `genre`, `section`, `tempo`, `chords` and `tracks`. As future work, this encoding could be extended to include more control signals (e.g. note density for a track). The encoding of a full piece of music will consist of: all prompt bars in the piece; then, a special `end_of_prompt` token; then, all song bars in the piece; and finally a special `end_of_song` token.

During training stage, the model is trained to predict tokens in prompt bars as well, not distinguishing them from tokens in song bars. As mentioned previously, this design enables the user to input partial control signals (or no input at all), and the model is able to infer the missing ones.

Algorithm 1 Constrained Generation via FSM

```

1: procedure CONSTRAINEDSAMPLING( $\mathcal{M}, \mathcal{V}, \mathcal{R}$ )
2:    $s_0 \leftarrow x_0$  start token (bar in our encoding)
3:    $q_0 \leftarrow$  initial state
4:    $t \leftarrow 0$ 
5:   while not end of sequence do
6:      $\mathcal{V}_{t+1} \leftarrow$  GETSUBVOCAB( $\mathcal{R}, q_t, x_t$ )
7:      $q_{t+1} \leftarrow$  UPDATESTATE( $\mathcal{R}, q_t, x_t$ )
8:      $x_{t+1} \leftarrow$  SAMPLE( $\mathcal{M}, \mathcal{V}_{t+1}$ )
9:      $s_{t+1} \leftarrow s_t \circ x_{t+1}$ 
10:     $t \leftarrow t + 1$ 
11:  end while
12:  return  $s_t$ 
13: end procedure

```

3.2 Constrained Generation via FSM

In the controlled symbolic music generation setting, there are two types of constraints:

Grammar constraint: The encoding of symbolic music follows a specific format. For example, for our proposed encoding shown in Fig. 1, a bar token will always be followed by a `genre` token.

User input constraint: Generated token sequence should conform with user inputs. For example, if the user wants to generate “rock” style music, the `genre` token can only be `genre<rock>`.

Since we are already aware of these constraints in advance, there is no need to sample from the entire vocabulary space during inference. Instead, we can sample from

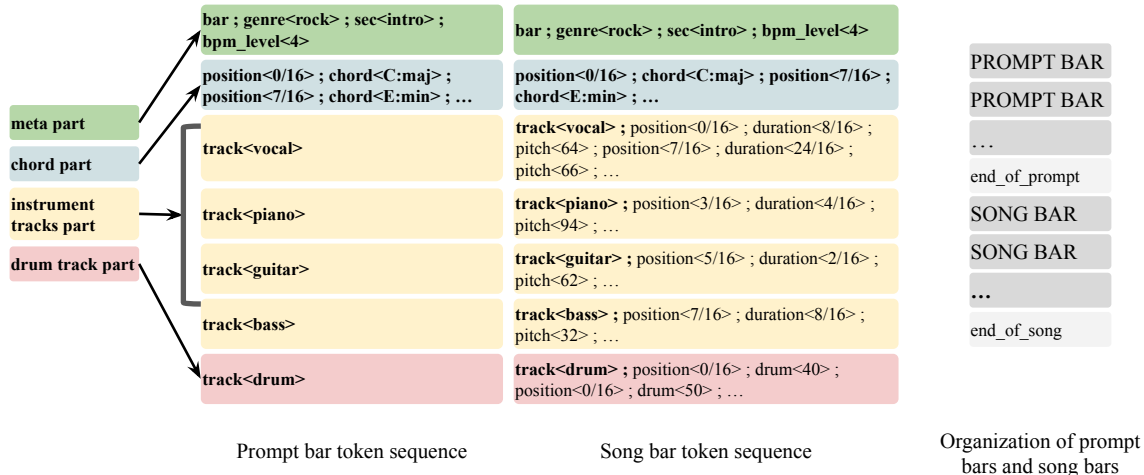

Figure 1: Illustration of our symbolic music encoding.

a subspace that is in accordance with the constraints.

To achieve this, we employ a Finite State Machine (FSM) to interact with the language model \mathcal{M} during inference. Let x_t denote the token generated by \mathcal{M} at time step t . The FSM takes x_t , the current state q_t and the predetermined rule set \mathcal{R} , and outputs a subset of the vocabulary \mathcal{V}_{t+1} , from which the language model \mathcal{M} can sample at time $t + 1$. We call this procedure Constrained Generation via FSM, which is formally defined in Algorithm 1. This algorithm is analogous to regular expression matching, where it checks if a given input string conforms to a specified pattern. Here the pattern and input string are equivalent to rule set \mathcal{R} and token sequence s_t respectively.

4. EXPERIMENTS AND RESULTS

To validate our contributions, we conduct experiments to assess whether the system is scalable (i.e., improves when scaling up training data) and controllable (i.e., there is consistency between generation output and user inputs).

In Sec. 4.3, we conduct a quantitative analysis to compare models trained on different amounts of training data, in order to assess scalability. In Sec. 4.4, we examine two common types of control inputs: chord progression and section structure. The impact of these control inputs is tested through both quantitative metrics and qualitative examples. Lastly, in Sec. 4.5, we compare our models trained on different datasets with other baseline symbolic music generation systems through subjective evaluation.

4.1 Datasets

We use three datasets in our experiments. We always use each dataset individually; i.e., we never merge the datasets to train a single model. The datasets are:

Lakh MIDI Dataset (LMD) [24]. A dataset in MIDI format, containing around 170K songs. We use this to compare with models trained on transcribed audio data.

Million Song Dataset (MSD) [26]. A public dataset used extensively by MIR researchers. We use the 30–60s pre-view audio clips, representing the highlight of the song.

In-House Dataset (IHD). We use a licensed internal collection with about 1M full songs in audio format, covering a wide range of Western modern genres.

4.2 Training Settings

We train a decoder language model with the Llama [21] architecture. We set the number of layers, number of attention heads and embedding dimensions to be 12, 12 and 768 respectively, resulting in a model with about 86M trainable parameters. We concatenate token sequences of all pieces into a 1-D array, and randomly pick a window of size 10,240 as one training sample. As the average sequence lengths of LMD, MSD and IHD are 900, 1500 and 8000 respectively, this window size would contain 11.4, 6.8 and 1.3 pieces on average for each dataset.

When training data are limited, data augmentation and data filtering (to ensure that unusual data do not pollute the training) are commonly used. However, we adopt neither approach, for two reasons. First, since we have a large dataset of audio samples, the training data are likely to cover a broad spectrum of examples already, reducing the need to filter out unusual data points. Second, augmentation may alter the training data in unwanted ways. For example, a common augmentation approach is to transpose all the pitches in a piece [11, 28]. However, this may distort the pitch ranges of each instrument: e.g., if the input bass parts are transposed up and down, the model will not learn the correct range of realistic bass notes.

Metric Class	IHD 100%	IHD 10%	IHD 1%
Chord	0.112	0.119	0.347
Structure	0.348	0.220	0.786
Vocal Note	0.416	0.892	1.086
Guitar Note	0.222	0.257	0.397
Piano Note	0.178	0.403	0.686
Bass Note	0.180	0.867	1.038
Drum Note	0.650	2.902	1.248

Table 2: Average Kullback-Leibler Divergence (KLD) of metrics in different metric classes for models trained on different dataset against a held-out validation set.

4.3 Unconditioned Generation

Intuitively, increasing the amount of data should enhance the performance of the model. In this experiment, we use objective metrics to validate this. Designing objective metrics to evaluate symbolic music remains an open question. A common approach is to prepare a reference dataset, calculate embeddings or metrics of the generated samples and reference set, and then compare these using distance metrics such as the Fréchet Distance or Kullback-Leibler Divergence (KLD). For a detailed review on evaluation methods for symbolic music, see [34, 35].

In our experiment, we prepare a held-out validation set with 3000 samples. We use a range of metrics that can be categorized into the following classes: chord, structure, instrument note (including vocals, guitar, piano and bass) and drum note. Detailed definitions are provided in supplements. In general, the metrics in each class are as follows:

- **Chord:** chord label, chord root, chord transition;
- **Structure:** section label, section label bigram, instrument labels per bar;
- **Instrument Note:** note pitch, note duration, pitch class, min/max pitch per bar, max number of notes per bar, uniformity of number of notes per bar;
- **Drum Note:** drum key, max number of notes per bar, uniformity of number of notes per bar, and unique drums per bar.

We compare models trained on 100%, 10% and 1% of the IHD data, and do generation in an unconditioned setting. For each model, we generate 800 samples to compute metric distributions. KLD values are then computed between distributions of generated samples and distribution of the validation set for each metric. Lower KLD indicates that two distributions are closer, suggesting the generated samples sound more similar to the validation set. We report the average KLD values for the same class, and provide a full list of KLDs for each metric in supplements.

The results are shown in Table 2. We can see that the model trained with 100% IHD data has the lowest KLD against the validation set on 6 out of 7 classes, and the model trained on only 1% data has the highest KLD on 6 out of 7 classes. The results confirm that a model trained on more data can generate samples closer to the training data. Furthermore, we observed that the benefit of using more data is greater for the 'Note' metrics than for the 'Chord' or 'Structure' ones. This is likely because note tokens are more numerous and have complex distributions, which needs larger scale of data to learn. Counterintuitively, the KLD for 'Structure' was better when using 10% of the data instead of 100%. We speculate that since the structure tokens are scarcest, this could be the result of a lucky alignment between the validation set at the 10% of the data used, but this deserves more study.

4.4 Controlled Generation

The SymPAC framework aims to give users flexible control over the music generation process. However, we need to

verify that this control is effective: do the notes generated agree with the control inputs? To this end, we conduct controlled generation experiments on two input scenarios: chord progression inputs and section structure inputs.

Chord Progression Inputs. In this experiment, we randomly pick 20 top trending chord progressions from *Hook-Theory*² as the chord progression inputs. We only include major and minor triad chords. We then let the model generate 64 bars of music by looping the chord progressions. To evaluate the match between the input chord progression and the output, we apply a symbolic chord detection method on the generated samples. Details about the method can be referred in the supplementary materials.

The accuracy of detected chord from the input chord progression is shown in Table 4. As shown in the result, the models trained on MSD, IHD 100% and IHD 10% all have similar overall accuracy, with MSD slightly outperforming the others. But the model trained on IHD 1% (just 10K songs) is much worse than the other three. This suggests that a dataset at the scale of 100K songs is sufficient to model low-level control signals like chord, given the model and encoding we are using here. We also provide examples in supplementary audios of outputs when given unusual chord progressions.

Section Structure Inputs. In this experiment, we take 10 typical section sequences as inputs (listed in supplements), ranging in length from 4 to 13 sections (16 to 68 bars), and use each model to generate 100 outputs per prompt. We compare the same 4 models from the previous section. For each generated output, we leverage a Music Structure Analysis (MSA) algorithm [36] to predict its structure, and compare this to the input structure. The MSA algorithm's predictions may be inaccurate, but we still expect that a greater match between the intended and estimated structure indicates more success at controlling the structure. We use Foote's algorithm [37] for segmentation and the 2D-Fourier magnitude algorithm [38] for section labeling, with a beat-wise feature embedding that averages the pitch-wise MIDI piano rolls within a beat interval. We evaluate the results using `mir_eval` [39], and report three metrics: boundary prediction f -measure with a 3-second tolerance (HR3F); pairwise clustering f -measure (PWF); and the normalized entropy score f -measure (Sf). To test directly how similar the repeated sections are, we also report PWF and Sf when the ground-truth segmentation is used.

We find that all metrics are worse (lower) when the system is trained on MSD or IHD 1%, and improve substantially when at least 10% of the data are used (Table 5). This is expected, since the audio clips in MSD are only excerpts and thus not instructive for modelling full-song structure.

Fig. 2 shows the piano roll of a typical output, where the match between the intended and predicted structure was average (Sf = 0.508). Even so, the match between the intended and realized structure is evident in the piano roll: the chorus sections are similar but not identical to each other, and so are the verse sections.

In both controlled generation experiments, the gap be-

Model	Coherence	Richness	Arrangement	Structure	Overall
FIGARO	3.12 ± 0.82	2.73 ± 0.92	2.85 ± 0.96	2.62 ± 0.80	2.74 ± 0.89
MMT	2.37 ± 0.35	2.27 ± 0.36	2.37 ± 0.34	2.08 ± 0.30	2.16 ± 0.35
Ours (IHD)	3.55 ± 0.53	3.58 ± 0.38	3.45 ± 0.49	3.73 ± 0.32	3.60 ± 0.39
Ours (LMD)	3.25 ± 0.34	3.25 ± 0.35	3.28 ± 0.30	3.20 ± 0.61	3.25 ± 0.46
Ours (MSD)	3.16 ± 0.27	3.17 ± 0.33	3.09 ± 0.32	3.15 ± 0.29	3.07 ± 0.28

Table 3: Results of subjective evaluation, mean opinion score (MOS)

Training Dataset	Accuracy
IHD 100%	87.2%
IHD 10%	86.9%
IHD 1%	74.0%
MSD	87.6%

Table 4: Accuracy of chord progressions in controlled generation with chord input.

Dataset	Regular			Oracle	
	HR3F	PWF	Sf	PWF	Sf
IHD 100%	0.60	0.50	0.50	0.72	0.80
IHD 10%	0.60	0.49	0.49	0.70	0.79
IHD 1%	0.54	0.47	0.47	0.62	0.73
MSD	0.57	0.47	0.47	0.63	0.74

Table 5: Accuracy of structure predicted from generated songs with no guidance (left) and with ground truth segmentation (right).

tween 100% and 10% IHD is very small, indicating that 10% IHD data combined with SymPAC is sufficient for achieving good adherence to control inputs. However, it is important to remember that the metrics of these two experiments only reflect whether the control signals are well-followed, not the overall quality of the generated pieces.

4.5 Subjective Evaluation

The models tested so far were all trained on transcribed audio data, so it is worth comparing with models trained directly on MIDI data. In this experiment, we compare our model trained on LMD, MSD and IHD, and also two baselines, FIGARO [10] and MMT [11], in a subjective listening test. We recruited 12 participants with the background of MIR researchers or music producers. Similar to [11], we asked each participant to rate 10 audio samples generated by each model on a 5-point Likert scale on five criteria: coherence, richness, arrangement, structure and overall ³.

The result is summarized in Table 3. All of our proposed models outperform the baselines in all dimensions. Our model trained on IHD has higher performance than the other two training data setups, which attests to the viability of leveraging audio data by running MIR models

³ These criteria are described as: (1) Coherence: The rhythm is stable; The chord progression develops logically; Dissonant notes are not excessive. (2) Richness: The melody and accompaniment are interesting and diverse. (3) Arrangement: Collaboration among multiple instruments is harmonious and natural; Arrangements for different instruments are diverse and reasonable. (4) Structure: The piece includes a clear and engaging structure with appropriate repetitions and variations; The piece has obvious connections and reasonable developments between sections. (5) Overall: I like this piece in general.

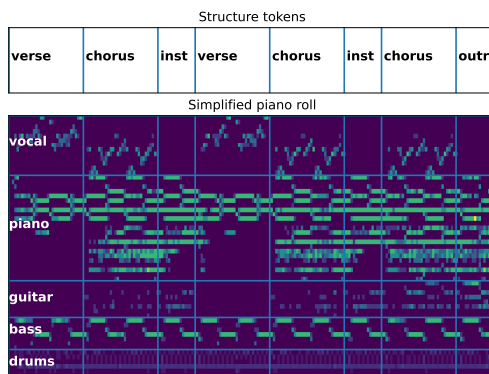

Figure 2: Constrained generation output with user-defined structure using IHD 100% model. The simplified piano roll gives beat-averaged values and excludes empty lines.

at scale. The result using LMD was better than MSD, despite having fewer songs; this could be due to LSD having more notes than MSD (see Tab 1), or due to it containing full songs instead of only excerpts. We only compare FIGARO and Ours (LMD) with a statistical test, since these were trained on the same dataset. Mann-Whitney U tests found significant differences in Richness ($p = .005$), Structure ($p = .0005$), and Overall ($p = .027$) ratings, but not in Coherence ($p = .85$) or Arrangement ($p = .122$).

5. CONCLUSIONS AND FUTURE WORK

We trained a language model for symbolic music generation leveraging audio data and pre-trained MIR models. We proposed the SymPAC framework, which includes prompt bars in encoding and Constrained Generation via FSM during inference time. We showed how combining these two components enables a user to control the generation process, and we evaluated the results through quantitative and qualitative analysis.

Future work could improve at least two aspects of this system: (1) We quantified position and duration to 1/16 per bar, which does not support 3/4 or 6/8 time signatures well. Also, the chord detection model we used only supports 12 major and minor chords, limiting the user input options. We can expand the encoding to support finer-grained quantization and more advanced chords. (2) Our token sequence length is long: 8000 on average for samples in IHD. We could use tokenization methods such as Byte Pair Encoding [40] or use compound word tokens [41] to compress sequences and improve training efficiency.

UNSUPERVISED COMPOSABLE REPRESENTATIONS FOR AUDIO

Giovanni Bindi, Philippe Esling

ABSTRACT

Current generative models are able to generate high-quality artefacts but have been shown to struggle with compositional reasoning, which can be defined as the ability to generate complex structures from simpler elements. In this paper, we focus on the problem of compositional representation learning for music data, specifically targeting the fully-unsupervised setting. We propose a simple and extensible framework that leverages an explicit compositional inductive bias, defined by a flexible auto-encoding objective that can leverage any of the current state-of-art generative models. We demonstrate that our framework, used with diffusion models, naturally addresses the task of unsupervised audio source separation, showing that our model is able to perform high-quality separation. Our findings reveal that our proposal achieves comparable or superior performance with respect to other blind source separation methods and, furthermore, it even surpasses current state-of-art supervised baselines on signal-to-interference ratio metrics. Additionally, by learning an a-posteriori masking diffusion model in the space of composable representations, we achieve a system capable of seamlessly performing unsupervised source separation, unconditional generation, and variation generation. Finally, as our proposal works in the latent space of pre-trained neural audio codecs, it also provides a lower computational cost with respect to other neural baselines.

1. INTRODUCTION

Generative models recently became one of the most important topic in machine learning research. Their goal is to learn the underlying probability distribution of a given dataset in order to accomplish a variety of downstream tasks, such as sampling or density estimation. These models, relying on deep neural networks as their core architecture, have demonstrated unprecedented capabilities in capturing intricate patterns and generating complex and realistic data [1]. Although these systems are able to generate impressive results that go beyond the replication of training data, some doubts have recently been raised about their ac-

tual reasoning and extrapolation abilities [2, 3]. Notably, a critical question remains on their capacity to perform *compositional reasoning*. The principle of compositionality states that the meaning of a complex expression is dependent on the meanings of its individual components and the rules employed to combine them [4, 5]. This concept also plays a significant role in machine learning [6], with a particular emphasis in the fields of NLP and vision. Indeed, compositionality holds a strong significance in the *interpretability* of machine learning algorithms [7], ultimately providing a better understanding of the behaviour of such complex systems. In line with recent studies on compositional inductive biases [8, 9], taking a compositional approach would allow to build better representation learning and more effective generative models, but research on compositional learning for audio is still lacking.

In this work, we specifically focus on the problem of compositional representation learning for audio and propose a generic and simple framework that explicitly targets the learning of composable representations in a fully unsupervised way. Our idea is to learn a set of low-dimensional latent variables that encode semantic information which are then used by a generative model to reconstruct the input. While we build our approach upon recent diffusion models, we highlight that our framework can be implemented with any state-of-the-art generative system. Therefore, our proposal effectively combines diffusion models and auto-encoders and represents, to the best of our knowledge, one of the first contributions that explicitly target the learning of unsupervised compositional semantic representations for audio. Although being intrinsically modality-agnostic, we show that our system can be used to perform *unsupervised source separation* and we validate this claim by performing experiments on standard benchmarks, comparing against both unsupervised and supervised baselines. We show that our proposal outperforms all unsupervised methods, and even supervised methods on some metrics. Moreover, as we are able to effectively perform latent source separation, we complement our decomposition system with a prior model that performs *unconditional generation* and *variation generation* [10]. Hence, our method is able to take an audio mixture as input, and generate several high-quality variations for one of the instrumental part only, effectively allowing to control regeneration of a source audio material in multi-instrument setups. Furthermore, we train a masking diffusion model in the latent space of composable representation and show

that our framework is able to handle both decomposition and generation in an effective way without any supervision. We provide audio examples, additional experiments and source code on a supporting webpage¹

2. BACKGROUND

In this section, we review the fundamental components of our methodology. Hence, we briefly introduce the principles underlying diffusion models and a recent variation rooted in autoencoders, referred to as Diffusion Autoencoder [11], which serves as the basis for our formulation.

Notation. Throughout this paper, we suppose a dataset $\mathcal{D} = \{\mathbf{x}_i\}_{i=1}^n$ of *i.i.d.* data points $\mathbf{x}_i \in \mathbb{R}^d$ coming from an unknown distribution $p^*(\mathbf{x})$. We denote $\theta \in \Theta \subseteq \mathbb{R}^p$, $\phi \in \Phi \subseteq \mathbb{R}^q$ and $\psi \in \Psi \subseteq \mathbb{R}^r$ as the set of parameters learned through back-propagation [12].

2.1 Diffusion models

Diffusion models (DMs) are a recent class of generative models that can synthesize high-quality samples by learning to reverse a stochastic process that gradually adds noise to the data. DMs have been successfully applied across diverse domains, including computer vision [13], natural language processing [14], audio [15] and video generation [16]. These applications span tasks such as unconditional and conditional generation, editing, super-resolution and inpainting, often yielding state of the art results.

This model family has been introduced by [17] and has its roots in statistical physics, but there now exist many derivations with different formalisms that generalise the original formulation. At their core, DMs are composed of a *forward* and *reverse* Markov chain that respectively adds and removes Gaussian noise from data. Recently, [18] established a connection between DM and denoising score matching [19, 20], introducing simplifications to the original training objective and demonstrating strong experimental results. Intuitively, the authors propose to learn a function ϵ_θ that takes a noise-corrupted version of the input and predicts the noise ϵ used to corrupt the data. Specifically, the *forward* process gradually adds Gaussian noise to the data $\mathbf{x} \rightarrow \mathbf{x}_t$ according to an increasing noise variance schedule β_1, \dots, β_T , following the distribution

$$q(\mathbf{x}_t | \mathbf{x}_{t-1}) = \mathcal{N}(\mathbf{x}_t; \sqrt{1 - \beta_t} \mathbf{x}_{t-1}, \beta_t \mathbf{I}), \quad (1)$$

with $T \in \mathbb{N}$ and $t \in \{1, \dots, T\}$. Following the notation $\alpha_t = 1 - \beta_t$ and $\bar{\alpha}_t = \prod_{s=1}^t \alpha_s$, diffusion models approximate the *reverse* process by learning a function $\epsilon_\theta : \mathbb{R}^d \times \mathbb{R} \rightarrow \mathbb{R}^d$ that predicts $\epsilon \sim \mathcal{N}(\epsilon, \mathbf{0}, \mathbf{I})$ by

$$\min_{\theta \in \Theta} \mathbb{E}_{t, \mathbf{x}_0, \epsilon} [\|\epsilon_\theta(\sqrt{\bar{\alpha}_t} \mathbf{x}_0 + \sqrt{1 - \bar{\alpha}_t} \epsilon, t) - \epsilon\|], \quad (2)$$

with ϵ_θ usually implemented as a U-Net [21] and the step $t \sim \mathcal{U}[0, T]$.

Deterministic diffusion. More recently, [22] introduced Denoising Diffusion Implicit Models (DDIM), extending the diffusion formulation with non-Markovian

modifications, thus enabling deterministic diffusion models and substantially increasing their sampling speed. They also established an equivalence between their objective function and the one from [18], highlighting the generality of their formulation. Finally, [23] further generalized this approach and proposed Iterative α -(de)Blending (IADB), simplifying the theory of DDIM while removing the constraint for the target distribution to be Gaussian. In fact, given a base distribution² $p_n(\mathbf{x}_0)$, we corrupt the input data by linear interpolation $\mathbf{x}_\alpha = (1 - \alpha)\mathbf{x}_0 + \alpha\mathbf{x}$ with $\mathbf{x}_0 \sim p_n(\mathbf{x}_0)$ and learn a U-Net ϵ_θ by optimizing, e.g.,

$$\min_{\theta \in \Theta} \mathbb{E}_{\alpha, \mathbf{x}, \mathbf{x}_0} [\|\epsilon_\theta(\mathbf{x}_\alpha, \alpha) - \mathbf{x}\|_2^2], \quad (3)$$

with $\alpha \sim \mathcal{U}[0, 1]$. This is known as the *c* variant of IADB, which is the closest formulation to DDIM. In our implementation, we instead use the *d* variant of IADB, which has a slightly different formulation that we do not report for brevity. We experimented with both variants and did not find significant discrepancies in performances.

Diffusion Autoencoders. All the methods described in the preceding paragraph specifically target unconditional generation. However, in this work we are interested in conditional generation and, more specifically, in a conditional encoder-decoder architecture. For this reason, we build upon the recent work by [11] named Diffusion Autoencoder (DiffAE). The central concept in this approach involves employing a learnable encoder to discover high-level semantic information, while using a DM as the decoder to model the remaining stochastic variations. Therefore, the authors equip a DDIM model ϵ_ϕ with a semantic encoder $E_\theta : \mathbb{R}^d \rightarrow \mathbb{R}^s$ with $s \ll d$ that is responsible for compressing the high-level *semantic* information³ into a latent variable $\mathbf{z} \in \mathbb{R}^s$ as $\mathbf{z} = E_\theta(\mathbf{x})$. The DDIM model is, therefore, conditioned on such semantic representation and trained to reconstruct the data via

$$\min_{\theta \in \Theta, \phi \in \Phi} \mathbb{E}_{t, \mathbf{x}_0, \epsilon} [\|\epsilon_\phi(\sqrt{\alpha} \mathbf{x}_0 + \sqrt{1 - \alpha} \epsilon, \mathbf{z}, t) - \epsilon\|] \quad (4)$$

with $\alpha = \prod_{s=1}^t (1 - \beta_s)$ and β_i being the variance at the *i*-th step. Since the DiffAE represents the state of the art for encoder-decoder models based on diffusion, we build our compositional diffusion framework upon this formulation, which we describe in the following section.

3. PROPOSED APPROACH

In compositional representation learning, we hypothesize that the information can be deconstructed into specific, identifiable parts that collectively makes up the whole input. In this work, we posit these parts to be distinct instruments in music but we highlight that this choice is uniquely dependent on the target application. Due to the lack of a widely-accepted description of compositional representations, we formulate a simple yet comprehensive definition that can subsequently be specialized to address particular

² For simplicity we assume $p_n(\mathbf{x}_0) = \mathcal{N}(\mathbf{x}_0; \mathbf{0}, \mathbf{I})$.

³ In the domain of vision this could be the identity of a person or the type of objects represented in an image.

¹ https://github.com/ismir-24-sub/unsupervised_compositional_representations

Figure 1. The overall architecture of our decomposition model. We first mix the sources, map the data \mathbf{x} to the latent space through a frozen, pre-trained EnCodec model, and then decompose it into a set of latent variables (two shown here). These variables then condition a parameter-sharing diffusion model whose generation are then recomposed by an operator \mathcal{C} .

cases [24, 25]. Specifically, we start from the assumption that observations $\mathbf{x} \in \mathbb{R}^d$ are realizations of an underlying latent variable model and that each concept is described by a corresponding latent $\mathbf{z}_i \in \mathcal{Z}_i$, where $i \in \{1, \dots, N\}$ with N being the total number of possible entities that compose our data. Then, we define a compositional representation of \mathbf{x} as

$$\mathbf{x} = \mathcal{C}(\hat{\mathbf{z}}_1, \dots, \hat{\mathbf{z}}_N) = \mathcal{C}(f_1(\mathbf{z}_1), \dots, f_N(\mathbf{z}_N)), \quad (5)$$

where $\mathcal{C} : \hat{\mathcal{Z}}_1 \times \hat{\mathcal{Z}}_2 \times \dots \times \hat{\mathcal{Z}}_N \rightarrow \mathbb{R}^d$ is a *composition operator* and each $f_i : \mathcal{Z}_i \rightarrow \hat{\mathcal{Z}}_i$ is a *processing function* that maps each latent variable to another *intermediate* space. By being intentionally broad, this definition does not impose any strong specific constraints a priori, such as the requirement for each subspace to be identical or the algebraic structure of the latent space itself. Hence, to implement this model, we rather need to consider careful intentional design choices and inductive biases. In this work, we constrain the intermediate space to be the data space itself, i.e. $\hat{\mathcal{Z}}_i = \mathbb{R}^d$ for all $i = 1, \dots, N$ and we focus on the learning of the latent variables and the processing functions. Finally, we set the composition operator to be a pre-defined function such as *mean* or *max* and leave its learning to further investigations.

3.1 Decomposition

In this section, we detail our proposed model, as depicted in Figure 1. Globally, we follow an encoder-decoder paradigm, where we encode the data $\mathbf{x} \in \mathbb{R}^d$ into a set of latent representations $\mathcal{Z} = \{\mathbf{z}_1, \dots, \mathbf{z}_N\}$, where $\mathbf{z}_i \in \mathcal{Z} \subseteq \mathbb{R}^h$ for each $i = 1, \dots, N$. This is done through an encoder network $E_\theta : \mathbb{R}^d \rightarrow \mathcal{Z} \times \dots \times \mathcal{Z}$ that maps the input \mathbf{x} to the set of variables \mathcal{Z} , i.e. $[\mathbf{z}_1, \dots, \mathbf{z}_N] = E_\theta(\mathbf{x})$. Each latent variable is then decoded separately through a parameter-sharing diffusion model, which implements the *processing function* $f : \mathcal{Z} \rightarrow \mathbb{R}^d$ in Equation 5, mapping the latents to the data space. Finally, we reconstruct the input data \mathbf{x} through the application of a *composition operator* \mathcal{C} and train the system end-to-end through a vanilla iterative α -(de)Blending (IADB) loss. Specifically, we learn a U-Net network $g_\phi : \mathbb{R}^d \times \mathbb{R} \times \mathbb{R}^h \rightarrow \mathbb{R}^d$ and a

semantic encoder E_θ via the following objective

$$\min_{\theta \in \Theta, \phi \in \Phi} \mathbb{E}_{\alpha, \mathbf{x}, \mathbf{x}_0} [\|\hat{g}_\phi(\mathbf{x}_\alpha, \alpha) - \mathbf{x}\|_2^2], \quad (6)$$

with $\alpha \sim \mathcal{U}[0, 1]$, $\mathbf{x}_0 \sim \mathcal{N}(\mathbf{x}_0; \mathbf{0}, \mathbf{I})$ and

$$\hat{g}_\phi(\mathbf{x}_\alpha, \alpha) = \mathcal{C}(g_\phi(\mathbf{x}_\alpha, \alpha, \mathbf{z}_1), \dots, g_\phi(\mathbf{x}_\alpha, \alpha, \mathbf{z}_N)), \quad (7)$$

with $\mathbf{x}_\alpha = (1 - \alpha)\mathbf{x}_0 + \alpha\mathbf{x}$ and $[\mathbf{z}_1, \dots, \mathbf{z}_N] = E_\theta(\mathbf{x})$. We chose the IADB paradigm due to its simplicity in implementation and intuitive nature, requiring minimal hyperparameter tuning.

At inference time, we reconstruct the input by progressively denoising an initial random sample coming from the prior distribution, conditioned on the components obtained through the semantic encoder.

A note on complexity. We found that using a single diffusion model proves effective instead of training N separate models for N latent variables. Consequently, we opt for training a parameter-sharing neural network g_ϕ . Nonetheless, the computational complexity of our framework is therefore N times that of a single DiffAE.

3.2 Recomposition

One of our primary objectives is to endow models with *compositional generation*, a concept we define as the ability to generate novel data examples by coherently re-composing distinct parts extracted from separate origins. This definition aligns with numerous related studies that posit compositional generalization as an essential requirement to bridge the gap between human reasoning and computational learning systems [26]. In this work, we allow for compositional generation by learning a prior model in the components' space. Specifically, once we have a well-trained decomposition model $D_{\theta, \phi} = (E_\theta, g_\phi)$ we learn a diffusion model in \mathcal{Z} in order to obtain a full generative system. We define $\mathbf{z} = [\mathbf{z}_1, \dots, \mathbf{z}_N] = E_\theta(\mathbf{x})$ and train a IADB model to recover \mathbf{z} from a masked view $\tilde{\mathbf{z}}$. At training time, with probability p_{mask} , we mask each latent variable \mathbf{z}_i with a mask $\mathbf{m}_i \in \{0, 1\}^{dim(\mathcal{Z})}$ and optimize the diffusion model ϵ_ψ by solving

$$\min_{\psi \in \Psi} \mathbb{E}_{\alpha, \mathbf{z}, \mathbf{z}_0, \mathbf{m}} [\|\mathbf{z} - \epsilon_\psi(\mathbf{z}_\alpha, \alpha, \mathbf{m})\|_2^2], \quad (8)$$

 end for
end while
Return: ϵ_ψ

where $\mathbf{z}_\alpha = \tilde{\mathbf{z}}_\alpha \odot \mathbf{m} + (1 - \mathbf{m}) \odot \mathbf{z}$ and $\tilde{\mathbf{z}}_\alpha = (1 - \alpha)\mathbf{z}_0 + \alpha\mathbf{z}$. Here, $\mathbf{z}_0 \sim \mathcal{N}(\mathbf{z}_0; \mathbf{0}, \mathbf{I})$ and $\tilde{\mathbf{z}}_\alpha$ denotes the α -blended source \mathbf{z} . At each training iteration we randomly mask $\tilde{\mathbf{z}}_\alpha$ via \mathbf{m} and train the diffusion model ϵ_ψ to recover the masked elements given the unmasked view \mathbf{z} . Our masking strategy allows for dropping each latent separately as well as all the latents simultaneously, effectively leading to a model that is able to perform both conditional and unconditional generation at the same time. In our application case, the conditional generation task reduces to the problem of generating variations. As our decomposition model proves to be effective in separating the stems of a given mixture, we obtain a system that is able to generate missing stems given the masked elements. Hence, this also addresses the accompaniment generation task. Algorithm 1 resumes the training process of the prior model.

4. EXPERIMENTS AND RESULTS

This section provides an overview of the experiments aimed at assessing the performance of our proposal in both decomposition (section 4.1) and recomposition (section 4.2) scenarios. Prior to diving into the specifics of each experiment, we provide a brief overview of the shared elements across our experiments, including data, evaluation metrics, and neural network architectures.

Data. We rely on the Slakh2100 dataset [27], a widely recognized benchmark in source separation, comprising 2100 tracks automatically mixed with separate stems. We selected this dataset because of its large-scale nature and the availability of ground truth separated tracks. Following recent approaches in generative models [28, 29], we rely on a pre-trained neural codec to map the audio data to an intermediate latent space, where we apply our approach. Specifically, we employ the EnCodec model [30], a Vector Quantized-VAE (VQ-VAE) model [31] that incorporates Residual Vector Quantization [32] to achieve state-of-the-art performances in neural audio encoding. We take 24 kHz mixtures from the Slakh2100 dataset, which we then feed to the pre-trained EnCodec model to extract the continuous representation obtained by decoding the discrete codes. EnCodec maps raw audio to latent trajectories with

MS-STFT	FAD (LC-A)	FAD (LC-M)
4.7	0.05	0.04

Table 1. EnCodec reconstruction quality, measured in terms of MS-STFT and FAD and computed following the procedure described in section 4.

a sampling rate of 75 Hz. Specifically, we take audio crops of approximately 7s (6.82s), which are mapped via EnCodec to a latent code $\mathbf{x} \in \mathbb{R}^{128 \times 512}$.

Evaluation metrics. Throughout this section, we report quantitative *reconstruction* metrics in terms of both Mean Squared Error (MSE) and Multi-Scale Short-Time Fourier Transform (MS-STFT) [33, 34] for latent and audio data, respectively. We perform the MS-STFT evaluation using five STFT with window sizes {2048, 1024, 512, 256, 128} following the implementation of [34]. In order to evaluate the quality of the generated samples and the adherence to the training distribution, we also compute Fréchet Audio Distance (FAD) [35, 36] scores. Specifically, we obtain the FAD scores via the `fadt` library [36], employing both the LAION-CLAP-Audio (LC-A) and LAION-CLAP-Music (LC-M) models [37], as it was shown in [36] that these embedding models correlate well with perceptual tests measuring subjective quality of pop music. In assessing FAD scores, we utilize the complete test set of Slakh2100, while for MSE and MS-STFT values, we randomly select 512 samples of 7s (~ 1 hour) from the same test set and report their mean and standard deviation. Finally, in order to provide the reader a reference value, we report in Table 1 the reconstruction metrics for the pre-trained EnCodec.

When assessing the effectiveness of *source separation* models, we adhere to common practice by relying on the `museval` Python library [38] to compute standard separation metrics: Source-to-Interference Ratio (SIR), Source-to-Artifact Ratio (SAR), and Source-to-Distortion Ratio (SDR) [39]. These metrics are widely accepted for evaluating source separation models, where SDR reflects sound quality, SIR indicates the presence of other sources, and SAR evaluates the presence of artifacts in a source. Specifically, following [39] we compute their scale-invariant (SI) versions and, hence, provide our results in terms of SI-SDR, SI-SIR and SI-SAR. The values shown are expressed in terms of mean μ and standard deviation σ computed on 512 samples of ~ 7s from the Slakh2100 test set.

Architectures. We use a standard U-Net [21] with 1D convolution and an encoder-decoder architecture with skip connections. Each processing unit is a ResNet block [40] with group normalization [41]. Following [42], we feed the noise level information through Positional Encoding [43], conditioning each layer with the AdaGN mechanism. We also add multi-head self-attention [43] in the bottleneck layers of the U-Net. The semantic encoder mirrors the U-Net encoder block without the attention mechanism and maps the data $\mathbf{x} \in \mathbb{R}^{128 \times 512}$ to a set of variables $\mathbf{z} = [\mathbf{z}_1 \dots \mathbf{z}_i \dots \mathbf{z}_N]$ whose dimensionality is $\mathbf{z}_i \in \mathbb{R}^{1 \times 512}$.

Finally, these univariate latent variables condition the U-Net via a simple concatenation, which proved to be a sufficiently effective conditioning mechanism for the model to converge. We use the same U-Net architecture for both the decomposition and recomposition diffusion models.

4.1 Decomposition

In order to show the effectiveness of our decomposition method described in section 3.1, we perform multiple experiments on Slakh2100. Throughout this section, we fix the number of training epochs to 250 and use the AdamW optimizer [44] with a fixed learning rate of 10^{-4} as our optimization strategy. The U-Net and semantic encoder have 13 and 8 million trainable parameters, respectively. Finally, we use 100 sampling steps at inference time.

First, we show in Table 2 that our model can be used to perform unsupervised latent source separation and compare it against several non-neural baselines [45–49], as well as a recent study that explicitly targets neural latent blind source separation [50]. We also report the results obtained by Demucs [51], which is the current top performing fully-supervised state-of-the-art method in audio source separation. As the only non-neural baseline, LASS, has been trained and evaluated on the Drums + Bass subset, we perform our analysis on this split and subsequently perform an ablation study over the other sources.

Model	SI-SDR (\uparrow)	SI-SIR (\uparrow)	SI-SAR (\uparrow)
rPCA [45]	-2.8 (4.8)	5.2 (7.3)	<u>5.6</u> (4.6)
REPET [48]	-0.5 (4.8)	6.8 (7.0)	3.0 (5.2)
FT2D [49]	-0.2 (4.7)	5.1 (7.0)	3.1 (4.7)
NMF [46]	1.4 (5.0)	8.9 (7.6)	2.9 (4.5)
HPSS [47]	2.3 (4.8)	9.9 (7.5)	5.1 (4.6)
LASS [50]	-3.3 (10.8)	17.7 (11.6)	-1.6 (11.2)
Ours	<u>5.5</u> (4.6)	41.7 (9.3)	<u>5.6</u> (4.6)
Demucs [51]	11.9 (5.0)	<u>37.6</u> (8.7)	12.0 (5.0)

Table 2. Blind source separation results for the *Drums + Bass* subset. Our model is trained with the *mean* composition operator. The results are expressed in dB as the mean (standard deviation) across 512 elements randomly sampled from the test set of Slakh2100.

As we can see, our model outperforms the other baselines in terms of SI-SDR and SI-SIR and performs on par with respect to SI-SAR. Interestingly, our model outperforms the Demucs supervised baseline in terms of SI-SIR, which is usually interpreted as the amount of other sources that can be heard in a source estimate. In order to test LASS performances, we used their open source checkpoint which is trained on the Slakh2100 dataset, and followed their evaluation strategy. Unfortunately, we were not able to reproduce their results in terms of SDR but we found that their model performs well in terms of SI-SIR, which they did not measure in the original paper. Moreover, as LASS comprises training one transformer model per source, we found their inference phase to be more com-

Operator	MSE (\downarrow) $\times 10^4$	MS-STFT (\downarrow)
<i>Sum</i>	1.87820 (0.13418)	3.6 (0.1)
<i>Mean</i>	1.87020 (0.13183)	3.6 (0.1)
<i>Min</i>	2.54182 (0.17714)	4.5 (0.1)
<i>Max</i>	2.43302 (0.17510)	4.3 (0.1)

Table 3. Reconstruction quality in latent space (MSE) and audio (MS-STFT) of our decomposition-recomposition model for different recomposition operators for the *Drums + Bass* subset.

putationally demanding than ours. Finally, among non-neural baselines, we see that the HPSS model outperforms the others. This seems reasonable as HPSS is specifically built for separating percussive and harmonic sources and hence naturally fits this evaluation context.

Moreover, in order to show the robustness of our approach against different sources and number of latent variables, we train multiple models on different subset of the Slakh2100 dataset, namely *Drums + Bass*, *Piano + Bass* and *Drums + Bass + Piano*. The interested reader can refer to our supplementary material and listen to the separation results.

Subsequently, we show that our objective in Equation 6 is robust across different composition operators. We show that, for simple functions such as *sum*, *min*, *max* and *mean* our model is able to effectively converge and provide accurate reconstructions. Again, we provide this analysis by training our model on the *Drums + Bass* subset of Slakh2100, fixing the number of components to 2. We report quantitative results in terms of two reconstruction metrics, the Mean Squared Error (MSE) and Multi-Scale STFT distance (MS-STFT) in Table 3. As we can see, *sum* and *mean* operators provided the best results, while *min* and *max* proved to be less effective. Nonetheless, the audio reconstruction quality measured in terms of MS-STFT provided reconstruction scores that are lower or comparable with respect to those obtained by evaluating EnCodec performances.

4.2 Recomposition

As detailed in section 3.2, once we are able to decompose our data into a set of composable representations we can then learn a prior model for generation from this new space. Since our decomposition model is able to compress meaningful information through the semantic encoder, we can learn a second latent diffusion model on this compressed representation to obtain a full generative model able to both decompose and generate data.

Here, we validate our claims by training a masked diffusion model for the *Drums + Bass* split of the Slakh2100 dataset. In Table 4, we show that our model can indeed produce good-quality unconditional generations by comparing it against a fully unconditional model. We measure the generation quality in terms of FAD scores computed against both the original as well as the encoded test data. Here, by original data we mean the audio coming

	Original		Encoded

Bass	0.03	0.03	0.01	0.01
Drums	0.09	0.08	0.05	0.05

Table 4. Audio quality of unconditional generations by our generative model. We demonstrate that we can jointly learn an unconditional and conditional model by showing that the FAD scores of $p_{mask} = 0.8$ are comparable to those of an unconditional latent diffusion model.

	Type	MSE $\times 10^3$	MS-STFT
Real	Drums	2.3259 (0.1287)	13.6 (0.4)
	Bass	1.4393 (0.0874)	9.38 (0.2)
Rand	Drums	4.8170 (0.1136)	20.5 (0.6)
	Bass	4.8814 (0.1157)	21.7 (0.7)

Table 5. Diversity of variations generated by our prior model, measured via the MSE and MS-STFT distances against ground truth and random components.

from the test split of Slakh2100, while the encoded data represents the same elements reconstructed with our decomposition algorithm. As we train on the representations obtained through the semantic encoder, the natural benchmark for the unconditional generation is given by the reconstructions that we can obtain through our decomposition model, which represents the bottleneck in terms of quality. Nonetheless, we show that the FAD scores do not drop substantially when comparing against the original audio, showing that we can indeed achieve a good generation quality. In the same table, we report the partial generation FAD scores. Instead of generating both components unconditionally, we generate the Bass (Drums) given the Drums (Bass), and measure the FAD against the original and the encoded test data, as done for the unconditional case. Given the presence of a ground-truth element, the FAD scores are lower, which is to be expected. Specifically, we can see that the drums generation is a more complex task with respect to the bass generation, as the model needs to synthesize more elements such as the kick, snare and hi-hats, matching the timing of a given bassline.

Lastly, as we strive for high-quality generations, we also aim to enhance diversity within our generations. Table 5 shows the diversity scores for partial generations obtained with our model. We measure diversity in terms of MSE and MS-STFT scores computed, respectively, in the latent and audio space. We compare our partial generations against real and random components, in order to provide the lower and upper bound for generation diversity. Specifically, given the Drums (Bass) we generate the Bass (Drums) and we compute both MSE and MS-STFT scores against the ground truth (Real) and random elements (Rand) coming from the test set of Slakh2100. From the values reported in Table 5, we can deduce that our model produces meaningful variations. We invite the interested readers to listen

to our results on our support website.

5. DISCUSSION AND FURTHER WORKS

While our model proves to be effective for compositional representation learning, it still has shortcomings. Here, we briefly list the weaknesses of our proposal and highlight potential avenues for future investigations.

Factors of convergence. In this paper, we used En-Codec which already provides some disentanglement and acts as a sort of initialization strategy for our method. We argue that this property, jointly with the low dimensionality of the latent space enforced by our encoder leads our decomposition model to converge efficiently, not requiring further inductive biases towards source separation.

Limitations. First, there is no theoretical guarantee that the learned latent variables are bound to encode meaningful information. Exploring more refined approaches, as proposed by [52], could be interesting in order to incorporate a more principled method for learning disentangled latent representations. Furthermore, we observed that the dimensionality of the latent space significantly influences the representation content. A larger dimensionality allows the model to encode all the information in each latent, hindering the learning of distinct factors. Conversely, a smaller dimensionality may lead to under-performance, preventing the model to correctly converge. It could be interesting to investigate strategies such as Information Bottleneck [53] to introduce a mechanism to explicitly trade off expressivity with compression. Finally, using more complex functions as well as learnable operators is an interesting research direction for studying the interpretability of learned representations.

6. CONCLUSIONS

In this work, we focus on the problem of learning unsupervised compositional representations for audio. We build upon recent state-of-the-art diffusion generative models to design an encoder-decoder framework with an explicit inductive bias towards compositionality. We validate our approach on audio data, showing that our method can be used to perform latent source separation. Despite the theoretical shortcomings, we believe that our proposal can serve as a useful framework for conducting research on the topics of unsupervised compositional representation learning.

ABSTRACT

Lyrics play a crucial role in affecting and reinforcing emotional states by providing meaning and emotional connotations that interact with the acoustic properties of the music. Specific lyrical themes and emotions may intensify existing negative states in listeners and may lead to undesirable outcomes, especially in listeners with mood disorders such as depression. Hence, it is important for such individuals to be mindful of their listening strategies. In this study, we examine online music consumption of individuals at risk of depression in light of lyrical themes and emotions. Lyrics obtained from the listening histories of 541 Last.fm users, divided into At-Risk and No-Risk based on their mental well-being scores, were analyzed using natural language processing techniques. Statistical analyses of the results revealed that individuals at risk for depression prefer songs with lyrics associated with low valence and low arousal. Additionally, lyrics associated with themes of *denial*, *self-reference* and *blame* were preferred. This study opens up the possibility of an approach to assessing depression risk from the digital footprint of individuals and potentially developing personalized recommendation systems.

Keywords: depression, lyrics, lastfm, emotions, themes

1. INTRODUCTION

Depression is one of the leading causes of disability in young adults globally, according to the World Health Organization [1]. It has the potential to hinder and curb development in personal and social avenues of life, making it a debilitating condition. This underscores the imperative to identify and address it in the early stages.

Music plays an important role in regulating mood and emotions [2]. Musical preferences and music listening habits are known to invoke and reinforce moods and emotions and satisfy psychological needs [3, 4]. Emotionally vulnerable young adults were found to have more intense

relationships with music [5]. An increased emotional reliance on music was also observed in such individuals [6]. However, certain music engagement behaviors and strategies are associated with indicators of poor mental health and do not always lead to the alleviation of existing depressive symptoms [7]. Individuals who are depressed or at risk of depression are often unconscious of using music as a tool to improve emotional states [8], which might lead to adverse outcomes. This highlights the importance of addressing and studying music listening behaviors of individuals prone to depression risk for developing intervention methods to come up with listening strategies that may lead to positive outcomes.

Online music streaming platforms such as Spotify¹, Last.fm², and Apple Music³ offer their users a large variety of songs across genres and make it possible to study the musical digital footprints of their users. Last.fm allows the extraction of the listening histories of its users and the corresponding metadata, which prompted several studies that utilized Last.fm to study naturally occurring user listening behaviors in light of depression risk [9, 10, 11]. However, the relationship between lyrics, specifically the semantics and emotional connotations of lyrics, and depression has received little to no attention in the literature, while lyrics were found to play a crucial role in affecting emotional states [12]. Lyrics were also found to be essential for depicting *sadness* in music [13]. This study seeks to address this gap by examining the relationship between lyrical emotions and themes extracted from user listening histories and depression risk.

2. BACKGROUND AND RELATED WORK

We highlight previous studies that used online music listening histories from Last.fm and preferences to identify different trends and characteristics in music listening behaviors of individuals at risk of depression. Surana et al. [9] was the first such study, which used user-annotated tags from Last.fm, to identify emotion- and genre-tag preferences of individuals at risk of depression. The results of this study revealed that At-Risk individuals consume music that is tagged with emotions representing sadness, such as *sad*, *depressed*, *dead*, *low* and *miserable*, and belonging to

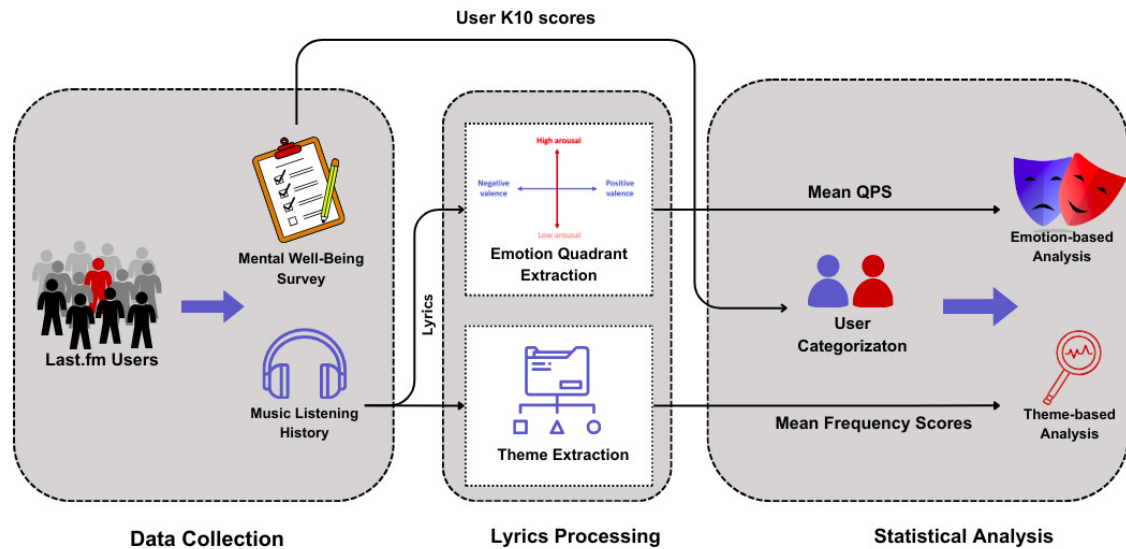

Figure 1: Methodology

genres such as *neo-psychedelic*, *dream-pop* and *indiepop*. In a later study, Surana et al. [10] studied emotions in relation to acoustic features of music as dynamic measures across the span of six months by dividing the listening history into sessions based on periods of inactivity to observe any dynamic patterns in music listening behaviors of At-Risk individuals. This study found that individuals at risk of depression rely more heavily on music and tend to listen to the same songs repeatedly. It was also found that they tend to listen to sad music for longer periods.

Shriram et al. [11] were the first to study lyrics in this context in terms of lyrical repetitiveness and compressibility. The results revealed that At-Risk individuals prefer music with lower lyrical simplicity (lower compressibility) and greater information content, especially for music that is characterized as sad.

However, no study to date has explored the link between lyrical emotions and themes extracted from online listening histories and depression risk, to the best of our knowledge. This link is crucial to investigate because lyrics reinforce negative states and, in dire situations, lead to maladaptive outcomes. The only study that has looked into lyrical themes associated with maladaptive listening strategies, which is known to be a proxy for depression risk [14], was done by Singh et al. [15]. They explored the link between lyrical themes extracted using DICTION⁴ and unhealthy music engagement strategies characterized by the Unhealthy-Healthy music scale (HUMS) [14], which indirectly indicates depression risk. This study revealed that individuals who engage in unhealthy and maladaptive listening strategies listen to music with lyrical themes representing *self-reference* and *blame*. However, this has been done in the context of online discourse surrounding depression on Reddit. This raises the question of whether similar behavior can be observed in the lyrical content derived from the listening histories of individuals at risk on music

streaming platforms. In this study, we investigated the relationship between individuals' online listening histories and their risk of depression in the context of lyrical emotions and themes.

Based on previous research in the field [9, 10, 11, 15], we hypothesize the following:

- Building on prior research demonstrating a preference for *sad* music among At-Risk individuals [9, 10], we hypothesize that these individuals exhibit a greater preference for music with lyrics associated with low valence and low arousal.
- In line with the established link between lyrical themes and unhealthy music engagement behaviors shown by Singh et al. [15], we hypothesize that At-Risk individuals consume music that is higher in terms of themes such as *self-reference*, and *blame*.

3. METHODOLOGY

Figure 1 summarizes the procedure used in our study, which is described as follows.

3.1 Dataset

We used the dataset from Surana et al. [9, 10] for our analysis. The dataset consists of the six-month music listening history of 541 Last.fm users (Mean Age = 25.4, SD = 7.3), of which 444 were male, 82 were female, and 15 identified as other. This data was acquired by means of a survey that was posted on Reddit⁵ and Facebook⁶ Last.fm pages. Informed consent was taken from the participants and participation was completely voluntary. They were informed that the study posed no risks and that their confidentiality would be maintained. The analysis was performed at a group level, ensuring no individuals could be identified.

⁴ www.dictionsoftware.com

⁵ www.reddit.com

⁶ www.facebook.com

3.1.1 Measure of Depression Risk

To assess mental well-being, Kessler’s Psychological Distress Scale (K10) questionnaire [16] is utilized, which measures psychological distress with a focus on symptoms of anxiety and depression. Following the approach of Surana et al. [9], participants scoring 29 or higher on the K10 questionnaire were classified as being in the “At-Risk” group for depression, while those scoring below 20 constitute the “No-Risk” group. Out of the total users, 193 individuals were in the No-Risk group, and 142 were in the At-Risk group.

3.1.2 Listening History and Lyrics

Lyrics for the tracks in the listening histories are extracted from Genius.com and MetroLyrics.com. Lyrics for approximately 76% of the entire repository of songs were obtained. Songs with no lyrics comprised around 4% of the dataset.

3.2 Lyrics Processing

3.2.1 Lyrics-Emotion Mapping

Figure 2: Two-dimensional Valence-Arousal space

Lyrics were projected onto the Russell’s Complex Model of Affect [17], which is used to organize emotions along two orthogonal dimensions: *Valence*, which represents pleasantness and *Arousal*, which represents energy. As can be seen in Figure 2, The first quadrant represents high valence and high arousal (happiness), the second quadrant represents low valence and high arousal (anger), the third quadrant represents low valence and low arousal (sadness), and the fourth quadrant represents high valence and low arousal (tenderness). We employed a model proposed in Agarwal et al. [18] to map each song’s lyrical content to a quadrant in the VA space. The architecture of the model is a deep neural network architecture that employs XLNet [19], an advanced bidirectional transformer, to perform multitask learning for emotional classification

based on song lyrics. The model is trained on the Moody-Lyrics [20] and MER [21] datasets, which consist of songs uniformly distributed across the four quadrants of the Russell’s Valence-Arousal circumplex model. The model was used to return a single quadrant label for each song by mapping the song’s lyrical content to the 2D Valence-Arousal space, which was used to categorize the tracks into one of the four quadrants.

To quantify user preferences for quadrant categories, we computed a quadrant prevalence (QPS) score for each quadrant, which is determined by the proportion of tracks from each user’s listening history, within the respective quadrants, as shown in Equation 1. The top 100 most frequently listened songs were identified and assigned weights based on listening frequency. The QPS for each user and quadrant was then calculated as the average weighted frequency of songs belonging to that specific quadrant in their listening history.

$$QPS(u_j, q_k) = \frac{\sum_{s_i \in L(u_j)} w(s_i) \cdot I(q(s_i) = q_k)}{\sum_{s_i \in L(u_j)} w(s_i)} \quad (1)$$

where,

$QPS(u_j, q_k)$: QPS of quadrant q_k for user u_j

s_i : a song in the top 100 songs of the user’s listening history $L(u_j)$

$w(s_i)$: the weight (listening frequency) of song s_i .

$q(s_i)$: quadrant assigned to song s_i

$I(\cdot)$: indicator function that equals 1 if the condition inside is true (song s_i belongs to quadrant q_k) and 0 otherwise.

3.2.2 Lyrics-Semantic Themes Mapping

Following a similar approach to Singh et al. [15], we used DICTION to analyze the lyrics and identify underlying semantic themes. DICTION operates through the use of dictionaries that contain lists of words associated with specific linguistic, emotional and cognitive contexts. There are 5 themes and 35 sub-themes in total. We chose the themes *Self-reference*, *Blame*, *Optimism*, *Hardship*, *Satisfaction*, *Inspiration*, *Exclusion* and *Denial*. The frequency scores corresponding to all the themes and sub-themes for each song were obtained, based on the occurrence of the words from the lyrics in the dictionary lists. Similar to the quadrant prevalence scores, mean frequency scores (MFS) were computed for all the themes per user, as shown in Equation 2.

$$MFS(u_j, t_k) = \frac{\sum_{s_i \in L(u_j)} w(s_i) \cdot T_k(s_i)}{\sum_{s_i \in L(u_j)} w(s_i)} \quad (2)$$

where,

$MFS(u_j, t_k)$: MFS of theme t_k for user u_j

s_i : a song in the top 100 songs of listening history $L(u_j)$

$w(s_i)$: the weight (listening frequency) of song s_i .

$T_k(s_i)$: the frequency score assigned to song s_i for theme t_k .

3.3 Statistical Testing

We divided the users into At-Risk and No-Risk groups based on their K10 scores, as mentioned before. For each quadrant, we performed a two-tailed Mann-Whitney U (MWU) test on the quadrant prevalence score between the At-Risk and No-Risk groups. Similarly, a MWU test was performed for the mean frequency score between At-Risk and No-Risk groups, for each theme selected.

4. STATISTICAL TESTING AND RESULTS

4.1 Lyrical Emotion-Based Results

A statistically significant difference ($p < 0.05$) was observed for the QPS corresponding to Q3, which is representative of low valence and low arousal values (U-statistic = 15727.5, $p = 0.02$), with a higher median for the At-Risk group, as can be seen in 3. We observed no significant differences between the distributions of the At-Risk and No-Risk groups for the other quadrants. The same trend was observed when the top 250 songs were considered.

Figure 3: Violin plots of mean QPS per quadrant for At-Risk and No-Risk groups

4.2 Lyrical Theme-based Results

We found significant differences ($p < 0.05$) between At-Risk and No-Risk groups in the case of *denial*, *self-reference* and *blame*. As can be inferred from Table 1, The median for the At-Risk group is higher in the cases of the themes *denial*, *self-reference* and *blame*.

	Theme	U-statistic	p-value
At-Risk > No-Risk	Denial	15950.0	0.010
	Self-reference	15968.0	0.009
	Blame	15691.5	0.023

Table 1: MWU Test results for the Mean Frequency Scores between the At-Risk and No-Risk groups; Here At-Risk > No-Risk refers to the themes where the median is greater in the case of the At-Risk group

5. DISCUSSION

This study is the first of its kind to explore the association between risk for depression and the emotional and the-

matic connotations of the lyrical content of the music individuals engage with online, as opposed to studies in lab settings or self-reported data. Our results are in concordance with our initial hypotheses, in addition to revealing novel findings.

The At-Risk group exhibited a higher median score for Q3 (low valence, low arousal) than the No-Risk group. This finding suggests a greater prevalence of sadness-related lyrical content in the music listened to by the At-Risk group. The stronger association of the At-Risk group with sadness aligns with the results of past research studies on the topic. These results suggest that At-Risk individuals tend to consume music with lyrics that reflect their negative emotional states.

As hypothesized, the themes *self-reference* and *blame* were more prevalent in the At-Risk group. Additionally, the themes *denial* was also shown to be preferred by At-Risk individuals. Since the themes of *blame* and *self-reference* in lyrics were found to be associated with unhealthy listening strategies [15], listening to music associated with these themes would not be beneficial to individuals at risk of depression, and in some cases may lead to negative outcomes. This highlights the importance of mindful consumption strategies for music for people at risk of depression.

In conclusion, our results show that certain music engagement strategies are maladaptive in nature and should be avoided to prevent the worsening of mood, building on top of previous studies in the area. These results can potentially aid in developing intervention strategies based on lyrical content that should be avoided for better outcomes from music listening.

5.1 Limitations

A limitation of this study is the exclusive focus on lyrical emotions and themes. The interaction of these with the acoustic properties of music and lyrical complexity, as well as in the context of depression risk, could be explored, which could possibly yield a better understanding. The interaction between lyrical themes and emotional connotations is also something that is yet to be studied. Another limitation is that this study exclusively focuses on music with English lyrics. We have also used a predetermined set of themes offered by DICTION, which may not be enough to capture several lyrical themes. An approach to solve this would be to use Large Language Models (LLMs) to generate themes from a repository of songs and then using them for the scoring.

5.2 Future Work

The results from this paper can be used in building music recommendation systems for depressed individuals that tailor the recommendations, keeping in mind the emotions and themes that are associated with mood worsening and maladaptive behaviors to maximize the positive outcomes through music listening. These results could be combined with other measures associated with such behaviors. This work also opens up the possibility of early depression risk

prediction from online music listening behaviors, in terms of lyrics, by cementing lyrical emotions and themes as indicators for depression risk. These measures, in addition to acoustic features [10] and other indicators such as lyrical complexity and social tags [11, 9], could potentially be used to develop a multi-modal depression risk prediction system.

A STEM-AGNOSTIC SINGLE-DECODER SYSTEM FOR MUSIC SOURCE SEPARATION BEYOND FOUR STEMS

Karn N. Watcharasupat Alexander Lerch

{kwatcharasupat, alexander.lerch}@gatech.edu

ABSTRACT

Despite significant recent progress across multiple sub-tasks of audio source separation, few music source separation systems support separation beyond the four-stem vocals, drums, bass, and other (VDBO) setup. Of the very few current systems that support source separation beyond this setup, most continue to rely on an inflexible decoder setup that can only support a fixed pre-defined set of stems. Increasing stem support in these inflexible systems correspondingly requires increasing computational complexity, rendering extensions of these systems computationally infeasible for long-tail instruments. We propose Banquet, a system that allows source separation of multiple stems using just one decoder. A bandsplit source separation model is extended to work in a query-based setup in tandem with a music instrument recognition PaSST model. On the MoisesDB dataset, Banquet — at only 24.9 M trainable parameters — performed on par with or better than the significantly more complex 6-stem Hybrid Transformer Demucs. The query-based setup allows for the separation of narrow instrument classes such as clean acoustic guitars, and can be successfully applied to the extraction of less common stems such as reeds and organs.

1. INTRODUCTION

Music Source Separation (MSS) is the task of separating a musical audio mixture into its constituent components, commonly referred to as stems. The releases of DSD100 [1] and MUSDB18 [2, 3], both being four-stem MSS datasets, have defined a de-facto standard, with nearly every major work since relying on the four-stem *vocals, bass, drum*, and *others* (VDBO) setup [4–19]. While this has significantly improved the comparability and reproducibility of the task, it has also disproportionately favored the VDBO setup. Very few works have tackled MSS beyond the VDBO setup, each relying on datasets with significant limitations: Wang et al. [20] relied on MedleyDB [21, 22], whose stem ontology is somewhat unfriendly to source separation, Manilow et al. [23] relied on the syn-

thetically generated Slakh dataset [24], and others relied on proprietary data inaccessible to other research groups [11, 18], limiting reproducibility. The recently released MoisesDB [25], a multitrack source separation dataset, attempts to address these limitations, particularly in terms of stem availability and taxonomy. This aims at broadening the task beyond VDBO based on publicly available data. However, to the best of our knowledge, while MoisesDB was used in the 2023 Sound Demixing Challenge (SDX) [26], no published system has utilized MoisesDB for source separation beyond VDBO yet.

In this work, we propose Banquet,¹ a query-based source separation model that can separate an arbitrary number of stems using just one set of stem-agnostic encoder and decoder, and a pre-trained feature extractor [27]. Our model was adapted from the cinematic audio source separation Bandit model [28], which was in turn adapted from the music source separation Bandsplit RNN model [17]. Bandit significantly reduces the complexity of Bandsplit RNN by adopting a common-encoder approach with stem-specific decoders. In this work, we take the complexity reduction further by switching to a query-based setup, using only one decoder shared amongst all possible stems. Performance evaluation on MoisesDB demonstrated separation performance above oracle for drum and bass, state-of-the-art for guitar and piano, and at least 7.4 dB SNR for vocals. Our system additionally provided support for fine-level stem extraction currently available only in a few MSS systems.

2. RELATED WORK

Nearly every major MSS works since 2017 have relied on the VDBO setup. Early systems [4, 6, 29], including OpenUnmix [8], were usually Time-Frequency (TF) masking models with LSTM forming the core of the systems, with some experimenting with densely-connected convolutional systems [5, 12]. Beginning with Wave-U-Net [7], the U-Net architecture became a popular choice for MSS, with notable models such as Demucs [9, 10, 14, 18], Spleeter [11], ByteSep [13], and KUIELab-MDX-Net [15] all being some variations of a U-Net. More recently, Bandsplit RNN [17] became one of the few state-of-the-art systems to not rely on a U-Net setup. This was followed by the Bandsplit RoPE Transformer model [19] topping the

leaderboard of SDX 2023 [26]. Of existing open-source systems, very few offer separation functionality beyond the VDBO setup. Spleeter [11] supports 5-stem separation with VDBO and piano. HT-Demucs [18] supports a 6-stem setup with VDBO, piano, and guitar.

2.1 Conditional source separation

The systems mentioned above were mostly designed with either stem-specific models, stem-specific decoders, or a shared decoder with predetermined outputs. As a result, these systems are not particularly amenable to the addition of new stems, especially if these new stems have limited data availability. Below we review some of the common approaches for conditional source separation that may be useful for extending existing systems beyond VDBO.

Meseguer-Brocal and Peeters [30] were likely amongst the first to attempt a conditioned U-Net for source separation using a single decoder. They used multiple feature-wise linear modulation (FiLM) [31] layers within the encoder to perform MSS in a VDBO setup. Slizovskaia et al. [32] used a similar setup with FiLMs either throughout the encoder, at the bottleneck layer, or at the final decoder layer. The systems in [32] were tested on the 13-instrument URMP dataset [33], with up to 4 active instruments in any recording, but all performed poorly in terms of mean signal-to-distortion ratio (SDR). Lin et al. [34] proposed a joint separation-transcription U-Net system, which performed well for string and brass instruments in URMP, but struggled on woodwind instruments. The system in [34] used FiLMs throughout the encoder with a query embedding from another convolutional model, and across all skip connections with transcription embeddings.

Lee et al. [35] proposed a U-Net with two methods of less aggressive conditioning with examples beyond VDBO, but only provided objective results for a VDBO setup on MUSDB18. Wang et al. [20] also proposed a U-Net, with FiLM conditioning only at the bottleneck layer. The system in [20] was able to support a substantial number of stems beyond VDBO with the caveat that its reported performance is significantly below contemporary models for VDBO stems. Gfeller et al. [36] utilized a FiLM-conditioned wave-to-wave U-Net to perform one-shot conditional audio filtering. Similar approaches were also adopted in Choi et al. [37] and Jeong et al. [38] for MSS, in Chen et al. [39] for source activity-queried separation, in Kong et al. [40] for universal source separation, and in Liu et al. [41, 42] for language-queried source separation. These works [36–42] applied FiLM or generalizations thereof to nearly every single layer of the network, significantly increasing the computational complexity of the system. We surmise that the apparent need for multiple conditioning in a U-Net is probably due to the nature of its information flow [43], which may require a significant number of information streams to be conditioned to achieve acceptable performance.

In a different direction, source separation systems relying on audio embedding “distances” have also been developed, notably with Le Roux et al. in [23, 44, 45]. In 2018,

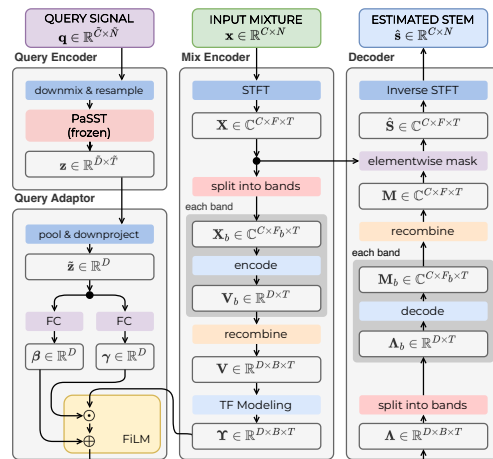

Figure 1. Overview of the Banquet System.

Kumar et al. [46] presented an early work using Euclidean audio embedding distance from a “query” embedding to inform music source separation. A similar system using a Gaussian mixture posterior in lieu of standard distance was proposed in [44]. Hierarchical masking [23] was later utilized to allow the extraction of stems at multiple levels of specificity. More recently, source separation systems with audio embedding in a low-dimensional hyperbolic space have been developed to allow music [45] and speech [47] source separation with some degrees of control on the specificity of the extraction. Uniquely, Samuel et al. [48] proposed a network-generating network approach for instrument-conditioned source separation.

3. PROPOSED SYSTEM

The overview of the proposed Banquet system is shown in Fig. 1. The system is a single-encoder single-decoder adaptation of Bandit [28], that takes in a mixture signal x and a query signal q , and extracts a stem estimate \hat{s} from the mixture signal of the “same” stem type as the query signal using a complex-valued TF mask. This is done by (i) encoding the mixture into a subband-level time-varying embedding tensor Υ , (ii) encoding the query into a single-vector representation \tilde{z} , (iii) adapting the mixture embedding, conditioned on the query, into a stem-specific embedding $\Lambda = \mathcal{Q}(\Upsilon; \tilde{z})$, then (iv) decoding the Λ to a TF mask M that is used to obtain the source estimate.

3.1 Bandit encoder

The encoder module of the system used in this work is the *musical* variant of the Bandit encoder, with $B = 64$ bands. Specifically, given an input mixture $x \in \mathbb{R}^{C \times N}$ with C channels and N samples, a short-time Fourier transform (STFT) of x is computed to obtain $X \in \mathbb{C}^{C \times F \times T}$ with a frame size of $N_{FFT} = 2(F - 1) = 2048$ and 75% overlap. The STFT is then split into overlapping subbands as detailed in [28]. Each of the subbands is then viewed as a real-valued tensor in $\mathbb{R}^{2CF \times T}$, passed through a layer norm and an affine transformation with $D = 128$ neurons to obtain $V_b \in \mathbb{R}^{D \times T}$. These tensors are then stacked to

obtain $\mathbf{V} \in \mathbb{R}^{D \times B \times T}$. TF modeling is then applied on \mathbf{V} to obtain \mathbf{Y} using 8 pairs of residual gated recurrent units (GRUs), the first of each pair operating along the time axis and the second along the band axis.

Note that this TF modeling is the only part of the model that is recurrent across either the time or the subband axes. The rest of the encoder and the decoder operate in a subband-wise manner identically for any time frame.

3.2 Query encoding

To obtain the query embedding, a PaSST model [27] trained on the OpenMIC-2018 dataset [49] is used. The 20 instruments in OpenMIC span all coarse-level classes of MoisesDB, except *other*. For compatibility, each query signal is downmixed to mono and downsampled to 32 kHz before being fed to PaSST. Although the query feature extractor could, in theory, be jointly trained with the rest of the system, preliminary experiments showed that this can result in considerable instability during training, especially if the query feature extractor is not at least pretrained. Due to the size and complexity of PaSST, the query feature extractor is fully frozen in this work. The embedding from the PaSST variant used is a time series with a feature dimension of $\tilde{D} = 784$. The embedding is averaged over time and linearly down-projected to obtain $\tilde{\mathbf{z}} \in \mathbb{R}^D$.

3.3 Query-based adaptation

In the original Bandit system [28], each stem was estimated through a dedicated decoder. As a result, \mathbf{Y} typically contains information from all stems, with most of the “separation” occurring within each of the decoders. This is evident in the fact that the encoder of a Bandit system trained on the cinematic audio Divide and Remaster (DnR) dataset [?] could be successfully used in a 4-stem MSS on the MUSDB18-HQ dataset [2] with separation quality on par with Open-Unmix [28].

In this work, only a single decoder is responsible for mask estimation for any stem. As a result, the query-based adaptation $\mathcal{Q}: (\mathbb{R}^{D \times B \times T}, \mathbb{R}^D) \mapsto \mathbb{R}^{D \times B \times T}$ has an important role in filtering out irrelevant information from \mathbf{Y} , or at least “hinting” to the decoder the nature of the target stem. A single FiLM layer is used to map from the mixture embedding to the stem-specific embedding, that is,

$$\mathbf{A}[d, b, t] = \gamma[d] \cdot \mathbf{Y}[d, b, t] + \beta[d], \quad \forall d, b, t, \quad (1)$$

where modulating variables $\gamma, \beta \in \mathbb{R}^D$ are obtained from a two-layer nonlinear affine map of $\tilde{\mathbf{z}}$. This is similar to the conditioning method used in [20].

Crucially, note that the modulating variables are not subband-specific. Due to the nature of the TF modeling module within the encoder, features of \mathbf{Y} are already aligned across subbands and time frames. Moreover, BSRNN-like models only contain one stream of information flow, with a clear bottleneck, thus lending itself to the global conditioning mechanism significantly more than, for example, U-Net-style models in [20, 41, 42].

The use of embedding-based query, as opposed to one-hot class-based query, provides significant practical flexibility in adding new instruments as data become available or in adjusting the level of specificity in the querying, as these can be done via finetuning with no architectural changes to the model. Moreover, class-based query can be emulated in an embedding-based system but not vice versa.

3.4 Bandit decoder

The decoder used is identical in structure to that in [28]. The major difference is that there is only one stem-agnostic decoder. Given a conditioned embedding tensor \mathbf{A} , the embedding tensor is split into subband-level representation $\mathbf{A}_b = \mathbf{A}[:, b, :]$. Each \mathbf{A}_b is passed through a layer norm and a gated linear unit (GLU) to obtain a real-valued tensor $\mathbb{R}^{2CF_b \times T}$ which is then viewed as a complex-valued tensor $\mathbf{M}_b \in \mathbb{C}^{C \times F_b \times T}$. Frequency-domain overlap-add is then applied to obtain the full-band mask using

$$\mathbf{M}[c, f, t] = \sum_{b=0}^{B-1} \frac{\mathbf{W}[b, f] \cdot \mathbf{M}_b[c, f - \min \mathfrak{F}_b, t]}{\sum_{k=0}^{B-1} \mathbf{W}[k, f]} \quad (2)$$

Finally, the source estimates are then obtained using elementwise masking $\hat{\mathbf{S}} = \mathbf{X} \circ \mathbf{M}$.

3.5 Loss function

The loss function used in this work is the multichannel version of the L1SNR loss proposed in [28]. The contribution for each sample of the loss function is given by

$$\mathcal{L}(\hat{\mathbf{s}}; \mathbf{s}) = \mathcal{D}(\hat{\mathbf{s}}; \mathbf{s}) + \mathcal{D}(\Re \hat{\mathbf{S}}; \Re \mathbf{S}) + \mathcal{D}(\Im \hat{\mathbf{S}}; \Im \mathbf{S}), \quad (3)$$

$$\mathcal{D}(\hat{\mathbf{y}}; \mathbf{y}) = 10 \log_{10} \frac{\|\text{vec}(\hat{\mathbf{y}} - \mathbf{y})\|_1 + \epsilon}{\|\text{vec}(\mathbf{y})\|_1 + \epsilon}, \quad (4)$$

where $\hat{\mathbf{s}} = \text{iSTFT}(\hat{\mathbf{S}})$, \mathbf{s} and \mathbf{S} are defined similarly for the ground truth, $\text{vec}(\cdot)$ is the vectorization operator, and $\epsilon = 10^{-3}$ for stability.

4. DATA AND EXPERIMENTAL SETUP

This work utilizes the MoisesDB dataset [25], which consists of 240 songs from 47 artists, in stereo format at 44.1 kHz. MoisesDB defined their stem ontology with more than 30 fine-level classes, which are then grouped into 11 coarse-level classes [25, Table 2]. Due to the lack of official splits for MoisesDB, we performed a five-fold split² on the dataset stratified by genres. The first three splits are used as the training set, the fourth as the validation set, and the last as the test set.

4.1 Query extraction

For each possible stem of each song, a 10-second chunk of the clean audio of the same stem is extracted as the query signal. This is done by computing a time series of onset strength for each stem and then aggregating the mean onset

² The splits are available in the repository. Note that not all stems contain a sufficient number of data points to be split into a five-fold validation setup. As a result, some stems are only present in a subset of folds.

strength for each 10-second sliding window with a hop size of 512 samples. The 10-second window with the strongest average onset is taken as the query signal. A t-SNE plot of the query embedding is shown in Fig. 2. While clusters can be clearly seen amongst related stems, it can also be seen that there are varying degrees of non-separability of the embedding between fine-level stems.

4.2 Training

Each model was trained using an NVIDIA H100 GPU (80 GB) for up to 150 epochs, unless otherwise stated. A training epoch consists of 8192 mixture-query pairs, with a batch size of 4. We used Adam optimizer with an initial learning rate of 10^{-3} and a decay factor of 0.98 per epoch.

In the default sampling strategy, a random song is chosen, a random trainable stem for that song is chosen as the target stem, then a random chunk of 6 s is chosen. If the current target chunk has an RMS below -36 dBFS, a new random chunk is chosen for up to 10 more trials. Otherwise, the threshold is dropped to -48 dBFS for another 10 trials. If a suitable chunk is still not found, the next random chunk is chosen regardless of RMS. A pre-extracted query of the same stem is then randomly chosen from the available pool of songs, including the song of the mixture.

4.3 Testing and inference

During testing and inference, each track is split into 6-s segments with a hop size of 0.5 s, as per [17]. The estimated stems were then reconstructed into a full track using time-domain overlap-add with a Hann window. The Banquet models are tested in two scenarios: one using a query from a different song, and another using a query from the same song (SSQ). In different-song querying, the query song for each stem is randomly chosen from another song within the test split that contains the stem. When possible, the query song is chosen so that it is from the same genre as the mixture song but from a different artist. Otherwise, a song from any genre with a different artist is chosen.

4.4 Evaluation metric

In this work, we report the full-track multichannel signal-to-noise ratio (SNR)³ as the main metric. Specifically, for a test signal \hat{s} and a reference signal s , both in $\mathbb{R}^{C \times N}$, the SNR is computed by

$$\text{SNR}(\hat{y}; y) = 10 \log_{10} \left(\frac{\|s\|_F^2}{\|\hat{s} - s\|_F^2} \right). \quad (5)$$

5. RESULTS AND DISCUSSION

In this section, we provide the results and discussion of our experiments. Section 5.1 discusses pretraining of the Bandit/Banquet encoder. Section 5.2 trials the use of the query-based setup on a subset of vocals, drums, and bass

³ Signal-to-interference ratio (SIR) and signal-to-artifact ratio (SAR) were not computed as the number of the constituent stems can be large, making the required subspace projection intractable and/or unreliable. It is also unclear if coarse-level ground truth or fine-level ground truth should be used for such a projection. See [50–52] for background.

Figure 2. A t-SNE plot of the PaSST embeddings of the query signals. Stems from the same coarse-level grouping, as defined by [25], share the same symbol.

stems. Section 5.3 extends the system to include fine-level stems from *guitar* and *piano* families. Finally, Section 5.4 attempts to perform extraction on all possible fine-level stems with sufficient data.

5.1 Encoder pretraining

Preliminary experiments indicated that encoder pretraining is an important step to stabilize the training of the query-based model, especially as the number of query stems grows. The encoder pretraining is done with a common-encoder multi-decoder setup similar to [28] with a VDBO setup for 100 epochs. The VDBO decoders were discarded and the encoder was used for subsequent experiments. The performance of the pretrained model is shown in Table 1, with performance above oracle ideal ratio mask (IRM) for drums and bass, and on par with HT-Demucs for vocals.⁴

5.2 Learning to separate from queries

As a first step to verify the query-based ability of the model, a Banquet model is trained to extract only *lead female singer*, *lead male singer*, *drums*, and *bass* stems, referred to as the Q:VDB setup. We experimented with training from scratch, using a frozen pretrained encoder (FE), and using a trainable pretrained encoder (TE). While the frozen-encoder setup did not demonstrate any sign of overfitting during the training, the trainable-encoder system demonstrated (very slight) overfitting. As a result, an additional setup with data augmentation (DA) was attempted with the trainable encoder setup, using simple stem-wise within-song random gain (up to ± 6 dB), random time shifting, polarity inversion, and channel swapping.

The results are shown in Table 2. All three variants with pretrained encoder provided better performance than the model trained from scratch, except for drums in the trainable-encoder model without DA being 0.1 dB lower. Thus, for all subsequent experiments, the encoder is always pretrained. Without DA, there was no clear benefit to unfreezing the encoder. However, in a trainable en-

⁴ All coarse-level results for oracle methods, HT-Demucs, and Spleeter were recomputed only on the test set using song-wise results from github.com/moises-ai/moises-db. The song-wise results were missing for five of the songs (as of 6 April 2024), two of these belong in the test set, thus the aggregates were computed over 46 songs instead of 48 songs.

Table 1. Median SNR of the models trained on the VDBO setup, evaluated on the test set of MoisesDB.

Model	Median SNR (dB):	Vocals	Drums	Bass	Other
Bandit [28]		9.1	9.9	10.6	6.4
HT-Demucs [18]		9.1	11.0	12.2	7.3
Spleeter [11]		7.4	6.6	6.8	5.0
Oracle IRM		10.3	9.2	8.8	7.6

Table 2. Median SNR of Banquet models on the Q:VDB setup, evaluated with different-song queries.⁶

Pretrained Enc.	FE	DA	Female Vox	Male Vox	Drums	Bass
N	N	N	8.3	7.2	9.4	9.4
Y	Y	N	9.8	7.6	9.9	10.2
Y	N	N	9.8	8.0	9.3	9.8
Y	N	Y	10.2	8.0	10.1	10.8

coder system with DA, slight to moderate improvements were observed across all but the male vocal stem. Note, however, that allowing full-model training significantly increases the number of trainable parameters from 13.5 M to 24.9 M thus the computational cost and training time also increases accordingly. The performances of the drums and bass stems are on par or better than the dedicated-stem setup in Table 1. Generally, the models perform better on female vocals than on male vocals.

5.3 Extending to guitar and piano

Amongst systems that tackled MSS beyond four stems, the next two stems beyond VDBO are usually guitar and piano, due to their high prevalence within pop/rock music. The set of possible queries is thus extended from Q:VDB to also include *acoustic guitar*, *clean electric guitar*, *distorted electric guitar*, *grand piano*, and *electric piano*. This is referred to as the Q:VDBGP setup. Due to the significantly lower number of available training data for guitar and piano stems, we also experimented with a balanced sampling (BS) strategy. In this strategy, a random stem is first chosen as the target stem, then a random song containing that stem is chosen. The remainder of the sampling process is the same as the default. This strategy ensures that every stem has a similar number of training pairs, but distorts the “natural” distribution of stem occurrences.

For comparability with existing systems, the inference outputs of fine-level stems in this setup were added together to form their respective coarse-level predictions.⁷ Coarse-level results are shown in Table 3. Fine-level results for trainable-encoder models are shown in Table 4.

At the coarse level, most variants of Banquet continue to perform above the oracle IRM for drums and bass. With the default-sampling trainable encoder systems, the Banquet performed better than HT-Demucs on guitar and piano. Without DA, balanced sampling generally did not lead to consistent improvements for guitar and piano. With balanced sampling and DA on a trainable-encoder model,

⁶ Median results for the same-song query and different-song query are within 0.2 dB of each other.

⁷ The ground truth signals for are the full coarse-level tracks, e.g. *vocals* ground truth include contributions from *background vocals* even if we do not have *background vocals* in the predictions.

Table 3. Coarse-level performance of the Banquet models with different-song queries on the Q:VDBGP setup

Model	FE	DA	BS	Vox	Lead Vox	Drums	Bass	Guitar	Piano
Banquet	Y	N	N	8.0	7.9	9.8	10.5	2.3	0.8
			Y	7.9	7.7	9.6	10.5	2.2	0.9
	N	N	N	7.4	8.0	9.6	10.6	3.0	2.3
			Y	7.6	7.7	9.3	10.2	2.9	2.5
	Y	N		7.8	7.9	10.1	10.9	3.2	2.2
		Y		7.6	7.9	9.5	11.0	3.3	2.5
HT-Demucs (VDBGPO)				8.9	—	11.6	12.4	2.4	1.7
Spleeter (VDBPO)				7.0	—	6.9	6.7	—	0.7
Oracle IRM				10.0	—	9.6	7.8	5.2	5.0

Bold: best Banquet model **and/or** best non-oracle model.

however, slight gains in median SNRs of guitar and piano were observed, albeit at the cost of vocals and drum SNRs.

At the fine level, the model performance follows a similar trend to that of the coarse level. Drums and bass continue to perform above the oracle IRM, while both lead vocals performed close to the IRM. Guitar and piano performances are still well below IRM. Interestingly, it appears that querying with excerpts from the same or different track did not affect the model performance for most stems except for electric piano. This is likely due to both the small sample size of electric piano limiting generalizability, and the highly diverse set of possible timbres thus the intertwined nature of both the query embedding and the target audio with other keyboard instruments. The ability of the model to query with stems from different tracks is a double-edged sword, however, since this also means that the model is somewhat insensitive to fine differences in timbre between different renditions of the “same” instruments. This could potentially limit its usefulness when applied to a scenario where multiple target stems have very similar timbres.

5.4 Extending beyond guitar and piano

The results for the Q:VDBGP setup demonstrated that the model is able to learn to extract 5 additional stems. In this experiment, we extend the set of possible queries to include all remaining stems with at least one data point per fold: *effects*, *pitched percussion*, *organs & electronic organs*, *synth pad*, *synth lead*, *string section*, *brass*, and *reeds*. Additionally, *bass* is now broken up into *bass guitar* and *bass synth*. This is referred to as the Q:ALL setup. Although these are all fine-level stems as defined by MoisesDB, some of these classes are more specific than others. For example, *brass* is a fine-level stem despite possibly including trumpets, trombones, horns, and tuba. The experimental setups are similar to that of Setup B.⁸

The same-song query results⁹ for the models trained in

⁸ BS and DA models for Q:ALL were significantly more unstable during training than for the Q:VDBGP setup, despite being identical architecturally. When this happens, we discard the collapsed model and restart the training from scratch until we have a model that completes the entire training run with nonsilent output for most stems. No TE+DA+BS system was stable enough to finish the training run without collapse.

⁹ Note that when the FE and the TE+DA systems have SNR concentrated at 0 dB for the long-tail stems, these are indicators of the model outputting very soft, practically silent output. In general, a model yielding negative SNR for a particular stem might be more desirable than a model that has collapsed for a particular stem.

Table 4. Model performance on the Q:VDBGP setup fine-level stems.

FE: frozen encoder, DA: data augmentation, BS: balanced sampling, SSQ: same-song query, Q1: lower quartile, Q2: median, Q3: upper quartile

Figure 3. Performance of the Banquet models with same-song queries on Q:ALL fine-level stems

Q:ALL are shown in Fig.3. The performances of the model trained on Q:ALL on the stems from the Q:VDBGP setup are similar to those in Table 4, with the exception of the significant drop in performance for the balanced-sampled trainable-encoder model. Amongst the newly added stems, there are significant variations in performance, but they are all still very weak in terms of SNR, with no sample performing above 5 dB SNR. For organs, background vocals, and both synth stems, the trainable-encoder model yielded the better upper quartile and maximum performance, but is also very unreliable. Unfortunately, balanced sampling on a trainable encoder model only worsened the performance. DA on a trainable-encoder model with default sampling slightly improved the lower quartile performance, but is also accompanied by lower maximum and upper quartile performance. Frozen-encoder system collapsed for most long-tail stems in default sampling, but balanced sampling interestingly was more stable and performed the best for bass synth, pitched percussion, reeds, and brass. Evidently, the classical tradeoffs are at play here; allowing the model more flexibility with a trainable encoder also comes with a higher risk of model collapse or unreliable

performance. More surprisingly, the fact that even a frozen encoder trained on a VDBO setup was able to function at all beyond Q:VDB indicates that the embedding space of a Bandit encoder already contains information that is partially generalizable beyond VDBO, as also observed in [28].

The results of the long-tail stems are somewhat unsurprising given that the genre distribution in MoisesDB skewed heavily toward pop, rock, and singer-songwriter. In addition to the low track counts, these long-tail instruments also tend to have infrequent active segments and relatively softer levels within a song. In fact, of the long-tail stems, reeds and pitched percussion are the only ones with median RMS above -35 dBFS. Analysis of the SNR distribution shows that the model performance is quite correlated to the track-level RMS of the target signal (Spearman’s ρ between 0.78 and 0.81). This is likely due to a combination of low data availability and the inherent difficulty associated with cleanly extracting these “supporting” stems when there are significant spectral overlaps from more prominent co-occurring stems. In light of the recently published analysis in [53], we may have been too conservative with our DA setup. In particular, we made a conscious choice to only perform gain augmentation close to the original levels, instead of significantly amplifying softer stems. Whether the latter may improve the result at all will have to be addressed in future work. Moreover, given that [34] saw partial success with the predominantly classical instrumentation of URMP, there may also be an opportunity for a much more aggressive cross-dataset DA.

6. CONCLUSION

In this work, Banquet, a stem-agnostic single-decoder query-based source separation system was proposed to address MSS beyond the VDBO stems. At 24.9 M trainable parameters, this highly modularized model with a single stream of information flow provided strong performance for vocals, drums, and bass; outperformed significantly more complex HT-Demucs on guitar and piano; and provided a proof-of-concept for extractions of additional long-tail and/or fine-grained stems at no additional complexity. While there remains room for improvements for long-tail stems with low data availability, this work demonstrated the opportunity for further research on single-decoder systems toward supporting a large and diverse set of stems.

7. ACKNOWLEDGMENTS

This work was supported by a Cyber-Infrastructure Resource Award from the Institute for Data Engineering and Science (IDEaS), Georgia Institute of Technology.

K. N. Watcharasupat was separately supported by the American Association of University Women (AAUW) International Fellowship, and the IEEE Signal Processing Society Scholarship Program.

The authors would like to thank Yiwei Ding and Chih-Wei Wu for their assistance with the project.

8. ETHICS STATEMENT

Machine learning-based systems are inherently data-dependent. Our models rely both directly and indirectly on datasets with inherent imbalance, not only in terms of instrument and genre distribution, but also in terms of cultural origins. As a result, our system inevitably inherit some bias and may not perform on music that have not been well represented in the training data. The authors acknowledge this important limitation and are committed to continue exploring approaches to correct these biases, both in terms of data acquisition and algorithmic development.

ABSTRACT

The importance of automatic drum transcription lies in the potential to extract useful information from a musical track; however, the low reliability of the models for this task represents a limiting factor. Indeed, even though in the recent literature the quality of the generated transcription has improved thanks to the curation of large training datasets via crowdsourcing, there is still a large margin of improvement for this task to be considered solved. Aiming to steer the development of future models, we identify the most common errors from training and testing on the aforementioned crowdsourced datasets. We perform this study in three steps: First, we detail the quality of the transcription for each class of interest; second, we employ a new metric and a pseudo confusion matrix to quantify different mistakes in the estimations; last, we compute the agreement between different annotators of the same track to estimate the accuracy of the ground-truth. Our findings are twofold: On the one hand, we observe that the previously reported issue that less represented instruments (e.g., toms) are less reliably transcribed is mostly solved now. On the other hand, cymbal instruments have unprecedented relative low performance. We provide intuitive explanations as to why cymbal instruments are difficult to transcribe and we identify that they represent the main source of disagreement among annotators.

1. INTRODUCTION

Automatic Music Transcription (AMT) is a particularly important task in music information retrieval because it provides access to many high-level features of a musical track, such as its structure, melody, and rhythm. A subtask of AMT is automatic drum transcription in the presence of melodic instruments (DTM), which focuses on the estimation of the onsets of drum sounds and the identification of what drum instruments play them. In this article, we focus on DTM and specifically on the transcription of drum and cymbal sounds.

Recently, Zehren et al. presented a DTM algorithm, which we refer to as “ADTOF-based” algorithm, based on supervised learning from abundant crowdsourced annotations [1]. Thanks to the size and diversity of the datasets, the algorithm surpasses the accuracy of the previous state-of-the-art [2]. However, the resulting models are still not perfect, as their estimations contain mistakes. In this work, we carefully investigate these state-of-the-art algorithms, aiming to identify the most common sources of errors.

We evaluated the models in two distinct conditions: (i) when the training and the testing take place on different datasets (out-of-domain), and (ii) when they take place on the same dataset (on-domain). In the first case, the model is not expected to achieve perfect accuracy because of generalization errors that can be attributed to differences between testing and training data. In the second case, testing on-domain, the errors are more concerning as they suggest flaws in the algorithm; in fact, if the dataset were large enough, the model would be expected to learn the data distribution and therefore achieve nearly perfect accuracy. Thus, in this study we focus specifically on the most common errors that arise in the latter case. This was done in three steps, as described in the following.

First, in order to identify the most difficult instruments to transcribe, we independently evaluated the performance of the models on the different instrument classes. When trained and evaluated on (a different split of) the crowdsourced datasets, we observed that the models can reliably transcribe those instruments that play less often, something that in previous studies was arguably problematic to achieve. On the flip side, we also observed that the models do not transcribe cymbals as precisely as drums.

Second, to understand why cymbals are problematic, we employed both a new metric, which we named “octave F-measure”, and a pseudo confusion matrix. Through the new metric, we identified that the models often mistook the beat subdivision at which cymbals are played. Specifically, the rhythm estimated is often half or double the speed of the ground truth (e.g., eighth notes are estimated instead of quarter notes). Through the pseudo confusion matrix, we showed that different kinds of cymbals are hard to discern.

Finally, we assessed how much the quality of crowdsourced annotations affected the evaluated performance of the models. Due to discrepancies in the labels, some of the correct estimations from the models could have been mistakenly reported as errors. To estimate the accuracy of the ground truth itself, we quantified the agreement among

different annotators of the same tracks. Any difference in the annotations of two or more annotators indicates that at least one of them made a mistake; this, in turn, leads to a harsher evaluation of the models than needed.

The remainder of this article is organized as follows: Previous works on the evaluation of DTM algorithms is presented in Sec. 2; in Sec. 3 the transcription accuracy of each class is evaluated, and in Sec. 4 different sources of errors are quantified; finally, the accuracy of the annotations is estimated in Sec. 5, conclusions are drawn in Sec. 6.

2. RELATED WORKS

Automatic drum transcription has evolved from a single, complex task into a series of intermediary steps of increasing difficulty. This evolution facilitated the development of new and more efficient algorithms [3]. Previously, the transcription was limited to simplified audio tracks or constrained vocabulary sizes. However, recent progress made through approaches based on supervised deep learning (DL) has been so significant that it becomes realistic to tackle such a complex task as the non-simplified DTM. The development of DL algorithms focused on two aspects: First, better and more complex architectures are exploited to improve the capabilities of the models, most recently with the introduction of the self-attention mechanism by Vaswani et al. [4] which has been adapted for DTM (e.g., [1, 5]). Second, better training procedures are employed to tune the models, e.g., with the creation of new datasets [1, 2, 6–9].

The de facto method to measure the accuracy of these DTM algorithms, as suggested by the Music Information Retrieval Evaluation eXchange (Mirex) [10], is the F-measure (also known as F1 score). This metric is computed with the harmonic mean between precision and recall of the drum onsets: An onset is considered correct when its estimation is within a small distance from the ground truth. A distance between 20 ms to 50 ms is what is generally used, but it can be tuned depending on the precision of the ground truth [1, 11]. Moreover, the F-measure can be computed at different levels of granularity: from a single class and track to the overall result for a whole dataset. To average multiple tracks and classes, the F-measure can be either computed as the mean value (mean F-measure) or by joining tracks and classes as if they were part of the same file and instrument (sum F-measure). In this study, we rely on the latter because it is more robust to rare edge cases (e.g., a track or class with very few onsets) [12, p.23]. However, since the F-measure gives the same importance to all onsets regardless of their position (i.e., strong or weak beats) or dynamics (loudness), this metric does not necessarily capture the opinion of human listeners [6].

Besides the F-measure, other tools are also used to assess a transcription. For example, Callender et al. used listening tests “where raters compared synthesized transcriptions to original recordings” to estimate the perceived quality of the transcriptions [6]. Vogl et al. relied on confusion matrices adapted to multi-label classification to identify the

errors performed by their model [2]. Ishizuka et al. proposed a “tatum-level error rate based on the Levenshtein distance” [5].

Besides questions related to metric issues, the results of an evaluation are also heavily impacted by the datasets used for testing. There are a handful of datasets suitable for DTM which we group into the following three categories. A thorough description of the datasets is provided by Zehren et al. [13].

- Small but accurate datasets, which have been mostly annotated by hand by their creators, such as RBMA [14], ENST [15], or MDB [16].
- Large but synthetic datasets, synthesized from MIDI files to generate the input audio, such as TMIDT [2].
- Large but inaccurate datasets, which have been annotated by a crowd of people and refined algorithmically, such as ADTOF-RGW [17], ADTOF-YT [1], or A2MD [9].

To choose which datasets to use for testing, we singled out two criteria: First, the characteristics of the datasets (their data distribution) constitute the distribution in which the model is evaluated and should ideally be representative of a real-world situation. For example, testing can be done on different musical genres [1,2], real-world or synthesized audio [5], or different mixtures of instruments (e.g., audio containing four or five sound sources) [18,19]. Second, the test dataset may be part of the training dataset or be a new one, never used during training. The latter is known as an out-of-domain evaluation and, although more challenging, gives a better approximation of the true performances of the model (i.e., its generalization capabilities) [1, 20].

3. CLASS-SPECIFIC RESULTS

In this section, we compare the F-measures for different classes (set of instruments), to identify the most difficult instruments to transcribe for a model when trained in different ways. For this purpose, we selected the “Frame self-att” deep-learning architecture, as it has been recently employed for drum transcription [1], and compared three existing training procedures: 1) training on TMIDT with refinement on ENST, MDB, and RBMA [2]; 2) training on ADTOF-RGW [17]; and 3) training on ADTOF-RGW and ADTOF-YT [1].¹

We evaluated the resulting models on a set of five datasets (RBMA, ENST, MDB, ADTOF-RGW, and ADTOF-YT), to be representative of a real-world situation and to include both on-domain and out-of-domain evaluations. These datasets were carefully mapped to a common vocabulary containing five classes: bass drum (BD), snare drum (SD), toms (TT), open and closed hi-hat (HH), and other cymbals (CY). For the sake of brevity, in Fig. 1 we only present the results of the tests on ENST and ADTOF-YT, as these are representative of the tests on all five datasets.

¹ The models are available at github.com/MZehren/ADTOF

Figure 1: F-measure for the individual classes when testing on ENST (top) and ADTOF-YT (bottom).

First, we analyzed the results on ENST (top) to assess if and to what extent our results are close to those of the original authors of the three existing training procedures. Notably, our reproduction of pre-training on TMIDT with refinement on the non-crowdsourced datasets by Vogl et al. (blue bars) is slightly ahead when compared to their original work (whose results are indicated by the dotted lines inside the blue bars) [2, p.6]. Due to the fact that the evaluation was performed on a vocabulary larger than what we used in our test, a comparison for all instruments was not possible. The little improvement of our model in transcribing the instruments that can be directly compared (BD, SD, TT, and HH) is an indication that we were successful in reproducing the original algorithm. The reproduction of training on only ADTOF-RGW (orange bars) is also slightly better than the results reported [17, p.823] (indicated by the dotted lines inside the orange bars). We attribute this improvement to adopting a more random sampling procedure, something that helped train the models; indeed, compared to the previous work where consecutive (back to back) sequences were drawn between multiple occurrences of the same track, we sampled randomly the datasets (i.e., random track and position, without replacement), thus creating a more homogeneous training. Finally, although the reproduction of training on ADTOF-RGW and ADTOF-YT (green bars) cannot be compared on the class-specific results since they were not previously reported, our model achieved virtually the same sum F-Measure. Namely, when testing on ENST, the model trained on the two ADTOF datasets matches the performance of the model trained on ENST. Thus, ADTOF-based training, as it allows generalization towards ENST, does not overfit models.

Second, we analyzed the results achieved on ADTOF-YT (bottom) to highlight the potential of this dataset. The model achieved a very high F-measure on ADTOF-YT when training on both ADTOF datasets [1] (green bars),

and almost a perfect score for BD, which is surprising considering that this dataset includes the fastest tempi and the densest sequences of onsets, which intuitively are features that hinder transcription. However, we noted that such a high performance is achieved only when ADTOF-YT is part of the training data, which means that the other datasets generalize poorly to it. The fact that only ADTOF-YT attains such a high accuracy both on-domain and out-of-domain may be explained by its large size and the homogeneity of its acoustic and drum patterns (due to the bias toward the metal music genre).

Third, although training and testing on ADTOF-YT yields the highest on-domain performance, we observed that the model has an atypical distribution of performance. In contrast to the usual result where the less represented instruments are less reliably transcribed (e.g., TT when training and testing on ENST), which is due to a lack of training examples, here, the model performs worse on frequently playing instruments. In fact, most of the mistakes of the model concern the transcription of cymbals (HH and CY).

4. ERRORS IN THE ESTIMATIONS

To identify why the transcription of cymbals is prone to mistakes, we quantified the errors made by the model when training and testing on ADTOF-YT. Note that this part of the study is not interested in the generalization capabilities of the model, but in assessing how well it can learn the target data distribution when training on it. We analyze the errors of the model with two tools: First, we approximated the number of errors due to quiet notes, also known as ghost notes, in the dataset with the octave F-measure. Second, we quantified the confusion between the instruments with a pseudo confusion matrix.

4.1 Octave F-measure

We attribute the low performance for cymbals, after conducting a preliminary inspection of the estimations, to both a specific characteristic of their timbre —long sustain that may mask the next onset and the presence of many quiet notes.² Both features make cymbals very challenging to transcribe and their transcription suffers from false negatives and false positives.

As a first step toward solving this problem, we created a new metric meant to quantify how often the presence of quiet notes leads to transcription mistakes. Unfortunately, because ADTOF-YT does not contain reliable velocity information in the annotations, we could not estimate the presence of quiet notes through velocity. Therefore, we started with an assumption from the expert knowledge according to which, in many music genres, cymbals are commonly played in alternation between loud (accentuated) and quiet notes.³ This insight is in agreement with our observation that errors in the estimations are often rhythms that are half or double the speed of the ground truth, so that the algorithm would transcribe a sequence of quarter notes where it should be an eighth note or vice versa. Assuming that this mismatch is due to quiet notes, we created the octave F-measure to allow rhythms that are exactly half or double the speed of the annotations (white bars in Fig. 1). A parallel can be drawn with tempo estimation that uses the “accuracy2” metric which is defined to accept estimations that have a double or triple relationship with ground truth, disregarding ipso facto the so-called octave tempo errors [21]. The octave F-measure gives us an upper bound of the performance of the models if these mistakes were not present in the estimation and the ground truth, and helps us quantify the issues yet to be solved in the algorithms.

When looking at the octave F-measure on ADTOF-YT, we confirm the presence of undetected annotations exactly at the middle point between two estimations, and the presence of extra estimations exactly at the middle point between two annotations. This phenomenon is more common in cymbals than in any other instrument of the drum kit and it is observed in most of the datasets. In other words, the models are mistaking the beat subdivision at which cymbals occur, a problem we attribute to their specific timbre and alternation between loud and quiet notes.

4.2 Confusion Between Classes

To identify typical errors made by the model on ADTOF-YT, we employed the pseudo confusion matrix represented in Fig. 2. Compared to a standard confusion matrix, ours differs in two aspects: First, since in AMT any time position may contain multiple labels—different instruments play simultaneously—the possible sets of labels, instead of each single class, are uniquely listed in the rows and

Figure 2: Pseudo confusion matrix on ADTOF-YT. The numbers represent a percentage of the ground truth.

columns of the matrix.⁴ As uniquely identifying sets of labels leads to a large matrix (2⁵ columns and rows with five classes), we truncated the figure for readability to show only the most frequent columns and rows. Second, to remove the imbalance between classes, we normalized the rows (i.e., the rows sum up to 100%). Thus, rather than displaying the count of each set of labels, we represented their proportion relative to the number of occurrences of the ground truth.

We categorize the errors (i.e., the cells outside of the diagonal) in three types following Vogl’s approach [2]: i) confusion, when the onset is detected but the label is wrong (false positives with false negatives); ii) masking, when an onset is missing, presumably because of another one, correctly detected, hides it (false negatives with true positives); iii) excitement where an extra onset is detected, presumably because another one, correctly detected, generates excitement (false positives with true positives). Additionally, another cause of mistakes, which we do not consider in this study, might be related to the low number of occurrences of some combinations of labels (e.g., BD and SD played at the same time), which makes them more difficult to estimate for the model. In Fig. 2, we identified three trends.

First, the left-most column shows that CY, HH, and SD are missing ≈ 30% of the time when they play alone; at the same time, the bottom row highlights that they are incorrectly estimated 10 – 20% of the time when there should be no instrument playing. Surprisingly, this common issue cannot be categorized as due to confusion, masking, or

² SD also contains many quiet notes, but not to the same extent as HH and CY in this dataset.

³ An illustration of this phenomenon can be viewed in the ENST dataset: Notice how every second HH onsets sounds quieter in the example video "Drummer 3, Angle 1" <https://perso.telecom-paristech.fr/grichard/ENST-drums/>

⁴ In practice, since onsets that slightly deviate from the correct position are considered simultaneous, the confusion matrix was created by using an agglomerative clustering that group onsets with a tolerance of 50 ms. As a side effect, we do not count the true negatives (i.e., positions without onsets: ∅ in the ground truth and estimation).

excitement. Instead, we attribute these two phenomena to the presence of quiet notes for those three instruments, as already commented in Section 4.1.

Second, when looking at the intersection of the rows containing HH with the equivalent columns containing CY, such as the cell in the row “BD, HH” and column “BD, CY”, we notice that HH is often confused with CY. Similarly for the intersection of the rows containing CY with the equivalent columns containing HH, we observe that CY is often confused with HH. Again, this highlights that similar-sounding instruments are misinterpreted, as already identified by Vogl [2]. However, looking specifically at the rows “CY” and “HH”, we notice that CY and HH are less often confused with each other when they occur in isolation. Thus, we conclude that confusion is exacerbated by the presence of other instruments, likely because of their masking effects.

Lastly, the second column highlights that TT and SD are both missed $\approx 30\%$ of the time when they appear with BD. Presumably because BD’s wide spectral range masks the other instruments’ spectra, this illustrates that masking seems to be very prevalent on ADTOF-YT. Excitation, on the other hand, is not a common issue compared to masking or confusion. We only notice the presence of an extra CY onset 9% of the times that “BD, SD” occurs.

In addition to the Octave F-measure that illustrates how the model misjudges the beat subdivision at which cymbals are played, the confusion matrix shows that the model does not differentiate well the cymbals. However, one might wonder why these issues are prevalent on ADTOF-YT and not the other datasets.

5. ANNOTATIONS ACCURACY

To understand why the model is prone to make mistakes specifically with ADTOF-YT, we took a closer look at the accuracy of its annotations. Both the datasets ADTOF-RGW and ADTOF-YT are crowdsourced; since human annotations are not perfect and annotators do not always agree with each other, we expect mistakes in the datasets. While a cleansing/cleaning procedure was employed to improve the time position of the annotations and to remove label ambiguity [1, p.784], it is not realistic to expect that all mistakes will be corrected. Although DL is generally robust to label noise [22], incorrect labeling might affect the models during training and testing, especially with crowdsourced datasets that likely contain more mistakes than non-crowdsourced ones. Specifically during testing, any error in the annotations is indistinguishable from wrong estimations of the models and impacts their evaluation. Therefore, by assessing the accuracy of the annotations, it is possible to estimate an upper bound of the performance of the models tested on the dataset. As this bound corresponds to the score achieved by a perfect classifier, it can show how far the current models are from this ideal.

To estimate the annotations’ accuracy on a dataset and create a ground truth of high confidence, it is common to compare labels provided by independent annotators on the same data and measure the confidence of the annotations,

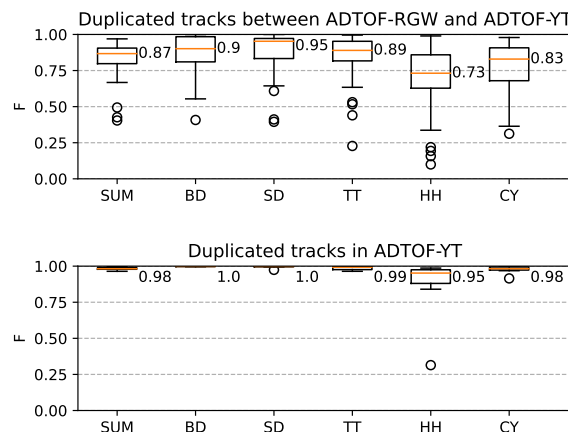

Figure 3: Box plots representing the distribution of the F-measure on tracks present both in ADTOF-RGW and ADTOF-YT (top) and on duplicated tracks in ADTOF-YT (bottom).

for example by grouping multiple independent annotations into a single set (e.g., [23, p.7], [24], [25, p.255]). Further, by comparing this ground truth with a new (group of) annotator(s), one can estimate either the ground truth accuracy or the human-level accuracy depending on how much one trusts the reference group (e.g., [23, p.7 and 31], [26]). In our context, similarly to what Flexer and Grill [27] did in their work, we aim to estimate an upper limit of the score achievable on the datasets by assessing the agreement among human annotators.

To do so, we rely on the tracks that appear multiple times and are annotated by different persons in the datasets. After aligning two instances of the same track according to their annotations, we were able to compute the agreement between the annotators the same way we evaluate any algorithmic estimation: By taking either set of annotations as the reference and the other one as the estimation, we can then compute the F-measure. Note that the results do not depend on which annotator is used as the reference: By switching the annotator used as the reference, precision and recall are also switched, without impacting the F-measure. The distribution of the F-measure for all the tracks found both in ADTOF-RGW and ADTOF-YT (34 couples, 4h28min) and duplicated in ADTOF-YT (7 couples, 34min) is shown in Fig. 3. There are no duplicated tracks within ADTOF-RGW.

On the one hand, the annotations in duplicated tracks of ADTOF-YT are almost identical, whereas they differ between ADTOF-RGW and ADTOF-YT. This is an indication that the annotators of ADTOF-YT agree more often with themselves than with the annotators of ADTOF-RGW. In turn, this is a sign that the annotations of ADTOF-YT are very accurate. If that is the case, then the models we evaluated on ADTOF-YT are far from perfect, as they do not achieve results close to the inter-rater agreement. However, we acknowledge that this trend is only supported by seven couples of tracks and further investigation is required to claim that this dataset contains so few errors.

On the other hand, the median agreement between annotators of ADTOF-RGW and ADTOF-YT is very similar to the best model’s sum F measure on ADOTF-YT (0.87 for the annotators Fig. 3 compared to 0.85 for the model Fig. 1). This suggests that the model performs as well as the annotators of ADTOF-RGW on ADTOF-YT. Moreover, this trend holds for the majority of the classes. Most notably, both the annotators and the model manifest difficulties with the discrimination between HH and CY (lowest agreement and performance). Similarly to the models in the previous sections, we attribute these human errors both to the fact that one instrument is mistaken for the other because of their similar timbre, and to the use of different rhythms because of the presence of quiet notes. See Fig. 4 (top) showing the disagreement between two annotators as an illustration of both phenomena. Although it is not clear if these discrepancies are part of ADTOF-RGW, ADTOF-YT, or both, they impact negatively the measure of the model performance. However, we noticed that the agreement between annotators is much lower than the performance of the model on BD (0.90 for the annotators compared to 0.97 for the model). This is due to the presence of simplified annotations in ADTOF-RGW. As represented in Fig. 4 (bottom), these simplifications are meant to ease the gameplay when a double bass drum technique is required (i.e., bass drum notes played with both feet) by omitting the notes played by the left foot. Despite such simplifications, the model still manages to achieve a high F-measure when testing on ADTOF-YT, which does not contain simplified annotations.

Although data is not enough to determine accurately an upper limit to the performance of the models, we believe that the agreement we measured among annotators is a reasonably good guess. Because it is not possible to know which of the annotators made a mistake (possibly both), the discrepancies between them do not always impact the measure of the model’s performance, making this estimation pessimistic.⁵ However, considering that the best performance we achieve on ADTOF-YT is close to the agreement among humans, it is intuitive that any improvement of the model beyond this point will not be easily measurable. In other words, this model is not far from a perfect classifier on this dataset.

6. CONCLUSIONS

In this work, we analyzed the performance of a state-of-the-art model for automatic drum transcription [1]. First, through the F-measure for the individual classes, we identified that ADTOF-YT is the only dataset able to train a model to such a high level of accuracy on its data distribution. In this context, when training and testing on ADTOF-YT, the transcription is: almost perfect for the bass drum (BD), better than previous methods for the sparse class of tom-toms (TT), but less reliable for cymbals. Second, to understand why cymbals are more difficult to transcribe,

⁵ In the hypothetical scenario where each disagreement is caused by only one of the annotator making a mistake, the discrepancies will affect the evaluation only 50% of the cases.

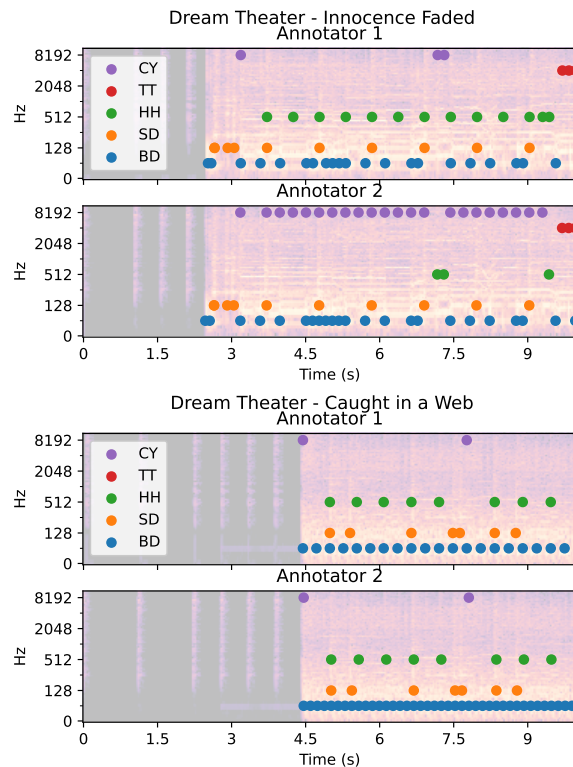

Figure 4: Spectrograms and annotations from ADTOF-RGW and ADTOF-YT for the first 10s of two tracks. Notice the confusion and the use of different subdivisions between CY and HH (top), as well as the simplification of the BD for fast rhythms (bottom).

we used a new metric we named Octave F-measure as well as a pseudo confusion matrix. We then concluded that what hinders the cymbals’ transcription is their typical accentuated-note/quiet-note pattern and their similar timbre to each other. Last, because the test data has been annotated by many people with different levels of expertise, we aimed to quantify the errors due to discrepancies in the ground truth rather than to mistakes made by the model. By estimating the accuracy of the annotations through the agreement between multiple annotators of the same tracks, we identified that the human-level accuracy is on par with the performance of the model. Thus, it is not clear whether the differences between the estimations and annotations originate from the model or the annotators, even though their causes are the same.

With this study, we quantified the main difficulties faced by the model or the annotators. The errors caused by the cymbals could be the focus of future research in ADT, which we believe could be tackled in one of two ways: Either existing annotations could be verified, possibly via a semi-automatic method relying on the estimation of a pre-trained model to detect likely errors, or complementary training data could be generated, possibly in a synthetic way, to ensure a perfect ground truth.

ABSTRACT

Automatic piano transcription models are typically evaluated using simple frame- or note-wise information retrieval (IR) metrics. Such benchmark metrics do not provide insights into the transcription quality of specific musical aspects such as articulation, dynamics, or rhythmic precision of the output, which are essential in the context of expressive performance analysis. Furthermore, in recent years, MAESTRO has become the de-facto training and evaluation dataset for such models. However, inference performance has been observed to deteriorate substantially when applied on out-of-distribution data, thereby questioning the suitability and reliability of transcribed outputs from such models for specific MIR tasks. In this work, we investigate the performance of three state-of-the-art piano transcription models in two experiments. In the first one, we propose a variety of musically informed evaluation metrics which, in contrast to the IR metrics, offer more detailed insight into the musical quality of the transcriptions. In the second experiment, we compare inference performance on real-world and perturbed audio recordings, and highlight musical dimensions which our metrics can help explain. Our experimental results highlight the weaknesses of existing piano transcription metrics and contribute to a more musically sound error analysis of transcription outputs.

1. INTRODUCTION

Automatic Music Transcription (AMT) refers to the task of converting audio signals into symbolic music representations. The target output format can be a full symbolic score including quantized rhythm, time signature and pitch spelling information, or a mid-level physical MIDI(-like) representation, describing notes in terms of their onset and offset times, pitch and velocity [1–3].

AMT methods are typically evaluated using information retrieval (IR) metrics like precision, recall and F1 score [4]. These IR metrics can be computed at the level of frames, by comparing binary piano roll-like matrices, or at

the level of note lists, by comparing notes in terms of their onset, offset, pitch and/or velocity attributes. Each error (i.e. misplaced frame or note activity) has equal weight, resulting in limited explanatory power of these metrics with respect to the underlying musical material [1, 5].

As in many other areas in MIR, the current state of the art is defined by deep neural networks [2, 3, 6, 7]. To a large extent, this progress has been enabled by the release of the MAESTRO dataset [8], which made well-aligned audio-MIDI piano performance data available on a large scale. The most up-to-date version of the MAESTRO dataset¹ contains close to 200 hours of performance data from close to 1300 recordings of Western classical piano repertoire. State-of-the-art piano transcription systems achieve beyond 90% frame-level, or 80% note-level F1 scores on its test split [2, 3, 8, 9], and have led to the release of large-scale transcribed solo piano performance datasets [10, 11].

Although these results are impressive, we believe that two important aspects have been largely overlooked: first, the validity and (lack of) explanatory power of the standard evaluation metrics with respect to musically relevant information, and second, the reliability of these transcription models on out-of-distribution data. In this work, we address the first problem by proposing a set of musically informed evaluation metrics that support a more nuanced understanding of piano transcription errors. The metrics are intended to be used in the context of computational performance studies, and therefore focus on musical dimensions that are commonly studied in the context of expressive piano performance analysis and generation. We demonstrate our metrics on a subset of the MAESTRO dataset, which we transcribe using three state-of-the-art transcription models. In particular, we contrast the performance of these models, as evaluated with the standard IR metrics, with their performance on musical dimensions such as timing, articulation and dynamics which we can evaluate using our set of musically informed metrics.

Then, to elucidate the second problem, we re-record a subset of the MAESTRO dataset on a Yamaha Disklavier grand piano and further manipulate the audio recordings by adding different levels of noise and reverberation. An analysis of the outputs of these trained transcription models on these recordings provides some detailed insights into the lack of generalization on out-of-distribution data.

We make our set of metrics, data and all experimental results available at <https://github.com/CPJKU/mp-teval>.

2. RELATED WORK

This section briefly reviews the standard IR evaluation metrics along with criticism related to these, followed by a description of the benchmark datasets typically used for evaluating transcription methods.

Precision, recall and F1 score are the standard evaluation metrics used in AMT [1–4]. They can be computed either at the level of frames or at the level of notes. For frame-level evaluation, two binary piano roll matrices $M, \hat{M} \in \{0, 1\}^{P \times T}$ are compared, where $p = 1, \dots, P$ defines the pitch range and $t = 1, \dots, T$ the time step (typically with a resolution of 10ms [4]). Both M and \hat{M} are sparse matrices where 1 at a given index p, t indicates that a note with pitch p is active at time frame t .

Note-level metrics are computed by comparing lists of notes, in which each note is described by a tuple describing the onset, offset, pitch, and (where predicted) velocity. Note-based metrics can be based on onset information only, onset and offset information (i.e., note durations), or on predicted onset, offset and velocity. In onset-only note evaluation, a note is considered correct if its onset falls within a ± 50 ms threshold of its respective target onset. For onset-and-offset note-level evaluation, the note offset must fall within the greater of either an offset tolerance threshold of ± 50 ms, or a duration threshold 20% of the ground truth duration [4]. If velocity is included in the evaluation, an estimated note is considered correct if its velocity (after some normalization and rescaling operations) falls within a 0.1 tolerance threshold of the velocity of the corresponding reference note [1].

The need for better (i.e., musically or perceptually sound) transcription metrics has been expressed by various researchers before. Hawthorne et al. [1] point out that frame- and onset-only note-level evaluation does not sufficiently capture musically relevant information. Similarly, Ycart et al. [5] and Daniel et al. [12] focus on the problem of perceptual saliency of different kinds of transcription errors and each propose a new, perceptually (more) valid transcription metric. Finally, McLeod and Steedman [13] focus on the problem of audio-to-score transcription and propose a new metric that jointly evaluates voice separation, metrical alignment, note value detection and harmonic analysis along with multi-pitch detection.

With respect to training and evaluation data for solo piano transcription, until the introduction of MAESTRO [8], MAPS [14] was used as the standard dataset. Apart from size, the biggest difference between the two is the diversity of the captured recording environments: while MAESTRO exclusively contains Disklavier recordings from the Yamaha International Piano e-Competition², MAPS contains Disklavier recordings and synthesized audio simulating various recording environments. The prevailing trend

in evaluating current piano transcription models centers around the MAESTRO dataset [2, 3, 6], and most models that do include MAPS in their evaluation [1, 3] use the split proposed in [15], which only includes Disklavier recordings in the test split. Both frame- and note-level metrics are usually computed for each piece in a given test set, and their mean is subsequently reported as the inference performance for a given model and dataset/split. Frame-level metrics are typically higher than note-level ones due to common known transcription errors such as merged or segmented notes.

3. MUSICALLY INFORMED METRICS

In this section we describe our proposed metrics that are meant to capture different musical dimensions commonly studied in the context of expressive performance. Each metric compares a ground truth to a predicted MIDI performance by measuring the Pearson correlation between a performance parameter computed from the ground truth and from the predicted MIDI, respectively. We choose a correlational measure to ensure all metrics fall into the same range. The goal is to quantify dimensions of musical quality of transcriptions that are otherwise obscured by standard IR metrics. In particular, we wish to capture dimensions that are important for computational performance studies that make use of automatically transcribed piano performances.

3.1 Timing

Timing can be described as expressive deviations from the metrical grid. A common measure of expressive timing in computational performance analysis is the inter-onset-interval (IOI), that is, the amount of time passed between two consecutive notes belonging to the same stream.³

To evaluate how well a transcription preserves the micro onset deviations, we predict a monophonic melody line and the accompaniment part (i.e., all notes not belonging to the melody line) in a given MIDI using the skyline algorithm for melody identification [17].⁴

Then we compute the IOIs of these streams both on the ground truth and predicted performance, and measure their correlation. Note that for non-strictly monophonic streams (like the accompaniment part), the IOI between notes that belong to the same onset (i.e., chords) is zero. The result of this process gives us two measures, which we call *Melody IOI* and *Accompaniment IOI*.

3.2 Articulation

Articulation in expressive piano performance refers to how (adjacent) notes are played in terms of their duration, intensity, and clarity, resulting in expressive strategies such

³ We use the term *stream* as a generalization of the concept of a voice in polyphonic music [16].

⁴ The skyline algorithm has been shown to be very competitive in identifying melody lines in Western classical piano music, even when compared to more recent machine learning-based algorithms. (e.g., see Figure 5 in [18]).

² <http://piano-e-competition.com/>

as *legato*, *staccato* or *marcato*. Computationally, articulation is measured as the ratio between the time interval from the offset of the current note to the onset of the next note, and the time between the onsets of the two notes. [19–21].

We use the skyline algorithm [17] to extract monophonic melody and bass lines within a performance, and compute a sequence of KOR values, for each pair of successive note events, for both the target and the predicted performance MIDI for both streams, and their ratio. We define three metrics for capturing articulation:

1. *Melody KOR*: the correlation between the KOR sequences of the melody lines of the ground truth and the predicted performance MIDI.
2. *Bass KOR*: the correlation between the KOR sequences of the bass lines of the ground truth and the predicted performance MIDI.
3. *Ratio KOR*: for this metric, we consider the ratio of KOR sequences of the melody to the bass line. A ratio KOR greater than 1 indicates that the melody voice is played more legato than the bass voice. The Ratio KOR metric is computed as correlation of this ratio between the ground truth and the predicted performance MIDI.

3.3 Harmony

Aspects such as harmonic tension have been shown to be determining factors for various performance decisions (particularly relating to expressive tempo and dynamics [22, 23]). To quantify how well harmonic tension is preserved in a transcription, we use two features proposed by Herremans and Chew [24] based on Chew’s spiral array model [25]. This model is a three dimensional representation of pitch classes, chords and keys constructed in such a way that spatial proximity represents close tonal relationships.⁵ We use two metrics to capture the preservation of harmonic tension:

1. *Cloud Diameter*: this metric measures the maximal tonal distance as the maximum dispersion between notes in a musical segment
2. *Cloud Momentum*: this metric captures the harmonic movement in a segment as the tonal distance between consecutive sections.

For both metrics, we compute the respective feature on overlapping windows for both the ground truth and transcribed MIDI, and measure their correlation.

3.4 Dynamics

For comparing the performance of transcription models regarding expressive dynamics, we use the loudness ratio of the melody and bass lines as a proxy to identify how well a transcription preserves the dynamics of the performance.

⁵ We chose this model for its simplicity and music-theoretical grounding. Note that these features were designed for Western tonal music and may be less effective in capturing tension in other types of music.

composer	pieces	performances	duration (min)
Bach	1	7	23.36
Beethoven	5	28	285.54
Chopin	4	15	150.28
Debussy	2	3	32.06
Glinka	1	2	10.35
Haydn	3	9	90.23
Liszt	3	12	58.98
Mozart	2	4	29.02
Rachmaninoff	2	3	11.87
Schubert	3	17	107.27
Scriabin	1	5	55.05
Total	27	105	854.01

Table 1: Overview of chosen composers, pieces, and performances in the MAESTRO subset in our evaluation set.

We estimate the loudness as the “energy” of a stream (i.e., melody or bass line), which is computed using the MIDI velocity following a model proposed by Dannenberg [26]. The loudness ratio is then computed as follows (cf. Equation 8 in [26]):

$$R(t) = \log \left(\frac{m \cdot \text{vel}_{mel}(t) + b}{m \cdot \text{vel}_{bass}(t) + b} \right) \quad (1)$$

where $\text{vel}_{mel}(t)$ and $\text{vel}_{bass}(t)$ are the MIDI velocities of the melody and bass lines at time t , respectively, and m and b are constant parameters that depend on the dynamic range of the audio signal. We compute the loudness ratio for both the ground truth and estimated performance MIDI, and compute the correlation between these ratios as our metric for dynamics.⁶

4. DATA

For our experiments, we create an evaluation set with three subsets:

1. *MAESTRO*: We select audio recordings from the MAESTRO dataset, covering a diverse range of musical repertoire, composers, and performers, using all (train, validation, and test) splits as provided by the authors [3]. This choice tests whether the split category affects model generalization.⁷ An overview of the selected subset is shown in Table 1.
2. *Disklavier*: We re-record our MAESTRO subset on a Yamaha Disklavier Enspire ST C1X using the Focusrite Scarlett 18i8 and a pair of AKG P420 microphones in a moderately bright, fully carpeted room with asymmetric geometry and low background noise level.
3. *revnoise*: To simulate more challenging real-world environments, we further add perturbations using

⁶ Dannenberg’s model was chosen for its simplicity, relying only on MIDI velocity and dynamic range (note that parameters m and b cancel each other out when computing the correlation of the loudness ratio).

⁷ The official MAESTRO splits [8] ensure a unique piece-to-split mapping.

different levels of reverberation and noise (see Section 6) on selected recordings from both the *MAESTRO* and *Disklavier* subsets.

We compare three state-of-the-art piano transcription models: Onsets and Frames [8] and the Transformer transcription model [3] by Google/Magenta (which we will refer to as OaF and T5 respectively, in the following), and the high-resolution onset and offset regression model by Bytedance [2] (referred to as Kong).

We transcribe all the recordings in our MAESTRO, *Disklavier*, and *revnoise* subsets using the (officially provided) trained models, and these transcriptions then form our evaluation set. Note that all audio recordings from the *Disklavier* and *revnoise* subsets are only used for testing; we use the MAESTRO-trained models as they are provided by the respective authors via their repositories.

5. DEMONSTRATION OF MUSICALLY INFORMED METRICS

We now discuss the experimental results obtained with the three systems and explain the relation between our metrics and the standard IR metrics as computed on transcriptions of the MAESTRO subset of our evaluation set. We focus in particular on the musical dimensions that can be better understood through our metrics. For the standard evaluation, we include the frame-level score, and all note-level F1 scores other than the onset-only one as it does not capture offset and velocity information. We compute the note-level metrics with the official `mir_eval` python implementation [27].

We start our discussion with Table 2, which summarizes the evaluation results per model and metric. For comparative reasons, we also include a perceptually informed piano transcription metric, PEAMT [5].

Generally, it can be observed that the Kong model performs the best across most metrics. This implies that most of our metrics, overall, correlate with the performance ranking as measured on the standard metrics. Furthermore,

Metric	OaF	Kong	T5
Frame F1	0.8710	0.9138	0.7048
Note Offset F1	0.6167	0.8736	0.6358
Note Offset Velocity F1	0.5917	0.8587	0.6309
Melody IOI	0.2377	0.5481	0.2217
Accompaniment IOI	0.2168	0.3679	0.4329
Melody KOR	0.4057	0.7415	0.2825
Bass KOR	0.2638	0.6967	0.2672
Ratio KOR	0.4247	0.6938	0.3094
Cloud Diameter	0.7240	0.8301	0.7472
Cloud Momentum	0.2461	0.2250	0.1671
Dynamics	0.5501	0.6503	0.6355
PEAMT [5]	0.6570	0.6241	0.5789

Table 2: Model performance measured by standard metrics, our musically informed metrics, and PEAMT [5] on the MAESTRO subset of our evaluation set

it can be seen that the two Magenta models perform considerably different when measured against frame-level F1 score, yet this difference becomes less pronounced when evaluated on note-level metrics, which would suggest superior performance of the T5 model. Comparing these results to the model performance as evaluated on our set of metrics, however, reveals that while both models perform similarly on onset time prediction, the T5 model is worse at adequately capturing note durations, particularly in lower voices/frequency ranges, but superior in estimating MIDI velocity and the overall loudness ratio between voices than the OaF model. Lastly, we can observe that the perceptually informed PEAMT metric correlates most with the frame-level and harmony metric *Cloud Momentum*, which might suggest (if PEAMT is indeed a veridical listening model) that listeners place relatively high importance on harmonic context.

We continue our discussion in Figure 1, which compares the note-offset F1 score per composer (averaged over pieces and performers) and model to our musically in-

Figure 1: Model performance comparison as evaluated on note-offset F1 score and our proposed musical metrics, by composer.

Figure 2: Relationship between model performance evaluated on note-offset-velocity F1 score and our proposed dynamics measure.

formed timing, articulation and harmony metrics. We can see again that the Kong model performs best across all composers and metrics except for the *Accompaniment IOI* timing and the *Cloud Momentum* harmony metrics. The fact that it performs better on the *Bass KOR* articulation metric, but poorly on those timing accompaniment and harmony metrics might suggest that this model detects many out-of-key extra notes that both erroneously influence the IOI sequence on the accompaniment part, and the estimation of the tonal context. Interestingly, we can also observe, as a general trend, that the F1 score somewhat deteriorates with increasing virtuoso and challenging musical repertoire. This general deterioration with increasing musical difficulty is not reflected correspondingly by our metrics, which show more variation with respect to different composers and aspects of the underlying music: While the F1 score for Bach, Mozart, Haydn and Schubert all suggest a near-perfect transcription, our metrics indicate more diverse results, and e.g., suggest poor(er) accuracy (and therefore reliability in a performance study context) in the *Melody IOI* and *Melody KOR* metrics. Another illustrative example can be found in the case of Chopin: here again the F1 score (particularly of the Kong model) would suggest a highly accurate transcription output, while our metrics reveal that the expressive dimension of articulation is not well captured. Lastly, we can observe again that

the PEAMT and harmony metric *Cloud Momentum* show a similar trend for most composers, suggesting a greater weight of the harmonic context in that trained metric.

We conclude our discussion by examining the dynamics aspect. Figure 2 illustrates the relationship between the note-offset-velocity F1 score and our proposed *Dynamics* metric. While both metrics show a weak correlation (Pearson $r = 0.21$), the figure also indicates that our metric evaluates dynamics in a more differentiated way and leads to a wider range of evaluation results than the standard metric. Note that our metric only evaluates the dynamics aspect, in particular how well the overall balance in loudness between different voice streams is preserved in a transcription. It does not account for onset, offset and pitch information, which also explains the results in the very left part of the figure that score low on F1 score but high on our metric.

6. OUT-OF-DISTRIBUTION INFERENCE

In this section we illustrate the problem of out-of-distribution performance of the models analysed. We believe that this is an important aspect to emphasize, as transcription models are ultimately intended to be (and have been) used on real-world audio performances [10, 11].

We approach the problem in two stages: First, we elucidate the problem by performing a short evaluation of the three analysed models on real-world recordings using only the standard IR metrics. Second, we simulate more challenging real-world environments using different levels of noise and reverberation, and evaluate the analysed models again using the standard and our proposed metrics, where we highlight how our musically informed metrics can reveal aspects that the standard metrics would otherwise have missed.

6.1 Generalization on real-world recordings

Table 3 shows the mean frame- and note-level F1 scores per model and per piano/acoustic recording environment on the three splits of the MAESTRO dataset (as they are officially defined).⁸

⁸ We note that for the two Magenta models, OaF and T5, our evaluation results do not come close to the reported ones in [8] and [3]. The

split	model/audio	frame			note _{off}			note _{off-vel}		
		OaF	Kong	T5	OaF	Kong	T5	OaF	Kong	T5
train	MAESTRO	0.8807	0.9207	0.7262	0.6183	0.8899	0.6350	0.5929	0.8756	0.6308
	Disklavier	0.8185	0.8508	0.6157	0.5269	0.7384	0.5132	0.4853	0.6660	0.4663
validation	MAESTRO	0.8404	0.8936	0.6546	0.6492	0.8617	0.7117	0.6236	0.8471	0.7063
	Disklavier	0.7696	0.8678	0.6093	0.5539	0.8142	0.6570	0.5161	0.7480	0.6031
test	MAESTRO	0.8527	0.9002	0.6552	0.5931	0.8215	0.5968	0.5695	0.8041	0.5896
	Disklavier	0.8049	0.8530	0.6048	0.4989	0.6979	0.5135	0.4607	0.6304	0.4624

Table 3: Frame-, note-offset, and note-offset-velocity F1 score results computed on our evaluation set, grouped per data set split, evaluated model and piano / audio environment.

We group the results per split to test whether the analysed models would perform worse on out-of-distribution recordings of performances (pieces) from the test set compared to those from the train/validation sets. Next we conduct a Kruskal Wallis ANOVA [28] to test for differences between frame-, note-offset and note-offset-velocity F1 scores, grouping the evaluation scores each by *split* and by *audio environment* and comparing each model separately. For each ANOVA we use a significance threshold of $\alpha = 0.05$. The ANOVA on the *audio environment* dimension show a statistically significant difference ($p < 0.05$) between the MAESTRO and Disklavier audio recordings for all three analysed models.

The ANOVA on the *split* dimension yields more differentiated results: For all models, the frame-level F1 scores are significantly different, and there are no statistically significant differences in the note-offset-velocity F1 scores. For the model by Kong, the note-offset-score is significantly different depending on the split, whereas the two Magenta models show no significant differences. This suggests that the most musically meaningful metric from the current set of standard metrics [1] does not sufficiently capture overfitting tendencies.

6.2 Evaluation on perturbed audio recordings

Similar as in Section 5, we again compare our musically informed metrics to the standard IR and the PEAMT metrics, however, this time on a set of more challenging audio recordings. To this end, we choose six (MAESTRO and *Disklavier*) audio recordings which we artificially perturb by introducing reverberation and synthetic noise. We use three Impulse-Response filters, modelling short, medium and long reverberation times ($RT_{60}@1\text{kHz} \in \{0.19, 1.85, 10.5\}$ seconds) and sourced from the OpenAIR⁹ database. We further add white noise into the recordings at three different Signal-to-Noise Ratio levels ($SNR_{dB} \in \{24, 12, 6\}$). Following a factorial design with these two independent variables, each with four levels, we first perturb the audio recordings on all conditions, and transcribe these recordings using all three analysed models. Following this procedure, we obtain 284 transcribed MIDI performances.¹⁰

Each grid cell in Figure 3 compares the mean note-offset F1 scores per model to the *Melody IOI* timing metric and *Cloud Momentum* harmony metric, where grid rows represent increasing reverb levels, and grid columns represent increasing noise levels. Generally, it can be observed that the performance range of models as measured by the F1 score is notably reduced compared to our metrics, indicating that our metrics possess higher discriminative capacity than the standard ones.

As expected, the inference performance of all three

differences are particularly pronounced in the note-level F1 scores.

⁹ <https://www.openair.hosted.york.ac.uk>

¹⁰ Note that 6 pieces x 4 noise levels x 4 reverberation levels x 3 models yield 288 transcriptions, but 4 recordings (each at the two higher most of either reverberation and/or noise levels) resulted in empty transcriptions (zero predicted note events) by the T5 model, and are therefore excluded from the evaluation.

Figure 3: Performance degradation measured by note-offset F1, *Melody IOI* and *Cloud Momentum* metrics.

analysed models deteriorates with increasing noise and reverberation levels, though the deterioration is less pronounced on the noise than on the reverberation axis. Furthermore, analysing the results on the timing metric *Melody IOI* suggests that the model by Kong predicts onset times worse with increasing noise levels, while the onset times prediction by OaF seems to be more resistant to this form of perturbation. Finally, the results measured on the harmony metric *Cloud Momentum* suggest that the overall harmonic context is relatively well preserved at higher perturbation levels by the OaF and Kong models, and less so by the T5 model.

7. CONCLUSION

In this study, we investigated two aspects that are commonly neglected in the evaluation of transcription models: (i) limited explanatory power of the standard IR evaluation metrics with respect to the underlying musical material, and (ii) poor inference on out-of-distribution data. We study both problems in the context of solo piano transcription, and, in addressing the first aspect, propose a set of musically informed metrics designed to capture more musically relevant information, particularly for the context of computational studies of expressive performance.

We demonstrated our metrics on transcriptions obtained by three state-of-the-art piano transcription models on a subset of the MAESTRO dataset, the de-facto standard train and test set for current transcription models, and highlighted musical dimensions for which they provide more informative value than the standard information retrieval metrics. We have further illustrated the lack of generalization with respect to the acoustic environment, both on real-world and perturbed audio recordings.

Future work in this direction may include an extension and further validation of our new musically informed metrics, in order to capture additional qualities of expressive performance, potentially by making use of score alignment information. Additionally, a listening study with human experts could help further investigate the perceptual validity of our proposed metrics.

USING ITEM RESPONSE THEORY TO AGGREGATE MUSIC ANNOTATION RESULTS OF MULTIPLE ANNOTATORS

Tomoyasu Nakano Masataka Goto

ABSTRACT

Human music annotation is one of the most important tasks in music information retrieval (MIR) research. Results of labeling, tagging, assessment, and evaluation can be used as training data for machine learning models that estimate them automatically. For such machine learning purposes, a single target (*e.g.*, song) is usually annotated by multiple human annotators, and the results are aggregated by majority voting or averaging. Majority voting, however, requires the number of annotators to be an odd number, which is not always possible. And averaging is sensitive to differences in the judgmental characteristics of each annotator and cannot be used for ordinal scales. This paper therefore proposes that the *item response theory (IRT)* be used to aggregate the music annotation results of multiple annotators. IRT-based models can jointly estimate annotators' characteristics and latent scores (*i.e.*, aggregations of annotation results) of the targets, and they are also applicable to ordinal scales. We evaluated the IRT-based models in two actual cases of music annotation — semantic tagging of music and Likert scale-based evaluation of singing skill — and compared those models with their simplified models that do not consider the characteristics of each annotator.

1. INTRODUCTION

Various annotations of music, such as song structure, beat timing, emotion, genre, singing phoneme, tempo, F0, singing skill, and preference, play essential roles in music information retrieval (MIR). The results of these annotations can be used not only for training machine learning models, such as deep learning models, but also for analyzing music characteristics. The results of annotations by different annotators, however, are not necessarily the same due to the ambiguity in music interpretation as well as to differences in annotators' characteristics that are individual biases stemming from factors like the experience, ability, and situation of each annotator.

Therefore, in music annotation, multiple annotators are usually assigned to the same target (*e.g.*, a song or part

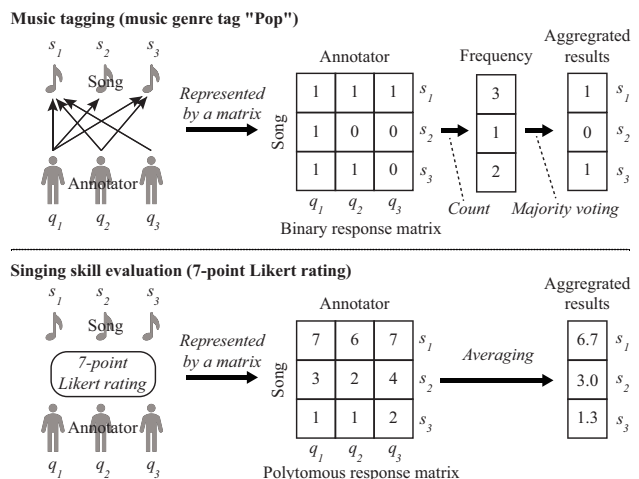

Figure 1. Examples of music annotation results of three annotators. Results of music tagging (binary rating) are aggregated by majority voting. Results of singing skill evaluation (7-point Likert rating) are aggregated by averaging.

of a song). Many studies have used multiple annotators in annotations such as singing semantic tag [1], singing ability/quality [2, 3], absolute valence-arousal annotation [4], relative valence-arousal annotation [5], song structure [6, 7], beat timing [8, 9], music semantic tag [10], and musical concept [11].

Figure 1 shows two annotation examples by multiple annotators. The first example, of music tagging, shows that annotation results of three annotators are aggregated using *majority voting*. Each annotator judges whether or not the semantic tag (music genre tag) “Pop” is applicable to each of the three target songs. The second example, of singing skill evaluation, shows that annotation results of three annotators are aggregated using *averaging*. Each annotator assigns a 7-point Likert rating to assess the singing skill in each of the three target songs. Multiple music annotation results are thus usually aggregated by two methods, majority voting [1, 5, 8, 10] and averaging [2–4].

The majority voting method requires an odd number of annotators, which is not possible in all situations. For example, if equal numbers of male and female annotators are required, the total number of annotators will be even. The binarization caused by majority voting lose information, and the averaging method cannot be used for ordinal scale values. Moreover, the two aggregation methods cannot take into account the differences in annotators' characteristics. One example of differences in annotators' char-

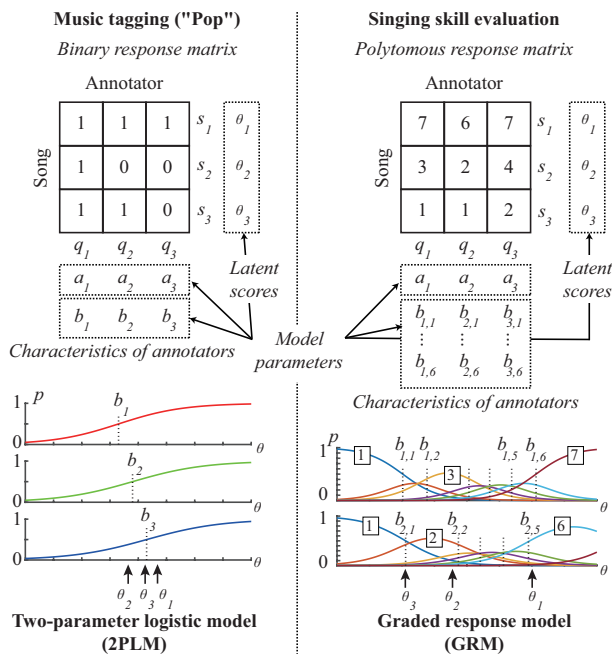

Figure 2. Examples of aggregation with two different IRT-based models, the 2PLM and the GRM. Latent scores θ can be used as aggregated results.

acteristics is that there are differences in the threshold for determining whether to tag a song in music tagging, and another is that the level of proficiency considered deserving of a perfect score in singing skill evaluation can vary depending on the annotator.

We therefore propose an aggregation method based on the *item response theory* (IRT) [12, 13] for music annotations. The IRT can take into account the differences in annotators' characteristics and aggregate annotations into latent continuous values. The first advantage of IRT is that it can be used with any number of annotators. There is no need for the number of annotators to be odd, as in majority voting, since it can estimate latent annotation scores (*i.e.*, aggregated results) for each piece of music as continuous values. The second advantage is that, when used for ordinal-scale ratings like Likert scales, it can estimate, for each annotator, different actual intervals between integer values of the rating scale.

Figure 2 shows examples of annotation aggregation by using IRT-based models. Although detailed definitions of the variables are given later in Section 3, θ_i is the latent score of a song s_i for that tag. b_j represents the annotator q_j 's characteristic, meaning the rating threshold. In the binary rating example on the left side of Figure 2, three item response functions of music tagging based on the parameters of annotators q_1 , q_2 , and q_3 are shown at the bottom of the figure. Since the song s_3 was tagged by the annotator q_2 but not by the annotator q_3 , the latent score θ_3 was higher than b_2 and lower than b_3 . On the other hand, in the singing skill evaluation example (*i.e.*, graded/polytomous rating) on the right side of Figure 2, seven functions for two annotators q_1 and q_2 are shown at the bottom of the figure as the probability that the annotators assigned each rating point based on a 7-point Likert-based rating. In this

example, a song s_2 with the latent score of θ_2 has a probability of being given scores of 3 and 2 by the annotator q_1 and q_2 , respectively. Seven such functions for each annotator represent each of these characteristics.

To show the usefulness of these IRT-based aggregation methods, we focus on two annotation tasks: music tagging as an example of binary rating and singing skill evaluation as an example of Likert scale rating. To aggregate the multiple annotation results, we use the two-parameter logistic model (2PLM) [13] and the graded response model (GRM) [14] as well-known IRT-based models. These are simple and basic models that assume unidimensionality of latent scores. These models, however, have more parameters (*e.g.*, rating thresholds and intervals) than majority voting and averaging, and cannot be properly estimated when the number of data is small [15]. This paper therefore proposes simplified versions of these models, which do not take into account the differences in annotators' characteristics, and then compares them and evaluates which model is more appropriate according to the information criterion.

2. RELATED WORK

This section describes previous research on music annotation by multiple annotators and the aggregation of their results. In addition, this section also describes applications of IRT to annotation cases.

2.1 Music Annotation Results Aggregation

There have been many cases of multiple annotators annotating the same songs in music annotation. Studies on annotators' agreement have been conducted for music genre classification [16, 17], music emotion recognition [5, 18, 19], music similarity [20], chord [21], and semantic tagging [1, 10]. The degree of inter-annotator agreement can be measured by Krippendorff's α , which is usually much smaller than 1.0 (perfect agreement) in music annotation [1, 5, 18, 19, 21], meaning that there are disagreements. Since it is only useful for evaluating agreement, not for aggregating multiple annotations, other methods such as majority voting are needed [1, 5, 10]. Even though the numbers of annotators (*i.e.*, frequencies) before majority voting were used to show the appropriateness of annotations [1, 22], they were not utilized as training data for machine learning despite their potential utility.

Music tagging or labeling is the task of binary annotation, whether tags and labels are assigned or not. Kim *et al.* [1] assigned three annotators for semantic tagging of singing voices and aggregated the results by majority voting. On the other hand, non-binary values have also been tagged. Turnbull *et al.* [10] asked annotators to vote on a 3-point scale of -1 (negative), 0 (unsure), and 1 (positive) whether the tag indicated the song. To aggregate the votes, the negative votes were subtracted from the positive votes, and the result was divided by the number of annotators.

As a polytomous annotation of ordinal scales by multiple annotators, Bogdanov *et al.* [5] performed relative annotation by three annotators and aggregated the results by

majority voting. Gupta *et al.* [2] and Sun *et al.* [3] aggregated singing quality scores on a 5-point Likert scale by averaging them. Yang *et al.* [4] assigned more than 10 annotators per song to label valence-arousal values on an 11-point scale and aggregated the results by averaging.

To overcome the limitations discussed in Section 1, we propose to use IRT for music annotation, which to the best of our knowledge has not been reported.

2.2 IRT Applications to Annotation

Although IRT has not been used in the MIR field, it has been used in the research field of natural language processing (NLP) [23]. Lalor *et al.* [24] proposed a method to generate a gold standard using IRT’s 3PLM to account for differences in item difficulty in the NLP test set. Martínez-Plumed *et al.* [25] also proposed a method to evaluate the estimation results of multiple machine learning models using 3PLM, taking into account the item difficulty of the test set. Otani *et al.* [26] proposed a framework for comparative evaluation of translation systems, utilizing an extension of the GRM. Amidei *et al.* [27] applied the IRT-based model to annotator responses and proposed a method to detect biased annotators through visualization. As a python package that can handle IRT models, `py-irt` by Lalor *et al.* [28] has been used in NLP research [29, 30].

In crowd sourcing-based annotation not limited to music, a strategy of aggregation while estimating the reliability of crowd workers has been adopted [31] and referred to as “learning from crowds” [32]. Khattak *et al.* [33] proposed and used an IRT-based model for label estimation in crowd labeling. They showed that the binarized labels based on the estimated latent scores yield better performance than conventional methods such as majority voting. Paun *et al.* [34] evaluated six Bayesian item-response models that can estimate the “true” response by aggregating multiple annotations. Several of them can estimate annotator characteristics and item difficulty. Irene Martín-Morató *et al.* [35] extended the multiple annotator competence estimation (MACE) model [36] and applied it to the sound event detection task, estimating annotator competence and excluding results from less competent annotators. Cartwright proposed a model using annotator features for crowdsourced audio quality evaluation [37].

Most closely related to this paper, Uto *et al.* [38] utilized an IRT-based model to generate training data for a deep learning model for automatic essay evaluation and to remove rater bias. This paper contributes differently from Uto *et al.* [38] not only by targeting music annotation but also by using an information criterion to compare two aggregation models and their nine simplified models.

3. IRT-BASED MUSIC ANNOTATION AGGREGATION

Item response theory (IRT) [12] is a mathematical modeling technique for testing and evaluation that was originally developed in the field of psychometrics. It models multiple *responses* (e.g., responses by multiple examinees) to

multiple *items* (e.g., questions in an exam). In our case, it models responses to multiple songs by multiple annotators. In the example in Figure 2, a probability model defines the relationship between the latent variable θ representing the latent song score and the parameters a , b representing the characteristics of the annotators. This allows, for example, music annotated with the same scores to have different latent scores θ depending on the annotators’ characteristics.

3.1 Model for binary response data

An item response model for binary response data introduces a latent score θ_i for a song i and represents the probability that the song is tagged by annotator j as follows:

$$p_{i,j}^{(2PLM)} = [1 + \exp(-a_j(\theta_i - b_j))]^{-1}, \quad (1)$$

where we used the 2PLM [13] in which the item response function is represented by a logistic function. In this equation, b_j is called *difficulty* because the tag is assigned when the score θ_i is higher than its value as shown in Figure 2. a_j is the slope of the logistic function and is called *discrimination* because it is easier to distinguish whether θ_i is higher than b_j (whether a tag is assigned) if a_j is higher.

3.2 Model for graded response (polytomous) data

The GRM [14] is a model that extends the 2PLM to response data with ordinal relationships such as those indicated by different values on a K -point Likert scale. Let $p_{i,j,k}$ be the probability that an annotator j responds to song i as category $k \in 1, \dots, K$ as follows:

$$p_{i,j,k} = p_{i,j,k-1}^{*(GRM)} - p_{i,j,k}^{*(GRM)}, \quad (2)$$

$$p_{i,j,k}^{*(GRM)} = [1 + \exp(-a_j(\theta_i - b_{j,k}))]^{-1}, \quad (3)$$

where k means the order of the categories. $p_{i,j,0}^* = 1$, and $p_{i,j,K}^* = 0$. The $b_{j,k}$ represents the difficulty in responding to categories greater than k in annotator j .

3.3 Nine originally simplified models

To evaluate usefulness of the above 2PLM and GRM in music annotation, we compare the simpler 1PLM [13] in which the parameter a_j is removed from the 2PLM (*i.e.*, the slope is not considered) as follows:

$$p_{i,j}^{(1PLM)} = [1 + \exp(-(\theta_i - b_j))]^{-1}. \quad (4)$$

Moreover, we here propose two further simpler models with reduced parameters, in which the parameters a_j and b_j are replaced by a and b (*i.e.*, the characteristics of the annotator are not considered), as follows:

$$p_{i,j}^{(2PLM')} = [1 + \exp(-a(\theta_i - b))]^{-1}, \quad (5)$$

$$p_{i,j}^{(1PLM')} = [1 + \exp(-(\theta_i - b))]^{-1}. \quad (6)$$

Regarding the GRM, we also propose the following three simplified models based on the same idea:

$$p_{i,j,k}^{*(GRM-a)} = [1 + \exp(-(\theta_i - b_{j,k}))]^{-1}, \quad (7)$$

$$p_{i,j,k}^{*(GRM')} = [1 + \exp(-a(\theta_i - b_k))]^{-1}, \quad (8)$$

$$p_{i,j,k}^{*(GRM-a')} = [1 + \exp(-(\theta_i - b_k))]^{-1}. \quad (9)$$

Although the GRM is designed for ordinal scales, we further propose four simplified models that assume that annotators’ responses are on interval scales (i.e., the intervals between the (cut) points are equally spaced) as follows.

$$p_{i,j,k}^{*(\text{GRMi})} = [1 + \exp(-a_j(\theta_i - (o_j + k'b_j)))]^{-1}, \quad (10)$$

$$p_{i,j,k}^{*(\text{GRMi-a})} = [1 + \exp(-(\theta_i - (o_j + k'b_j)))]^{-1}, \quad (11)$$

$$p_{i,j,k}^{*(\text{GRMi}') } = [1 + \exp(-a(\theta_i - (o + k'b)))]^{-1}, \quad (12)$$

$$p_{i,j,k}^{*(\text{GRMi-a}') } = [1 + \exp(-(\theta_i - (o + k'b)))]^{-1}, \quad (13)$$

where o_j and b_j denote the annotator-dependent origins and intervals, respectively, and o and b are annotator-independent origin and interval, respectively. We set $k' = k - 1$ in our current implementation.

4. EXPERIMENT

Using the IRT-based models described in the previous sections, we report the results of aggregating annotation results from multiple annotators in two real cases (Figure 1): music tagging (binary response) and singing skill evaluation based on 7-point Likert rating (polytomous response).

4.1 Aggregation of music tagging results

As an actual example of the aggregation of music annotation using the 2PLM, we targeted Japanese lyrics songs in our in-house database and music tags assigned to them.

4.1.1 Data (songs and annotations)

We prepared 120 songs with Japanese lyrics. However, as we only aim to demonstrate the effectiveness of the proposed models, any dataset of annotated songs will suffice. Annotators were six music experts whose native language was Japanese (three males, referred to as M1-M3, and three females, referred to as F1-F3). Each annotator tagged 60 songs, half of the 120 songs. To avoid gender distribution bias, the annotators were divided into two groups of three: “M1, F1, F3” (Group 1) and “M2, M3, F2” (Group 2), and the annotators in the same group tagged the same songs.

The annotators were instructed to annotate one or more of each of 15 genres, 38 subgenres, and 28 semantics. They tagged genres first, then subgenres and semantics. The 15 music genres are based on Discogs¹, which is a large open database of music genres and has been the target of research on metadata analysis [39] and music genre embedding [40, 41]. The 38 subgenres and 28 semantics (emotions, moods, and themes) were based on previous works [10, 42–46] using well-known datasets: MagnaTagATune (MTAT) [47], Million Song Dataset (MSD) [48], MTG-Jamendo [45], and CAL500exp [46]. In total, 81 tags were thus annotated.

4.1.2 Model

As described in Section 3.1, the 2PLM shown in Equation (hereafter Eqn) (1) and its simplified models (Eqns (4, 5, 6)) are used to model music tagging. For each tag t , we

¹ <https://www.discogs.com/ja/>

Table 1. Pairwise comparison of the four models. The columns represent the reference models, and the rows represent the models being compared. Bolded numbers indicate the number of tags with higher ELPD than those of the model being compared.

Model	Annotator independent		Annotator dependent	
	b Eqn (6)	a, b Eqn (5)	b_j Eqn (4)	a_j, b_j Eqn (1)
b	–	15 + 17	54 + 55	21 + 32
a, b	66 + 64	–	61 + 59	46 + 46
b_j	27 + 26	20 + 22	–	4 + 4
a_j, b_j	60 + 49	35 + 35	77 + 77	–

jointly estimate parameters, θ_i^t , a_j^t , and b_j^t using binary response data $U^t = \{u_{i,j}^t\} (i = 1 \cdots N_s^t, j = 1 \cdots N_a^t)$. Here θ_i^t represents the latent score of t for song i . a_j^t and b_j^t represent a characteristic of annotator j . N_s^t is the number of songs and N_a^t is the number of annotators.

In this paper we assume the following prior distributions for the parameters of the 2PLM.

$$\theta_i^t \sim \text{Normal}(0.0, 1.0), \quad i = 1 \cdots N_s^t, \quad (14)$$

$$a_j^t \sim \text{HalfNormal}(1.0), \quad j = 1 \cdots N_a^t, \quad (15)$$

$$b_j^t \sim \text{Normal}(0.0, 1.0), \quad j = 1 \cdots N_a^t. \quad (16)$$

Here a_j^t is not used when using the 1PLM, and a^t and b^t are used for the simplified models.

In this paper, since there is no overlap between the songs annotated by the two groups, we estimate θ_i by treating the results for “M1, F1, F3” and “M2, M3, F2” separately. Thus, the number of songs $N_s^t = 60$ and the number of annotators $N_a^t = 3$. The model parameters θ, a, b were estimated directly using the No-U-Turn Sampler (NUTS) [49], a type of Markov chain Monte Carlo (MCMC) method. We used a python package PyMC5 [50] to implement it. The number of burn-in samples was set to 5000, the number of draws to 10000, and the number of chains to 4. In other words, 40000 posterior samples were used and their posterior mean was used as the estimation result. Convergence was confirmed using the convergence diagnostic $\hat{R} < 1.01$ and effective sample size (ESS) > 400 as proposed by Vehtari *et al.* [51].

4.1.3 Results

To evaluate the proposed models, we used *expected log pointwise predictive density (ELPD)* values [52] as an information criterion. To estimate ELPD, we employed the leave-one-out (LOO) cross-validation estimate with Pareto smoothed importance sampling (PSIS) [52]. The higher the ELPD, the better the model. We conducted a pairwise comparison of the four models to evaluate the 81 tags annotated by the two groups. Table 1 shows, for each model in a column, the number of tagging evaluations that had a higher ELPD than the model in the corresponding row. For example, b denotes the model in Eqn (6). Here, the number of tags with higher ELPD is $66 + 64 = 130$ when compared to the a, b model in Eqn (5). The left side of the “+” sign indicates the number in Group 1, and the right side indicates the number in Group 2.

The results in Table 1 show that 1PLM (Eqn (4)) was

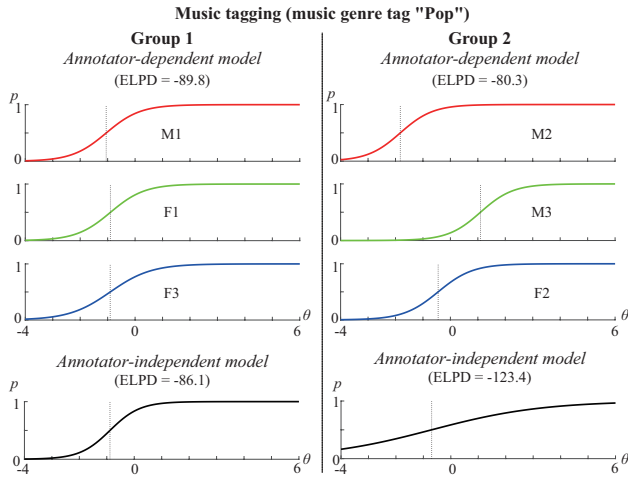

Figure 3. Examples of annotator characteristic curves for groups of three annotators each, annotating different 60 songs, for the music tag “Pop”. Parameter estimation results obtained by using annotator-dependent (Eqn (1)) and annotator-independent (Eqn (5)) models are shown.

most often the best IRT-based model for aggregating music tagging results. Table 1 also shows that in many cases the model that does not take into account the characteristics of annotators (Eqn (6)), was also better. Estimation results for the annotator-dependent and annotator-independent models are shown in Figure 3. When the annotators have different characteristics in annotating the tag “Pop” as shown in Group 2, the annotator-dependent 2PLM model has higher ELPD value to the simplified annotator-independent model as expected. Conversely, since the characteristics of Group 1 annotators are similar, the simplified annotator-independent model is superior in this case.

4.2 Aggregation of Likert scale evaluation results

As an actual example of the aggregation of music annotation using the GRM and its simplified models, we targeted the singing of Japanese lyrics in our in-house database and the results of singing skill evaluation annotated to them.

4.2.1 Data (songs and annotations)

We prepared another database comprising a total of 140 solo singing renditions with Japanese lyrics. This contains 20 songs of RWC-MDB [53], as well as 120 cover versions in which each of the 20 songs was sung by six additional singers. Ten songs were sung by male singers, while the remaining ten songs were sung by female singers. For 120 cover versions, there are a total of 40 singers, 20 male and 20 female, with a wide variety of singing experience (*i.e.*, each additional singer sung 3 songs).

These songs were annotated with detailed singing evaluations by 10 annotators who are experts for music and singing: 5 males (M4 to M8) and 5 females (F4 to F8). Singing evaluations were conducted on the singing voices mixed with the accompaniments (karaoke). Annotators conducted a 7-point evaluation from six evaluation perspectives: pitch, rhythm, pronunciation, expression, vocal projection, and overall performance. In order to control

Table 2. 7-point criteria for singing skill evaluation

Score	Criteria
7	Professional singer
6	Semi-professional (can receive a reward)
5	Amateur taking lessons to become a pro
4	Good at karaoke
3	Not so good at karaoke, but not so bad
2	Goes to karaoke, but is not very good at it
1	Poor singer and does not go to karaoke

Table 3. Results of the singing evaluation for a female singer song (evaluation perspective: overall performance). The singer ID “-” means the original singer.

ID	M4	M5	M6	M7	M8	F4	F5	F6	F7	F8
-	6	4	7	5	6	5	6	5	5	6
23	6	5	6	6	7	6	6	6	6	7
26	4	4	5	4	5	3	4	4	5	3
31	3	3	4	4	4	3	4	4	3	3
34	4	3	3	3	3	3	3	3	3	3
37	2	2	2	2	2	2	2	2	2	2
40	1	1	1	1	1	1	1	1	1	1

the evaluation criteria for each annotator, we specified the criteria shown in Table 2 and presented actual singing examples for each of the seven scores in advance.

4.2.2 Example of data

Table 3 shows the results of the 7-point evaluation of the singing skill for an example (RWC-MDB-P No.7) out of the 20 songs for “overall performance”. Although only the results of one evaluation perspective for one song are shown here, these evaluation results were actually obtained for each of the 140 songs, with the 6 different perspectives.

From Table 3 it can be seen that the evaluation scores differed among the annotators, and that there were cases where the evaluation values differed as much as 3 out of 7 points among the annotators (ID “-”). On the other hand, there were cases where all annotators had the same evaluation value of 1, as in the case of ID 40 for this song.

4.2.3 Model

As described in Section 3.2, the GRM is used to model the Likert scale in the singing skill evaluation. For each perspective p , we jointly estimate parameters, θ_i^p , a_j^p , and $b_{j,k}^p$ using polytomous response data $X^p = \{x_{i,j}^p\} (i = 1 \cdots N_s^p, j = 1 \cdots N_a^p)$, where $N_s^p = 140$ is the number of songs, $N_a^p = 10$ is the number of annotators, and $K = 7$.

In this paper we assume the following prior distributions for the parameters of the GRM.

$$\theta_i^p \sim \text{Normal}(0.0, 1.0), \quad i = 1 \cdots N_s^p, \quad (17)$$

$$a_j^p \sim \text{HalfNormal}(1.0), \quad j = 1 \cdots N_a^p, \quad (18)$$

$$b_{j,k}^p \sim \text{Normal}(\mu_k, 1.0), \quad k = 1 \cdots K - 1, \quad (19)$$

where μ_k is equally spaced from $\mu_1 = -0.1$ to $\mu_{K-1} = 0.1$. The models in Eqns (7, 9, 11, 13) do not use a_j^p , and the models without j use a^p and b_k^p .

The prior distributions in the simplified GRM-based models that assume an interval scale are as follows:

$$\theta_j^p \sim \text{Normal}(-4.0, 3.0), \quad j = 1 \cdots N_a^p, \quad (20)$$

$$b_j^p \sim \text{HalfNormal}(3.0), \quad j = 1 \cdots N_a^p. \quad (21)$$

The MCMC setting was same as in Section 4.1.2.

Table 4. PSIS-LOO estimates (values of the expected log pointwise predictive density (ELPD)). The higher, the better. The highest value in each perspective is bolded and underlined, and the second highest value is underlined.

Perspective	Annotator independent				Annotator dependent			
	$o + k'b$		b_k		$o_j + k'b_j$		$b_{j,k}$	
	$-$	a	$-$	a	$-$	a_j	$-$	a_j
	Eqn (13)	Eqn (12)	Eqn (9)	Eqn (8)	Eqn (11)	Eqn (10)	Eqn (7)	Eqn (3)
Expression	-1864.0	-1720.8	-1857.3	-1699.8	-1864.1	-1685.3	-1871.9	-1706.7
Overall performance	-1729.6	-1496.4	-1726.9	<u>-1456.4</u>	-1729.5	-1414.6	-1759.1	-1528.5
Pitch	-1871.2	-1712.3	-1853.8	-1658.8	-1870.9	-1569.6	-1796.9	-1600.8
Pronunciation	-1887.3	-1773.9	-1870.8	-1747.5	-1887.2	-1741.3	-1885.6	-1763.9

Vocal projection	-1828.1	-1671.3	-1807.4	-1630.1	-1828.1	-1608.6	-1832.3	-1667.7

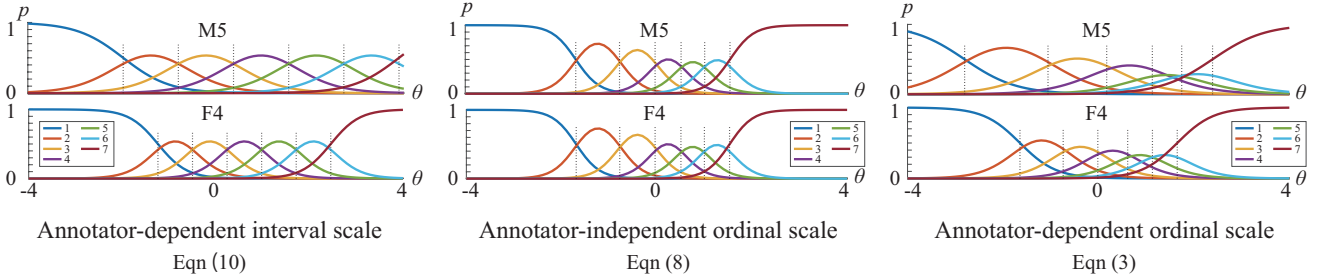

Figure 4. Item response category characteristic curves based on estimates of the parameters of annotators M5 and F4 for “overall performance”. The leftmost curves are for a simplified model (Eqn (10)) with interval scales. The center curves are for a simplified annotator-independent GRM-based model (Eqn (8)). The rightmost are for the GRM model (Eqn (3)).

4.2.4 Results

Table 4 shows the results of the model comparison. The model assuming annotator-dependent and interval measures (Eqn (10)) always performed the best. The second-best performing model was the annotator-independent one with variable intervals between cut points (Eqn (8)), or one that is the GRM (Eqn (3)).

Figure 4 visualizes the characteristics of two annotators, M5 and F4, by the three models that obtained the best evaluation results in Table 4. It can be seen that, given the same annotation data, the best simplified model in Eqn (10) estimates an equal interval scale for each annotator. While the GRM model in Eqn (3) can estimate the intervals that vary depending on both the seven categories and the two annotators, the simplified GRM-based model of Eqn (8) estimates the intervals that are shared by the ten annotators. These results suggest that evaluation scores tend to vary in intervals between annotators and/or within annotators. This means that these models potentially outperform conventional averaging-based methods, which assume annotator-independence and interval scales.

5. DISCUSSION

In the task of estimating music tags by using deep learning, binary labels are used to indicate whether the tag is assigned (1) or not (0), and are learned using the binary cross entropy loss [54]. Thus a continuous value of 0 to 1 is obtained during prediction, but the training data did not have such a continuum. In actual music tagging, however, the lack of perfect agreement among annotators means that it would be useful to represent each tag as a continuous value θ obtained by IRT when preparing the ground-truth training data for each tag. In fact, there are studies that have an-

alyzed the degree of such agreement based on the annotation results of multiple annotators in the annotation of segment boundaries of music structure in a musical piece [22].

In addition, if Likert scale-based ratings are used as machine learning data, they are typically averaged to obtain aggregated values. However, our experimental results show that these intervals can indeed differ among annotators. Thus, the proposed IRT-based aggregation has the advantage of dealing with ordinal scales.

In deep learning, there are methods to output discrete categories with ordinal relations by replacing the ordinal regression problem with binary classification subproblems and aggregating them [55, 56]. The IRT-based aggregation can replace ordinal regression as a regression problem and treat it with continuous values, which has the potential to improve machine learning performance even more.

6. CONCLUSION

This paper proposes the use of IRT for aggregating music annotation results from multiple annotators. Among the diverse types of music annotation, we targeted tagging and Likert scale-based evaluation, both of which have high practical potential. Specifically, we focused on aggregating results of music semantic tagging and singing skill evaluation using IRT’s 2PLM and GRM, respectively. We also proposed nine simplified models and verified the effectiveness of the proposed IRT-based models.

In the future, we plan to evaluate the effectiveness of IRT-based models on various datasets and annotations. Depending on the dataset, there may be new challenges to consider, such as introducing models to estimate the reliability and competence of the annotators [34–36]. Moreover, we will verify the effectiveness of using θ as training data in machine learning.

JUST LABEL THE REPEATS FOR IN-THE-WILD AUDIO-TO-SCORE ALIGNMENT

ABSTRACT

We propose an efficient workflow for high-quality offline alignment of in-the-wild performance audio and corresponding sheet music scans (images).¹ Recent work on audio-to-score alignment extends dynamic time warping (DTW) to be theoretically able to handle *jumps* in sheet music induced by repeat signs—this method requires no human annotations, but we show that it often yields low-quality alignments. As an alternative, we propose a workflow and interface that allows users to quickly annotate jumps (by clicking on repeat signs), requiring a small amount of human supervision but yielding much higher quality alignments on average. Additionally, we refine audio and score feature representations to improve alignment quality by: (1) integrating measure detection into the score feature representation, and (2) using raw onset prediction probabilities from a music transcription model instead of piano roll. We propose an evaluation protocol for audio-to-score alignment that computes the distance between the estimated and ground truth alignment in units of measures. Under this evaluation, we find that our proposed jump annotation workflow and improved feature representations together improve alignment accuracy by 150% relative to prior work (33% \rightarrow 82%).

1. INTRODUCTION

Sheet music has been used as a primary means of communicating musical ideas for centuries. Accordingly, sheet music is a profoundly important modality for MIR, not only because of the breadth of musical knowledge and history contained within, but also because sheet music constitutes a vital interface between MIR systems and musicians. However, while multimodal MIR systems are rapidly improving at tasks like music transcription [3–6] and controllable generation [7–9], these systems typically operate on MIDI as a symbolic music format. This may be less useful to musicians, e.g., a musician might prefer transcription systems to output sheet music instead of MIDI.

We conjecture that the scarcity of fine-grained alignment data linking sheet music to corresponding performance audio is a key bottleneck to incorporating sheet music into multimodal MIR systems. Alignments allow multimodal MIR data to be segmented into input-output chunks of tractable length for training models, and the lack of sheet music alignments may partially explain why sheet music is mostly overlooked. Moreover, alignments have practical utility outside of multimodal MIR, e.g., they may be used by musicians to practice along with pre-recorded accompaniments. Unfortunately, collecting alignments is deceptively tricky. For example, one could have a musician use a touch screen to point to the current location in sheet music while listening to a recording in real time. However, their tracking may be imprecise (due to expressive performance timing) and lack non-obvious details that are essential for segmentation (bar line locations, number of active staves).

In this work, we investigate the task of alignment of offline in-the-wild performance audio and corresponding sheet music scans (images), with a long-term goal of aligning large corpora of sheet music and performance recordings at scale. Much of the past work on audio-to-score alignment make at least one of several common assumptions that inhibit their practicality for collecting aligned data at scale: (i) the presumed availability of digital scores like MIDI or MusicXML as opposed to sheet music images [10–14], (ii) the alignment of MIDI performances or synthesized audio instead of real audio recordings [12, 15, 16], (iii) limitations in instrument diversity, commonly piano only [10, 16, 17], or (iv) dependence on time-consuming human annotation [18, 19].

Here we propose an audio-to-score alignment procedure that makes none of these assumptions, potentially offering a path forward for large-scale data collection. Most closely related to our approach is that of Shan et al. [16, 17], who examine offline alignment of in-the-wild piano sheet music images and performance recordings by aligning feature representations derived from the score and audio via MIR methods. In addition to operating on more diverse ensembles, our work has two primary distinctions: (1) we take a different approach to handling *jumps* in scores, and (2) we modify their feature representations.

A key challenge in audio-to-score alignment is handling inter-measure jumps in scores induced by repeat signs. Shan et al. [16, 17] propose extensions to DTW that are capable of automatically handling jumps. Here we propose a pragmatic alternative: a workflow and interface that allows humans to quickly annotate jumps, and a system that incor-

Figure 1. An overview of the task of audio-to-score alignment and our proposed approach. Given a score image (as a PDF) and corresponding performance audio (e.g., an MP3) as input, the task involves outputting an alignment between time in the recording and playheads in the score image. A key challenge in this task is handling jumps in the score, e.g., those created by repeat signs. In lieu of robust automatic methods for detecting or handling jumps, we propose a pragmatic approach of having experts simply label the repeats, which can be done quickly and greatly improves task performance. Our proposed system combines the repeat labels with score feature representations inspired by past work on bootleg scores [1]. This score representation is aligned with audio feature representations inspired by [2] using ordinary DTW.

porates these jump labels. We find that this approach can yield much higher-quality alignments than the automatic one, costing only seconds of annotator time.

We additionally extend the *bootleg score* feature representations used by Shan et al. [17], first proposed by Yang et al. [1]. Creating a bootleg score involves detecting noteheads and staff lines to produce a simple binary representation of a score that is conducive to alignment. We find that the use of measure bounding box detection as a preprocessing step improves the quality of underlying notehead and staff line detection algorithms. Additionally, motivated by findings in [2], we find that using raw onset probabilities predicted by a music transcription model as the audio feature representation produces higher quality alignments than using the MIDI transcriptions—see Figure 1 for a summary.

Motivated by our long-term goals of bringing sheet music into multimodal MIR, we also propose a new measure-aware evaluation scheme for comparing alignments. We speculate that measure-level alignment granularity is necessary for tractable training of multimodal MIR systems in the short term and that human perception of alignment quality is tied to measures. Accordingly, we prescribe new measure-aware alignment metrics for this task, such as an accuracy metric which reports the proportion of time where the estimated alignment is within a half measure radius of the ground truth alignment. On a small but diverse dataset of in-the-wild sheet music and aligned audio [18], we observe that our proposed system achieves an accuracy of 120% relative to that of Shan et al. (33% → 72%). By providing repeat labels, we improve the absolute accuracy of our system from 20% → 83% on a subset of pieces that have repeats. Our work makes the following contributions:

- A system capable of high-quality in-the-wild alignment of sheet music images and performance audio.
- A pragmatic workflow we call *Just Label The Repeats* that further improves alignment accuracy.
- An interface that enables rapid jump annotation.

2. TASK DESCRIPTION

Motivated by Thickstun et al. [20], here we formalize both the task of in-the-wild audio-to-score alignment and our proposed measure-aware evaluation. For a sheet music image with P pages (henceforth, a *score*), we define a *score playhead* (aligned position marker) as a tuple $(p, y, h, x) \in \mathcal{S} = \{0, \dots, P - 1\} \times [0, 1]^3$, where p is the page number, y and h are the offset and height of the current *system* (collection of staves) relative to the top edge and height of the page, and x is the playhead offset relative to the left edge of the page (see Figure 2). An analogous *audio playhead* is comparatively straightforward: a timestamp $t \in [0, T)$, where T is the audio length in seconds. An *alignment* is a mapping from audio to score playheads, i.e., $[0, T) \rightarrow \mathcal{S}$.

Figure 2. A score playhead (blue line), the output of an audio-to-score alignment, is characterized by its vertical offset (y), horizontal offset (x), and height (h), all relative to the page. A measure-aware alignment is indexed by m , a fractional measure, that can be converted to a score playhead by lookup and interpolation in a list of bounding boxes (brown outlines). Our measure-aware evaluation compares estimated playheads m' to ground truth m^* .

2.1 Measure-aware alignment

The above task definition is intended to be broad enough to encompass both past and future work on this task. Here we define a more specific form of alignment based around the location and ordering of *measures* in the score.

In this setting, measures are characterized by an ordered list of M bounding boxes $\mathbb{M} = [b_0, \dots, b_{M-1}]$, where $b_i = (b_i^p, b_i^y, b_i^h, b_i^x, b_i^w)$. Respectively, this tuple defines for each bounding box its page number, vertical offset, height, horizontal offset, and width. The ordering of this list is defined as the *logical* order that an expert would traverse when performing the piece—all *jumps* (repeat signs, Dal segno, etc.) are unrolled. For example, a score with 4 measures and a repeat implies that $M = 8$ and $b_i = b_{i+4}$.

Given a list of bounding boxes, a *measure-aware* score playhead can be characterized by a single continuous value $m \in [0, M)$, where $b_{\lfloor m \rfloor}$ is the bounding box of the current measure and fractional residual $m - \lfloor m \rfloor$ represents the offset from the left edge of the bounding box relative to its width. To convert a measure-aware score playhead in $[0, M)$ to an ordinary score playhead in \mathcal{S} , we define $h_{\mathbb{M}} : m \mapsto (b_{\lfloor m \rfloor}^p, b_{\lfloor m \rfloor}^y, b_{\lfloor m \rfloor}^h, b_{\lfloor m \rfloor}^x + b_{\lfloor m \rfloor}^w(m - \lfloor m \rfloor))$.

Given \mathbb{M} , a *measure-aware alignment* is a function $g : [0, T) \rightarrow [0, M)$. Because outputs of g index logical order (where jumps are unrolled), a measure-aware alignment g is a monotonically increasing function, i.e., $g(t_a) \leq g(t_b) \iff t_a \leq t_b$. Furthermore, we can compose $h_{\mathbb{M}}$ and g to induce an alignment that outputs score playheads, i.e., $h_{\mathbb{M}} \circ g : [0, T) \rightarrow \mathcal{S}$.

2.2 Measure-aware evaluation

Here we propose three measure-aware metrics for evaluating estimated alignments. **Our primary evaluation metric, MAcc, is defined as the proportion of time where the estimated score playhead is within a half measure radius of the ground truth score playhead**, which we posit is sufficiently precise for broader goals of multimodal MIR systems. ME_{err} and MD_{ev} are the mean and standard deviation (across time) of the absolute error between the estimated and ground truth playheads in units of ground truth measures.

More formally, given a ground truth measure-aware alignment g^* characterized by measures \mathbb{M}^* , and an estimated alignment g' characterized by \mathbb{M}' , we define:

$$\begin{aligned} \text{MDiff}(t) &= \text{Reindex}(g'(t), \mathbb{M}', \mathbb{M}^*) - g^*(t), \\ \text{MAcc} &\equiv \frac{1}{N} \sum_{i=0}^{N-1} \begin{cases} 1 & \text{if } |\text{MDiff}(\frac{Ti}{N})| \leq \frac{1}{2} \\ 0 & \text{otherwise.} \end{cases} \\ \text{MErr} &\equiv \frac{1}{N} \sum_{i=0}^{N-1} \left| \text{MDiff}\left(\frac{Ti}{N}\right) \right|, \\ \text{MDev} &\equiv \sqrt{\frac{1}{N} \sum_{i=0}^{N-1} \text{MDiff}\left(\frac{Ti}{N}\right)^2} \end{aligned}$$

We set $N = 100T$, i.e., we compute all metrics at a resolution of 100 comparisons per second. As an example, Figure 2 shows a single comparison where $\text{MDiff} = 0.25$.

The `Reindex` procedure ensures that the evaluation is based in units of ground truth measure indices, despite potential discrepancies between \mathbb{M}' and \mathbb{M}^* . Informally, this procedure matches each box in \mathbb{M}' to the box in \mathbb{M}^* that it is closest to in terms of Euclidean distance between mid-points, using the ordering from \mathbb{M}^* to break ties that occur for repeated measures.

3. SYSTEM DESCRIPTION

In this section, we detail our proposed system for in-the-wild audio-to-score alignment. At a high level, our method uses DTW to align piano roll-like feature representations extracted independently from the audio and score (Figure 1). Both representations are matrices where one axis corresponds to time (either in units of seconds or measures) and the other corresponds to 88 MIDI pitches from A0 to C8 (piano range). Specifically, score feature representations are matrices in $\{0, 1\}^{48M \times 88}$ (binary) where M is the number of measures in the score, and audio feature representations are matrices in $[0, 1]^{Tf_k \times 88}$ (continuous) for performance length T and frame rate $f_k = 31\text{Hz}$.

3.1 Score feature representation

Our proposed score feature representation is an extension of *bootleg scores* proposed by Yang et al. [1]. Extracting bootleg scores involves detecting noteheads and staff lines, and then combining this information into a binary matrix where a 1 encodes the presence of a notehead at a particular horizontal position on a particular staff line. Our system extends this representation in two ways: (1) we use measure detection as a preprocessing step and run notehead detection algorithms on segmented measure images instead of full pages, and (2) we translate notehead positions on staff lines into MIDI pitches before alignment.

Measure, notehead and staff line detection. We use the methods from [1] to detect noteheads and staff lines from score images. Instead of operating on full page images, we first segment pages into measures using the measure detection model from [21], and detect noteheads and staff lines on individual measure images resized to fixed dimensions. In preliminary experiments, we found that measure segmentation improved detection consistency—our intuition is that these methods are sensitive to absolute pixel sizes of noteheads and stafflines, and resizing individual measures to uniform size reduces variance in the sizes of these attributes across measures and pieces. Here we resize measures by resizing the smaller of their height and width to 900 pixels, preserving aspect ratio for the larger of the two. For each notehead, we retain its *bootleg location*, defined as its raw (pixel-wise) horizontal location within the measure, and its semantic (discrete) vertical position within the detected staff lines (e.g., an F and G natural in treble clef are one apart in their *staff positions*).

Piano rolls. We create a binary piano roll-like representation of the score using the bootleg locations of noteheads. Specifically, for each logical measure image index $k \in \{0, \dots, M-1\}$, we construct a binary matrix $S_k \in \{0, 1\}^{48 \times 88}$, where a 1 at row i and column j corresponds to a notehead with horizontal location $\frac{j}{48}$ relative to the

measure width, and its staff position converted to a pitch j . We pick a measure representation to have 48 rows to give sufficient resolution to a variety of rhythmic patterns and note durations. We concatenate $[S_0, \dots, S_{M-1}]$ together to form our final representation $S \in \{0, 1\}^{48M \times 88}$.

Converting staff position to pitch. A key obstacle is that, without key signature and clef information, the mapping from staff positions to MIDI pitches is ambiguous. If we had these attributes, we could simply look up the pitch associated with each staff line. However, we found existing OMR systems to have brittle support for detecting this information for in-the-wild sheet music—hence, our method does not assume that we have access to this information. Accordingly, we convert bootleg scores into piano rolls by simply assuming treble and bass clefs respectively when two staves are detected—if more or fewer staves are detected, we default to the treble clef—and the key of C major. Surprisingly, perhaps because of the global optimality of DTW, these assumptions lead to reasonable alignments even when they are incorrect. We note that ground truth key signature and clef information for each measure can be fed into our method to facilitate and improve this conversion, but we do not require it.

3.2 Audio feature representation

Our audio feature representation pipeline is comparatively simple. To compute it, we simply pass the audio through the Onsets and Frames piano transcription model [3]. Motivated by [2], we use the raw onset prediction probabilities from this model as our audio feature representation, which is a matrix in $[0, 1]^{Tf_k \times 88}$. Despite this transcription model being trained on piano, we find that its onset probabilities can yield reasonable alignments even for non-piano audio.

3.3 Alignment

Finally, we align the score representations in $\{0, 1\}^{48M \times 88}$ and audio representations in $\mathbb{R}^{Tf_k \times 88}$. We use the implementation of standard DTW from `librosa` [22] with default parameters: equal-weighted transitions $(1, 1)$, $(0, 1)$, and $(1, 0)$, and Euclidean distance to compute costs.

4. EXPERIMENTS

Here we detail our experiments, which center around comparing our proposed method to that of Shan et al. [17] on the MeSA-13 [18] and SMR [1] datasets using our proposed measure-level evaluation (see Section 2.2).

4.1 Datasets

We evaluate our approach and relevant baselines on two different datasets. The first is MeSA-13 [18], a dataset of 13 sheet music scans and corresponding real (i.e., not synthesized) performance audio. This dataset contains expert annotations of measure bounding boxes in logical order (\mathbb{M}^*) and the timestamp of every measure in the performance audio (we linearly interpolate between timestamps to get a continuous ground truth mapping g^*). While small, MeSA-13 has reasonable diversity in score typesetting, performance acoustics (two pieces feature instruments besides piano), and jumps (two pieces have repeats).

The second dataset is a subset of the Sheet MIDI Retrieval v1.0 (SMR) dataset [1]. The full dataset contains scanned scores from IMSLP for 100 solo piano pieces (none of which have jumps), corresponding MIDI performances synthesized as audio, and human annotations of measures per line and measure timestamps. Of notable absence are annotations of measure bounding boxes, which are required for our proposed evaluation. Accordingly, we detect measures [21] and discard pieces where the detections do not agree with annotations of measures per line—this leaves us with a subset of 60 pieces for evaluation. Henceforth, SMR refers to this subset.

4.2 Access to additional annotations

We primarily evaluate systems in an automatic setting where systems are only given the score and audio as input. Because our system can incorporate additional score annotations when available, we also evaluate in settings where our system has access to additional annotations from the ground truth, simulating workflows where experts are in the loop during alignment. Specifically, we explore settings where our method has access to ground truth repeat annotations (R), measure bounding boxes (M), and staff information (S)—clef and key signatures. We only evaluate in these settings on MeSA-13 where we have these labels.

4.3 Baselines

We compare the performance of our system, composed of our feature extraction pipeline and vanilla DTW, to that of [17]. In the latter system, the feature extraction pipeline uses bootleg scores and staff line detection on the score images to extract staff lines (referred to as segments). For audio features, a transcribed MIDI representation is obtained from the Onsets and Frames piano transcription model [3] which is then used to compute bootleg scores. Finally, Hierarchical DTW performs a segment-level alignment between score features and audio features while handling jumps and repeats that occur at segment boundaries, but not those within segments. Thus, we opt to evaluate this baseline approach at the measure level instead of the segment level (which also allows for comparison with our system) by converting the segment-level alignment to a measure-level one via an algorithm with several key steps.

We first use measure detection [21] to locate measures in each segment. Then, we map segment indices to measure indices based on the positions of detected measures. Finally, we turn the given alignment between audio timestamps and segment indices to one between audio timestamps and measure indices via linear interpolation.

We compare these two systems as proposed instead of comparing their components for two reasons. First, in [17] it is claimed the system performs segment-level alignment on pieces without repeat info; we aim to test this. Second, while Hierarchical DTW allows backwards jumps to prior segments, it only allows forward jumps to one segment past the last one seen. Using Hierarchical DTW at the measure level would limit possible forward jumps to only one measure past the last one observed, which is insufficient for realistic alignment tasks.

Dataset	Given	System	MAcc	MErr	MDev
M13	-	[17]	0.33	10.9	11.6
	-	Ours	0.72	1.9	3.7
	R [†]	Ours	0.82	0.4	0.2
	R,M	Ours	0.86	0.4	0.2
	R,M,S	Ours	0.88	0.3	0.2

SMR	-	[17]	0.36	14.2	18.7
	-	Ours	0.82	2.9	18.8

Table 1. Evaluation on MeSA-13 (including subsets with Repeats and No Repeats) and SMR. Our method outperforms that of [17] across all datasets except the subset of MeSA-13 with no repeats. R[†] is our recommended setting where our method is given access to ground truth Repeats that require little time for humans to annotate—we observe limited gains from more time-consuming annotations of Measure bounding boxes and Staff metadata.

4.4 Results and discussion

In Table 1, we report the measure-level alignment metrics (Section 2.2) of our system in all four settings and the system of [17] across the MeSA-13 (M13) and SMR datasets. To emphasize the effect of jumps on alignment performance, we separately report performance on the subset of MeSA-13 pieces with and without repeats (M13_R and M13_{NR}, respectively).

We observe that our system outperforms that of [17] in the automatic setting across all datasets. The superior performance of our system over that of [17] is likely due to our refinements to feature representations. We also note here that the system of [17] is designed to work on line-level, therefore evaluating it using our measure-level metric yields lower accuracy than what was reported in [17].

Additionally, we observe that given repeats and ground truth measure annotations, our system’s performance improves by 22% relative (MAcc 0.72 → 0.88) on M13. However, we also observe a relative performance improvement of 14% (MAcc 0.72 → 0.82) using our system on the same dataset when we only pass in repeats. Given that repeats are much easier for humans to annotate than measure bounding boxes, we propose to have humans *just label the repeats* as a recommended tradeoff between alignment quality and annotator time. We also explore providing our system with measure-level key signature and clef

Representation	M13	SMR

information, finding that this information only marginally improves performance relative to the default key and clef assumptions described in Section 3.1.

4.5 Different audio feature representations

Here we compare alternative audio feature representations by evaluating MAcc on M13 given all additional information (i.e., the R,M,S setting described in Section 4.2). While we primarily use raw onset prediction probabilities (Section 3.2), the Onsets and Frames model [3] provides other possibilities including onset predictions (thresholded probabilities), frame probabilities and predictions, and the postprocessed MIDI transcription converted to piano roll (see [3] for details). Table 2 shows that onsets consistently outperform frames as an alignment representation—our intuition is that onsets are more appropriate for our setting as the bootleg score representation does not encode note durations. Additionally, while transcribed MIDI is a common feature representation for music alignment, in our setting we find it to be the worst choice.

5. LABELING INTERFACE

Here we describe a web-based interface that we built to enable experts to quickly annotate jumps in scores (induced by repeat signs, D.S. al coda, etc.). Our experiments show large improvements in alignment quality given jump labels. Accordingly, we designed an interface to make this process efficient—experts can label jumps in a matter of seconds. We include videos demonstrating the end-to-end process and qualitative results of our proposed workflow for pieces outside our evaluation data.² In these videos, labeling jumps takes less than 6s per page on average.

Our interface features a unified workflow for jump annotation based on clicking the starting and ending measure of a jump (Figure 3). To enable this workflow, we first run measure detection [21] on the backend and visualize detected measures on the frontend as a user hovers over the score. Then, users can simply click on two different measures to set a jump—this simple unified workflow accommodates a long tail of jump glyphs. The interface also visualizes the logical order of the measures induced by the measure bounding boxes and any jumps the user has set (M from Section 2.1). Finally, a user can download the

Figure 3. Illustration of our web-based interface for labeling jumps (e.g. repeats) in scores. Our interface enables rapid jump annotation (just seconds per page after training), which we find to dramatically improve alignment quality on pieces with jumps.

logical-order measures as a simple JSON file, which can then be loaded into our Python-based alignment package.

6. RELATED WORK

Our work relates to prior work in offline audio-to-score alignment, score following, and score annotation tools.

6.1 Offline alignment

Offline alignment entails building a correspondence between sheet music and performance recording of the contained music. As described previously, our work is inspired by the bootleg score line of research [1, 16, 17, 23, 24] as well as the usage of raw audio prediction scores in [2]. Our contributions stem from combining these approaches with minimal human annotations to outperform prior baselines. Other prior work in this area includes [15, 25], which use MIDI events as an intermediate representation between scores and audio, and [26–31], which use chroma vectors (where components correspond to the 12 pitch types in Western music). We perform a similar procedure to the methods used in these works except that we use bootleg scores as our intermediate representation. We diverge from [14], which uses MusicXML as an intermediate representation, and from [32], which uses LilyPond representations, but we mention them here as related approaches. We also incorporate reasoning from [20] regarding evaluation metrics.

6.2 Score following

In contrast to offline alignment, *score following* involves building a real-time alignment between sheet music and live performance audio. Initial solutions to this problem include [33, 34], with later works addressing jumps and repeats [35, 36]; for more on related work in past decades, see survey papers [37, 38]. Unlike most other research in score following which often assumes that a digital score

representation (like MIDI) is available, our emphasis is on *solely using score images* with an aim to perform alignment at scale. This said, some recent work does attempt to solve this problem in images. For instance, works such as [39–42] map audio snippets to corresponding places in score images using neural networks, but they are limited to piano music. We diverge from them by considering a range of different types of raw score images and audio (such as ones with instrumentation beyond solo piano) and leveraging bootleg scores [1, 16, 17, 23, 24] for mapping, but these are still related to our work.

6.3 Sheet music annotation interfaces

Our work also relates to past work on designing interfaces to assist in the annotation of sheet music. Most directly related is that of Feffer et al. [18] which attempts to facilitate interactive annotation of sheet music and audio alignment via a workflow based on aligning detected beat timestamps [43] to detected measures [21]. This interface was used to compile the MeSA-13 dataset of aligned audio and scores, which we use to evaluate our work, though we note that their interface required 20 hours of expert time to collect less than an hour of aligned data. In contrast, our interface is designed to be used for a matter of seconds to annotate repeats. Other interfaces focus on facilitating measure bounding box annotations [44, 45], which is complementary to our workflow that focuses on repeat annotation using predicted bounding boxes. Lastly, Soundslice [19] is a commercial product that offers an interactive alignment workflow based on stronger notions of OMR, but its implementation details are proprietary.

7. CONCLUSION

In summary, we introduce a workflow for efficiently aligning sheet music images to performance audio. The key insight we leverage is that while automated alignment algorithms are currently not robust to repeats in scores, humans can quickly label these repeats, thereby improving alignment performance. We validate this approach on a dataset of in-the-wild sheet music scans and real performance recordings, showing that we outperform existing baselines that only use automated approaches.

Given these results, one future project we aim to undertake is to collect jump annotations at scale to create large aligned datasets. We acknowledge that the datasets we used to evaluate our approach are small, but the insights gained from them can help scale up data for future evaluations. For instance, we could extend the interface from Section 5 to allow annotators to quickly audit and adjust alignments to collect more data, as in [18]. Moreover, other future work could revisit the creation of a fully automated alignment algorithm with insights from our work, namely that such an algorithm that leverages OMR to identify jumps and repeats may be more successful than one that does not. Collecting more data would therefore be helpful for developing and evaluating future approaches. Lastly, as described in the start of our paper, large aligned datasets could be used to derive multimodal MIR systems for music students and professionals alike.

8. ETHICS STATEMENT

As described previously, advancements in audio-to-score alignment can result in new multimodal datasets derived from existing repositories of sheet music and audio (such as IMSLP [46]) and new interactive music systems tailored for performance. Our motivation for pursuing this direction is to unlock multimodal MIR systems that (1) supplement music education by helping performers rehearse, (2) understand or generate sheet music to unlock seamless communication with human musicians, and (3) reduce reliance on copyrighted material for building music AI (i.e., by leveraging public domain scores and recordings).

We also recognize several potential ethical concerns stemming from our work. Firstly, our method is firmly rooted in conventions of Western music. Accordingly, downstream systems and data derived from our method may reflect a Western bias that does not generalize well to other musical traditions, especially those with different notation or tuning systems. Secondly, though our goal is to lessen the amounts of copyright infringement taking place to build generative music AI, multimodal MIR systems could be used to circumvent data protections, e.g., by transcribing copyrighted recordings as less-protected sheet music. Lastly, increased ability to understand sheet music could lead to deepfakes or misinformation, e.g., scores that could be falsely attributed to Beethoven, or ragtime recordings that could be falsely attributed to Joplin. In response to these concerns, we recommend that future work mitigate these risks by, for example, developing analogous systems capable of improving understanding of non-Western music notation. We also recommend that MIR researchers should be mindful of data protections, copyright violations, and artistic mimicry that, if subverted, could threaten the livelihood of musicians.

ABSTRACT

We introduce a series of transdisciplinary corpus studies aimed at investigating cross-cultural trends in time-line-based music traditions. Our analyses concentrate on a compilation of field recordings from the Centre de Recherche en Ethnomusicologie (CREM) sound archive. To demonstrate the value of an interdisciplinary approach combining ethnomusicology and music information research to rhythmic analysis, we propose a case study on the bell patterns used in the musical practices of Candomblé, an Afro-Brazilian religion. After removing vocals from the recordings with a deep learning source separation technique, we further process the instrumental segments using non-negative matrix factorization and select the bell components. Then, we compute a tempo-agnostic rhythmic feature from the bell track and use it to cluster the data. Finally, we use synthesized patterns from the musical literature about Candomblé as references to propagate labels to the rhythmic clusters in our data. This semi-supervised approach to pattern analysis precludes the need for downbeat and cycle annotations, making it particularly suited for extensive archive investigations. Lastly, by comparing bell patterns in Candomblé and a West African music tradition, we lay the foundation for our future cross-cultural research and observe the potential application of this methodology to other time-line-based music.

1. INTRODUCTION

Over the years, the music information retrieval/research (MIR) community has embraced more culturally-inclusive research geared towards the analysis of non-Western music [1]. Many of these studies have done extensive work to increase the representation of certain musical styles

from specific cultures [2]. However, few MIR initiatives have attempted to investigate multiple musical cultures simultaneously at a larger scale due to the level of difficulty and lack of data. These hardships reinforce a cycle of under-representation of various populations and risk further emphasizing the perspective of MIR through a Western-centric lens.

In this paper, we propose one of several studies aimed at a more global, inclusive, and transdisciplinary approach to MIR that puts humanistic (ethnomusicological and anthropological) and computational approaches in dialogue within a framework defined as Sonic Digital Humanities [3]. Our work centers on a substantial corpus of data from the Centre de Recherche en Ethnomusicologie (CREM). While we will explore only a part of this archive in this paper, we discuss its contents and their importance in Section 3. In Sections 4-7, we introduce a preliminary investigation on a subset of the archive analyzing bell patterns in Brazilian Candomblé and music from West Africa to demonstrate the potential this data has for future cross-cultural research on time-line-based acoustic traditions.

2. RELATED WORK

Ethnomusicology and MIR are often associated in a way that one is viewed as the source discipline while the other is the target [4]. However, researchers have suggested treating them as partners rather than as a hierarchy [5, 6]. With this approach, the MIR community can develop new computational methodologies which incorporate external information, such as cultural context, to better understand audio signals [1]. Specifically, we apply a framework known as the Sonic Digital Humanities (SDH) to our investigation. SDH is a branch of the Digital Humanities concerned with digital collections of music and other forms of sonic culture. It provides a space in which computational means to the analysis of sound culture may be developed and carried out in a productive dialogue with humanistic modes of data collection and critical inquiry [3].

By analyzing collections from an SDH perspective, we intend to ask questions about the cross-cultural relationships of different musical styles on a global scale. While engaging in data-driven analyses of these musical

styles, we attempt to understand (1) whether these findings support evidence collected from ethnomusicological studies about cross-cultural influences and (2) how these large-scale computational investigations can provide further insights into comparing music cross-culturally. In the case of (1), validating (or not) musicological evidence about cross-cultural relationships can improve MIR approaches to provide more reliable large-scale studies of lesser-known styles in the digital world. With (2), these methods can yield new findings of what characterizes a musical style born out of cross-cultural influence.

The first steps in expanding MIR beyond the exclusive sphere of Western music involved improving cultural representation in datasets. As a result, several culture- or style-specific corpora have been published for studies on music such as American ragtime, Beijing opera, and more [7, 8]. These advancements have improved access to a variety of data, but have yet to make a dent in the dominance of Western methodologies in MIR. A recent push by Huang et al. [9] for the MIR community to go beyond the collection of diverse data, collaborate with musicologists, and reflect on the way we engage with music serves as an appropriate objective for our studies of the CREM archive.

Despite the variety and richness of the information available in the CREM archive, very few studies have been published about this data. One MIR study utilizes the database to evaluate a proposed timbre classification method on a diverse set of musical instruments with the intent of allowing the indexing of ethnomusicological databases [10]. This sparseness of research presents major opportunities to explore the CREM archive in greater detail over a series of long-term, novel studies.

Our first investigation concerns the analysis of time lines, also known as bell patterns, in large collections of music. Time lines are short, cyclic patterns played in ostinato, often with a bell, castanet, or sticks [11, 12], that are used as a “controlling structural concept” [13, p. 1] in African music. This type of organization extends beyond geographical boundaries and can be heard in Afro-diasporic musical styles from the Caribbean or South America, for example. A key aspect of time lines is that they are qualitatively different from the concept of meter, as they originate from the movement of feet in dance [11], and denote a circularity that is characteristic of African music traditions [13]. This distinguishing factor calls for computational pattern recognition strategies that go beyond traditional methods of meter detection.

Toussaint proposed several mathematical methods, including geometric and graphical ones, for the analysis of clave-bell rhythm time lines [14]. Despite not being originally automated, they served as foundational work for future research concerning rhythmic complexity. Soon after, Toussaint continued their work on clave-bell time lines by comparing metrics for rhythmic similarity, such as Hamming distance and Euclidean interval vector distance [15]. All of the methods described in [14] and [15] require manual annotations, which are time-consuming and not scalable to a corpus as vast as the CREM archive.

Consequently, our proposed pipeline for time line pattern analysis is semi-supervised, with the majority of feature extraction and similarity computations automated. We draw inspiration from [16], who used template matching to track tempi of Afro-Cuban clave rhythms. However, their method has the drawback of requiring an exhaustive search for matching every tempo at each onset. Additionally, we consider the approach by [17], who inferred meter from Candombe recordings using rhythmic templates learned with the help of annotations. We improve upon these methodologies by using reference tracks to compute similarity measures based on [18]. The scale transform magnitudes (STM) [18] operate on the autocorrelation of the signal’s onset strength. They are robust to tempo variation, which facilitates the transfer of labels from the references to the tracks under study.

In this paper, we use Candomblé as a case study of time-line-based music. Candomblé is an Afro-Brazilian religion known for syncretically combining elements from many cultures, most notably Yoruba, Bantu, and Fon — which were brought to Brazil by enslaved West African populations [19]. Music plays a crucial role in the religious practices of Candomblé. Antiphonal songs are performed throughout the entire ceremony, accompanied by a drumming ensemble, always with the intent of allowing the participants and certain deities (*orixás*) to communicate [20]. Different rhythmic patterns, in both singing and drumming, are associated with different *orixás*. There are a few historical collections of Candomblé field recordings in the CREM archive, serving as a valuable resource of audio data for our investigation.

3. CREM-NYUAD COLLECTION

The CREM database is an extensive archive of digitized audio recordings from cultures around the world. Spanning from the beginning of the 20th century to today, the archive contains over 48,000 field recordings and more than 17,000 published commercial recordings representing over 1300 ethnic groups across 199 countries. The public has access to rich metadata cataloguing the database as well as thousands of recordings available to listen to for free on the archive’s website.¹

Through a partnership with the Centre National de la Recherche Scientifique (CNRS), New York University Abu Dhabi (NYUAD) has acquired a subset of the CREM archive for the purpose of analyzing the sound recordings. Henceforth, we call this subset the CREM-NYUAD collection. The CREM-NYUAD collection consists of 14,379 records from 129 countries, with a majority coming from Africa, Asia, and South America. In particular, Vietnam, Nepal, Madagascar, Gabon, and Algeria are among the countries with the most records in the dataset. Each item consists of audio features, such as spectrograms and tempograms, extracted during a prior collaboration between CREM and NYU. The associated metadata for each record contains basic data about the item, such as the collec-

¹ <https://archives.crem-cnrs.fr>

tion name and date, but also includes valuable information about the location, language, instrumentation, and ethnographic context of the recording. This information provides a significant advantage in our pilot study of Candomblé bell patterns, as we will see in Sections 4-7.

An important feature of our collection, which distinguishes it from many other datasets used in MIR research, is the prevalence of field recordings in the corpus. Field recordings provide important cultural context through the settings in which the traditions are recorded, such as in the *terreiros* (places of worship) of Candomblé [21]. In contrast to commercial studio tracks, field recordings are often taken in natural conditions where there are various social and environmental sounds, as well as noise, in the final recording [22, 23]. Furthermore, the time span over which these field recordings are collected often reflects the technological progress of the time period with more recent recordings producing higher quality audio. The acoustic diversity of the collection poses additional challenges to our computational methods in the form of silence, noise, and artifacts (e.g., clicks). We attempt to overcome some of these obstacles to the analysis in our pipeline, but save any audio restoration endeavors for future work.

4. BELL PATTERNS IN CANDOMBLÉ

The drumming ensemble in Candomblé typically consists of three differently-sized drums called *atabaques*, a dried gourd covered in beads known as *xequerê*, and a single or double clapperless bell called *gan* or *agogô*. Figure 1 shows ten essential Candomblé bell patterns as notated in [24]. These motifs were identified as the main patterns utilized by the Ketu nation, the largest branch of the Candomblé religion today. For example, pattern 1 represents the bell part in *vassi*, which is a common pattern in many different rhythms of Candomblé and is performed by bells with two accompanying drums. Pattern 2 is the same as the Son clave [14]. Pattern 3, known as *ijexá*, gained popularity in not only religious contexts, but also in the festive *Carnaval* parades held in Salvador, Bahia.

Figure 1: Examples of Candomblé bell patterns in time unit box system (TUBS) notation [24]. Open and closed dots indicate the use of high- and low-pitched bells.

5. METHODOLOGY

The process we employ to extract rhythmic features associated with bell patterns in field recordings is encapsulated in Figure 2, and explained further in this section.

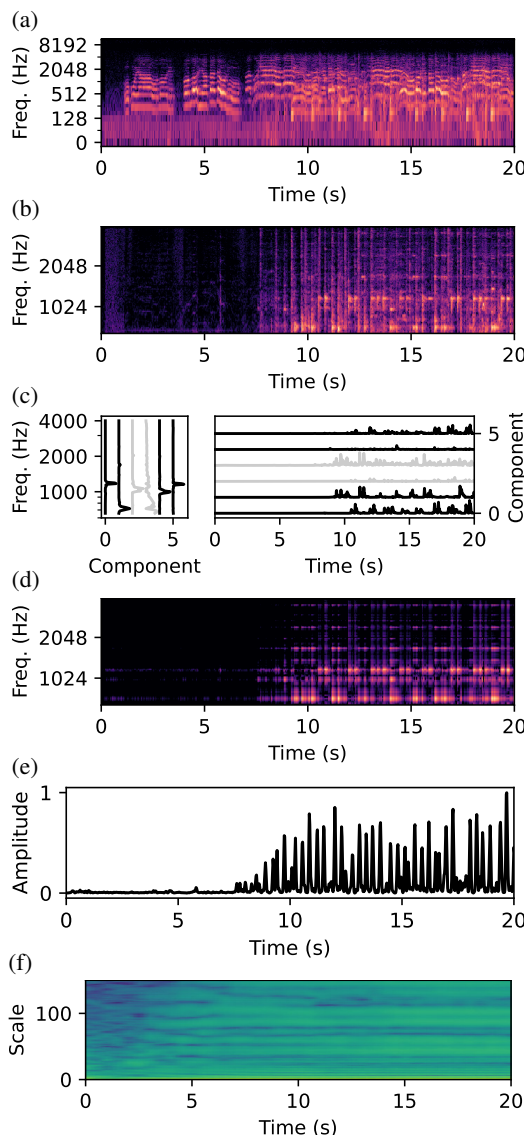

Figure 2: Workflow for extracting rhythmic features for bell patterns: (a) spectrogram of the original track (vocals and instruments); (b) the isolated instrumental part, from 650 to 4000 Hz; (c) NMF-learned templates and activations (highlighting those selected via the spectral crest); (d) reconstructed spectrogram of the bell part; (e) smooth bell activation function; and (f) frame-wise STM.

5.1 Source Separation

In order to analyze the bell patterns in greater detail, we need to isolate them from the remainder of the audio track. To do so, we first remove the vocals from each track due to their potential obstruction of the bells’ frequency band. Using the pre-trained state-of-the-art hybrid transformer source separation model, Demucs [25], we preserve the instrumentals by separating the vocal stem.

To further abstract the bell patterns from the rest of the rhythm sections, we decompose the non-vocal track with

non-negative matrix factorization (NMF) [26]. First, we resample the non-vocal signal to 8000 Hz. Then, we compute its short-time Fourier transform (STFT) with a 64-ms window and a hop size of 20 ms. We restrict the NMF analysis from 650 to 4000 Hz, which discards the main frequencies from low-pitched drums. At this time, we assume that the signal contains primarily the bell tones (sometimes in two distinct pitches, when both bells of the *agogô* are used) and noise-like components emanating from the *xéquerê* or the other drums’ attacks. For this reason, we run the NMF algorithm with $n = 6$ components. After the algorithm converges, we use the spectral crest [27] to identify sources corresponding to the bells by selecting components whose templates are more tonal in nature. The geometric mean of all crest factors serves as a threshold. Finally, we reconstruct the separated spectrogram of the bell part with the dot product of the matrices composed by the selected template–activation pairs.

5.2 Feature Extraction

The next step in our workflow is computing a rhythmic feature based on the scale transform magnitudes [18]. We first compute the time derivative of the log-compressed reconstructed source spectrogram, using a factor of compression $C = 1000$ as in [28]. All of the bins are summed up, and we apply half-wave rectification to keep only positive peaks. To smooth this accent signal, we use a lag of 3 frames in the computation of the time-difference [29] and further process the signal by convolving it with a Gaussian kernel ($\sigma = 20$ ms). Finally, we follow the procedure of [18] and determine the local autocorrelation of the accent signal with an 8-second moving rectangular window (hop size of 0.5 s). The direct scale transform [30] converts the autocorrelation at each frame into the scale domain, such that tempo is not encoded in the representation, and we keep only the first 150 scale coefficients. We discard all frames at the start of the signal whose energy lies below a threshold of -60 dB. Feature vectors can be compared using cosine similarity or Euclidean distance [18], with the former being better suited for handling changes in level between the recordings.

5.3 Label Propagation

We follow a semi-supervised procedure to classify patterns in the dataset. For this purpose, we create synthetic versions of the patterns in Figure 1 with no accents or timing deviations. We extract the rhythmic patterns of these synthesized reference tracks using the same pipeline as before. The only differences are that we use all $n = 3$ NMF components to generate a single activation and that we summarize the STM feature by taking the average along the time axis. Lastly, we propagate labels to the original (unlabeled) dataset in the following fashion:

1. For each track i in the dataset, we measure the maximum pairwise distance, σ_i , between STM frames;
2. For each frame j of track i , we find the closest data

point, r_k , from the reference set, such that the distance $d(x_{ij}, r_k)$ is minimal;

3. If $d(x_{ij}, r_k) \leq \sigma_i$, x_{ij} receives the same label as r_k , else it receives a “null” label;
4. “Winner-take-all”: we perform plurality voting among all labels for x_i where the most prevalent label is used to represent the entire track.

While the labels can be propagated within the feature space, this process can also be intuitively performed in a lower-dimension embedding space.

6. EXPERIMENTS AND RESULTS

We select a specific set of tracks from the CREM-NYUAD collection on which to run our entire pipeline. We rely on the metadata described in Section 3 to identify which files contain bell sounds. Table 1 shows the countries in West Africa (and Brazil) with these bell patterns and the number of recordings from each country.

Country	# Records
Congo-Brazzaville	98
Brazil	71
Benin	42
Angola	30
Gabon	27
Mali	24
Côte d’Ivoire	11

Table 1: Number of records with bell patterns per country.

In this initial experiment, we further restrict our scope by selecting, from those files recorded in Brazil, a set of recordings by ethnographer (and Candomblé initiate) Pierre Verger.² Moreover, with the assumption that bells mostly establish a cyclic pattern, we consider only the first 60 s of each recording. Next, we proceed with the analysis from Section 5; i.e., after our pre-processing steps, we extract the rhythmic features for all tracks in the subset and in the reference set. We then perform label propagation from the reference set to the subset. Using UMAP [31], a manifold learning technique, we present the results in Figure 3.

With regards to structure, our pipeline clearly extracts meaningful information from the rhythmic patterns in the subset, as many distinct clusters are visible. Interestingly, we observe that the reference patterns are well distributed among these clusters.

The label propagation procedure also reveals important aspects of the data distribution. For instance, we notice that the approach labels a large portion of the frames as belonging to the “pattern 1” archetype. Furthermore, note how closely patterns 7 and 9 are represented in the embedding. This proximity is easily explained by them differing on only a single beat (see again Figure 1). The families of patterns 2 and 5 also appear near each other in the manifold, but this time their pattern lengths are unequal. However, by “interpolating” pattern 5 and cyclically rotating

²https://archives.crem-cnrs.fr/archives/collections/CNRSMH_I_2007_011/

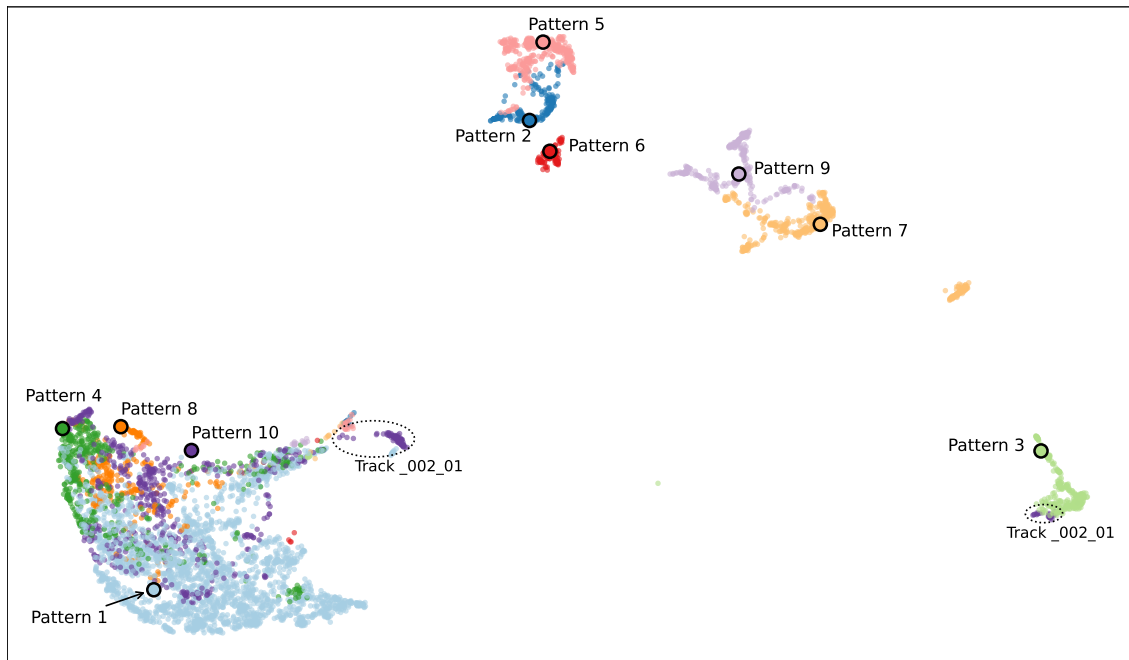

Figure 3: UMAP projection of the Candomblé bell patterns and reference patterns (cosine metric, n -neighbors = 70, min-dist = 0.1). The same color coding of Figure 1 is used here. Circled: the frames corresponding to track `_002_01`.

pattern 2 (Figure 4), we see that they are more alike than they appear at the surface level, especially considering that the STM feature is independent of tempo. A similar argument explains the close proximity of clusters for patterns 5 and 6.

Figure 4: Interpolation and cyclical rotation of patterns 5 and 2 reinforce the similarities found in the embedding. Three of the five onsets match, and the remaining two are a slight shift away from their counterparts.

We can also assess the label propagation method’s performance by investigating some information from the metadata. For example, recordings `_002_01`, `_004_03`, `_005_04`, and `_005_05` contain the indication “*ijexá* rhythm” (“*rhythme ijexá*”) in their titles, so presumably they correspond to the same type of bell pattern as pattern 3. Consequently, in the embedding, their frames are clustered and labeled together as part of the “pattern 3” archetype. The only exception is recording `_002_01` (circled), which was incorrectly classified as pattern 10 and divided into two sections: the majority of frames are situated in the easternmost region of the large 1–4–8–10 cluster, while a handful of remaining frames are found near pattern 3. In this case, the misclassification could be attributed to the crest selection procedure’s inability to retrieve the main component of the highest-pitched bell.

Figure 5 showcases selected examples of the onset activations from the subset, juxtaposed with their corresponding reference activations. To ensure alignment, we manually adjusted the references’ timing to match the excerpts.

Differences between the references and audio realizations, such as additional or missing notes, can be ascribed to recording conditions or introduced by the pipeline. Despite these discrepancies, the workflow demonstrates robustness, as evidenced by the confirmation of the automatic classification through listening tests. Pattern variations can also originate from the player, who may miss a note or add embellishments (flams). Another type of discrepancy we have identified, resulting from small scale deviations, is illustrated with recording `_004_09`.

Lastly, we conduct another analysis which uses a larger number of recordings with bell patterns from the Republic of the Congo (see Table 1). We follow the same procedure as before, but lower the minimum frequency for the NMF decomposition from 650 to 300 Hz, since West African bells are typically larger and lower pitched. Figure 6 displays the embedding of both the Brazilian and Congolese patterns from our subset. This visualization shows similarities between some of the patterns; these potential cross-cultural intersections require further investigation. In particular, with a “plurality voting” procedure similar to our label propagation scheme, we can detect that recording `_030_03` from collection `CNRSMH_I_1974_013`³ is the most akin to the patterns of the Brazilian recordings. A short listening test confirms that the bell in this recording performs a rhythmic pattern similar to that of pattern 1 (the most common one in the Brazil subset).

7. DISCUSSION

We emphasize two important consequences of our study. Both observations emerge from our attempt to balance

³https://archives.crem-cnrs.fr/archives/items/CNRSMH_I_1974_013_030_03/

Figure 5: Excerpts of onset activations and their corresponding references. The same color coding of Figure 1 is used here.

Figure 6: Embedding of rhythmic features from Brazilian and Congolese bell patterns in the subset.

data-driven methodologies with more humanistic perspectives using the SDH framework.

Firstly, the non-negative matrix factorization presents a significant bottleneck in our analysis. Ideally, we would use source separation to isolate the bells from the track directly. However, the out-of-the-box Demucs model is trained only to separate 4-6 stems of specific Western instruments. A blind application of this model often results in an unpredictable placement of the bell patterns, as they may end up in the drum stem for one track, but in the “other” category for another. This inconsistency underscores the need for a more culturally-inclusive, tailored approach, such as the few-shot source separation model proposed in [32], or even a new perspective on source separation as a task. Improvements such as these could offer a more accurate and consistent separation of the bells, enhancing the rhythmic salience.

Secondly, despite the technical challenges produced by field recordings, our feature extraction pipeline has proven to be remarkably robust. Most importantly, it respects the unique characteristics of West African and Afro-diasporic music, particularly the concept of rhythmic cycles. Time

lines are qualitatively different from the concept of meter as a temporal hierarchical grouping mechanism and serve culture-specific purposes depending on the context of their use. While they can be mapped into meters due to their cyclic or recurrent nature, they often play “against” their metrical grid [12]. Anku [13] suggests that they should be perceived as a “circular concept” rather than a linear one, allowing performers to seamlessly enter and exit the performance with little inhibition. Our pipeline, which makes no assumptions regarding the notions of meter or downbeat and uses no annotations, was designed to respect these unique characteristics. The only attribute we infer is the cyclic nature of the rhythmic patterns to ease our computational load. Our minimal suppositions demonstrate the capacity of our methodology to expand to other styles of cyclic music, beyond what is studied in this paper.

8. CONCLUSION

We presented a pilot study investigating bell patterns in Candomblé from historical field recordings in a subset of the CREM archive, the CREM-NYUAD collection. Our approach is a preliminary venture in following the Sonic Digital Humanities (SDH) framework, to address the inherent challenges and complexities of applying computational methods to musical traditions which have been underrepresented in MIR. SDH aims to combine computational and ethnographic approaches in a dialogue on the same plane, while embracing any tensions which may entail in an agonistic fashion to push the traditional boundaries of interdisciplinarity [6].

Our study was influenced by the distinct characteristics of West African and Afro-diasporic music. Without requiring meter annotations, we could detect and classify patterns from the collection using a robust and adaptable pipeline, despite encountering challenging recording conditions and unique rhythmic structures. Our code is available at <https://github.com/nyuad-masc/crem-time-lines>. Future work will focus on addressing shortcomings and further refining our methods (e.g., source separation) to improve the analysis of time-line-based music traditions and allow the study of cross-cultural influences.

9. ETHICS STATEMENT

Our highest priority in this study is to respect the cultural heritage and to protect the privacy of the communities represented in the CREM-NYUAD collection. We recognize that every culture and tradition has nuances which cannot be captured by computational methods alone and should not be subjected to reductions or generalizations. Any analyses implemented using the materials from this corpus are solely for academic purposes in an effort to increase cultural diversity by establishing a dialogue between the humanities and music information research.

10. ACKNOWLEDGEMENTS

The authors would like to thank Mark Cartwright for his prior work extracting audio features from the CREM database, which serves as a crucial foundation for this and future research. We also thank Joséphine Simonnot, whose efforts were instrumental in the curation and acquisition of the CREM-NYUAD collection.
