

25th International Society for Music Information Retrieval Conference

ISMIR 2024

November 10-14, 2024
San Francisco, California, USA
and Online

Proceedings

ISMIR 2024 was organized by Blair Kaneshiro (Stanford University), Gautham Mysore (Adobe Research), Oriol Nieto (Adobe Research), Kennedy Knight (Conference Catalysts), and a diverse international committee of chairs and volunteers.

Preface

Message from the General Chairs

We are delighted to present the proceedings of the 25th International Society for Music Information Retrieval Conference, which took place in hybrid format in the vibrant city of San Francisco and online from November 10–14, 2024. This event marked a significant culmination of the efforts of the organizing team, transforming our ambitious vision into a memorable reality. The conference brought together a diverse and dynamic group of researchers, practitioners, and enthusiasts from around the globe, all united by a passion for music information research.

The planning for ISMIR 2024 began with a conviction that the San Francisco Bay Area, with its rich legacy in both AI and music, would provide an ideal background for the conference. Our team of organizers worked to ensure that every detail was meticulously planned, from selecting ideal venues (including a legendary music hall for the jam!) to managing logistics and securing sponsorships. Despite the high costs associated with the location, our commitment to inclusivity and accessibility allowed us to welcome a broad spectrum of attendees at the conference venue and online.

The 25th ISMIR conference introduced several exciting new elements. We embraced a **Special Theme**, "Bridging Technology and Musical Creativity", which was reflected in **Creative Practice** sessions designed to connect creative and research communities. We also implemented a form of **Open Review**, making several reviews and meta-reviews publicly available alongside accepted papers. We proudly presented the first-ever **Test of Time Award** and included presentations of recent **Transactions of the International Society for Music Information Retrieval (TISMIR) publications** in the scientific program. Finally, we appointed an **Accessibility Chair** who made significant cross-functional contributions in areas that are often overlooked.

The success of ISMIR 2024 is a testament to the collaborative spirit and innovative thinking that define the MIR community. We are proud to share the insights, research, and discussions that emerged from this conference, and we look forward to the continued growth and evolution of the field. Thank you to everyone who contributed to this year's ISMIR. We had a wonderful time organizing this busy yet epic event, and we sincerely hope that attendees enjoyed it as much as we did.

Blair Kaneshiro, Gautham Mysore, and Oriol Nieto
Anchorage, AK and San Francisco, CA
December 2024

Hybrid Conference

Recent virtual and hybrid ISMIR conferences have shown that remote participation options make the conference accessible to a broader range of participants. Accordingly, this year's conference was organized in a hybrid format, with goals of enabling all attendees—whether attending in person or online—to engage with the conference program, share their work, and interact with other attendees.

The hybrid format of ISMIR 2024 included the following:

- The organizing team included a dedicated Virtual Chair and Virtual Logistics Chairs.
- Remote presentation was freely offered—that is, without needing to request special permission—for ISMIR paper, TISMIR, and LBD submissions. Presenting authors were assigned to poster sessions according to their preferred availability. Tutorial presenters could also participate remotely, as long as at least one presenter for each Tutorial was onsite.
- The virtual conference ran on a 24-hour schedule so that each participant could attend from their preferred time zone. The program was designed around a primarily synchronous online experience to foster community and engagement amongst attendees. Both the original and replay sessions included a live Slack backchannel for Oral sessions (see "Diversity and Inclusion" section, below) as well as live online sessions. The virtual conference offered asynchronous options as well, including session recordings shared amongst attendees; the ability for attendees to access all papers and LBD materials via MiniConf; and dedicated Slack channels for each presentation so that attendees could interact with authors and keynotes.

- For the first time, the ISMIR conference included a Virtual Pre-Conference. This two-day event included keynotes and other sessions across global time zones.
- The organizers aimed to support each attendee’s preferred mode of presentation as much as possible, maximizing financial support to those wishing to attend in person and offering lower registration fees (and additional need-based discounts) for virtual attendees.
- Virtual platforms of the conference were streamlined to Slack, Zoom, and the online MiniConf program hosted on the conference website.
- Finally, onsite attendees were granted full virtual access to the conference, enabling them to attend original and replay sessions online, interact via Slack, and access session recordings.

Scientific Program

The ISMIR 2024 scientific program comprised 123 papers. A total of 346 submissions (up from 229 in 2023) were reviewed out of 410 abstracts that were registered on the submission system (up from 272 in 2023). In keeping with the practices of the previous years, a two-tier double-blind review process was conducted involving a total of 256 reviewers and 70 meta-reviewers. Each paper was assigned to a single meta-reviewer and at least three reviewers, and replacement reviewers were found when the originally assigned reviewer was unable to complete their review. Meta-reviewers were also instructed to complete a full review of each of their assigned papers, in addition to the final meta-review summarizing the individual reviews. Each meta-reviewer and reviewer was responsible for no more than 5 papers, in order that the reviewing load would be manageable, thus promoting careful and thorough reviews. The initial reviewing phase was followed by a discussion period, in which reviewers and meta-reviewers could discuss and revise their assessments of each paper. Meta-reviewers were then instructed to summarize the discussion and reviews in the final report. The Scientific Program Chairs (SPC) made the final decisions on each paper, based on the recommendations of meta-reviewers and reviewers. 124 papers were accepted (one of which was later withdrawn by the authors), giving an acceptance rate of 35.84%. The SPC would like to express their thanks to the ISMIR community of reviewers and meta-reviewers for their wholehearted support of this critical aspect of a successful ISMIR technical program.

Table 1 summarizes the number of reviewed and accepted papers in each subject area (as selected by authors during the submission process) together with the corresponding proportion of papers in the program. Table 2 summarizes the publication statistics over the 24-year history of the conference. In this table, we add the “Unique Authors” column to illustrate how many authors appear on more than one paper (i.e., if the columns “Authors” and “Unique Authors” would have the same number, then all authors would only appear on exactly one paper).

Table 1: Papers submitted and accepted by subject area

Subject Area	Submitted	Accepted	Accepted %
MIR tasks	94	35	37.2%
MIR fundamentals and methodology	38	13	34.2%
Musical features and properties	36	12	33.3%
Evaluation, datasets, reproducibility	34	13	38.2%
Generative Tasks	32	15	46.9%
Knowledge-driven approaches to MIR	30	9	30.0%
Applications	28	8	28.6%
Computational musicology	16	7	43.8%
Human-centered MIR	16	2	12.5%
Creativity	12	6	50.0%
Philosophical and ethical discussions	6	3	50.0%
MIR and machine learning for musical acoustics	4	0	0.0%
Total	346	123	35.5%

Table 2: Summary of publication statistics over the 25-year-history of the ISMIR conference

Year	Location	Oral	Poster	Total	Authors	Unique Authors	<u>Authors Paper</u>	<u>Unique Authors Paper</u>
2000	Plymouth	19	16	35	68	63	1.9	1.8
2001	Indiana	25	16	41	100	86	2.4	2.1
2002	Paris	35	22	57	129	117	2.3	2.1
2003	Baltimore	26	24	50	132	111	2.6	2.2
2004	Barcelona	61	44	105	252	214	2.4	2.0
2005	London	57	57	114	316	233	2.8	2.0
2006	Victoria	59	36	95	246	198	2.6	2.1
2007	Vienna	62	65	127	361	267	2.8	2.1
2008	Philadelphia	24	105	105	296	253	2.8	2.4
2009	Kobe	38	85	123	375	292	3.0	2.4
2010	Utrecht	24	86	110	314	263	2.0	2.4
2011	Miami	36	97	133	395	322	3.0	2.4
2012	Porto	36	65	101	324	264	3.2	2.6
2013	Curitiba	31	67	98	395	236	3.0	2.4
2014	Taipei	33	73	106	343	271	3.2	2.6
2015	Málaga	24	90	114	370	296	3.2	2.6
2016	New York	25	88	113	341	270	3.0	2.4
2017	Suzhou	24	73	97	324	248	3.3	2.6
2018	Paris			104	337	265	3.2	2.5
2019	Delft			114	390	315	3.4	2.8
2020	Virtual			115	426	343	3.7	3.0
2021	Virtual			104	334	269	3.2	2.6
2022	Bengaluru			113	423	355	3.8	3.0
2023	Milan			103	374	311	3.6	3.0
2024	San Francisco			123	497	433	4.0	3.5

Open Review

In recent years, the ISMIR community has discussed whether implementing an Open Review process would be of benefit. This year, the ISMIR 2024 General Chairs and Scientific Program Chairs, in consultation with the ISMIR Board, launched a pilot of Open Review, in which reviews of accepted papers were published when all authors, reviewers, and meta-reviewers of a given paper opted in. To do so, we discussed a potential Open Review framework, described as follows:

- **Consent for Publication:** We sought consent from all reviewers, meta-reviewers, and authors to publish their reviews and meta-reviews during the peer review process.
- **Anonymity:** All content was published anonymously to protect the identities of the reviewers and meta-reviewers.
- **Soft Release:** We conducted a soft release of the reviews to gauge the community’s reception.
- **Positive Reception:** The response was overwhelmingly positive. A total of 32 papers had all authors, reviewers, and meta-reviewers consenting to share their reviews and meta-reviews. These are now published and available in the official program.
- **Historical Milestone:** This marks the first time ISMIR has published some of its reviews, setting a precedent for future transparency in the review process.

Best Paper Awards

The selection process for Best Paper Awards varies from year to year, depending on the organizers of the conference. One goal of the ISMIR 2024 selection process was to come up with a model that can be applied more consistently in the future. Given the growth in the number of papers, we wanted to give awards to a more reasonable number of papers to acknowledge people's contributions. We recommend aiming to award Best Paper Awards to the top 3% of accepted papers and Honorable Mentions to the remaining papers in the top 10%. Unlike some past ISMIR conferences, we do not distinguish between Best Paper and Best Student Paper.

This year, the SPC selected 33 candidate papers (approximately 10% of all submissions) based on reviewers' and meta-reviewers' nominations as well as the paper review scores and comments. This year, given 123 accepted papers, we aimed for 3–4 Best Papers and 7–8 honorable mentions. We awarded 3 papers for Best Paper Award and 4 papers for Honorable Mention. The final selections were made by the SPCs, all of whom were MIR researchers who had no conflict of interest with any of the award candidates.

The following papers received the Best Paper Awards:

- *Six Dragons Fly Again: Reviving 15th-Century Korean Court Music with Transformers and Novel Encoding*, Danbinaerin Han, Mark R. H. Gotham, DongMin Kim, Hannah Park, Sihun Lee, Dasaem Jeong
- *ST-ITO: Controlling Audio Effects for Style Transfer with Inference-Time Optimization*, Christian J. Steinmetz, Shubhr Singh, Marco Comunità, Ilias Ibyahya, Shanxin Yuan, Emmanouil Benetos, Joshua D. Reiss
- *MuChoMusic: Evaluating Music Understanding in Multimodal Audio-Language Models*, Benno Weck, Ilaria Manco, Emmanouil Benetos, Elio Quinton, George Fazekas, Dmitry Bogdanov

Honorable Mentions were given to the following papers:

- *Cluster and Separate: A GNN Approach to Voice and Staff Prediction for Score Engraving*, Francesco Foscarin, Emmanouil Karystinaios, Eita Nakamura, Gerhard Widmer
- *Green MIR? Investigating Computational Cost of Recent Music-AI Research in ISMIR*, Andre Holzapfel, Anna-Kaisa Kaila, Petra Jääskeläinen
- *Formal Modeling of Structural Repetition using Tree Compression*, Zeng Ren, Yannis Rammos, Martin A. Rohrmeier
- *Scoring Intervals Using Non-Hierarchical Transformer for Automatic Piano Transcription*, Yujia Yan and Zhiyao Duan

Best Paper Awards or Honorable Mention awardees will be invited to submit extended versions of their ISMIR papers to the TISMIR journal; accepted papers will be published at no cost to the authors.

Best Reviewer Awards

The Best Reviewer Awards were determined based on specific criteria to ensure fairness and recognition of excellence. Award recipients achieved an average rating of 3/3, indicating they exceeded expectations across at least two reviews. Alternatively, reviewers could qualify with an average rating greater than 2/3, meaning they consistently met or exceeded expectations, over a minimum of five reviews. This dual-criteria approach ensured that both consistently high-performing reviewers and those who excelled in fewer but impactful reviews were acknowledged.

Congratulations to this year's Best Reviewer Awardees (listed in alphabetical order of first name):

- Akira Maezawa
- Alon Ziv
- Christian Steinmetz
- Dasaem Jeong
- Emilia Parada-Cabaleiro
- Fabian-Robert Stöter
- Jaehun Kim
- Lorenzo Porcaro
- Maximilian Schmitt
- Pablo Alonso-Jiménez
- Simon Durand
- Simon Schwär
- William Wilson

Test of Time Award

To commemorate the 25th anniversary of ISMIR, we introduced the Test of Time Award for the first time. This award aims to recognize research that has had a significant long-term impact on MIR.

Eligible candidates for this award included all ISMIR papers published from 2000, the year of the first ISMIR conference, to 2004. A total of 261 papers were considered. This year's recipient was selected by the ISMIR 2024 General Chairs.

For ISMIR 2024, the inaugural Test of Time Award was given to the paper titled "Automatic Musical Genre Classification of Audio Signals" by George Tzanetakis, George Essl, and Perry Cook, published at ISMIR 2001. This paper has had a profound impact on MIR and beyond, defining classic MIR tasks, remaining highly relevant to this day.

During the awards ceremony, the first author of the winning paper delivered a 10-minute presentation, highlighting the paper's contributions and its enduring influence on the field.

Accessibility

One goal of ISMIR 2024 was to make accessibility an intentional facet of the conference planning: We wanted to ensure that all attendees experienced a sense of inclusivity and belonging, whether attending in person or online. To this end, ISMIR 2024 welcomed its first-ever Accessibility Chair, who worked cross-functionally to ensure a number of accessibility factors were implemented for the conference:

- **Publication** best practices included recommendations and instructions for alt-text, color choice, and fonts; a captioning requirement and instructions for video submissions; and captioning of any session recordings that will be posted online.
- Various **onsite accessibility features** were confirmed with the conference venue including wheelchair accessibility, assistive listening devices available upon request, service animal accommodation, food labels, gender-neutral bathrooms, reader boards on every floor, and nearby public transportation options.
- Attendees' **name tags** included pronouns and language(s) spoken in order to communicate identities and how attendees would like to be addressed, and help attendees find others who speak their language.
- The conference supported onsite attendees who wished to take safety measures with regard to **COVID-19** by providing written guidelines for all attendees as well as freely available COVID-19 tests, KN95 masks, and hand sanitizer at the conference venue.
- Finally, a **virtual registration discount program** was implemented separately from the Grants program in order to make virtual attendance more accessible.

Diversity & Inclusion

The mission of Diversity, Equity, and Inclusion (DEI) work at ISMIR is to highlight the research contributions of MIR researchers from marginalized and underrepresented intersectional identities. As part of that work, the DEI efforts at the ISMIR conference seek to support, encourage, and advocate for researchers in MIR who occupy marginalized identities. Initiatives include highlighting work by MIR researchers through keynotes and talks, supporting conference registrations and accommodation grants at the conference hotel, bringing DEI experts from adjacent fields to help our community think more expansively, and periodically re-evaluating our efforts towards creating a more inclusive and equitable ISMIR conference and society.

This year as we thought about the 25th ISMIR, we wanted to take stock of our efforts as a conference towards inclusion and assess if we were engaging in Equity or Equality. As a result of those conversations, we decided it was time to "grow the I", shifting to the acronym at the conference level from WiMIR (meaning Women in MIR) to WIMIR (meaning Widening Inclusion in MIR), and to include many axes of diversity including geographic location and racial diversity. In truth we had already been doing that work to some degree, but we felt it was time to be more explicit.

This year, the DEI initiatives included programming both before and during the main conference. The overarching theme of this programming was the "Growing the I": Kicking off the rebranding of WiMIR → WIMIR. We had a DEI Session

in the Virtual Pre-Conference (see “Virtual Pre-Conference” section, below) and welcomed Dr. Valerie Joseph as the DEI Keynote speaker (see “Main Conference Keynotes” section, below). We introduced the new Slack Backchannel initiative to engage with our virtual attendees in a new way. We continued providing financial support through accommodation and registration grants, welcoming new attendees through Newcomer Initiatives, and mentoring prospective new authors in the New-to-ISMIR Paper Mentoring Program.

Slack Backchannel

New to ISMIR this year was the Slack Backchannel. For each of the 7 paper sessions, plus the replays, there was a host who offered running commentary on each session over Slack in real time. Paper authors were asked to submit interesting behind-the-scenes factoids about their papers, fun facts about themselves, and/or relevant background information about their work to help those new to the field contextualize their work. While not identical to a “hallway” track at the in-person conference, these hosts helped virtual attendees learn more about the presenters themselves as well as connect with in-person participants. There were numerous fun conversations had on the backchannel. We thank our backchannel hosts:

- Amélie Anglade
- Stefan Balke
- Dan Ellis
- Arthur Flexer

Grants

As part of ISMIR’s continued commitment to supporting new and diverse voices in the community, ISMIR 2024 offered the opportunity for presenters and attendees to apply for registration, accommodation, and childcare grants. Though anyone could apply, grants were awarded based on financial need, student and Diversity & Inclusion eligibility, and availability of funds. For registration waiver grants, the following funding categories were prioritized:

- Student: Applicants enrolled in a degree-granting academic program in the 2023-2024 and/or 2024-2025 academic year(s)
- Minorities in MIR: Applicants identifying as Black, African, African-American, or an ethnic/racial minority (of the applicant’s region)
- Applicant’s professional affiliation is in a low- or middle-income country
- Queer in MIR: Applicants identifying as LGBTQIA+
- Unaffiliated researcher: Applicants who currently have no professional affiliation that will cover the conference registration fee
- Women in MIR: Applicants identifying as a woman or other gender minority
- Caregiver: Applicants seek financial support to cover childcare costs so that they may attend the conference

This year, 91 people applied for financial support from the conference, for a total nearly double that of available funds. For ISMIR 2024, we were able to support 10 virtual registrations, 30 in-person registrations, and 12 accommodation grants.

Newcomer Initiatives

Multiple Newcomer Initiatives were carried out during ISMIR 2024, with the goal of helping less-experienced attendees get the most out of the conference and gain a foothold in the MIR community.

The first of these initiatives was a “Navigating the Conference” session that took place during the virtual pre-conference program. This session, led by the Newcomer Initiatives Chair, contained information about the ISMIR Society, the field of MIR, ISMIR 2024 online resources, as well as general advice on networking and attending an academic conference.

The “Newcomer Squads” initiative assigned groups of new attendees to experienced community members for the duration of the conference. The squads were connected via Slack and conducted meetups during the conference (either virtually or in-person). The 2024 Newcomer Squads featured 8 leaders and over 75 newcomers!

Finally, the “Anonymous Question Board” initiative provided a public space for attendees to ask questions anonymously. Question were submitted via a Google Form link, and could be viewed/answered in a Google Sheet.

We thank the following individuals (listed in alphabetical order of last name) for generously volunteering to lead Newcomer Squads at this year’s conference:

- Stefan Balke
- SeungHeon Doh
- Nick Gang
- Blair Kaneshiro
- Jin Ha Lee
- Brian McFee
- Ajay Srinivasamurthy
- Daniel Wolff

Late Breaking/Demo Session

As a forum for presenting prototype systems, initial concepts, and early research results, the Late Breaking/Demo (LBD) session has been growing steadily. This year, we accepted a record total of 81 submissions for both in-person and virtual presentations. We rejected 3 submissions that failed to adhere to the submission guidelines. It is worth noting that 50 submissions were self-identified as first-time attendees to ISMIR, showcasing the importance of LBD as the entry point for newcomers to engage with the ISMIR community. Based on the feedback from last year’s LBD chairs, we explicitly instructed the in-person presenters to interact with virtual attendees towards the end of the allocated presentation time. This change aimed to make LBD a more inclusive space for both in-person and virtual attendees. Despite not being part of the official proceedings, LBD offers a unique opportunity for both senior and junior members of the ISMIR community to socialize over exciting and interesting demos.

MIREX

The Music Information Retrieval Evaluation eXchange (MIREX) was established in 2005 to provide a platform for MIR researchers to compare and discuss their results. MIREX became an annual event at the ISMIR conference but paused after 2021 due to hosting challenges. Given its significance and community interest, MIREX is being revived in 2024 with plans to modernize it by introducing new platforms, tasks, and evaluation methods to keep pace with advancements in computer music research.

In this year’s MIREX, modern MIR tasks were added to reflect new directions in the MIR community. A Call for Challenges was also released to collect new tasks that the community was interested in. Two submissions were received that year, and one was selected for the MIREX 2024 task list (Singing Voice Deepfake Detection).

Since MIREX 2024 ran on limited scalability, the final MIREX 2024 task list included eight tasks as shown in Table 1, with three traditional MIR tasks and five modern MIR tasks.

Table 3: MIREX 2024 tasks. # Teams and # Subs denote the number of teams and submissions, respectively.

	Tasks	Submission Platform	# Teams	# Sub.
Traditional MIR Tasks	Audio Chord Estimation	Forum	0	0
	Lyrics-to-Audio Alignment	Forum	1	1
	Cover Song Identification	Email	3	3
Modern MIR Tasks	Symbolic Music Generation	Email	1	1
	Music Audio Generation	Email	1	1
	Music Description & Captioning	Codabench	4	15
	Polyphonic Transcription	Forum	3	3
	Singing Voice Deepfake Detection	Codabench	4	7

Instead of using the IMIRSEL submission system, new submission platforms were explored. A new submission forum was built for submissions and discussions, but task captains could freely choose their preferred method of receiving

submissions. In the end, three tasks adopted forum submission (i.e., submitting by posting on the forum), three tasks adopted email submission to the task captain, and two tasks adopted the Codabench platform.

Codabench is an online platform to organize AI benchmarks and host custom competitions. The task captain created an automatic evaluation system that could be used to update the leaderboard in real time. Participants did not have to upload their models to the platform. Instead, they received a public test set from the task captain and ran model inference on their own computational resources. The inference results were uploaded to Codabench for metric calculation and leaderboard updates.

This new submission process had many advantages. For example, it eliminated potential issues in sharing code with the task captain or configuring the model on the task captain's environment. It also showed popularity in practice. The two tasks using Codabench received 21 submissions from eight teams in total, surpassing all other submission platforms. It should be noted that Codabench is not suitable for some tasks. The fact that the test set is shared with participants may raise potential concerns, including difficulty in distributing proprietary test sets and test set contamination. Many tasks may have to adopt other methods of submission.

Since generative tasks were included that year, the idea of subjective evaluation was also explored. The task captain of symbolic music generation created a questionnaire containing samples of the submission and baselines generated under the same conditions. Listeners were asked to score the generated pieces according to their coherency, naturalness, creativity, and musicality in a blind listening test. Twenty-two responses were received and were used to calculate the results.

Out of eight tasks in MIREX 2024, seven tasks successfully received at least one submission. Among the tasks that received submissions, four tasks reported significantly better performance compared to baselines:

- In cover song detection, ByteDance's submission achieved the best performance using a ResNet architecture with a dimensional reduction module, while other systems also achieved impressive performance, like Discog-VI from MTG-Sony.
- In music audio generation, the team S1-CodecLM achieved better overall performance compared to baselines using a transformer decoder structure with two-stage semantic tokenization.
- In music description and captioning, the team ee895 achieved the highest ROUGE-L score among all entries using Llama and the Joint Music and Language Attention (JMLA) architecture. The architecture was also used in other entries like CUHKDSP.
- In singing voice deepfake detection, the submission UNIBS1 achieved the lowest error rate on both test sets with a ResNet model that received a log-spectrogram of the vocal sound as input. Other submissions also used WavLM, SingGraph, or ensemble methods.

The Future of MIREX

We want to gradually recover the scalability of MIREX and make it a yearly event for the ISMIR community. More tasks are planned for MIREX 2025 with a new call for challenge proposals. The submission platform will be more formal with better guidance. Besides that, we also want to gradually introduce other improvements over the years.

- **Open:** To make the evaluation process transparent and open-sourced, and also to encourage (but not force) submissions to be open-sourced.
- **Interactive:** To make the evaluation process more interactive, e.g., automatic evaluation for real-time leaderboards on more tasks.
- **Modernized:** To host more emergent MIR tasks while refining traditional tasks, making MIREX keep pace with the community's rapid advancements.

Finally, the time and efforts of the ISMIR organizers, all task captains, participants, and MIREX 2024 organizers are greatly appreciated.

Unconference

An Unconference was held both during the pre-conference and on the last day of the conference, immediately following the Society Meeting. Discussion topics were proposed using the Dotstorming platform, and participants voted live using the Wooclap platform. Two rounds of discussions took place, each lasting 45 minutes. Afterward, the secretary of each discussion group presented a summary of their group's discussion results to all participants, including those attending via Zoom. The following topics were discussed:

- Safety and human rights considerations for selecting ISMIR conference venues for members of the community
- What will be the next direction in Music Research?
- Change our name from Music Information Retrieval to Music Information Research?
- Moving away from Twitter (and other questionable organizations)
- GenAI Copyright/ GenAI Cultural Diversity
- Open Review

Social Program

The Social Program this year contained the following activities:

- Concert by Camilo y Los Cruzers at the Welcome Reception during the first night at ISMIR
- Concert by Wil Blades during the official ISMIR Banquet
- Jam Session during the Banquet, with over 40 sets of performers sign ups

Additionally, the Social Chairs assembled a list of restaurants/bars/music venues near the conference hotel, which was published on the ISMIR website.

Hackathon

HAMR: Hacking Audio and Music Research was rebranded as Highlighting Audio and Music Researchathon for 2024. HAMR took place after the conference on Saturday, November 16 in San Francisco. The event applied the hackathon model to the development of new techniques for analyzing, processing, and synthesizing audio and music signals. This was a free event open to researchers and hackers from any stage in their career.

The hackathon was an all-day event with around 20 participants. Individuals and teams worked on research projects, or took time to catch up on personal work, review conference materials, and socialize and brainstorm for future projects.

The organizers thank Replicate (<https://replicate.com/>) for offering up their hackage for the ISMIR 2024 Hackathon.

Satellite Events

In addition to the main conference, ISMIR 2024 included the following satellite events hosted around the dates of the conference:

- **3rd Workshop on NLP for Music and Audio (NLP4Musa 2024)**
November 15, 2024, Oakland, CA, USA
Website: <https://sites.google.com/view/nlp4musa-2024>
- **HAMR 2024: Music and Audio Hackathon**
November 16, 2024, San Francisco, CA, USA
Website: <https://partiful.com/e/pnNRBcvgLBf0Jej9QX36>
- **6th International Workshop on Reading Music Systems (WoRMS 2024)**
November 22, 2024, Online
Website: <https://sites.google.com/view/worms2024>
- **1st Latin American Music Information Retrieval Workshop (LAMIR)**
December 9–11, 2024, Rio de Janeiro, BR
Website: <https://lamir-workshop.github.io/>

Acknowledgements

We are happy to present to you the proceedings of ISMIR 2024. The conference program was made possible thanks to the hard work of many people, including the ISMIR 2024 conference chairs, ISMIR Board members, volunteers, and the many reviewers and meta-reviewers from the program committee.

We would also like to thank our sponsors, whose contributions made this conference possible:

Diamond sponsor

- Music.AI

Platinum sponsor

- Adobe

Gold sponsors

- ByteDance
- Google
- Riffusion
- Splice
- Suno

Silver sponsors

- Deezer
- Pro Sound Effects
- Steinberg
- Universal Music Group
- Yamaha

Bronze sponsors

- Audible Magic
- BMAT
- Cochlear
- Dolby
- Kits.ai
- Netflix
- SiriusXM
- Yousician

We would like to thank the sponsors that explicitly chose to sponsor WiMIR, its grants, and its initiatives:

Patrons

- Adobe
- Deezer

Contributor

- Music.AI

Supporters

- Kits.ai
- Pro Sound Effects
- Riffusion
- Steinberg
- Yousician

ISMIR 2024 would not have been possible without the exceptional contributions of our community in response to our call for participation. The biggest acknowledgment goes to you, the researchers, presenters and participants.

Chris Donahue

General Chairs

Table of Contents

Virtual Pre-Conference	1
Keynote Talks	3
The Advent of Quantum Computer Music	
<i>Eduardo Miranda</i>	3
The MIR Field: From Knowledge to Data-Driven, from Features to Ethical and Regulatory Considerations	
<i>Emilia Gómez</i>	4
Invited Presentations and Sessions	5
Keynote Talks	7
Towards a Fairer Approach to Generative AI Training	
<i>Ed Newton-Rex</i>	9
Listening For Diversity: The Ways in Which Critical Attention to Words Helps Move Us Closer Towards Realizing Our Full Humanity	
<i>Valerie Joseph</i>	10
Navigating the Intersection of AI and Music: Innovation, Ethics, and the Future of the Industry	
<i>Elizabeth Moody</i>	12
Status Report: AI Music in Q1 of the 21st Century	
<i>Douglas Eck</i>	13
Tutorials	15
Connecting Music Audio and Natural Language	
<i>SeungHeon Doh, Ilaria Manco, Zachary Novack, Jongwook Kim, and Ke Chen</i>	17
Exploring 25 Years of Music Information Retrieval: Perspectives and Insights	
<i>Masataka Goto, Jin Ha Lee, and Meinard Müller</i>	19
From White Noise to Symphony: Diffusion Models for Music and Sound	
<i>Chieh-Hsin Lai, Koichi Saito, Bac Nguyen Cong, Yuki Mitsufuji, and Stefano Ermon</i>	21
Humans at the Center of MIR: Human-subjects Research Best Practices	
<i>Claire Arthur, Nat Condit-Schultz, David R. W. Sears, John Ashley Burgoyne, and Josuha Albrecht</i>	22
Deep Learning 101 for Audio-based MIR	
<i>Geoffroy Peeters, Gabriel Meseguer Brocal, Alain Riou, and Stefan Lattner</i>	24
Lyrics and Singing Voice Processing in Music Information Retrieval: Analysis, Alignment, Transcription and Applications	
<i>Daniel Stoller, Emir Demirel, Kento Watanabe, and Brendan O'Connor</i>	26

Special Session: Remembering Don Byrd	29
Creative Practice Sessions	33
Industry Sessions	37
Live Online Sessions	41
TISMIR Presentations	47
Papers – Session I	51
Formal Modeling of Structural Repetition Using Tree Compression <i>Zeng Ren, Yannis Rammos, Martin A. Rohrmeier</i>	53
Saraga Audiovisual: A Large Multimodal Open Data Collection for the Analysis of Carnatic Music <i>Adithi Shankar, Genís Plaja-Roglans, Thomas Nuttall, Martín Rocamora, Xavier Serra</i>	61
X-Cover: Better Music Version Identification System by Integrating Pretrained ASR Model <i>Xingjian Du, Mingyu Liu, Pei Zou, Xia Liang, Zijie Wang, Huidong Liang, Bilei Zhu</i>	70
Harmonic and Transposition Constraints Arising From the Use of the Roland TR-808 Bass Drum <i>Emmanuel Deruty</i>	78
FruitsMusic: A Real-World Corpus of Japanese Idol-Group Songs <i>Hitoshi Suda, Shunsuke Yoshida, Tomohiko Nakamura, Satoru Fukayama, Jun Ogata</i>	86
Classical Guitar Duet Separation Using GuitarDuets - A Dataset of Real and Synthesized Guitar Recordings <i>Marios Glytsos, Christos Garoufis, Athanasia Zlatintsi, Petros Maragos</i>	95
Can LLMs "Reason" in Music? an Evaluation of LLMs' Capability of Music Understanding and Generation <i>Ziya Zhou, Yuhang Wu, Zhiyue Wu, Xinyue Zhang, Ruibin Yuan, Yinghao Ma, Lu Wang, Emmanouil Benetos, Wei Xue, Yike Guo</i>	103
Music2Latent: Consistency Autoencoders for Latent Audio Compression <i>Marco Pasini, Stefan Lattner, George Fazekas</i>	111
Robust and Accurate Audio Synchronization Using Raw Features From Transcription Models <i>Johannes Zeitler, Ben Maman, Meinard Müller</i>	120
Harnessing the Power of Distributions: Probabilistic Representation Learning on Hypersphere for Multimodal Music Information Retrieval <i>Takayuki Nakatsuka, Masahiro Hamasaki, Masataka Goto</i>	128
Towards Automated Personal Value Estimation in Song Lyrics <i>Andrew M. Demetriou, Jaehun Kim, Sandy Manolios, Cynthia Liem</i>	137
Audio Conditioning for Music Generation via Discrete Bottleneck Features <i>Simon Rouard, Yossi Adi, Jade Copet, Axel Roebel, Alexandre Défossez</i>	146
Variation Transformer: New Datasets, Models, and Comparative Evaluation for Symbolic Music Variation Generation <i>Chenyu Gao, Federico Reuben, Tom Collins</i>	154
Automatic Detection of Moral Values in Music Lyrics <i>Vjosa Preniqi, Iacopo Ghinassi, Julia Ive, Kyriaki Kalimeri, Charalampos Saitis</i>	164

Semi-Supervised Piano Transcription Using Pseudo-Labeling Techniques <i>Sebastian Strahl, Meinard Müller</i>	173
Note-Level Transcription of Choral Music <i>Huiran Yu, Zhiyao Duan</i>	182
Learning Multifaceted Self-Similarity Over Time and Frequency for Music Structure Analysis <i>Tsung-Ping Chen, Kazuyoshi Yoshii</i>	189
A Contrastive Self-Supervised Learning Scheme for Beat Tracking Amenable to Few-Shot Learning <i>Antonin Gagneré, Slim Essid, Geoffroy Peeters</i>	198
Using Pairwise Link Prediction and Graph Attention Networks for Music Structure Analysis <i>Morgan Buisson, Brian McFee, Slim Essid</i>	207
Papers – Session II	215
Six Dragons Fly Again: Reviving 15th-Century Korean Court Music With Transformers and Novel Encoding <i>Danbinaerin Han, Mark R. H. Gotham, DongMin Kim, Hannah Park, Sihun Lee, Dasaem Jeong</i>	217
Lessons Learned From a Project to Encode Mensural Music on a Large Scale With Optical Music Recognition <i>David Rizo, Jorge Calvo-Zaragoza, Patricia García-Iasci, Teresa Delgado-Sánchez</i>	225
The Changing Sound of Music: An Exploratory Corpus Study of Vocal Trends Over Time <i>Elena Georgieva, Pablo Ripollés, Brian McFee</i>	232
Music Proofreading With RefinPaint: Where and How to Modify Compositions Given Context <i>Pedro Ramoneda, Martín Rocamora, Taketo Akama</i>	240
Notewise Evaluation for Music Source Separation: A Case Study for Separated Piano Tracks <i>Yigitcan Özer, Hans-Ulrich Berendes, Vlora Arifi-Müller, Fabian-Robert Stöter, Meinard Müller</i>	248
Automatic Estimation of Singing Voice Musical Dynamics <i>Jyoti Narang, Nazif Can Tamer, Viviana De La Vega, Xavier Serra</i>	256
Joint Audio and Symbolic Conditioning for Temporally Controlled Text-to-Music Generation <i>Or Tal, Alon Ziv, Itai Gat, Felix Kreuk, Yossi Adi</i>	264
Diff-a-Riff: Musical Accompaniment Co-Creation via Latent Diffusion Models <i>Javier Nistal, Marco Pasini, Cyran Aouameur, Maarten Grachten, Stefan Lattner</i>	272
Exploring Internet Radio Across the Globe With the MIRAGE Online Dashboard <i>Ngan V.T. Nguyen, Elizabeth Acosta, Tommy Dang, David Sears</i>	281
MIDI-to-Tab: Guitar Tablature Inference via Masked Language Modeling <i>Andrew C. Edwards, Xavier Riley, Pedro Pereira Sarmiento, Simon Dixon</i>	288
Transcription-Based Lyrics Embeddings: Simple Extraction of Effective Lyrics Embeddings From Audio <i>Jaehun Kim, Florian Henkel, Camilo Landau, Samuel E. Sandberg, Andreas F. Ehmann</i>	295
A Method for MIDI Velocity Estimation for Piano Performance by a U-Net With Attention and FiLM <i>Hyon Kim, Xavier Serra</i>	304
MusiConGen: Rhythm and Chord Control for Transformer-Based Text-to-Music Generation <i>Yun-Han Lan, Wen-Yi Hsiao, Hao-Chung Cheng, Yi-Hsuan Yang</i>	311
End-to-End Piano Performance-MIDI to Score Conversion With Transformers <i>Tim Beyer, Angela Dai</i>	319

From Real to Cloned Singer Identification <i>Dorian Desblancs, Gabriel Meseguer-Brocal, Romain Hennequin, Manuel Moussallam</i>	327
Emotion-Driven Piano Music Generation via Two-Stage Disentanglement and Functional Representation <i>Jingyue Huang, Ke Chen, Yi-Hsuan Yang</i>	335
Efficient Adapter Tuning for Joint Singing Voice Beat and Downbeat Tracking With Self-Supervised Learning Features <i>Jiajun Deng, Yaolong Ju, Jing Yang, Simon Lui, Xunying Liu</i>	343
Which Audio Features Can Predict the Dynamic Musical Emotions of Both Composers and Listeners? <i>Eun Ji Oh, Hyunjae Kim, Kyung Myun Lee</i>	352
Exploring Musical Roots: Applying Audio Embeddings to Empower Influence Attribution for a Generative Music Model <i>Julia Barnett, Hugo Flores García, Bryan Pardo</i>	360
Papers – Session III	369
Green MIR? Investigating Computational Cost of Recent Music-Ai Research in ISMIR <i>Andre Holzapfel, Anna-Kaisa Kaila, Petra Jääskeläinen</i>	371
Field Study on Children’s Home Piano Practice: Developing a Comprehensive System for Enhanced Student-Teacher Engagement <i>Seikoh Fukuda, Yuko Fukuda, Masamichi Hosoda, Ami Motomura, Eri Sasao, Masaki Matsubara, Masahiro Niitsuma</i>	381
Inner Metric Analysis as a Measure of Rhythmic Syncopation <i>Brian Bemman, Justin Christensen</i>	389
HAISP: A Dataset of Human-AI Songwriting Processes From the AI Song Contest <i>Lidia J. Morris, Rebecca Leger, Michele Newman, John Ashley Burgoyne, Ryan Groves, Natasha Mangal, Jin Ha Lee</i>	397
Cue Point Estimation Using Object Detection <i>Giulia Argüello, Luca A. Lanzendörfer, Roger Wattenhofer</i>	405
The ListenBrainz Listens Dataset <i>Kartik Ohri, Robert Kaye</i>	413
SpecMaskGIT: Masked Generative Modeling of Audio Spectrogram for Efficient Audio Synthesis and Beyond <i>Marco Comunità, Zhi Zhong, Akira Takahashi, Shiqi Yang, Mengjie Zhao, Koichi Saito, Yukara Ikemiya, Takashi Shibuya, Shusuke Takahashi, Yuki Mitsufuji</i>	420
Long-Form Music Generation With Latent Diffusion <i>Zach Evans, Julian D. Parker, CJ Carr, Zachary Zukowski, Josiah Taylor, Jordi Pons</i>	429
Composer’s Assistant 2: Interactive Multi-Track MIDI Infilling With Fine-Grained User Control <i>Martin E. Malandro</i>	438
Towards Zero-Shot Amplifier Modeling: One-to-Many Amplifier Modeling via Tone Embedding Control <i>Yu-Hua Chen, Yen-Tung Yeh, Yuan-Chiao Cheng, Jui-Te Wu, Yu-Hsiang Ho, Jyh-Shing Roger Jang, Yi-Hsuan Yang</i>	446
Mel-RoFormer for Vocal Separation and Vocal Melody Transcription <i>Ju-Chiang Wang, Wei-Tsung Lu, Jitong Chen</i>	454

Unsupervised Synthetic-to-Real Adaptation for Optical Music Recognition <i>Noelia N. Luna-Barahona, Adrián Roselló, María Alfaro-Contreras, David Rizo, Jorge Calvo-Zaragoza</i>	462
MMT-BERT: Chord-Aware Symbolic Music Generation Based on Multitrack Music Transformer and MusicBERT <i>Jinlong Zhu, Keigo Sakurai, Ren Togo, Takahiro Ogawa, Miki Haseyama</i>	470
Discogs-VI: A Musical Version Identification Dataset Based on Public Editorial Metadata <i>Recep Oguz Araz, Xavier Serra, Dmitry Bogdanov</i>	478
Who’S Afraid of the ‘Artyfyshall Byrd’? Historical Notions and Current Challenges of Musical Artificiality <i>Nicholas Cornia, Bruno Forment</i>	486
End-to-End Automatic Singing Skill Evaluation Using Cross-Attention and Data Augmentation for Solo Singing and Singing With Accompaniment <i>Yaolong Ju, Chun Yat Wu, Betty Cortiñas Lorenzo, Jing Yang, Jiajun Deng, Fan Fan, Simon Lui</i>	493
Papers – Session IV	501
Cluster and Separate: A GNN Approach to Voice and Staff Prediction for Score Engraving <i>Francesco Foscarin, Emmanouil Karystinaios, Eita Nakamura, Gerhard Widmer</i>	503
From Audio Encoders to Piano Judges: Benchmarking Performance Understanding for Solo Piano <i>Huan Zhang, Jinhua Liang, Simon Dixon</i>	511
Towards Explainable and Interpretable Musical Difficulty Estimation: A Parameter-Efficient Approach <i>Pedro Ramoneda, Vsevolod E. Eremenko, Alexandre D’Hooge, Emilia Parada-Cabaleiro, Xavier Serra</i>	520
Purposeful Play: Evaluation and Co-Design of Casual Music Creation Applications With Children <i>Michele Newman, Lidia J. Morris, Jun Kato, Masataka Goto, Jason Yip, Jin Ha Lee</i>	529
El Bongosero: A Crowd-Sourced Symbolic Dataset of Improvised Hand Percussion Rhythms Paired With Drum Patterns <i>Nicholas Evans, Behzad Haki, Daniel Gómez-Marín, Sergi Jordà</i>	540
Utilizing Listener-Provided Tags for Music Emotion Recognition: A Data-Driven Approach <i>Joanne Affolter, Martin A. Rohrmeier</i>	547
PiCoGen2: Piano Cover Generation With Transfer Learning Approach and Weakly Aligned Data <i>Chih-Pin Tan, Hsin Ai, Yi-Hsin Chang, Shuen-Huei Guan, Yi-Hsuan Yang</i>	555
Diff-MST: Differentiable Mixing Style Transfer <i>Soumya Sai Vanka, Christian J. Steinmetz, Jean-Baptiste Rolland, Joshua D. Reiss, George Fazekas</i>	563
Semi-Supervised Contrastive Learning of Musical Representations <i>Julien PM Guinot, Elio Quinton, George Fazekas</i>	571
Improved Symbolic Drum Style Classification With Grammar-Based Hierarchical Representations <i>Léo Géré, Nicolas Audebert, Philippe Rigaux</i>	580
Nested Music Transformer: Sequentially Decoding Compound Tokens in Symbolic Music and Audio Generation <i>Jiwoo Ryu, Hao-Wen Dong, Jongmin Jung, Dasaem Jeong</i>	588
Continual Learning for Music Classification <i>Pedro González-Barrachina, María Alfaro-Contreras, Jorge Calvo-Zaragoza</i>	596
TheGlueNote: Learned Representations for Robust and Flexible Note Alignment <i>Silvan Peter, Gerhard Widmer</i>	603

GAPS: A Large and Diverse Classical Guitar Dataset and Benchmark Transcription Model <i>Xavier Riley, Zixun Guo, Andrew C. Edwards, Simon Dixon</i>	611
A Kalman Filter Model for Synchronization in Musical Ensembles <i>Hugo T. Carvalho, Min Susan Li, Massimiliano Di Luca, Alan M. Wing</i>	618
Stem-JEPA: A Joint-Embedding Predictive Architecture for Musical Stem Compatibility Estimation <i>Alain Riou, Stefan Lattner, Gaëtan Hadjeres, Michael Anslow, Geoffroy Peeters</i>	625
Audio Prompt Adapter: Unleashing Music Editing Abilities for Text-to-Music With Lightweight Finetuning <i>Fang Duo Tsai, Shih-Lun Wu, Haven Kim, Bo-Yu Chen, Hao-Chung Cheng, Yi-Hsuan Yang</i>	634
MelodyT5: A Unified Score-to-Score Transformer for Symbolic Music Processing <i>Shangda Wu, Yashan Wang, Xiaobing Li, Feng Yu, Maosong Sun</i>	642
GraphMuse: A Library for Symbolic Music Graph Processing <i>Emmanouil Karystinaios, Gerhard Widmer</i>	651
Papers – Session V	659
ST-ITO: Controlling Audio Effects for Style Transfer With Inference-Time Optimization <i>Christian J. Steinmetz, Shubhr Singh, Marco Comunità, Ilias Ibyahya, Shanxin Yuan, Emmanouil Benetos, Joshua D. Reiss</i>	661
ComposerX: Multi-Agent Symbolic Music Composition With LLMs <i>Qixin Deng, Qikai Yang, Ruibin Yuan, Yipeng Huang, Yi Wang, Xubo Liu, Zeyue Tian, Jiahao Pan, Ge Zhang, Hanfeng Lin, Yizhi Li, Yinghao Ma, Jie Fu, Chenghua Lin, Emmanouil Benetos, Wenwu Wang, Guangyu Xia, Wei Xue, Yike Guo</i>	669
Do Music Generation Models Encode Music Theory? <i>Megan Wei, Michael Freeman, Chris Donahue, Chen Sun</i>	680
PolySinger: Singing-Voice to Singing-Voice Translation From English to Japanese <i>Silas Antonisen, Iván López-Espejo</i>	688
On the Validity of Employing ChatGPT for Distant Reading of Music Similarity <i>Arthur Flexer</i>	697
Sanidha: A Studio Quality Multi-Modal Dataset for Carnatic Music <i>Venkatakrishnan Vaidyanathapuram Krishnan, Noel Alben, Anish A. Nair, Nathaniel Condit-Schultz</i>	705
Between the AI and Me: Analysing Listeners’ Perspectives on AI- and Human-Composed Progressive Metal Music <i>Pedro Pereira Sarmiento, Jackson J. Loth, Mathieu Barthet</i>	713
Combining Audio Control and Style Transfer Using Latent Diffusion <i>Nils Demerlé, Philippe Esling, Guillaume Doras, David Genova</i>	721
Computational Analysis of Yaredawi YeZema Silt in Ethiopian Orthodox Tewahedo Church Chants <i>Mequanent Argaw Muluneh, Yan-Tsung Peng, Li Su</i>	729
Lyrics Transcription for Humans: A Readability-Aware Benchmark <i>Ondřej Čířka, Hendrik Schreiber, Luke Miner, Fabian-Robert Stöter</i>	737
A Critical Survey of Research in Music Genre Recognition <i>Owen Green, Bob L. T. Sturm, Georgina Born, Melanie Wald-Fuhrmann</i>	745
Content-Based Controls for Music Large Language Modeling <i>Liwei Lin, Gus Xia, Junyan Jiang, Yixiao Zhang</i>	783

Exploring the Inner Mechanisms of Large Generative Music Models <i>Marcel A. Vélez Vásquez, Charlotte Pouw, John Ashley Burgoyne, Willem Zuidema</i>	791
Quantitative Analysis of Melodic Similarity in Music Copyright Infringement Cases <i>Saebyul Park, Halla Kim, Jiye Jung, Juyong Park, Jeounghoon Kim, Juhan Nam</i>	799
Robust Lossy Audio Compression Identification <i>Hendrik Vincent Koops, Gianluca Micchi, Elio Quinton</i>	807
RNBert: Fine-Tuning a Masked Language Model for Roman Numeral Analysis <i>Malcolm Sailor</i>	814
Papers – Session VI	823
MuChoMusic: Evaluating Music Understanding in Multimodal Audio-Language Models <i>Benno Weck, Ilaria Manco, Emmanouil Benetos, Elio Quinton, George Fazekas, Dmitry Bogdanov</i>	825
Human Pose Estimation for Expressive Movement Descriptors in Vocal Musical Performances <i>Sujoy Roychowdhury, Preeti Rao, Sharat Chandran</i>	834
Enhancing Predictive Models of Music Familiarity With EEG: Insights From Fans and Non-Fans of K-Pop Group NCT127 <i>Seokbeom Park, Hyunjae Kim, Kyung Myun Lee</i>	842
Mosaikbox: Improving Fully Automatic DJ Mixing Through Rule-Based Stem Modification and Precise Beat-Grid Estimation <i>Robert Sowula, Peter Knees</i>	850
MidiCaps: A Large-Scale MIDI Dataset With Text Captions <i>Jan Melechovsky, Abhinaba Roy, Dorien Herremans</i>	858
A New Dataset, Notation Software, and Representation for Computational Schenkerian Analysis <i>Stephen Ni-Hahn, Weihan Xu, Zirui Yin, Rico Zhu, Simon Mak, Yue Jiang, Cynthia Rudin</i>	866
DITTO-2: Distilled Diffusion Inference-Time T-Optimization for Music Generation <i>Zachary Novack, Julian McAuley, Taylor Berg-Kirkpatrick, Nicholas J. Bryan</i>	874
The Concatenator: A Bayesian Approach to Real Time Concatenative Mosaicing <i>Christopher J. Tralie, Ben Cantil</i>	882
Deep Recombinant Transformer: Enhancing Loop Compatibility in Digital Music Production <i>Muhammad Taimoor Haseeb, Ahmad Hammoudeh, Gus Xia</i>	890
I Can Listen but Cannot Read: An Evaluation of Two-Tower Multimodal Systems for Instrument Recognition <i>Yannis Vasilakis, Rachel Bittner, Johan Pauwels</i>	897
Streaming Piano Transcription Based on Consistent Onset and Offset Decoding With Sustain Pedal Detection <i>Weixing Wei, Jiahao Zhao, Yulun Wu, Kazuyoshi Yoshii</i>	906
Towards Universal Optical Music Recognition: A Case Study on Notation Types <i>Juan Carlos Martinez-Sevilla, David Rizo, Jorge Calvo-Zaragoza</i>	914

Virtual Pre-Conference

The Virtual Pre-Conference was a new initiative this year and took place completely online from October 28–30 across global time zones. The Virtual Pre-Conference was organized with the goals of giving all attendees an opportunity to begin networking—whether attending the main conference online or in person; and helping newcomers gain context on the ISMIR conference and broader community.

The ISMIR 2024 Virtual Pre-Conference was organized by the General Chairs and Virtual Chair, and featured two keynote talks, invited presentations from conference and community organizers, social events, and informal topic-based discussion sessions.

Keynote Talks

Keynote Talk – 1

The Advent of Quantum Computer Music

Eduardo Miranda

University of Plymouth, UK

Abstract

Quantum computing technology is developing at a fast pace. The impact of quantum computing on the music industry is inevitable. The emerging field of Quantum Computer Music investigates and develops applications and methods to process music using quantum computing technology. This talk will discuss examples of approaches to leverage quantum computing to learn, process and generate music. The methods discussed range from rendering music using data from physical quantum mechanical systems and quantum mechanical simulations to computational quantum algorithms to generate music, including quantum AI. The ambition to develop techniques to encode audio quantumly for making sound synthesisers and audio signal processing systems is also discussed.

Biography

Eduardo Reck Miranda is a classically trained composer and computer scientist. He has composed for renowned ensembles such as the BBC Concert Orchestra, Scottish Chamber Orchestra and London Sinfonietta. He is a Professor of Computer Music at the University of Plymouth, UK, and works with at Moth, a quantum technology company building the next era of music, gaming and the arts. Prof Miranda published over 100 research papers in learned journals and 16 books. He is world-renowned for his groundbreaking work in AI and music. He is a pioneer of quantum computing with a focus on creativity and music composition. His latest book, *Quantum Computer Music*, comprising a collection of chapters by leading practitioners in the field, was published in 2022 by Springer Nature.

Keynote Talk – 2

The MIR Field: From Knowledge to Data-Driven, from Features to Ethical and Regulatory Considerations

Emilia Gómez

European Commission's Joint Research Centre, ES

Abstract

This talk focuses on audio-based music information retrieval (MIR) and reflects on the origins of the field, the different MIR eras, and the recent developments. I will first focus on the paradigm shift from knowledge-driven to data-driven algorithmic design, thanks to recent developments in machine learning. After that, I will discuss the current challenges that the MIR field addresses and the current and future research challenges, notably on the social and ethical impact of MIR algorithmic systems.

Biography

Dr. Emilia Gómez (MSc. Telecommunication Engineering, PhD in Computer Science, Full professor accreditation) is a senior scientist at the European Commission's Joint Research Centre, where she leads the Human Behaviour and Machine Intelligence (HUMAIN) team that provides scientific support to EU AI policies as part of the European Centre for Algorithmic Transparency, notably the AI Act and the Digital Services Act. She is also a guest professor in Music Technology at Universitat Pompeu Fabra in Barcelona, Spain.

Dr. Gómez has a long academic experience in the field of Music Information Retrieval, where she has contributed to different approaches for music content description, notably in pitch-content description. Starting from the music domain, she now studies the impact of AI in human behaviour, notably how AI affects jobs, decisions, fundamental rights and children. She was the first female president of ISMIR, is currently a member of the OECD One AI expert group, an ELLIS (European Laboratory for Learning and Intelligent systems) fellow, and her work has been recognized by means of citations and honors, e.g. EUWomen4Future, Red Cross Award to Humanitarian Technologies or ICREA Academia.

Invited Presentations and Sessions

DEI and “Growing the I”

Presenter: Katherine M. Kinnaird (ISMIR 2024 DEI Chair)

Ideation Session

Session host: Vinoo Alluri (ISMIR 2024 Virtual Chair)

ISMIR Board

Presenters: Emmanouil Benetos, Carlos Cancino-Chacón, Ajay Srinivasamurthy (representing the ISMIR Board)

ISMIR Ethics Working Group

Presenters: Fabio Morreale, Pedro Sarmiento (representing the ISMIR Ethics Working Group Organizers)

Open Review at ISMIR

Presenters: Magdalena Fuentes, Blair Kaneshiro, Oriol Nieto, Geoffroy Peeters (representing the ISMIR Open Review Working Group)

Navigating the ISMIR Conference

Presenter: Nick Gang (ISMIR 2024 Newcomer Initiatives Chair)

New-to-ISMIR Paper Mentoring Program

Presenter: Ajay Srinivasamurthy (representing the ISMIR 2024 New-to-ISMIR Paper Mentoring Program Chairs)

TISMIR

Presenter: Meinard Müller (representing the TISMIR Editors-in-Chief)

Unconference

Session host: Geoffroy Peeters (ISMIR 2024 Unconference Chair)

WiMIR Mentoring Program

Presenters: Yun-Ning (Amy) Hung, Zafar Rafii (representing the WiMIR Mentoring Program Organizers)

Keynote Talks

Keynote Talk – 1

Towards a Fairer Approach to Generative AI Training

Ed Newton-Rex

Fairly Trained

Abstract

Ed will discuss the issues that arise when generative AI companies scrape training data without consent, and the alternative - licensing training data - that is being embraced by many AI music companies.

Biography

Ed Newton-Rex is the founder of Fairly Trained, a non-profit that certifies generative AI companies for fair training data practices. He is also a Visiting Scholar at Stanford University.

In 2010, Ed founded Jukedeck, one of the first AI music generation startups. Jukedeck let video creators generate music for their videos, and was used to create more than a million pieces of music. It was acquired by ByteDance in 2019. At ByteDance, Ed led the AI Music lab, then led Product for TikTok in Europe.

In 2022 Ed joined Stability AI, the company behind Stable Diffusion, to lead their Audio team. His team launched Stable Audio, Stability's music generation product, which was named one of TIME Magazine's best inventions of the year in 2023. He resigned from Stability in November 2023 due to the company's policy of training AI models on copyrighted work without consent, and in 2024 founded Fairly Trained. He is a published composer of choral music.

DEI Keynote

Listening For Diversity: The Ways in Which Critical Attention to Words Helps Move Us Closer Towards Realizing Our Full Humanity

Valerie Joseph

Smith College

Abstract

Using her experience as a dancer, therapist, mediator, diversity trainer, anthropologist, college educator, and originator of Grounded Knowledge Panels®, Valerie Joseph distills lessons learned about the power of intentional and principled listening. She offers ideas on how to harness the energy derived from listening differently to fuel the capacity to have uncomfortable, rich, dynamic and productive thinking. This forms the basis upon which we are challenged to make transformative choices about how we operate with those other humans with whom we share the planet.

Biography

Valerie Joseph earned a Ph.D. in Cultural Anthropology from the University of Massachusetts at Amherst. Her doctoral research investigated the enduring legacies of British colonialism and African heritage memory among the members of the African Diaspora in Carriacou, Grenada. Specifically, she mapped how the game songs and dance play of Carriacouan Black girls as well as their words, beliefs, and attitudes reflected both the detrimental internalization of colonial ideology and the restorative nature of African retentions.

Prior to her fieldwork in Carriacou, Dr. Joseph lived and worked in Botswana for seven years starting as a Peace Corps Volunteer science teacher in a junior secondary school, then as a training coordinator at the Cheshire Foundation's Mogoditshane Rehabilitation Center. She closed out her years in the country by working as co-director of the School for International Training's college semester abroad program. During her time in Botswana, Dr. Joseph sharpened her interest in cross-cultural conflicts, including those that seemed to be intractable, though traceable, in part, to cultural mores as well as historical and social patterns embedded in racial or ethnic bias and discrimination.

Dr. Joseph has a Masters in Movement Therapy with a concentration in counseling psychology and a Masters in Social Justice Education. Her supplemental training, work and experience in several fields includes gymnastics coaching, dance performance, diversity training, Authentic Movement (a contemplative dance form), mediation, teaching and management in higher education.

Dr. Joseph is an educator-interventionist working at Smith College as the Mentoring Administrative Director for AEMES (Achieving Excellence in Math Engineering and Science). In that role, she manages programs to support the most marginalized students who are pursuing STEM. She also teaches college success seminars within the AEMES Scholars Program.

Dr. Joseph is co-founder of the Smith Roundtable Group. Started in 2020, the SRG is a small contingent of staff, faculty, and students dedicated to creating opportunities for information sharing and conversation about important current events. Past Roundtable offerings included: "Daring to be Hopeful: A Critical Response to the White Supremacist Storming of Our Capitol" and "Why is the Power of Young People so Threatening to the Status Quo?" The most recent Roundtable event took place in September of this year: "'Calling In' for Democracy and Human Rights: A Consideration of Project 2025."

In and outside of Smith, Dr. Joseph convenes a unique form of public discourse that she originated. Grounded Knowledge Panels® are public conversations by small groups of people who have realistic, authentic and personal experience and understanding of a particular topic or question. Emerging from core Black culture, Grounded Knowledge Panels are a synthesis of Dr. Joseph's study and work in various fields including anthropology, Authentic Movement, education and mediation. As panelists converse among themselves, audience members are invited as "witnesses" to observe the

discussion. Both groups - panelists and witnesses – bring a distinctive power, depth and responsibility to the experience of speaking and listening.

Dr. Joseph is a five time recipient of the Smith College Spotlight Award, an honor presented to staff members, chosen by peers, in appreciation of exceptional service. She is a 2020 recipient of the Elizabeth B. Wyant Gavel Award awarded by students to staff members who have performed outstanding work in the Smith community.

Dr. Joseph's first children's book, *This is What Maisie Believes*, is published by 619 Wreath Publishing.

Keynote Talk – 2

Navigating the Intersection of AI and Music: Innovation, Ethics, and the Future of the Industry

Elizabeth Moody

Granderson Des Rochers, LLP's New Media Group

Abstract

This speech explores the complex relationship between artificial intelligence and the music industry, tracing the evolution from early digital disruptions like Napster to today's AI-driven landscape. It examines how streaming platforms revolutionized music consumption and distribution, while also introducing new challenges such as streaming fraud. The speech delves into AI's multifaceted impact on music creation, production, and personalization, highlighting both its transformative potential and ethical concerns. The presentation also addresses controversial uses of voice AI technology and the legal and ethical considerations surrounding AI training data, including a fair use arguments and budding internal laws. Finally, we address proposed solutions, including the use of transparent attribution systems modeled after YouTube's Content ID and policies for opt-in/out rights management. This keynote calls for a balanced approach, urging collaboration between artists, technologists, and policymakers to ensure that AI's integration into music creation and distribution respects artistic integrity and promotes innovation.

Biography

Elizabeth Moody, partner and chair of Granderson Des Rochers, LLP's New Media Group, is a pioneer in the digital media world. Moody has been spearheading digital music and video initiatives since the post-Napster era, both as outside counsel, and as a business executive in-house at companies like YouTube and Pandora. Today, Moody remains positioned at the intersection of technology and music rights and continues to advise her technology and rightsholder clients toward new and innovative business models and licensing deals.

Moody is at the forefront of the developing issues and opportunities that AI presents to the music and entertainment industries. She counsels several prominent generative voice and audio AI companies, advises the non-profit Fairly Trained, which certifies AI companies who are training the data sets with fairly acquired, licensed or owned data, and Audioshake, an AI-based stem separation tool in use by record labels, movie studios, and entertainment companies today to ease production and marketing.

She is also keyed into the gaming and the web 3.0 world. She is partnerships counsel for the gaming company Roblox and also works closely with Wave XR, a virtual reality concerts start-up that works with artists to create unique live performances as avatar versions of themselves in imaginative digital landscapes. She developed and continues to grow Styng'r's efforts to power music in video games and online gaming experiences.

Along with gaming and the metaverse, she is passionate about the opportunities web 3.0 will bring to the music community and creators. She represents Audius, the blockchain-based music streaming service, in its efforts to help creators and their fans connect more authentically by embracing the opportunities offered through a decentralized network and Revelator, an all-in-one music platform providing digital distribution, analytics, and web 3.0 services to artists, record labels and publishers. She advises Copyright Delta, providing data connections to rights holders and AI tech platforms.

Moody is excited to bring opportunities to the music industry by forging deals with those in industries outside of music, including at the intersection of music and fitness. She represents connected fitness, yoga, pilates, mindfulness, cycling, and dance services to help them integrate music into their services. She has worked closely with Hydrow, the successful Peloton-style live reality-connected rowing experience, since its launch in 2019. She believes that VR plays an important role in fitness and works with Litesport and FitXR to ensure they have access to top-notch music experiences. She has also been working in the medical and wellness space exploring licensing structures to use music in the treatment of pain, dementia, and mental illness concerns through her work with MediMusic and her advisory participation on the board of Music Health.

Keynote Talk – 3

Status Report: AI Music in Q1 of the 21st Century

Douglas Eck

Google DeepMind

Abstract

I finished my PhD in 2000; a lot has happened over the ensuing ~25 years in the field of music and computation. It seems like an appropriate moment to look back at where we were, how far we've come, and where we're going next. I will discuss early experiments in RNN-generated music, the open-source Magenta project, the rise of LLM and diffusion models for music generation, and more recent work we've done at Google DeepMind in text, image, video and music generation. I'll also address the question of how AI might help us better understand music and maybe even give rise to new forms of musical expression.

Biography

Doug is a Senior Research Director at Google, and leads research efforts at Google DeepMind in Generative Media, including image, video, 3D, music and audio generation. His own research lies at the intersection of machine learning and human-computer interaction (HCI). In 2015, Doug created Magenta, an ongoing research project exploring the role of AI in art and music creation. Before joining Google in 2010, Doug did research in music perception, aspects of music performance, machine learning for large audio datasets and music recommendation. He completed his PhD in Computer Science and Cognitive Science at Indiana University in 2000 and went on to a postdoctoral fellowship with Juergen Schmidhuber at IDSIA in Lugano Switzerland. From 2003-2010, Doug was faculty in Computer Science in the University of Montreal machine learning group (now MILA machine learning lab), where he became Associate Professor. For more information see <http://g.co/research/douglaseck>.

Tutorials

Tutorial 1

Connecting Music Audio and Natural Language

Seung Heon Doh, Ilaria Manco, Zachary Novack, Jong Wook Kim and Ke Chen

Abstract

Language serves as an efficient interface for communication between humans as well as between humans and machines. Through the integration of recent advancements in deep learning-based language models, the understanding, search, and creation of music is becoming capable of catering to user preferences with better diversity and control. This tutorial will start with an introduction to how machines understand natural language, alongside recent advancements in language models, and their application across various domains. We will then shift our focus to MIR tasks that incorporate these cutting-edge language models. The core of our discussion will be segmented into three pivotal themes: music understanding through audio annotation and beyond, text-to-music retrieval for music search, and text-to-music generation to craft novel sounds. In parallel, we aim to establish a solid foundation for the emergent field of music-language research, and encourage participation from new researchers by offering comprehensive access to 1) relevant datasets, 2) evaluation methods, and 3) coding best practices.

Biographies of the Presenters

SeungHeon Doh is a Ph.D. student at the Music and Audio Computing Lab, KAIST, under the guidance of Juhan Nam. His research focuses on conversational music annotation, retrieval, and generation. SeungHeon has published papers related to music & language models at ISMIR, ICASSP and IEEE TASLP. He aims to enable machines to comprehend diverse modalities during conversations, thus facilitating the understanding and discovery of music through dialogue. SeungHeon has interned at Adobe Research, Chartmetric, NaverCorp, and ByteDance, applying his expertise in real-world scenarios.

Ilaria Manco is a Ph.D. student at the Centre for Doctoral Training in Artificial Intelligence and Music (Queen Mary University of London), under the supervision of Emmanouil Benetos, George Fazekas, and Elio Quinton (UMG). Her research focuses on multimodal deep learning for music information retrieval, with an emphasis on audio-and-language. Her contributions to the field have been published at ISMIR and ICASSP and include the first captioning model for music, and representation learning approaches to connect music and language for a variety of music understanding tasks. Previously, she was a research intern at Google DeepMind, Adobe and Sony, and obtained an MSci in physics from Imperial College London.

Zachary Novack is a Ph.D. Student at the University of California – San Diego, where he is advised by Julian McAuley and Taylor Berg-Kirkpatrick. His research is primarily aimed at controllable music and audio generation. Zachary seeks to build generative music models that allow for arbitrary musically-salient control mechanisms and enable stable multi-round generative audio editing, publishing such work at ICML, ICLR, and NeurIPS. Zachary has interned at Adobe Research, contributing such works as DITTO to be deployed in end-user applications. Outside of academics, Zachary is passionate about music education and teaches percussion in the southern California area.

Jongwook Kim is a Member of Technical Staff at OpenAI where he has worked on multimodal deep learning models such as Jukebox, CLIP, Whisper, and GPT-4. He has published at ICML, CVPR, ICASSP, IEEE SPM, and ISMIR, and he co-presented a tutorial on self-supervised learning at the NeurIPS 2021 conference. He completed a Ph.D. in Music Technology at New York University with a thesis focusing on automatic music transcription, and he has an M.S. in Computer Science and Engineering from the University of Michigan, Ann Arbor. He interned at Pandora and Spotify during the Ph.D. study, and he worked as a software engineer at NCSOFT and Kakao.

Ke Chen is a Ph.D. Candidate in the department of computer science and engineering at University of California San Diego. His research interests span across the music and audio representation learning, with a particular focus on its downstream applications of music generative AI, audio source separation, multi-modal learning, and music information retrieval. He has interned at Apple, Mitsubishi, Tencent, Bytedance, and Adobe, to further explore his research directions.

During his PhD study, Ke Chen has published more than 20 papers in top-tier conferences in the fields of artificial intelligence, signal processing, and music, such as AAAI, ICASSP, and ISMIR. Outside of academics, he indulges in various music-related activities, including piano performance, singing, and music composition.

Tutorial 2

Exploring 25 Years of Music Information Retrieval: Perspectives and Insights

Masataka Goto, Jin Ha Lee, and Meinard Muller

Abstract

This tutorial reflects on the journey of Music Information Retrieval (MIR) over the last 25 years, offering insights from three distinct perspectives: research, community, and education. Drawing from the presenters' personal experiences and reflections, it provides a holistic view of MIR's evolution, covering historical milestones, community dynamics, and pedagogical insights. Through this approach, the tutorial aims to give attendees a nuanced understanding of MIR's past, present, and future directions, fostering a deeper appreciation for the field and its interdisciplinary and educational aspects.

The tutorial is structured into three parts, each based on one of the aforementioned perspectives. The first part delves into the research journey of MIR. It covers the inception of query-by-humming and the emergence of MP3s, discusses the establishment of standard tasks such as beat tracking and genre classification, and highlights significant advancements, applications, and future challenges in the field. The second part explores the community aspect of ISMIR. It traces the growth of the society from a small symposium to a well-recognized international community, emphasizing core values such as interdisciplinary collaboration and diversity, and invites the audience to imagine the future of the ISMIR community together. Lastly, the third part discusses the role of music as an educational domain. It examines the broad implications of MIR research, the value of pursuing a PhD in MIR, and the significant educational resources available.

Each part invites audience interaction, aiming to provide attendees with a deeper appreciation of MIR's past achievements and insights into its potential future directions. This tutorial is not just a historical overview but also a platform for fostering a deeper understanding of the interplay between technology and music.

Biographies of the Presenters

Masataka Goto received the Doctor of Engineering degree from Waseda University, Tokyo, Japan, in 1998. He is currently a Principal Researcher at the National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan. In 1992 he was one of the first to start working on automatic music understanding and has since been at the forefront of research in music technologies and music interfaces based on those technologies. Over the past 32 years he has published more than 300 papers in refereed journals and international conferences and has received 68 awards, including several best paper awards, best presentation awards, the Tenth Japan Academy Medal, and Tenth JSPS PRIZE. He has served as a committee member of over 120 scientific societies and conferences, including the General Chair of ISMIR 2009 and 2014, the Program Chair of ISMIR 2022, and the Member-at-large of the ISMIR Board from 2009 to 2011. As the research director, he began the OngaACCEL project in 2016 and the RecMus project in 2021, which are five-year JST-funded research projects (ACCEL and CREST) related to music technologies. He gave tutorials at major conferences, including ISMIR 2015, ACM Multimedia 2013, ICML 2013, ICPR 2012, and ICMR 2012.

Jin Ha Lee is a Professor and the Founder and Director of the GAMER (GAME Research) Group at the University of Washington Information School. She holds an M.S. (2002) and a Ph.D. (2008) in Library and Information Science from the University of Illinois at Urbana-Champaign. Her research focuses on exploring new ideas and approaches for organizing and providing access to popular music, multimedia, and interactive media, understanding user behavior related to the creation and consumption of these media, and using these media for informal learning in venues such as libraries and museums. She has been actively engaging with the ISMIR community from the early days of ISMIR, and was at the forefront of user-centered MIR research at ISMIR, contributing a number of papers on user perception of music similarity and mood, music listening and sharing behavior, cross-cultural aspects of MIR, and human-AI collaboration. She served as the Secretary of the ISMIR Board from the inception to 2015, and also as the General Co-Chair of ISMIR 2021, and the Scientific Program Co-Chair of ISMIR 2014, 2020, and 2024. She also serves as an Editorial Board Member for the Transactions of the International Society for Music Information Retrieval.

Meinard Müller received the Diploma degree (1997) in mathematics and the Ph.D. degree (2001) in computer science from the University of Bonn, Germany. Since 2012, he has held a professorship for Semantic Audio Signal Processing at the International Audio Laboratories Erlangen, a joint institute of the Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU) and the Fraunhofer Institute for Integrated Circuits IIS. His recent research interests include music processing, music information retrieval, audio signal processing, and motion processing. He was a member of the IEEE Audio and Acoustic Signal Processing Technical Committee (2010-2015), a member of the Senior Editorial Board of the IEEE Signal Processing Magazine (2018-2022), and a member of the Board of Directors, International Society for Music Information Retrieval (2009-2021, being its president in 2020/2021). In 2020, he was elevated to IEEE Fellow for contributions to music signal processing. Currently, he also serves as Editor-in-Chief for the Transactions of the International Society for Music Information Retrieval (TISMIR). Besides his scientific research, Meinard Müller has been very active in teaching music and audio processing. He gave numerous tutorials at major conferences, including ICASSP (2009, 2011, 2019) and ISMIR (2007, 2010, 2011, 2014, 2017, 2019, 2023). Furthermore, he wrote a monograph titled “Information Retrieval for Music and Motion” (Springer 2007) as well as a textbook titled “Fundamentals of Music Processing” (Springer-Verlag 2015).

Tutorial 3

From White Noise to Symphony: Diffusion Models for Music and Sound

Chieh-Hsin Lai, Koichi Saito, Bac Nguyen Cong, Yuki Mitsufuji, and Stefano Ermon

Abstract

This tutorial will cover the theory and practice of diffusion models for music and sound. We will explain the methodology, explore its history, and demonstrate music and sound-specific applications such as real-time generation and various other downstream tasks. By bridging the gap from computer vision techniques and models, we aim to spark further research interest and democratize access to diffusion models for the music and sound domains.

The tutorial comprises four sections. The first provides an overview of deep generative models and delves into the fundamentals of diffusion models. The second section explores applications such as sound and music generation, as well as utilizing pre-trained models for music/sound editing and restoration. In the third section, a hands-on demonstration will focus on training diffusion models and applying pre-trained models for music/sound restoration. The final section outlines future research directions.

We anticipate that this tutorial, emphasizing both the foundational principles and practical implementation of diffusion models, will stimulate interest among the music and sound signal processing community. It aims to illuminate insights and applications concerning diffusion models, drawn from methodologies in computer vision.

Biographies of the Presenters

Chieh-Hsin Lai earned his Ph.D. in Mathematics from University of Minnesota in 2021. Currently, he is a research scientist at Sony AI and a visiting assistant professor at the Department of Applied Mathematics of National Yang Ming Chiao Tung University, Taiwan. His expertise is in deep generative models, especially diffusion models and its application for media content restoration. He has organized an EXPO workshop at NeurIPS 2023 on “Media Content Restoration and Editing with Deep Generative Models and Beyond”. Please refer here for his detailed information <https://chiehhsinjesselai.github.io/>.

Koichi Saito is an AI engineer at Sony AI. He has been working on deep generative models for music and sound, especially, solving inverse problems for music signals based on diffusion models and diffusion-based text-to-sound generation. He has extensive experience in showcasing advanced diffusion model technologies to businesses and industries related to music.

Bac Nguyen Cong earned his M.Sc. degree (summa cum laude) in computer science from Universidad Central de Las Villas in 2015, followed by a Ph.D. from Ghent University in 2019. He joined Sony in 2019, focusing his research on representation learning, vision-language models, and generative modeling. With four years of hands-on professional industry experience in deep learning and machine learning, his work spans various application domains, such as text-to-speech and voice conversion, showing his important contributions to the field.

Yuki Mitsufuji holds dual roles at Sony, leading two departments, and is a specially appointed associate professor at TokyoTech, where he lectures on generative models. He’s achieved Senior Member status in IEEE and serves on the IEEE AASP Technical Committee 2023-2026. He chaired “Diffusion-based Generative Models for Audio and Speech” at ICASSP 2023 and “Generative Semantic Communication: How Generative Models Enhance Semantic Communications” at ICASSP 2024. Please refer here for his detailed information <https://www.yukimitsufuji.com/>.

Stefano Ermon is an associate professor at Stanford, specializing in probabilistic data modeling with a focus on computational sustainability. He has received Best Paper Awards from ICLR, AACL, UAI, CP, and an NSF Career Award. He also organized a course on Diffusion Models at SIGGRAPH 2023. Please refer here for his detailed information <https://cs.stanford.edu/~ermon/>.

Tutorial 4

Humans at the Center of MIR: Human-subjects Research Best Practices

Claire Arthur, Nat Condit-Schultz, David R. W. Sears, John Ashley Burgoyne, and Joshua Albrecht

Abstract

In one form or another, most MIR research depends on the judgment of humans. Humans provide our ground-truth data, whether through explicit annotation or through observable behavior (e.g., listening histories); Humans also evaluate our results, whether in academic research reports or in the commercial marketplace. Will users like it? Will customers buy it? Does it sound good? These are all critical questions for MIR researchers which can only be answered by asking people. Unfortunately, measuring and interpreting the judgments and experiences of humans in a rigorous manner is difficult. Human responses can be fickle, changeable, and inconsistent—they are, by definition, subjective. There are many factors that influence human responses, some of which can be controlled or accounted for in experimental design, and others which must be tolerated but ameliorated through statistical analysis. Fortunately, researchers in the field of behavioral psychology have amassed extensive expertise and institutional knowledge related to the practice and pedagogy of human-subject research, but MIR researchers receive little exposure to research methods involving human subjects. This tutorial, led by MIR researchers with training (and publications) in psychological research, aims to share these insights with the ISMIR community. The tutorial will introduce key concepts, terminology, and concerns in carrying out human-subject research, all in the context of MIR. Through the discussion of real and hypothetical human research, we will explore the nuances of experiment and survey design, stimuli creation, sampling, psychometric modeling, and statistical analysis. We will review common pitfalls and confounds in human research, and present guidelines for best practices in the field. We will also cover fundamental ethical and legal requirements of human research. Any and all ISMIR members are welcome and encouraged to attend: it is never too early, or too late, in one's research career to learn (or practice) these essential skills.

Biographies of the Presenters

Claire Arthur is an assistant professor in the School of Music and co-director of the Computational and Cognitive Musicology Lab at the Georgia Institute of Technology, and adjunct faculty in the School of Psychology. She received her PhD in music theory and cognition from Ohio State University under David Huron. Her research largely focuses on modeling musical structure from a statistical perspective, as well as examining the cognitive and behavioral correlates of those structures, especially as it relates to musical expectations and emotional responses. Her MIR-related research interests lie in the intersection of music perception, computational musicology, and emotion prediction, with an emphasis on melody, voice-leading, and harmony.

Nat Condit-Schultz is a Lecturer and the Director of the Graduate Program for the Georgia Tech School of Music. Nat is a musician, composer, and scientist, specializing in the statistical modeling of musical structure. Nat directs the Georgia Tech rock and pop bands, and teaches courses in research methodology, music psychology, and music production. Nat's research interests include rhythm and tonality in popular music, the perceptual and structural roles of language and lyrics in music, and the music theory of hip-hop. Nat is a performer and composer, specializing in electric and classical guitar: as a composer, he specializes in imitative counterpoint and complex rhythmic/metric ideas like polyrhythm, “tempo spirals,” and irama, realized through classical guitar, rock instrumentation, and Indonesian Gamelan.

David R. W. Sears is Associate Professor of Interdisciplinary Arts and Co-Director of the Performing Arts Research Lab at Texas Tech University, where he teaches courses in arts psychology, arts informatics, and music theory. His current research examines the structural parallels between music and language using both behavioral and computational methods, with a particular emphasis on the many topics associated with pitch structure, including scale theory, tonality, harmony, cadence, and musical form. He also has ancillary interests in music on the global radio, music and emotion, and cross-cultural research. Recent publications appear in his Google Scholar profile.

John Ashley Burgoyne is Assistant Professor in Computational Musicology at the University of Amsterdam, teaching in the Musicology and Artificial Intelligence and conducting research in the Language and Music Cognition unit at the Institute for Logic, Language, and Computation. His current research focuses on using psychometric approaches in combination with representations and embeddings from deep learning models to improve the interpretability of AI models and flexibility in the design of musical stimuli and experiments. As director of the Amsterdam Music Lab, he is also interested in citizen science and online experimentation, and leads a team developing the MUSCLE infrastructure for facilitating online experiments requiring fine control of audio and music.

Joshua Albrecht is an Assistant Professor of Music Theory at the University of Iowa, and directs the Iowa Cognitive and Empirical Musicology lab. His current research blends statistical and computational musical analysis with behavioral studies to model listeners' perception of musical affect, melodic and harmonic complexity, and intonation. Working in a traditional School of Music, his research also focused on applying computational methods to traditional historical and analytical problems, using compositional output as proxies for investigating the cognition of historical compositional practices.

Tutorial 5

Deep Learning 101 for Audio-based MIR

Geoffroy Peeters, Gabriel Meseguer Brocal, Alain Riou, and Stefan Lattner

Abstract

Audio-based MIR (MIR based on the processing of audio signals) covers a broad range of tasks, including analysis (pitch, chord, beats, tagging), similarity/cover identification, and processing/generation of samples or music fragments. A wide range of techniques can be employed for solving each of these tasks, spanning from conventional signal processing and machine learning algorithms to the whole zoo of deep learning techniques.

This tutorial aims to review the various elements of this deep learning zoo commonly applied in Audio-based MIR tasks. We review typical audio front-ends (such as waveform, Log-Mel-Spectrogram, HCQT, SincNet, LEAF, quantization using VQ-VAE, RVQ), as well as projections (including 1D-Conv, 2D-Conv, Dilated-Conv, TCN, WaveNet, RNN, Transformer, Conformer, U-Net, VAE), and examine the various training paradigms (such as supervised, self-supervised, metric-learning, adversarial, encoder-decoder, diffusion). Rather than providing an exhaustive list of all of these elements, we illustrate their use within a subset of (commonly studied) Audio-based MIR tasks such as multi-pitch/chord-estimation, cover-detection, auto-tagging, source separation, music-translation or music generation. This subset of Audio-based MIR tasks is designed to encompass a wide range of deep learning elements. For each task we address a) the goal of the tasks, b) how it is evaluated, c) provide some popular datasets to train a system, and d) explain (using slides and pytorch code) how we can solve it using deep learning.

The objective is to provide a 101 lecture (introductory lecture) on deep learning techniques for Audio-based MIR. It does not aim at being exhaustive in terms of Audio-based MIR tasks nor on deep learning techniques but to provide an overview for newcomers to Audio-Based MIR on how to solve the most common tasks using deep learning. It will provide a portfolio of codes (Colab notebooks and Jupyter book) to help newcomers achieve the various Audio-based MIR Tasks.

Biographies of the Presenters

Geoffroy Peeters is a full professor in the Image-Data-Signal (IDS) department of Télécom Paris. Before that (from 2001 to 2018), he was Senior Researcher at IRCAM, leading research related to Music Information Retrieval. He received his Ph.D. in signal processing for speech processing in 2001 and his Habilitation (HDR) in Music Information Retrieval in 2013 from the University Paris VI. His research topics concern signal processing and machine learning (including deep learning) for audio processing, with a strong focus on music. He has participated in many national or European projects, published numerous articles and several patents in these areas, and co-authored the ISO MPEG-7 audio standard. He has been co-general-chair of the DAFx-2011 and ISMIR-2018 conferences, member and president of the ISMIR society, and is the current AASP review chair for ICASSP. At Telecom-Paris, he created the 40-hour program "Audio and Music Information Retrieval" for the Master-2 level "Data Science" which deals mostly with deep learning applied to MIR that inspired this tutorial.

Gabriel Meseguer Brocal is a research scientist at Deezer with over two years of experience at the company. Before joining Deezer, he completed postdoctoral research at Centre National de la Recherche Scientifique (CNRS) in France. In 2020, he earned his Ph.D. in Computer Science, Telecommunications, and Electronics with a focus on the Sciences & Technologies of Music and Sound at IRCAM. His research interests include signal processing and deep learning techniques for music processing, with a focus on areas such as source separation, dataset creation, multi-tagging, self-supervised learning, and multimodal analysis.

Alain Riou is a PhD student working on self-supervised learning of musical representations at Télécom-Paris and Sony CSL Paris, under the supervision of Stefan Lattner, Gaëtan Hadjeres and Geoffroy Peeters. Before that, he obtained a master degree in mathematics for machine learning at Ecole Normale Supérieure de Cachan (2020) and another one in signal processing and computer science applied to music at IRCAM (2021). His main research interests are related to

deep representation learning, with a strong focus on self-supervised methods for music information retrieval and controllable music generation. His work "PESTO: Pitch Estimation with Self-supervised Transposition-equivariant Objective" received the Best Paper Award at ISMIR 2023.

Stefan Lattner serves as a researcher leader at the music team at Sony CSL Paris, where he focuses on generative AI for music production, music information retrieval, and computational music perception. He earned his PhD in 2019 from Johannes Kepler University (JKU) in Linz, Austria, following his research at the Austrian Research Institute for Artificial Intelligence in Vienna and the Institute of Computational Perception Linz. His studies centered on the modeling of musical structure, encompassing transformation learning and computational relative pitch perception. His current interests include human-computer interaction in music creation, live staging, and information theory in music. He specializes in generative sequence models, computational short-term memories, (self-supervised) representation learning and musical audio generation. In 2019, Lattner received the best paper award at ISMIR for his work, "Learning Complex Basis Functions for Invariant Representations of Audio."

Tutorial 6

Lyrics and Singing Voice Processing in Music Information Retrieval: Analysis, Alignment, Transcription and Applications

Daniel Stoller, Emir Demirel, Kento Watanabe, and Brendan O'Connor

Abstract

Singing, a universal human practice, intertwines with lyrics to form a core part of profound musical experiences, conveying emotions, narratives, and real-world connections. This tutorial explores the commonly used techniques and practices in lyrics and singing voice processing, which are vital in numerous music information retrieval tasks and applications.

Despite the importance of song lyrics in MIR and the industry, high-quality paired audio & transcript annotations are often scarce. In the first part of this tutorial, we'll delve into automatic lyrics transcription and alignment techniques, which significantly reduce the annotation cost and enable more performant solutions. Our tutorial provides insights into the current state-of-the-art methods for transcription and alignment, highlighting their capabilities and limitations while fostering further research into these systems.

Moreover, we present "lyrics information processing", which encompasses lyrics generation and leveraging lyrics to discern musically relevant aspects such as emotions, themes, and song structure. Understanding the rich information embedded in lyrics opens avenues for enhancing audio-based tasks by incorporating lyrics as supplementary input.

Finally, we discuss singing voice conversion as one such task, which involves the conversion of acoustic features embedded in a vocal signal, often relating to timbre and pitch. We explore how lyric-based features can facilitate a model's inherent disentanglement between acoustic and linguistic content, which leads to more convincing conversions. This section closes with a brief discussion on the ethical concerns and responsibilities that should be considered in this area.

This tutorial caters especially to new researchers with an interest in lyrics and singing voice modeling, or those involved in improving lyrics alignment and transcription methodologies. It can also inspire researchers to leverage lyrics for improved performance on tasks like singing voice separation, music and singing voice generation, and cover song and emotion recognition.

Biographies of the Presenters

Daniel Stoller is a research scientist at MIQ, the music intelligence team at Spotify. He obtained his PhD from Queen Mary University in 2020, before researching causal machine learning at the German center for neurodegenerative diseases (DZNE). Experienced in audio source separation as well as generative modeling and representation learning, he develops machine learning models and techniques scalable to high-dimensional data such as raw audio signals, publishing in both machine learning and audio-related venues. With a special passion for music, he also worked extensively on lyrics alignment, and singing voice processing including separation, detection and classification.

Emir Demirel is a Senior Data Scientist at Music.ai / Moises, leading projects on lyrics and vocal processing. He obtained his Ph.D. at Queen Mary University of London, as a fellow to the "New Frontiers in Music Information Processing" project under EU's Marie Curie/Skladowska Actions. After completing his Ph.D, he joined Spotify's Music Intelligence team, enhancing his expertise before moving to Music.ai. His research interests span lyric transcription and alignment, speech recognition, and natural language processing, along with generative AI models.

Kento Watanabe is a senior researcher at the National Institute of Advanced Industrial Science and Technology (AIST), Japan. He received his Ph.D. from Tohoku University in 2018, and his work focuses on Lyrics Information Processing (LIP), natural language processing, and machine learning. He aims to bridge the gap between humans and computers in the field of music and language, and to improve interactions through advanced algorithms.

Brendan O'Connor has worked in music as a performer, composer, producer, teacher, and sound installation artist. He earned his Bachelor's in classical music at the MTU Cork School of Music (Ireland), followed by his Master's in music technology at the University of West London, specialising in the voice as the principal instrument in electroacoustic compositions. He then worked towards his Ph.D. in the field of singing voice conversion via neural networks at Queen Mary University of London. His research interests include the disentanglement of scarcely labelled vocal attributes, such as singing techniques. After completing his PhD, Brendan began working for a startup company in voice conversion, allowing him to continue working in his area of expertise with other researchers of the same field using SOTA machine learning techniques.

Special Session: Remembering Don Byrd

Host: Zhiyao Duan

Don Byrd, the General Chair of the very first ISMIR conference in 2000, has recently left us. This session remembered and celebrated the vision and contributions of this legend of the ISMIR community.

Creative Practice Sessions

Hosts: Cynthia Liem, Tomas Peire

On the occasion of ISMIR 2024's special focus on 'Bridging Technology and Musical Creativity', a dedicated Creative Practices track was initiated to especially focus on these bridging aspects. With this, we wanted to facilitate dialogues and collaborations on the bridge between technology and creativity, addressing the mutual needs and interests of artists, technologists, and industry professionals.

Leading up to ISMIR, a community call was published, allowing anyone with interest in music, technology and creativity to propose topics they wanted to collaborate on. In response, 15 proposals were submitted by a wide and international audience, including artists and a high school student.

At the main conference, the Creative Practices track organized several activities. First of all, two panel discussions were organized, featuring invited guests that have professionally been active on the bridge between technology and creative practice:

- **Session 1** largely featured artists who have been working with technology:
 - **Carlos Mosquera** - Musician, Programmer, CEO at CM MEDIA LLC
 - **Michelle Alexander** - Musician, Music Analyst & Mood Specialist at Pandora
 - **Mark Goldstein** - Percussionist, programmer, teacher, inventor; with an interest in the nexus of musical gesture, sound, and expression.
- **Session 2** featured guests (several having an artistic background) with strong connections to commercial and practical applications:
 - **Eyal Amir** - musician, software developer and musical instruments creator. Co-founder and CTO of the audio plugins company Modalics.
 - **Ben Cantil** aka Encanti - electronic music producer, software designer, educator, and scholar
 - **Seth Forsgren** - Amateur Musician, CEO at Riffusion
 - **Spencer Salazar** - Principal Engineer (formerly CTO) at Output

At the start of session 1, special attention was drawn to the community proposals, where proposers physically present at ISMIR also presented their projects/proposals:

- **Nicole Brady** - Music Performer, music producer, composer, music teacher. Project: Memory of Sun: Inspired by Anna Akhmatova's poignant poem "Memory of Sun," this project is a multisensory installation that explores themes of memory, transformation, and fading light through light, audio-visual, and interactive technologies
- **Jin Ha Lee, Michele Newman, Lidia Morris** - a team of researchers at the University of Washington, coming from a background of information science, with interest in MIR research. Interested in dialogues on Understanding the Creative Processes of Human-AI Music Collaboration, with particular interest in the role and viewpoint of the human creator.

The intention is to keep advertising for the community proposals until Spring 2025, where interested parties can directly engage with proposers. From resulting collaborations, we wish to draw practical lessons on how collaborations can be effective, and where vocabulary matches or does not yet match across disciplinary viewpoints.

Finally, a Creative Practice social was hosted by Riffusion at the Riffusion HQ and Phonobar, providing an informal networking platform, technical demos, and live performances. Apart from invited artists, there also were performances by the long-time ISMIR community members Dadabots and panelist Encanti.

The Creative Practice track was well received, with ISMIR audience members indicating they appreciated both the community call and the elements programmed at the conference. As for points to keep in mind for possible future continuations, it will be good to be aware early on that a track like this will especially attract an audience (both in terms of invitees to panels, as well as proposers to the community call) that would not normally attend ISMIR. As such, these attendees are not obviously having resources for conference attendance, nor will they naturally 'speak the language and know the culture' of ISMIR. It will thus be good to provide support for them, both in terms of travel/registration support, but also on a more translational note with regard to the work presented at the conference (this year's backchannel in the Slack community may have served that purpose). Furthermore, it will be good to more proactively rotate the community call early on and directly link possible collaborators, although this will need considerable chairing capacity and good knowledge of the ISMIR network.

Industry Sessions

Hosts: Brandi Frisbie, Minz Won

Sponsor presentation

Eleven ISMIR sponsors gave presentations on their vision, goals, research topics, demos, and potential job opportunities in two sessions.

Panel discussion

Five panelists and a moderator engaged in a discussion about the past, present, and future of music and technology. The session included insights from the panelists, followed by a Q&A and an opportunity for social networking. This event was open to the public.

Theme: Bridging Technology and Musical Creativity

Moderator: Jessica Powell (CEO and Co-founder of AudioShake)

Panelists:

- Stephen White (CPO of EMPIRE)
- Douglas McCausland (TAC Studio Manager and Faculty Lecturer at SFCM)
- Tony Brooke (Independent Consultant for Music Data Companies)
- Heidi Trefethen (Adjunct Professor at SFCM TAC, FOH/Monitor Engineer at SF Jazz)
- Cheng-Zhi Anna Huang (Assistant Professor at MIT)

Live Online Sessions

Mindfulness Sessions

Virtual Mindfulness Sessions were programmed during onsite lunch breaks (in live and replay time zones) to give online participants a chance to unwind between plenary sessions. The experiences presented in the ISMIR 2024 Mindfulness sessions were designed to help guide attendees into a deeper sense of Calm. All visuals were naturally produced and captured, with no AI intervention.

The ISMIR 2024 Organizers thank soundBrilliance (<https://www.soundbrilliance.com/>) for creating custom audiovisual experiences for these sessions.

soundBrilliance™

Online Social Events

Participants met over Zoom for informal conversation and contributed to the ISMIR 2024 Collaborative Playlist.

Online Special Sessions

Host: Vino Alluri

Five invited researchers from MIR and neighboring communities joined virtual sessions to give short presentations of their work and engage in informal conversation with attendees.

Kathleen Rose Agres: Affective Music Generation for Emotion Regulation in Listeners

There has been a surge of interest in automatic music generation in recent years, particularly in affective music generation. Numerous systems now offer controllable AI-based affective music generation (AI-AMG), as highlighted in Dash & Agres (2024). While these systems have been developed for various applications—including soundtrack creation in gaming and virtual reality, co-creativity, and health and well-being—this talk focuses on the use of AI-AMG to support emotion regulation in listeners. One such system, AffectMachine (Agres, Dash, & Chua, 2023), is designed to generate affective music in real time, and is capable of composing in both classical and pop-music styles. Recent findings across several studies demonstrate AffectMachine’s efficacy in producing music perceived as emotional and capable of inducing emotions, as shown by subjective emotion ratings and physiological responses. This talk will explore the implications of systems like AffectMachine for supporting emotion self-regulation.

Bio: Dr. Kat Agres is an Assistant Professor at the Yong Siew Toh Conservatory of Music at the National University of Singapore (NUS), and Founding Director of the Centre for Music and Health, the first dedicated research centre in Southeast Asia to spearhead evidence-based research leveraging the efficacy of music for health and well-being. Kat received her PhD in Cognitive Psychology from Cornell University and completed her postdoctoral fellowships in Music Cognition and Computational Creativity at the University of London. She also holds a bachelor’s degree in Cello Performance and Psychology from Carnegie Mellon University. Kat’s research explores music interventions and technologies for healthcare and well-being, music perception and cognition, and computational creativity. She has received numerous grants to support her research in Singapore, the US, and UK. Kat has presented her research in over twenty countries around the world, and has also performed professionally as a cellist.

Kaustuv Kanti Ganguli: Harmonic Convergence: Orchestrating the Synergy of Human Intuition and Machine Intelligence in Music

In the rapidly evolving landscape of computational musicology, we stand at a fascinating crossroads where human perception intertwines with machine-driven analysis. This convergence offers unprecedented opportunities to unravel the

complexities of musical structures, particularly in rich non-Eurogenetic traditions such as Indian art music. By harmonizing human cognition with artificial intelligence, we can decode the intricate artifacts of audio signal processing, revealing new dimensions in our understanding of music. This approach not only enhances our appreciation of musical nuances but also challenges us to rethink the boundaries between human creativity and computational analysis.

As we navigate this confluence, we must consider the profound implications for music education, composition, and appreciation. How can we leverage machine learning to augment human musical intuition? What new insights into musical cognition can emerge from this synthesis? By exploring these questions, we open doors to innovative pedagogical tools, more nuanced music recommendation systems, and perhaps even new forms of musical expression. The future of music analysis lies not in choosing between human expertise and artificial intelligence but in orchestrating a symphony where both play in perfect harmony, each enhancing the other's strengths and compensating for limitations.

Bio: Dr. Kaustuv Kanti Ganguli is an Associate Professor of Artificial Intelligence at Zayed University and a Scholar at New York University Abu Dhabi Scholar, spearheading computational musicology and machine learning research. His innovative work bridges AI and music, focusing on Arabian Gulf and South Indian repertoires. Dr. Ganguli develops AI models that enhance music understanding, preservation, and education by combining engineering approaches with human cognition. A President's Gold Medal recipient and accomplished Hindustani vocal performer, his expertise spans machine learning, virtual reality, and audio processing. His groundbreaking projects include Raga/Makam characterization, multi-sensory perception, and crossmodal correspondence that collectively foster a deeper appreciation for diverse musical traditions through the lens of artificial intelligence. Kaustuv envisions blending humanistic and computational methods in a cross-disciplinary environment within a liberal arts framework, focusing on cutting-edge research and sustainable, innovative teaching.

Martin Hartmann: Music and Movement: Exploring Social and Multimodal Dimensions of Rhythmic Entrainment

The talk addresses key challenges in the field of music and movement through two ongoing studies at the Centre of Excellence in Music, Mind, Body and Brain at the University of Jyväskylä. The first challenge explores rhythmic-social entrainment within the context of free dyadic dance. We present a study that examines the relationship between rhythmic-social entrainment and social as well as musical affiliation during adolescence, using markerless motion capture technology. Following a 2x2 factorial design, participants dance freely in dyads with a friend and with a stranger to music of their choice and to music selected by us. The second challenge focuses on the multimodality of rhythmic-social entrainment. We discuss a study that employs motion capture and surface electromyography to investigate the impact of visual cues and performed activities on acoustic features, physiological responses, and kinematic responses in choir singing. The goal is to understand how the visibility of other choir members and the performed activities (chat, homophony, polyphony, and musical improvisation) influence different types of individual and group responses. In addition to exploring the social aspects of rhythmic entrainment in dance and its multimodal nature in choir singing, we emphasize the extraction of musical features and individual and social acoustic and kinematic features. We also consider potential take-home messages from these studies for the music information retrieval community and beyond.

Bio: Martin Hartmann is an Assistant Professor of Musicology at the University of Jyväskylä, where he works for the Centre of Excellence in Music, Mind, Body, and Brain and for the European Research Council project MUSICCONNECT. His research encompasses music and movement, perception, information retrieval, and therapy. Currently, he specializes in the computational modeling of multimodal interactions in music and dance contexts. He is an executive group member of the Finnish Doctoral Network for Music Research and the local coordinator of the EU-funded FORTHEM Alliance Lab for Arts and Aesthetics in Contemporary Society. He led the project "Interaction in Music Therapy for Depression", maintains the MoCap (Motion Capture) Toolbox for MATLAB, and holds editorial roles for the journals Music Perception and Psychology of Music.

Amanda Krause: Can We Categorise Younger Adult Listeners?

The evolution of digital listening technologies continues to impact the way we think about music consumption and music listening practices. Krause and North's (2016) findings suggest that, in addition to demographic characteristics, psychological constructs should be considered when investigating listening practices and technology use. The present study uses latent profile analysis (LPA), which is a statistical technique that focuses on identifying latent subgroups within a population based on a set of variables. With this study, LPA affords us the opportunity to attempt to categorise types of music listeners. To explore this possibility, we draw on data collected from a sample of 584 younger adults residing in Australia

(Age = 19.62; 74.10% female). Participants were asked to complete an online questionnaire that included demographics, the musicianship module of the MUSEBAQ (Chin, et al., 2018), the Music Engagement Test (MET; Greenberg & Rentfrow, 2015), Langford's (2003) Big Five proxy personality scale, Krause and Hargreave's (2013) Music Self-Images Questionnaire, and Krause and Brown's (2021) format use measure. With analyses underway, preliminary indications suggest that format use and MET scores may differentiate listener typologies. Study findings further our theoretical understanding of how individuals consume music in everyday life.

Bio: Dr. Amanda E. Krause is a Senior Lecturer (Psychology) in the College of Healthcare Sciences at James Cook University (Queensland, Australia). As a music psychology scholar based at James Cook University, she studies how we experience music in our everyday lives.

Her passion for researching the social and applied psychology of music has led her to give guest lectures and public talks and serve as President of the Australian Music & Psychology Society (AMPS). She is the author of numerous peer-reviewed academic publications and has spoken on her research to academics and industry leaders at conferences around the world. Her research has made significant contributions to understanding how listening technologies influence people's experiences and how musical engagement impacts well-being. Dr Krause's current programs of research concern how everyday music and radio experiences influence people's well-being.

Sebastian Stober: Generative AI Training and Copyright Law

Training generative AI models requires extensive amounts of data. A common practice is to collect such data through web scraping. In the USA, AI developers rely on "fair use" and in Europe, the prevailing view is that the exception for "Text and Data Mining" (TDM) applies. In a recent interdisciplinary tandem-study with a legal expert, I have argued in detail that this is actually not the case because generative AI training fundamentally differs from TDM. In this talk, I will share our main findings and the implications for both public and corporate research on generative models. I will further discuss how the phenomenon of training data memorization leads to copyright issues independently from the "fair use" and TDM exceptions. Finally, I would like to outline how the ISMIR could contribute to the ongoing discussion about fair practices with respect to generative AI that satisfy all stakeholders.

Bio: Sebastian Stober is professor for Artificial Intelligence at the Otto-von-Guericke-University Magdeburg, Germany. He studied computer science with focus on intelligent systems in Magdeburg until 2005 and received his PhD with distinction on the topic of adaptive methods for user-centered organization of music collections in 2011. From 2013 to 2015, he was postdoctoral fellow at the Brain and Mind Institute in London, Ontario where he pioneered deep learning techniques for studying brain activity during music perception and imagination. Afterwards, he was head of the Machine Learning in Cognitive Science Lab at the University of Potsdam, before returning to Magdeburg in 2018. In his current research, he investigates and develops generative models for music and speech as well as methods to better understand what an artificial intelligence has learned and how it solves specific problems. To this end, he combines the fields of artificial intelligence and machine learning with cognitive neuroscience and music information retrieval.

TISMIR Presentations

This year marks the first time we have included presentations from the journal *Transactions of the International Society for Music Information Retrieval* (TISMIR) in the ISMIR conference program. This initiative aims to enhance the visibility of TISMIR and encourage more submissions and participation in the journal.

Any TISMIR paper published between June 1, 2023 and May 31, 2024 qualified for presentation, provided the authors registered during the regular registration period. We are pleased to announce that 10 TISMIR papers were registered and presented at this year's ISMIR conference (see list below).

These 10 papers were integrated into the Oral and Poster sessions, ensuring they received the same level of attention and relevance as regular ISMIR papers.

The ISMIR 2024 General Chairs extend our thanks to the TISMIR Editors-in-Chief and the ISMIR Board for their support and collaboration in making this possible.

The papers below are not included in the ISMIR 2024 proceedings, but can be accessed by visiting the TISMIR website (<https://transactions.ismir.net/>).

Papers presented (sorted alphabetically by first author):

1. Edwards, D., Dixon, S. and Benetos, E., 2023. PiJAMA: Piano Jazz with Automatic MIDI Annotations. TISMIR, 6(1), p.89–102.
2. Fabbro, G., Uhlich, S., Lai, C.-H., Choi, W., Martínez-Ramírez, M., Liao, W., Gadelha, I., Ramos, G., Hsu, E., Rodrigues, H., Stöter, F.-R., Défossez, A., Luo, Y., Yu, J., Chakraborty, D., Mohanty, S., Solovyev, R., Stempkovskiy, A., Habruseva, T., Goswami, N., Harada, T., Kim, M., Lee, J.H., Dong, Y., Zhang, X., Liu, J. and Mitsufuji, Y. ABSTRACT

Repetition is central to musical structure as it gives rise both to piece-wise and stylistic coherence. Identifying repetitions in music is computationally not trivial, especially when they are varied or deeply hidden within tree-like structures. Rather than focusing on repetitions of musical events, we propose to pursue repeated structural *relations* between events. More specifically, given a context-free grammar that describes a tonal structure, we aim to computationally identify such relational repetitions within the derivation tree of the grammar. To this end, we first introduce the *Template*, a grammar-generic structure for generating trees that contain structural repetitions. We then approach the discovery of structural repetitions as a search for optimally compressible *Templates* that describe a corpus of pieces in the form of production-rule-labeled trees. To make it tractable, we develop a heuristic, inspired by tree compression algorithms, to approximate the optimally compressible *Templates* of the corpus. After implementing the algorithm in Haskell¹, we apply it to a corpus of jazz harmony trees, where we assess its performance based on the compressibility of the resulting *Templates* and the music-theoretical relevance of the identified repetitions.

1. INTRODUCTION

Repetition has been widely recognized as an essential means of establishing effects of coherence in music [1–5]. In Western music, at least, it operates at multiple levels of structure—whether within individual compositions or across different pieces—and takes the shape of musical motifs, themes [6–9], and sectional forms [10–14], among others.

In formalizing repetition in, we need to clarify the *object*, the *means*, and the *scope* of repetition. The *object* specifies the kind of entities being repeated—for instance concrete pitch events or abstract relations between them. By *means* of repetition we refer to processes via which the

objects are repeated. The *scope* specifies the musical context in which any repetitions are identified.

This paper focuses on *structural repetitions* whose *objects* are not the musical events themselves but rather relations among them. By way of a musical example, consider the first eight bars in the jazz standard “Satin Doll.” In common form-theory [10] terms, is sentential; its first half (“presentation”) establishes and repeats a “basic idea” one step higher, whereas the second half (“continuation”) accelerates the harmonic rhythm towards a closing gesture.² A parse tree of the piece (see Figure 1a) based on the jazz harmony grammar by Rohrmeier [15] clarifies the chord dependency and constituency. Here we may observe that the varied repetition of the basic idea in the presentation is reflected in the parallelism between the respective tree components.³

One might think that the tree topology suffices to capture the musical intuition of the parallel structures within this phrase. Further observation reveals that the equality in topology is at most a necessary but not sufficient condition for parallelism. Equality between tree topologies can only express sameness of grouping structure (“constituency”), irrespective of group contents. This is not enough to describe common pattern-like tonal structures such as sequences. The essence of the phenomenon in this example lies also in the equality of the *relations* (edge labels). Listeners familiar with the genre would identify the repeating *objects* as “ii-V”-type motions. To make the relations explicit, we construct a production-rule-labeled tree as shown in Figure 1b. this representation, the parallelism is reflected in the equality of labeled tree components. This notion of repetition, now construed as equality of abstract relations, is crucial in formally capturing parallelism in music.

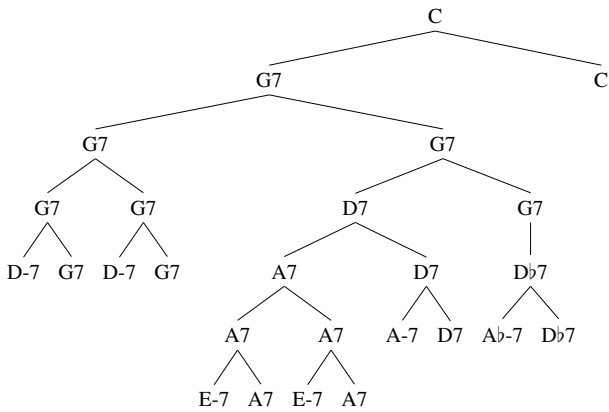

The *means* of repetition can be informally understood as the coloring present in the rule-labeled tree, which demarcates different rule types. This coloring imposes on the derivation of the piece a repetition constraint that is recursively constrained: indeed, one challenge is to express repetition not just between tree leaves or sub-trees, but also between connected subgraphs of the tree. This generalization would enable us to express deep-level repetitions of tonal frameworks despite non-parallel operations close to

the surface (e.g. ornaments). A constructive definition of repetition *means* is provided in section 3.

Finally, we distinguish two kinds of *scopes* for repetition: piece-wise and corpus-wise. This distinction is important for characterizing musical styles. For instance, the “ii-V-I” chord progression in jazz is a recurrent harmonic device **across the corpus**. In contrast, the two descending thirds arranged one descending step apart, which open Beethoven’s Fifth Symphony, establish themselves as a motive through specific processes of repetition **within the piece** (and not outside it).

2. RELATED WORK

Leaving aside historical texts, a plethora of contemporary theoretical studies have examined the phenomenon of repetition in music [16], as well as the distinction between—borrowing Eugene Narmour’s terms [17]—“style structures” [18, 19] and piece-specific “idiostructures” [7, 20].

To computationally model the repetition phenomena in

the “Satin Doll” example of section 1, we coordinate two kinds of hierarchical structures: one that explains musical entities in terms of a context-free grammar (CFG), and another that explains the repetition of grammar rule applications. Hierarchical models of tonal structure are not new [21–25]. The same can be said about the hierarchical understanding of repetition itself such as the String Pattern-Induction Algorithm (SPIA) [26]. Methods for repetition identification have primarily focused on the repeated material itself by searching for exact or inexact successions [27–32] (also see [33] for an overview of this body of research). However, to the best of our knowledge, and outside the sphere of purely music-theoretical contributions, little attention has been paid to computational models of repetition whose objects are relations (generative procedures). Variation, for example, is often understood as a departure from exact repetition by means of ad-hoc or systematic transformations on a concrete entity. In this paper, by contrast, we understand variation as a different elaboration of the same *abstract* entity. Building upon the work by Finkensiep et al. on repetition structure inference [34], we extend its notion of “formal prototypes” to accommodate non-exact repetitions.

In the field of computer science, grammar-based compression algorithms aim to compress data by factoring out repeated information and storing it only once. Grammar-based compression algorithms have been developed and studied both for strings [35] and trees [36–40]. With string-like input data, the Sequitur algorithm [41] encodes a compressed string by constructing a straight-line grammar—a subclass of CFGs—whose language size is equal to one. When the input data have tree or forest form, algorithms such as [35–37, 39, 40] construct a straight-line tree program by iteratively constructing repeated units using “digrams,” which assemble a unit of repetition from two adjacent units. In the case of tree patterns, a digram consists of a root plus one of its children. Among the related research, the *TreeRepair* algorithm by Markus Lohrey et al. [37] is relevant as it is specifically concerned with the notion of “deep-level repetition”, i.e. of connected graphs within a tree.

In this paper, we formalize repetition patterns as functions operating on generic abstract syntax trees. Using a new approach that is based on tree compression algorithms and formal prototypes, we introduce a model that can discover piece-specific and stylistic patterns from a forest of abstract syntax trees.

3. FORMALISM

Meta-rule. A *meta-rule* is a list of symbols in $\mathbb{N}^+ \cup \{_, \star\}$ where “_” denotes a new symbol, “ \star ” denotes the recurrence of the parent symbol (“parent repeat”), and “ n ” denotes the recurrence of the n -th argument (“sibling repeat”). In the rest of the paper, we use \mathcal{M} to denote the space of *meta-rules*. Each $m \in \mathcal{M}$ induces a repetition function $rep_m : (X, X^n) \rightarrow X^{m+k}$ where the first argument represents the root of a sub-tree and the second represents its children. Here are two examples of the workings

of the rep_m function:

$$rep_{\langle _, _, 1, \star \rangle}(5, [3, 1]) = [3, 1, 3, 5]$$

$$rep_{\langle \star, _, 2, _, _, 4 \rangle}(t, [a, b, c]) = [t, a, a, b, c, b].$$

Intuitively, a *meta-rule* encodes the atomic “means” of repetition within a tree structure without specifying the *object* of repetition.⁴ In addition, for $m \in \mathcal{M}$, we define $sizeIn(m)$ to be the number of “ $_$ ” symbols and the $sizeOut(m)$ to be the length of the *meta-rule*.

Template. Given a context-free Grammar G where P_G is the set of production rules, we define its corresponding *Template* \mathcal{T}_G constructively using following axioms:

1. (Rule Lifting)

$$\forall f \in P_G. f \in \mathcal{T}_G$$

2. (Composition)⁵

$$\forall f, g \in \mathcal{T}_G, i \leq \text{arity}(g). (i, g, f) \in \mathcal{T}_G$$

3. (Replication)

$$\forall g \in \mathcal{T}_G, m \in \mathcal{M}, \vec{f} \in \mathcal{T}_G^{sizeIn(m)}. (g, m, \vec{f}) \in \mathcal{T}_G$$

\mathcal{T}_G is effectively a context-free grammar that generates P_G -labeled trees. The template is a structured representation of a rule-labeled tree; each template can be mapped to a unique rule-labeled tree but each rule-labeled tree can be assigned to multiple templates. Each rule-labeled tree can be embedded as a template in a trivial way using the axioms *Rule Lifting* and *Replication* with the *meta-rules* containing only “ $_$ ”.

We view the problem of discovering *objects* and *means* of repetition as one of inferring optimally compressible *templates* that generate the given production-rule-labeled trees. Given a collection of rule-labeled trees, we want to parse them as *templates*, so that the total size of the list of *templates* is minimized under memoization.⁶

3.1 Atomic parsing operations for \mathcal{T}_G

P-rewrite. Given a pattern of form (i, f, x_i) , referred to as a “digram” in [37], the rewrite procedure operates as depicted in Figure 2 in a post-order fashion, replacing all non-overlapping instances of the pattern within the tree. Through iterative application, *P-rewrite* facilitates the abstraction of a connected subgraph of a tree in the form of a single node.⁷

⁴ Visualizing meta-rules as strings of literal symbols, for instance “ABAT”, would be more intuitive and readable. Here we opt for a referential representation as it facilitates the computational implementation.

⁵ Here the notion of composition extends single-argument function composition to multiple arguments. $g \circ_i f$ denotes the function obtained by passing the output of f to the i -th argument of g . For *composition* and *replication* we also require the functions involved to have compatible types. The *arity* of a template, informally speaking, is the number of arguments needed to form a complete tree. For a template lifted from a production rule, its *arity* is the number of child symbols. For templates constructed using *composition*, $\text{arity}((i, f, g)) = \text{arity}(f) + \text{arity}(g) - 1$. For templates constructed using *replication*, $\text{arity}((g, m, \vec{f})) = \sum_{x \in rep_m(g, \vec{f})} \text{arity}(x)$.

⁶ This connection to memoization is inspired by [42].

⁷ *P-rewrite* mirrors the “replacement step” described in [37]. To the best of our knowledge, this is the first application of this notion in the analysis of musical structure.

Figure 2: A single step of *P-rewrite* using the template $(3, g, f)$ arise from the *composition* axiom.

Figure 3: A single step of *R-rewrite* using the meta-rule $m = \langle _, \star, _, 1 \rangle$.

R-rewrite. *R-rewrite* is responsible for abstracting *means* of repetition. Given a $m \in \mathcal{M}$, *R-rewrite* applies to the tree whose first-level children are of the form $rep_m(g, \vec{f})$ for some g and \vec{f} . For example if $m = \langle _, \star, _, 1 \rangle$, then the rewrite procedure is the operation shown in Figure (3). *R-rewrite* corresponds to the *replication* case of \mathcal{T}_G .

Figure 4 demonstrates the relationship between a rule-labeled tree and the template that generates it. Note that at the most abstract level (Figure 4d) the template shows that the entire dominant region of the *Satin Doll* theme follows a “AABB” repetition pattern (indicated by the *meta-rule* $m_3 = \langle _, 1, _, 2 \rangle$) where “A” and “B” are templates T_2 and T_1 respectively. It is worth noting that the *objects* of this particular repetition pattern do not appear at the same structural level in the original rule-labeled tree. In general, the *Template* formalism allows us to coordinate tonal structure and repetition structure in a single hierarchical framework. It is the *Composition* axiom that makes this possible, since it can abstractly represent a connected graph of a tree as a single node. This mechanism is related to tree adjunction and substitution in Tree Adjoining Grammar (TAG) [43, 44].⁸

4. ALGORITHMS

The algorithm draws insights from [37] and [34], in particular their methods for tree and repetition pattern extraction. Departing from [37], our proposed algorithm introduces an additional replacement (*R-rewrite*) step to summarize repetition configurations. In comparison to [34], which operates with strings rather than trees, we introduce a mechanism that handles structural variations, and also derive *meta-rules* from data instead of prescribing a collection thereof. Furthermore, our algorithm differentiates

⁸ A *template* of the form (i, g, f) simulates tree adjunction when g is a non-trivial template, and tree substitution when f is a non-trivial template.

Figure 4: One possible parse of the rule-labeled tree in Figure 1b. Figures (a-d) demonstrate parsing steps (in bottom-up direction) using P and R rewrites, while figure (e) shows the definition of binded variables, which are colored accordingly.

repetition patterns by their scopes.

The algorithm works by incrementally constructing a table of mined patterns, whether *templates* or *meta-rules*. Its shape is identical to that of Table 1. Given a forest of rule-labeled trees, a pattern is *global* if it occurs at least in two trees, and *local* if it occurs at least twice in a single tree (but not in any other tree).

4.1 The Compression Algorithms

The goal is to find the minimal encoding achievable through a series of *P-Rewrite* and *R-Rewrite* operations. An exact solution would require us to try out all the possible rewrite steps (including all possible choices of patterns or meta-rules to write on), with each rewrite generating a new state dependent on the previous state of the program. Even with dynamic programming techniques, such an approach would be computationally intractable. To tame the computational complexity of the optimization problem, we

define two ‘greedy’ heuristics that help find rewrite candidates: a Local Compression for single trees (Algorithm 1) and a Global Compression for forests (Algorithm 2). The complete compression algorithm consists in an iteration of Algorithms 1 and 2 until a fixed-point is reached (when the result convergence).

Algorithm 1 The Local Compression Algorithm (a Single Step)

1: **Input**

t : Rule-labeled tree

dP : Dictionary from symbols to *templates*

dM : Dictionary from symbols to *meta-rules*

2: **function** $compress_L(t, dP, dM)$

3: $(o_P, o_r) \leftarrow occurrence_L(t)$

4: $c \leftarrow bestCandidate(o_P, o_r)$

5: **if** $c = Nothing$ **then**

6: **return** (t, tP, dM)

7: **else if** $c \in o_P$ **then**

8: $t' \leftarrow p\text{-Rewrite}(c, t)$

9: $dP' \leftarrow update(dP, c)$

10: $dM' \leftarrow dM$

11: **else if** $c \in o_r$ **then**

12: $t' \leftarrow r\text{-Rewrite}(c, t)$

13: $dP' \leftarrow dP$

14: $dM' \leftarrow update(dM, c)$

15: **end if**

16: **return** (t', dP', dM')

17: **end function**

The function $occurrence_L/occurrence_G$ constructs a dictionary of all the patterns and their locations in the tree/forest for potential rewrite. The function $bestCandidate$ in both algorithms is defined by comparing the *net memory savings* of the rewrite.⁹ Given a tree t , the local frequency of a *composition template* of the form $p = (i, g, f)$, $Freq_L^P(t, p)$, is equal to the maximal non-overlapping occurrences of the pattern within a tree. Its global frequency within a forest T , denoted as $Freq_G^P(T, p)$ is the number of pieces where it is present; if it occurs multiple times in a tree of the forest, it still contributes 1 to the global frequency.

The local frequency of $m \in \mathcal{M}$, $Freq_L^R(m)$ is the sum of all local frequencies of the patterns that match a *replication template* (g, m, \vec{f}) within a tree.¹⁰ The global frequency $Freq_G^R(T, m)$ simply counts the number of pieces where it occurs.

$$Freq_L^R(t, m) = \sum_{g \in label(t)} Freq_L^P((g, m, children(g))) \quad (1)$$

⁹ A net memory saving of a pattern defined as its unit memory saving multiplied by its number of occurrence minus the storage cost. If a pattern is already in the dictionary, then the storage cost is zero.

¹⁰ Similarly with the “non-overlapping” constraint of derivation patterns, we do not count re-occurrences of a meta-rule in a node if the same meta-rule also occurs in any of its children on a repeating position.

Algorithm 2 The Global Compression Algorithm (a single step)

```

1: Input

     $dE$  : Dictionary from piece-id to  $(t, dP, dM)$ 
     $dP_G$  : Dictionary from symbols to global templates
     $dM_G$  : Dictionary from symbols to global meta-rules

2: function  $compress_G(dE, dP_G, dM_G)$ 
3:    $(d_P^o, d_M^o) \leftarrow occurrence_G(dE)$ 
4:    $c \leftarrow bestCandidate(d_P^o, d_M^o)$ 
5:   if  $c = Nothing$  then
6:      $dE' \leftarrow compress_L$  over  $dE$ , only update
7:     local tables if the rule is not in  $dP_G$  or  $dM_G$ 
8:      $dP'_G \leftarrow dP_G$ 
9:      $dM'_G \leftarrow dM_G$ 
10:  else if  $c \in d_P^o$  then
11:     $dE' \leftarrow$  apply  $p$ -Rewrite( $c$ ) over trees in  $dE$ 
12:     $dP'_G \leftarrow update(dP_G, c)$ 
13:     $dM'_G \leftarrow dM_G$ 
14:  else if  $c \in d_M^o$  then
15:     $dE' \leftarrow$  apply  $r$ -Rewrite( $c$ ) over trees in  $dE$ 
16:     $dP'_G \leftarrow dP_G$ 
17:     $dM'_G \leftarrow update(dM_G, c)$ 
18:  end if
19:  return  $(dE', dP', dM')$ 
20: end function
    
```

As an example, in the tree in Fig 1b, the *meta-rule* $m_1 = \langle _ , 1 \rangle$ occurs six times¹¹ while the *template* $T_1 = (_ \searrow_5, m_1, *)$ occurs four times.¹²

The size for a *composition template* (i, g, f) is always 3 when g and f are stored in memory, because we only need two symbols to represent them, and an integer to specify the location at which they are composed. The *unitSave* of a *composition template* is always 1, as it replaces two nodes in the tree with one, thus decreasing the tree size by 1. The size of a *replication template* (g, m, \vec{f}) is $2 + sizeIn(m)$ for similar reason. The *unitSave* of meta-rule m is $sizeOut(m) - sizeIn(m)$ as the difference represents the number of symbol repeats.

5. EXAMPLE APPLICATION: REPETITION MINING ON THE JAZZ HARMONY TREE BANK

To exemplify an application of the proposed model, we turned to the Jazz Harmony Tree Bank dataset [45], which contains 150 pieces with annotated harmony labels. The annotations are in accordance with the formal-grammar trees of [15]. Since our focus is on modeling repeated relations among chords, rather than the chords alone, we need to transform our input from chord-labeled trees to rule-labeled trees in the same fashion as in Figure 1b. To this end, for every node in the tree we match chord labels with abstract production rules of [15]. The resulting rule-

Figure 5: Corpus size plotted against the number of global compression steps. The overall reduction in corpus size is from 7948 to 3385.

labeled trees are ranked trees,¹³ which is a required property for the compression algorithms (see [37]).

5.1 Results

In global compression, the decrease in tree size in the corpus is partly offset by the expansion of the global-rule table.¹⁴ In initial iterations, this trade-off is highly advantageous, as only few instances of certain patterns in the corpus are needed to offset the cost of storing rules. Thereafter, as shown in Figure 5, the compression size rapidly converges, demonstrating the efficiency of this process. It is worth noting a slight upward trend in the curve towards the end. This is because the algorithm does not mandate a reduction of the corpus size at each step; rather, it extracts patterns as long as they occur twice, whether locally or globally.

Following global compression, each piece is represented in a significantly more condensed format, utilizing the global-rule table. As shown in Figure 6, all pieces are compressed to at least 2/3 of their original size. In particular, four pieces are compressed to the size of one.¹⁵ These pieces and their changes are the following: “Equinox” (23 to 1), “Mr. P.C.” (23 to 1), “Subconscious Lee” (63 to 1), and “Hot House” (63 to 1). Notably, the first two pieces and the last two have the same rule-labeled tree representations respectively, indicating that they are derived in the same manner despite differences in chord labels. They compress to size 1, because their entire “piece” patterns occur at least twice and the algorithm therefore identifies

¹³ A ranked tree guarantees that the same symbol has the same arity. In a chord-labeled tree, a chord symbol can occur in both branching node (*arity* > 0) or leaf (*arity* = 0); such a tree is thus not ranked.

¹⁴ The size of a piece is defined by the sum of the size of the template nodes in the tree.

¹⁵ Only two of the pieces whose compressed size is equal to one are visible in the plot due to overlaying.

¹¹ as opposed to eight times because of the non-overlapping constraint

¹² This is made more explicit by the reduced tree in Figure 4a.

them as global *templates*. Table 1 summarizes the number of rules obtained after global compression of the corpus. The majority of the rules extracted are global, suggesting many common derivation patterns and meta-rules repeated in multiple pieces. To our surprise, all meta-rules found are global.¹⁶

Figure 6: Distribution of piece size before (x -axis) and after (y -axis) global compression. Each dot corresponds to a piece in the corpus. The indicator line represents 1-1 compression rate. Sizes refer to the individual compressed trees alone, not counting the size of global rule tables.

6. DISCUSSION AND CONCLUSION

We have presented a formal description and computational model of structural repetition in music, which also accounts for variations. In seeking a compressed representation of a forest of abstracted syntax trees, our goal has been to unveil *what* is actually repeated in a fundamental sense, and *how* entities recur within a specific style. To this end, we proposed a forest compression algorithm based on two rewrite operations, each catering to distinct musical abstractions.

The discovered global *meta-rules* (see Figure 7) include some of the hand-coded *meta-rules* outlined in [34] in line with musical intuition: $\alpha\alpha$ (M_1), $\alpha\alpha\beta$ (M_{64}) and $\alpha\alpha\beta\alpha$ (M_{62}). Also discovered are meta-rules such as $\alpha\beta\alpha\gamma$ (M_{20}), akin to (but not necessarily identical with) the “period” in standard contemporary form theory [10],

¹⁶ We think this is due to the abstract, general nature of *meta-rules*, which makes their recurrence in 150 pieces highly probable.

$M_1 = \langle _ , 1 \rangle$	$M_4 = \langle \star , _ \rangle$	$M_9 = \langle _ , _ , 1 , 2 \rangle$
$M_{13} = \langle \star \rangle$	$M_{16} = \langle _ , \star \rangle$	$M_{17} = \langle _ , 1 , 1 , 1 \rangle$
$M_{20} = \langle _ , _ , 1 , _ \rangle$	$M_{27} = \langle _ , _ , _ , 2 \rangle$	$M_{62} = \langle _ , 1 , _ , 1 \rangle$
$M_{63} = \langle _ , 1 , _ , _ \rangle$	$M_{64} = \langle _ , 1 , _ \rangle$	$M_{65} = \langle _ , _ , _ , 1 \rangle$
$M_{100} = \langle _ , _ , 1 , 1 \rangle$	$M_{101} = \langle _ , _ , _ , 3 \rangle$	$M_{148} = \langle _ , _ , 2 , _ \rangle$

Figure 7: The first 15 discovered global *meta-rules* (whose length is less than 5) out of total 36. The index n indicates the n -th discovered global pattern, including both *template* and *meta rules*.

as well as $\alpha\beta\gamma\alpha$ (M_{65}), which resembles an expanded ternary structure. *Meta-rules* with parent-child repeats (e.g. M_4, M_{13}, M_{16}) emerge quite early in the compression process. The *meta-rule* $\langle \star \rangle$ is the simplest way to nest a pattern. For example, applying it to the template “V region followed by I chord” results in the template “V/V region followed by V chord followed by I chord.”¹⁷ We believe such recursive repetitions of the same pattern are, in general, highly meaningful in music. By analyzing the compression rate of the individual pieces after global compression, one could argue that pieces with higher compression rates are generally likely to correspond to more “conventional” expressions of a style. In future research, considering the compression rate of individual pieces could shed light onto their stylistic attributes and patterns of interaction between style and structure.

We consider the distinction between global and local abstraction meaningful both for music interpretation and its computational representation. Global abstractions enable the creation of more efficient representations of an entire corpus in comparison with intra-piece, local compression. From a music-theoretical perspective, intertextual study is inextricable from the notion of style. For instance, while a ternary form may appear only once within a piece, analysts would still recognize it as a conventional entity because it recurs across the style. Galant schemata [18] can similarly be thought of as collections of stylistic patterns. Form archetypes such as *AABA* and *ABA* can likewise be seen as global meta-rules.

By integrating additional types of constraints, the model has the potential, with certain extensions, to express more sophisticated repetitions. For example, Schoenberg’s notion of “liquidation” [46] could be recast as the repetition of abstract relations constrained by decreasing elaboration depth. The notion of “fragmentation” [10] could also be modeled as repetition with a constraint on ordering, so that fragments appear only after the initial, integral structure. Our framework could also find use in algorithmic music generation under grammatical constraints. For instance, one could generate a piece in top-down fashion by sampling patterns and meta-rules discovered within a stylistically homogeneous corpus.

¹⁷ “Region” here indicates non-terminal symbol while “chord” indicates terminal symbol.

ABSTRACT

Carnatic music is a style of South Indian art music whose analysis using computational methods is an active area of research in Music Information Research (MIR). A core, open dataset for such analysis is the Saraga dataset, which includes multi-stem audio, expert annotations, and accompanying metadata. However, it has been noted that there are several limitations to the Saraga collections, and that additional relevant aspects of the tradition still need to be covered to facilitate musicologically important research lines. In this work, we present Saraga Audiovisual, a dataset that includes new and more diverse renditions of Carnatic vocal performances, totalling 42 concerts and more than 60 hours of music. A major contribution of this dataset is the inclusion of video recordings for all concerts, allowing for a wide range of multimodal analyses. We also provide high-quality human pose estimation data of the musicians extracted from the video footage, and perform benchmarking experiments for the different modalities to validate the utility of the novel collection. Saraga Audiovisual, along with access tools and results of our experiments, is made available for research purposes.

1. INTRODUCTION

In recent years, there has been an increasing emphasis on representing non-Western classical music styles within computational musicology [1, 2], an interdisciplinary research area involving musicology and computer science. To facilitate this research, many repertoire-specific datasets have been proposed that take into account the melodic, rhythmic and structural complexities of these traditions. Several of them are consolidated within the scope of Dunya, a collection of large music corpora dedicated to fuelling research of five major non-Western music traditions: Carnatic music, Hindustani music, Turkish Makam, Beijing Opera and Arab-Andalusian music [1].

One style of particular interest is Carnatic music, for which there has been numerous computational musicological studies carried out using the Saraga dataset, a subset of the Dunya corpora dedicated to the Indian Art Music (IAM) traditions of Hindustani and Carnatic music [3–6]. The Carnatic portion of this dataset comprises performance audio, expert/automatically extracted annotations, and associated relevant metadata [7].

The audio data includes the mixture and, for a number of recordings, multi-track signals for all instrument sources except the *tānpūrā*. Since Carnatic music is primarily performed and enjoyed in a live performance setting, the audio recordings gathered for the Saraga dataset are all recorded in this context, and hence contain some leakage interference in the individual stem signals.

Alongside these audio recordings, Saraga provides automatically extracted annotations, such as the predominant pitch track of the vocalist’s melody and rhythmic beats, and manual annotations, such as melodic patterns and musical sections. Finally, the dataset includes editorial metadata such as performer names, concert/composition titles, and musical tags such as melodic (*rāga*) and rhythmic (*tāla*) modes, which are crucial for this repertoire.

Whilst Saraga has proven to be a valuable resource for the analysis of IAM, there are nonetheless many challenges and important research questions for Carnatic music for which Saraga is insufficient. Some of these deficiencies – such as representativeness (e.g., instrument diversity, number of *rāgas*, demographics), completeness of annotations, and data access – have been pointed out in its open peer-review [8]. However, no new version of the dataset addressing said problems has been made available, and hence such deficiencies persist. Furthermore, Saraga contains automatically extracted features, which although may have been state-of-the-art at the time, could well be improved using more modern algorithms [9] and models [10].

In this work, we introduce *Saraga Audiovisual*, a new dataset built according to the principles of the original Saraga, that encompasses 42 new concerts totalling more than 60 hours of Carnatic music recordings. By including new artists, compositions, *rāgas*, and *tālas*, we improve the diversity and representativeness of the data. The new collection comprises multi-track audio, video recordings, and human pose estimation data, the latter two of which are entirely new modalities which are currently not considered in the first Saraga dataset. We hope that this multimodal data

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

will power further research of musically relevant problems in Carnatic music and encourage the development of underexplored research strands, particularly in music’s visual and kinetic aspects [11–13]. We also improve documentation, access, and tools, considering the issues raised for Saraga [8], and provide a detailed description of the new dataset regarding musical metadata and coverage.

To showcase the value of the new dataset we present two benchmarking experiments to (a) demonstrate that the features extracted from the new audio-visual data are useful for the analysis of codependencies between performer body movement and vocalisations, an active research area in IAM analysis [14–21]; and (b) show that the novel multi-track audio is valuable for Music Source Separation (MSS) in Carnatic music, a low-level feature extraction task for which distributed pre-trained models in the literature do not generalize [22].

2. BACKGROUND AND RELATED WORK

Digital technology has brought new research methods to musicology [23, 24]. With digital archives and computer science techniques, researchers can study music corpora more systematically and quantitatively [25, 26]. Hence, creating appropriate datasets and research corpora for different music traditions is a fundamental concern in music information research (MIR) [27–32]. Computational musicological studies have used various data sources: scanned sheet music, symbolic scores, audio/video recordings, and motion capture data [11–13, 21, 33–36].

With few exceptions [36, 37],¹ almost all openly available datasets in the literature for Carnatic and Hindustani music are compiled from the IAM corpora in CompMusic [28], and more recently, from the Saraga dataset, for which multi-track audio recordings and manual and automatically extracted annotations are available [7].

Dataset distribution is a major concern in the music information research community [38], in which data plays a key role, especially given the advent of DL models. Saraga is currently accessed through Python notebooks, but the process is complex, not standardized, and hindered by bugs and dependency incompatibilities. Such a distribution method requires regular maintenance, which is expensive and time-consuming. A unified and functioning access point for the canonical version of the dataset, and a documented toolkit to browse through the recordings and annotations are not available.

One other important limitation of Saraga is that it contains only audio recordings. However, music is not only an auditory experience; multiple lines of research have demonstrated that the visual and kinetic aspects are all part of what music fundamentally is [39–41]. Thus, a comprehensive study of music performance requires auditory, visual and kinetic components [11].

In the case of Carnatic music, visual cues like hand/head gestures and performer gaze can provide the artists con-

textual information for an improved dynamic on stage, whilst also playing a more individualistic expressive role. This has been investigated in various IAM studies using motion capture data and pose estimation extracted from video [14–21]. For this reason, a dataset of Carnatic music should ideally include as much of this multimodality as possible, which we are enabling through the contribution of the video recordings in the proposed dataset.

3. DATASET DESCRIPTION

Saraga Audiovisual aims to address some of the aforementioned issues attributed to the first version of Saraga. In this section, we present the proposed improvements, which are mainly based on fixes, new recordings, and the novel visual modality. Although the new dataset falls entirely in the Carnatic repertoire, the proposed pipeline could be extended to Hindustani Music in the future.

3.1 New concerts

A total of 42 new concerts are released as part of Saraga Audiovisual, including multi-track audio and video for all concerts. The multi-track audio covers three main stems: vocals, violin, and mṛdaṅgam for all renditions, with the addition of ghaṭam and tānpūrā for 9 other concerts. The audios are all stereophonic and encoded at 44.1 kHz. Since the audio is recorded during live performances, the individual stems contain interference from the other sources.

These 42 concerts consist of a total of 235 individual performances of 223 unique compositions from 131 lead and accompanying artists. All performances include manually annotated section annotations. 10 distinct tālas and 113 distinct rāgas are represented, an increase of 55 on the existing Saraga dataset. Figure 1 shows the combined statistics for the case of the frequency of occurrence of the same rāga performances over Saraga and Saraga Audiovisual. Our aim is to increase the representation of existing rāgas whilst including unrepresented rāgas.

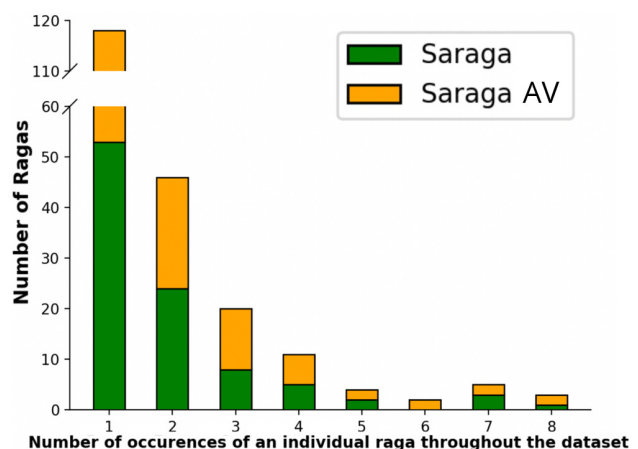

Figure 1. Number of occurrences of individual rāgas combining the two datasets. X-axis represents number of occurrences, whilst Y-axis indicates how many rāgas there are with 1, 2, ..., 8 occurrences.

¹ Using the IEMP North Indian Rāga: <https://osf.io/ks325/>, and Karnatak ālāpāna multimodal dataset: <https://osf.io/6huvd/> respectively

Figure 2. A video frame fragment from Saraga Audiovisual. The lead singer is VR Raghava Krishna, the violinist is VV Ravi and the mridangist is Guru Raghavendra.

Content	Saraga	Saraga AV
Total number of recordings	249	235
Total number of artists	64	131
Number of compositions	202	223
Total number of rāgas	110	235
Unique rāgas in collection	96	113
Total number of tālas	10	10
Total duration of the dataset	52.7	64.8

Table 1. Content comparison of the Carnatic subset of Saraga and the Saraga Audiovisual dataset (Saraga AV).

The most popular performance format today is vocal-led, either by a single or multiple vocalists. Despite the fair criticism of the shortage of instrumental recordings [8], we decide to consider only concerts led by a singer in Saraga Audiovisual. Moreover, the singing voice is extensively explored in the MIR literature, with numerous models designed to address various problems and research questions, offering opportunities for leveraging, training, and fine-tuning functional systems. We refine the statement around representativeness of Saraga to clarify that our dataset is intentionally vocal-centered.

3.2 Video recordings and human pose estimation

The videos corresponding to the concerts are rendered at 1080p and have a frame rate of 25 fps. They are recorded with a fixed wide-view position to frame all performing artists throughout the concert.

Figure 2 depicts the recording setting. The videos are recorded in a traditional concert set up with microphones occluding the view of the artists at most times. For example, if we observe a singer in this setting, they are in a seated position with the microphone directed towards their mouth. Consequently, the microphone head occludes the mouth, and the stand hampers the view of the singer’s hands in several instances. In general, occlusions can hinder human pose estimation by a very large margin. After careful examination of several human pose estimation models, we choose MMPose [42], a DL model which performs extremely well, given the tricky setting. We extract human skeletons with 17 key points through its 2-D model. See Figure 3 for an example of the gesture estimation on a Saraga Audiovisual example video recording.

Figure 3. Gesture extraction with MMPose. The artist depicted in the figure is VR Raghava Krishna

3.3 Improving dataset access

Hassle-free and canonical access to the Saraga audio, annotations, and also metadata is an issue raised by the community [8]. We implement a `mirdata`² loader for Saraga Audiovisual to download, load, and browse through the canonical dataset and easily filter the data by musically important aspects such as rāga, tāla, artist, and tonic. These functions are also available through `compIAM`³, where models and algorithms for the computational analysis of Carnatic music are also available.

3.4 Further improvements

Note that some of the features in Saraga are automatically extracted. Despite not being manually collected, these allow for faster, consistent, and reproducible research as we bypass the need to compute them multiple times. Since Saraga was first published, much research has been carried out by the MIR community, and new models to more reliably extract such features are available. Within the context of this work we compute the melody curves of the novel recordings using the Carnatic-optimized FTA-Net [10].

4. EXPERIMENTS

In this section we present two experiments using the audio and visual components of Saraga Audiovisual.

4.1 Multimodal study

There exists various studies that demonstrate the relationship between gesture and musical motifs in an IAM context [14–21]. Whilst most focus on the North Indian, Hindustani style, a recent study by Pearson et al. presents a quantitative attempt at characterising codependencies between the body movement and vocalisations of Carnatic performers using a combination of predominant pitch tracks extracted from audio, and motion tracking data captured using an inertial measurement system on the body during performance [37]. In an effort to demonstrate the value of

Table 2. Saraga Audiovisual performances used for multimodal experiment in Section 4.1. Duration’s (mm:ss) correspond to the rāga ālāpana section of the performance, the rest of the performance is not used for analysis.

Saraga Audiovisual in supporting such studies, we reproduce a part of Pearson et al’s analysis here using data extracted from the proposed multimodal dataset. In the original study, performer gesture data is extracted using motion capture equipment, since here we rely on inferring this information from video, we make some changes to that part of the process, outlined in the following section. All other steps remain identical to the original study and we refer the reader to the paper for more details.

4.1.1 Experimental setup

We reproduce Pearson et al’s Analysis 1: *Do sonic motif DTW distances covary with spatiotemporal patterns of gesture?* Our sonic data for such analysis is extracted from 4 performances (Table 2) in Saraga Audiovisual, from which we extract 4 time series corresponding to the rāga ālāpana section of the performance audio; (1) f_0 – the predominant vocal melodic line, measured in cents above the performer tonic, extracted using a Carnatic-specific methodology [10], (2) Δf_0 – the first derivative of f_0 , (3) loudness, L , computed as $L = 10 \cdot \log_{10} \frac{S}{ref}$, where S is the power spectrum of the raw audio signal and ref is its maximum value, and (4) the spectral centroid of the raw audio signal. Our gestural data is extracted using MMPose and limited to the performer’s left and right hands (see Section 3.1, and Figure 3), from which we compute the first and second derivatives to obtain two subsequent time series of velocity and acceleration, respectively, resulting in 6 gestural time series. The 6 time series are resampled so as to have identical sampling rates of 24 Hz, and all 10 time series are smoothed using a 2nd-order Savitzky-Golay filter with a window length of 125 ms.

In each of the 4 performances, we identify regions of repeated melodic motifs using a Carnatic-specific methodology [4]. For each motif, we isolate the corresponding segment in our 4 sonic and 6 gestural time series, and discard the gestural time series corresponding to the non-dominant hand. The dominant hand of the performer for each pattern is determined as that which has the highest kinetic energy, $K.E$, computed from the velocity tracks, v , where $K.E = \frac{mv^2}{2}$ and m is the mass of the moving body part, assumed equal for both sides. We note that for over 98% of the identified motifs, the ratio in $K.E$ between the dominant and non-dominant hand is greater than 1.2, i.e. there is almost always a clear dominant hand. 70% of motifs are identified as left-handed and 30% as right-handed. The

gesture space for each motif is transformed such that left and right-hand gestures occur in the same space by mirroring all right-handed gestures in the y-axis, and such that the gestural space origin corresponds to the centroid of the body of the performer. This centroid is determined for each motif as the centroid of the trapezoid corresponding to the performer’s body, provided by MMPose and visible in Figure 3.2. The result is a selection of 269 non-overlapping motifs across the 4 performances, each represented by 4 sonic time series (f_0 , Δf_0 , loudness and spectral centroid) and 3 gestural time series (position, velocity and acceleration of the dominant hand).

For each pairwise combination of our 269 motifs, we compute the dynamic time warping (DTW) distance between each of their 6 sonic time series and 4 gestural time series, i.e. f_0 compared to f_0 , hand position compared to hand position etc... Motifs are not compared to themselves and as such this constitutes 36,046 motif pairs. This analysis is concerned with whether there exists a relationship between the DTW distances of sonic and gestural features (sonic features: f_0 , Δf_0 , loudness and spectral centroid; gestural features: hand position, velocity and acceleration). For each combination of sonic to gestural features, we compute Spearman’s rank correlation coefficient to quantify this relationship, both on a performer level and across all performers.

4.1.2 Results

The correlation analysis results are presented in Figure 4. Tests for which the p-value is greater than our significance level of 0.0001 are excluded and replaced with a grey square in the heatmap. It is not within the scope of this paper to discuss the results of this analysis in detail, nor do we consider the size of the data analysed sufficient to make any meaningful conclusions (0.5 hours of performance compared to 3.8 in the original study). We do, however, emphasize that even with this limited scope, we are able to identify significant relationships between sonic motif distances and spatiotemporal patterns of gesture using the Saraga Audiovisual dataset, corroborating the results of Pearson et al.’s study. As in that study, we show loudness as having the strongest correlation with gestural features across the performers and demonstrate how distinct the individual performer gesturing styles are, with great variation in the extent to which performers’ gestures correlate with f_0 and spectral centroid.

4.2 Fine-tuning MSS models with data with bleeding

The current state-of-the-art MSS models are based on DL architectures which are trained using multi-track recordings. Some models that are widely used, namely Spleeter [43] or Demucs [44], are trained with multi-track stems available through datasets like MUSDB18HQ [45] or MoisesDB [46], mainly including Western pop styles or related genres. Although many research works on the analysis of IAM use the available Spleeter model for source separation [13,47,48], these models do not generalize well for Carnatic music due to its varied instrumentation and

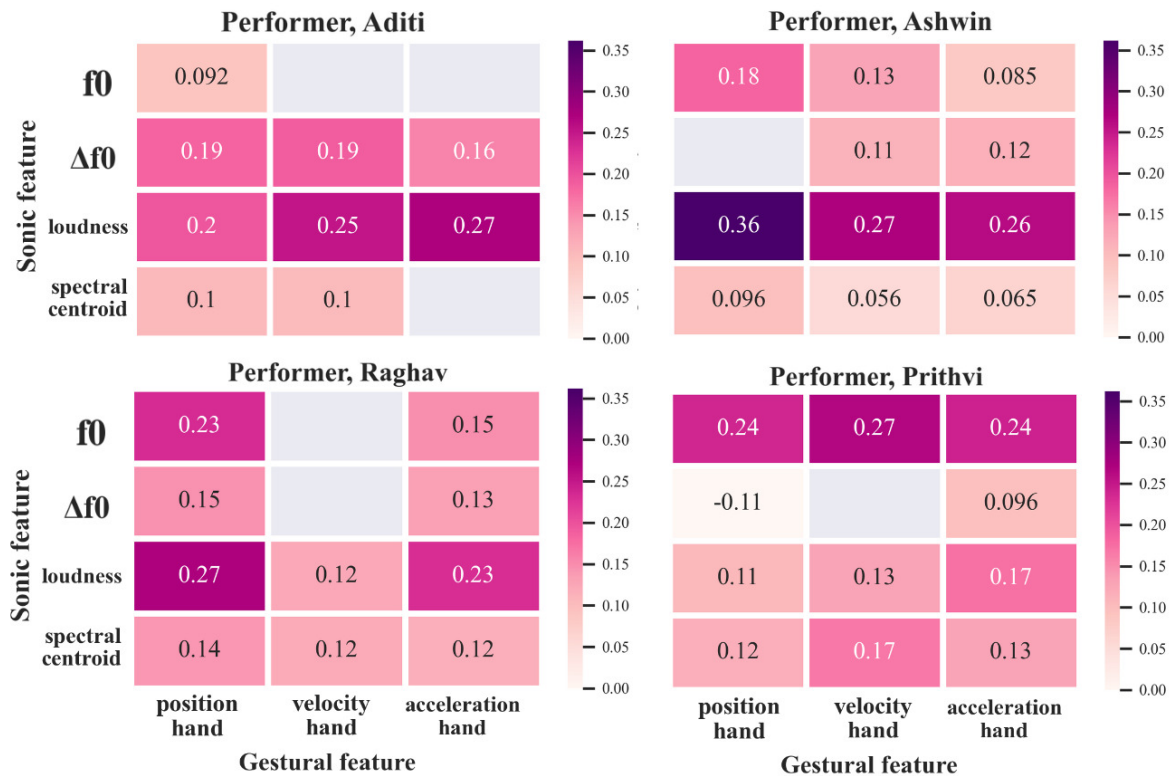

Figure 4. Spearman’s rank correlation coefficient for all performers and on an individual level. Insignificant test results are represented by a grey square.

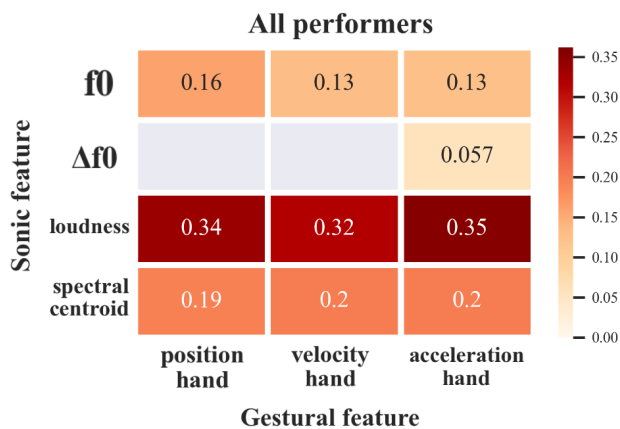

Figure 5. Spearman’s rank correlation coefficient for all performers in the dataset. Insignificant test results are represented by a grey square.

idiosyncratic singing technique. In Carnatic music, the violin usually replicates or closely follows the melody of the singing voice. The tānpūrā provides an ambient canvas, and the mṛdaṅgam, a pitched percussion instrument, is strongly present. Existing MSS models are unfamiliar with such music styles and struggle to give a clean, separated singing voice stem.

There have been some efforts by the community to improve MSS for the use case of Carnatic music [22], since much research is done on top of vocals. Therefore the availability of isolated vocal recordings is highly valuable

for the computational research of Carnatic music. Datasets like Saraga offer multi-track audio data, but given the fact that these recordings are from live concerts, there is leakage between sources that are part of the ensemble. The lack of clean multi-tracks for these music styles has been reported consistently, but Carnatic music is normally performed and recorded in a live setting. Therefore, recording musicians separately is not representative of how the tradition is generally performed. However, there has been some research on training MSS models with data with bleeding and some methods have been proposed to show the utility of data with bleeding [22].

Spleeter is a model based on a U-Net architecture that operates on the time-frequency domain. It is composed of a 6-layer encoder-decoder structure with skip-connections. Similar to most spectrogram-based separation models, Spleeter estimates n separation masks that are multiplied by the input mixture spectrogram to separate the sources. The official implementation of Spleeter provides a framework to fine-tune the available pre-trained models in order to adapt the system to a specific domain [43].

In an ideal case, clean Carnatic multi-track stems would be essential to fine-tune Spleeter. However, we utilize the data with leakage that is part of the Saraga Audiovisual dataset in an attempt to set up a baseline for bespoke Carnatic vocal separation. We use the provided 2-stem Spleeter model, trained on a private dataset of 25k samples of 30s. We fine-tune Spleeter using Saraga and Saraga Audiovisual, aiming also to study the effect of the newly collected multi-track data. The models are fine-tuned for

600k steps with a constant learning rate of $1e-5$. The fine-tuning process takes about a week in a TITAN XP GPU.

4.2.1 Experimental setup

Perceptual tests for MSS have gained interest in the research community, as objective metrics in [49] have been reported to not always correlate with the perceptual quality of MSS estimations [50]. Moreover, there is not a standardized and completely clean testing set for Carnatic separation. For that reason, we run a listening test with human subjects, including separations from recordings that we randomly collect from the Dunya dataset.

The listening test is based on the MUSHRA framework [51]. Subjects are asked to evaluate the vocal quality and the intrusiveness of other sources in separate stages. The scores are given on a scale from 1 to 5, with 5 being the maximum score. In each example, the subject is shown the original mixture as the reference stimuli, and the separations are shown unnamed and in a randomized order. The proposed subjective evaluation follows closely the ITU-T P.835 recommendation. We select and separate 6 Carnatic music concerts, ensuring diversity in audio quality and singer gender. Then, we randomly select a rendition from each concert, from which we collect a 30s chunk starting at a random point in time [22].

4.2.2 Results

We collect the results of the perceptual experiments and report the Mean Opinion Scores (MOS) per each model. We also report the Confidence Intervals (CIs) with $\alpha = 0.05$. A total of 20 subjects participated in the survey. Results are given in Table 3. While Spleeter samples are rated as having better vocal quality, Spleeter-FT-Sar improves over interference removal, while Spleeter-FT-SarAV is the most balanced solution among the three.

From the perceptual experiment, we conclude that Spleeter can better preserve the quality of the singing voice over the fine-tuned models. Using noisy data to fine-tune may be causing the model to lose some ability to properly discriminate the singing voice components. On the other hand, as the fine-tuned models improve on interference removal, we argue that it is possible for the pre-trained model to learn the instrumentation and vocal concepts of Carnatic music while preserving the knowledge to estimate separation masks for clean sources. In this particular experiment, Spleeter-FT-SarAV provides a balanced trade-off between artifacts and interferences. However, the overall performance is comparable to the other systems, suggesting that the multi-stem recordings have been obtained following the same peer-reviewed process in Saraga [7]. While establishing the baseline for Carnatic vocal separation, we also observe that leakage-aware systems such as [22] are still to be explored to take complete advantage of the multi-track data with leakage in both Saraga and Saraga Audiovisual, and outperform out of domain pre-trained models.

	Artifacts	Interferences
Spleeter [43]	3.89 _[3.75,4.04]	2.17 _[2.04,2.30]
Spleeter-FT-Sar	2.76 _[2.60,2.93]	3.80 _[3.68,3.93]
Spleeter-FT-SarAV	3.41 _[3.27,3.57]	2.88 _[2.74,3.02]

Table 3. MOS rating comparison between the default Spleeter [43] and a fine-tuned Spleeter using Saraga (FT-Sar) and Saraga Audiovisual (FT-SarAV). The higher, the better; 5 is the maximum rating. 95% CIs are also reported.

5. CONCLUSIONS

In this paper, we introduce Saraga Audiovisual, a multi-modal dataset for the analysis of Indian Art Music, specifically of the Carnatic style. The dataset includes multi-track audio, fundamental frequency extractions from that audio, performance videos, and human pose estimation extracted from the video footage. The dataset also includes metadata like rāga, tāla, composition, and structural annotations like the ālāpana, kalpanā svara, niraval, and thaṇi āvartana. The dataset is made available as a mirdata dataloader for easy and standardized access.

We perform two benchmarking experiments using the extracted audio and video features: (1) a multimodal analysis investigating the relationship between performer gesture and vocalisation, and (2) a fine-tuning experiment for Carnatic vocal source separation with audio data induced with leakage. Both experiments demonstrate the value of this data for music analysis in spite of imperfections in the automatically extracted feature data, such as audio leakage in the isolated instrument stems, or instability in the extracted pose estimations.

We expect Saraga Audiovisual to be a valuable resource for future work on tasks such as both vocal and instrument based leakage-aware source separation or predominant pitch extraction; and further multimodal studies of Carnatic music.

6. ETHICS STATEMENT

The Saraga Audiovisual dataset was recorded at the Arkay Convention Centre in Chennai. All of the artists appearing in the dataset gave informed consent for the dissemination of the data for research purposes through a consent form, and the Arkay Convention Centre was paid for their work in gathering the recordings.

With the release of this dataset, we wish to honour the cultural heritage of Carnatic music and safeguard its traditions. We recognize that to understand the distinctive intricacies of this culture and tradition, it is essential to go beyond computational methods alone. This understanding should not be oversimplified or broadly generalized.

7. ACKNOWLEDGEMENTS

This work was carried under the "IA y Música: Cátedra en Inteligencia Artificial y Música (TSI-100929-2023-1)",

funded by the Secretaría de Estado de Digitalización e Inteligencia Artificial, and the European Union-Next Generation EU, under the program Cátedras ENIA 2022 para la creación de cátedras universidad-empresa en IA. Special thanks to Suhit Chiruthapudi for actively helping with the preparation of the dataset. We would like to acknowledge Arkay Convention Centre, Chennai and all the musicians included in the dataset. Special thanks to Aaditya Rangan Raghavan, Samiksha Sreekanthan, Adithya Srinivasan and R Sarang for their invaluable contributions to the dataset. We would also like to extend our thanks to Dr. Lara Pearson for her valuable insights on the paper. We would like to thank Marius Rodrigues for helping with the pose estimation of the videos and Serafin Schweinitz for his contribution to the dataset. Finally, we would like to acknowledge the 20 participants who agreed to undertake the perceptual test.

ABSTRACT

Methods based on deep learning have emerged as a dominant approach for cover song identification (CSI) literature over the past years, among which ByteCover systems have consistently delivered state-of-the-art performance across major CSI datasets in the field. Despite its steady improvements along previous generations from audio feature dimensionality reduction to short query identification, the system is found to be vulnerable to audios with noise and ambiguous melody when extracting musical information from constant-Q transformation (CQT) spectrograms. Although some recent studies suggest that incorporating lyric-related features can enhance the overall performance of CSI systems, this approach typically requires training a separate automatic lyric recognition (ALR) model to extract lyric-related features from music recordings. In this work, we introduce X-Cover, the latest CSI system that incorporates a pre-trained automatic speech recognition (ASR) module, Whisper, to extract and integrate lyrics-related features into modelling. Specifically, we jointly fine-tune the ASR block and the previous ByteCover3 system in a parameter-efficient fashion, which largely reduces the cost of using lyric information compared to training a new ALR model from scratch. In addition, a bag of tricks is further applied to the training of this new generation, assisting X-Cover to achieve strong performance across various datasets.

1. INTRODUCTION

In the rapidly evolving field of music information retrieval, Cover Song Identification (CSI), which aims to identify different versions of a specific musical composition within a large database, remains a complex and computationally challenging task [1, 2]. This problem has received consid-

erable interest for its wide-ranging applications such as intellectual property management and enhancing music recommendation systems [3, 4].

With the advancements in deep learning, CSI systems based on neural networks gradually replace traditional models based on handcrafted features [5, 6] and become a new paradigm for real-world deployment. Existing methods typically frame CSI as either a classification problem [7–9], a metric learning problem [10], or a combination of both [11, 12]. On the other hand, the proliferation of social video platforms like TikTok has also led to a surge in short-form videos, which often contain remixed or covered segments of original compositions and hence involve copyright infringement issues. Unfortunately, as most of the existing works above contain a global pooling layer to directly aggregate the information from all time sections, they are found to suffer from identifying these seconds-long short segments.

To address this problem, the latest ByteCover3 system [13] first splits each full audio track into a set of short spectrogram chunks and then uses a neural-network-based extractor (i.e. the ResNet-IBN module introduced in the first ByteCover generation [11]) to encode them into latent embeddings. These low-dimensional embeddings are later sent to calculate a Local Alignment Loss (LAL) that uses the matching of local embeddings to identify short queries against full songs.

Despite the progress in detecting short cover songs, the ByteCover3 system is still found to be vulnerable to non-musical information in real-world scenarios. For instance, musical segments in short videos are frequently overlaid with ambient noise, speech, or poorly composed user-generated melodies. The presence of these non-musical elements that mask or distort the musical elements can mislead the feature extraction phase of ByteCover3, leading to inaccurate or ambiguous representations of the audio content. This misrepresentation can degrade the system’s ability to correctly match the audio sample against its database of known songs, reducing both the accuracy and reliability of the system in operational settings.

To enhance the robustness of existing CSI systems, an intuitive approach is to incorporate more discriminative information into model training. Recent research [14, 15] has demonstrated that lyric-related features are less susceptible to being masked by unrelated noise sources and can serve

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

as auxiliary inputs to bolster CSI systems. For example, one recent work [14] utilizes latent embeddings from an automatic lyrics recognition model (ALR) as lyric-related features for CSI. However, this approach requires training an extra ALR module from the beginning and employs Dali [16] as its training dataset, which implies that it only supports the recognition of English lyrics.

In this paper, we extend the current ByteCover3 system by leveraging a pre-trained Automatic Speech Recognition (ASR) model to jointly model both lyric and musical features for short-query identification, which eliminates the need for training an additional ALR model from scratch. Specifically, we use Whisper [17] as the pre-trained ASR module for its inherent scalability and robust recognition capabilities across multiple languages. However, the training is still quite challenging in terms of GPU memory consumption and inference time given the large parameter size of Whisper and its autoregressive nature at the text decoding stage. To counter these issues, we employ a prefix-tuning fashion that adapts the output of Whisper to CSI training. A trainable prefix latent is added before each text decoder block in Whisper to reprogram the model to extract features specific to CSI task without extensive retraining of the entire model. Finally, the fusion model is trained using the local alignment loss (LAL) scheme introduced in ByteCover3, and together with a bag of new techniques, we further improve the current ByteCover system to be more efficient and accurate in CSI tasks with controllable training GPU memory and reasonable inference time.

2. PRELIMINARIES

This paper builds on ByteCover series [11–13] training framework and model structure. The primary motivation of ByteCover series is to develop a highly accurate, robust and efficient cover song detection system for real-world industrial-level tasks with various query types and large music corpora, beyond typical laboratory settings.

ByteCover1 [11] introduced a streamlined framework designed to train a neural network that extracts version-related embeddings from the CQT spectrogram of input audio recordings. This model utilized Instance Batch Normalization (IBN) layer [18] within its ResNet architecture, which enhances the model’s capability to learn invariant features while preserving discrimination and is critical for handling diverse musical styles. Additionally, a Generalized Mean (GeM) pooling layer was employed to compress local features into a global feature, optimizing the model’s training objectives. Furthermore, ByteCover1 adopted a multi-loss training paradigm that combined classification loss and triplet loss, fostering a more robust representation and improved accuracy.

For improved throughput, the authors of ByteCover2 [12] identified an anisotropy in the embedding distribution of ByteCover1, which led to inefficient utilization of the embedding dimension size. To address this issue, ByteCover2 introduced a Principal Component Analysis - Fully Connected (PCA-FC) layer. The weights of this layer are informed by the transformation matrix de-

rived from a PCA analysis of the original ByteCover1 embeddings. This strategic adjustment effectively alleviated the anisotropy problem, enabling ByteCover2 to match the performance of ByteCover1 while only requiring one-eighth of the dimension size. Consequently, this reduction drastically accelerated the retrieval of query embeddings and linearly decreased the storage costs of the embedding database relative to the magnitude of the dimension size reduction.

With the emergence of short video content, more queries in CSI systems appear to be short audio clips. However, the authors of ByteCover3 [13] observed that state-of-the-art CSI methods performed suboptimally on these short queries, where the accuracy of previous deep learning CSI models [10–12, 19] degraded significantly as the duration of query audio decreased. This issue was linked to the global pooling modules employed in previous works that often neglected local features, which complicates the task of matching segments of songs to complete tracks. Traditional audio matching algorithms, such as the "shingling" method referenced in [20], slice inputs into segments and extract features separately to preserve local details. Unfortunately, this straightforward strategy struggled when applied to deep learning-based CSI methods, which are inherently data-driven rather than handcrafted. Consequently, there is a misalignment between training and inference objectives: while softmax and triplet losses focus on matching pairs of embedding vectors, the model deals with sequences of local embeddings at the inference phase.

To bridge this gap, ByteCover3 introduced a novel training paradigm known as Local-Aware Losses (LAL) for metric learning on sequence data. This approach extends softmax and triplet losses into a more general form that directly optimizes the metrics between two sequences of embeddings. Specifically, ByteCover3 employs the MaxMean Measure to assess the similarity between two sequences of vectors, consequently ensuring better alignment of the training and inference targets and enhancing performance. This measure calculates the similarity between each segment in the query audio and the most similar segment in the candidate song, averaging these similarities to produce a final similarity score. This method is computationally efficient and differentiable. With the use of LAL and the MaxMean measure, ByteCover3 demonstrated significant improvements in retrieval capabilities with 30-second queries.

The subsequent method section, Section 3, describes the details of X-Cover and is organized as follows:

- Subsection 3.1 introduces the overall framework of X-Cover, which retains a high-level similarity to ByteCover3.
- Subsection 3.2 discusses the incorporation of the pretrained ASR model, Whisper [17], to enhance the robustness of the CSI system. It also describes a non-autoregressive decoding method designed to accelerate Whisper’s decoding. Compared to previous methods that relied solely on cover song data,

Figure 1. The input CQT spectrogram and Mel spectrogram are split into n equal-sized chunks with overlap in temporal dimension. Subsequently, the ResNet-IBN extractor derived from [13] generates an embedding \mathbf{X}_m that contains N local features corresponding to N input chunks with the CQT spectrogram. The optimized Whisper variant generates an embedding \mathbf{X}_l that contains N local features corresponding to N input chunks with the log Mel spectrogram. Then, we optimize the model with a multi-loss objective that consists of a classification loss L_{lac} and a triplet loss L_{lat} using the *MaxMean* measure, where \mathbf{X}_p and \mathbf{X}_n represent the positive sample and negative sample in triplet loss.

X-Cover achieved superior performance without the necessity of pretraining on additional lyric data. This simplification and streamlining of the training process significantly enhance the efficiency of model preparation.

- Subsection 3.3 introduces a bag of tricks to improve the performance of the CSI model, covering aspects such as data augmentation, model architecture, and loss function design details.

3. X-Cover

In this section, we delineate the architecture and training paradigms of X-Cover, emphasizing its novelties: efficient adaption of Whisper and a bag of tricks for improving ByteCover3 in Cover Song Identification (CSI) tasks. The overall architecture is depicted in Fig. 1.

3.1 Overall Framework of X-Cover

The architecture of X-Cover is an evolutionary extension of ByteCover3, delineated in Section 3. X-Cover retains the multi-objective learning paradigm and the ResNet-Based Feature Extractor from ByteCover3. To incorporate lyric-related features, X-Cover introduces a pretrained ASR model, Whisper, alongside the existing ResNet-IBN architecture [11].

In ByteCover3, local features are extracted by initially resampling the audio to 22,050 Hz and partitioning it into N overlapping segments of 20 seconds each, with a 10-second hop. These segments are subsequently transformed into CQT spectrograms, serving as the input to the ResNet-IBN model. The model outputs a 4-D embedding, which

undergoes GeM pooling to yield a compact final local embedding $\mathbf{X}_m \in \mathbb{R}^{N \times C_m}$, comprising N local features.

To facilitate the integration of Whisper as an additional feature extractor, mel spectrograms are extracted from the input audio. To temporally align the features from both branches, the same chunking strategy as in ByteCover3 is employed. Post chunking, the specialized Whisper model for CSI utilizes these mel spectrograms to extract lyric-related embeddings $\mathbf{X}_l \in \mathbb{R}^{N \times C_l}$. Upon obtaining the two sets of latent embeddings, \mathbf{X}_m and \mathbf{X}_l , a straightforward feature-dimensional concatenation is performed to generate the fused embedding $\mathbf{X}_f \in \mathbb{R}^{N \times (C_m + C_l)}$, for the simplicity, we redefine it as $\mathbf{X} \in \mathbb{R}^{N \times C}$ where $C = C_f = C_m + C_l$. This is feasible due to the temporal alignment and identical lengths of \mathbf{X}_m and \mathbf{X}_l . X-Cover leverages the Local Alignment Loss (LAL) methodology, originally proposed in ByteCover3, to enhance local segments matching capabilities. The LAL comprises a classification loss \mathcal{L}_{lac} and a triplet loss \mathcal{L}_{lat} , defined as follows:

$$\text{logit}_k = \text{MaxMean}(\mathbf{X}, \mathbf{W}_k), \quad (1)$$

$$\mathcal{L}_{lac} = \text{CE}(\sigma(\{\text{logit}_k\}_{k=1}^K), y), \quad (2)$$

$$\mathcal{L}_{lat} = [\text{MaxMean}(\mathbf{X}_n, \mathbf{X}) - \text{MaxMean}(\mathbf{X}_p, \mathbf{X})]_+, \quad (3)$$

where $\text{CE}(\cdot, \cdot)$ is the cross entropy, $\sigma(\cdot)$ is the softmax function, $\mathbf{X}_n, \mathbf{X}_p \in \mathbb{R}^{N \times C}$ is the fused embedding of the negative sample and positive sample while calculating triplet loss. $\mathbf{W} \in \mathbb{R}^{K \times L \times C}$ is a trainable weight matrix in the linear layer before softmax, and $\mathbf{W}_k \in \mathbb{R}^{L \times C}$ denotes the proxy representation for class k . L is a hyperparameter which is set to 9 in ByteCover3 and X-Cover. These loss functions serve as a robust optimization objective, fortify-

ing the model’s performance and adaptability for emerging challenges in music information retrieval. The subsequent subsections will expound upon these enhancements and their contributions to the overarching efficacy of X-Cover.

3.2 Efficient Adaption of Whisper for CSI

Whisper [17] serves as a state-of-the-art ASR framework, exhibiting robust scalability through its Transformer-based encoder-decoder architecture. Its efficacy in ASR tasks has been corroborated by numerous studies [21, 22]. The encoder processes normalized spectrograms via an initial stem, consisting of two convolutional layers, before routing the output through multiple Transformer blocks employing pre-activation residual connections.

On the decoder end, learned positional embeddings are integrated with tied input-output token representations to generate the final transcript. To maintain architectural coherence, the encoder and decoder are structured to have an identical number of Transformer blocks and the same width.

In the Whisper decoder, an autoregressive approach is adopted, similar to the GPT series of language models. The probability each token is sequentially determined based on the preceding context. Nonetheless, extensive parameter count of Whisper renders it challenging for downstream applications. Conventional fine-tuning strategies are computationally expensive, leading us to adopt prefix-tuning [23], a more efficient alternative that utilizes a smaller set of trainable parameters.

Motivated by these advances, we introduce an optimized Whisper variant for lyric-based feature extraction from audio recordings. The detailed structure of it is shown in Figure 2. The audio encoder ingests chunked log mel spectrograms $\mathbf{S}_{mel} \in \mathbb{R}^{N \times F \times T}$ and comprises blocks with self-attention and MLP layers. Residual connections are employed in both layers, culminating in audio features $\mathbf{X}_{ac} \in \mathbb{R}^{N \times C_{ac}}$.

For every segment, the text decoder process the corresponding audio feature $\mathbf{X}_{ac}(i) \in \mathbb{R}^{C_{ac}}$ independently for transcribing. The text decoder starts with four initial tokens $\mathbf{t}_{init} \in \mathbb{R}^4$, which serve specific purposes such as indicating the start of prediction, speech presence, task specification, and timestamp prediction. These tokens pass through an embedding layer to yield embedded tokens $\mathbf{E}_{init} \in \mathbb{R}^{4 \times C_l}$, defined during the pretrain phase. A trainable suffix latent $\mathbf{E}_e \in \mathbb{R}^{L_e \times C_l}$ is appended to these initial tokens. Additionally, before each text decoder block, a trainable prefix latent $\mathbf{E}_{p_j} \in \mathbb{R}^{L_p \times C_l}$ is added, forming the input for the first text decoder block as $\mathbf{E}_{in_1} = [\mathbf{E}_{p_1}; \mathbf{E}_{init}; \mathbf{E}_e] \in \mathbb{R}^{(L_p+4+L_e) \times C_l}$. The prefix embeddings are learned to overwrite the instruction carried by init tokens, to reprogram Whisper to extract features that assist in the CSI task. Compared with the audio encoder block, the text decoder block incorporates an additional cross-attention layer. The decoder block consists of self-attention, cross-attention, and MLP layers, sequentially connected. The self-attention layer accepts the out-

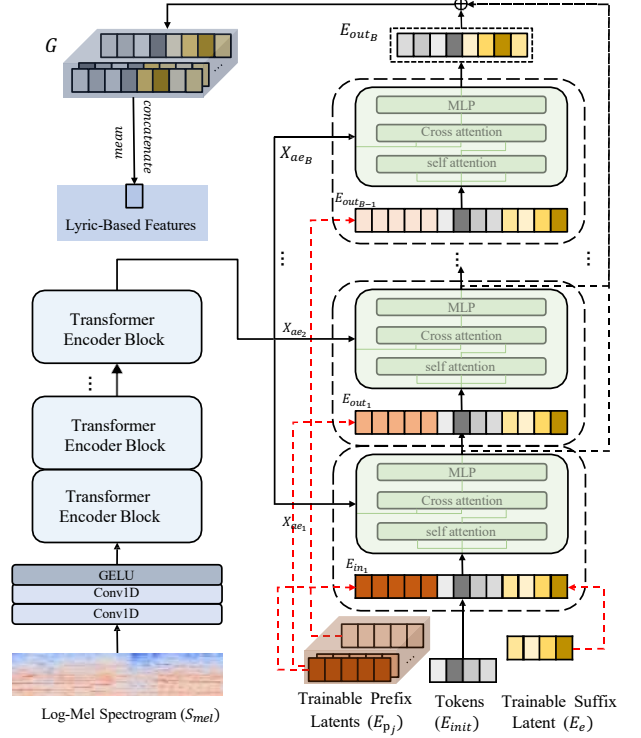

Figure 2. The detailed structure of modified Whisper Model.

put of the preceding text decoder block, while the cross-attention layer uses both the audio encoder output $\mathbf{X}_{ac}(i)$ as its key and value and the output of self-attention layer as its query. The MLP layer subsequently processes the cross-attention output. After processing through the first text decoder block and subsequent truncation, we obtain $\mathbf{E}_{out_1} \in \mathbb{R}^{(4+L_e) \times C_l}$. The same process is repeated for subsequent text decoder blocks, each time adding a new set of trainable prefix latents. Since the first L_p output embeddings of each text decoder block are truncated, the input dimensions of each decoder block remain consistent even after adding a new set of prefix latents. The outputs of each text decoder block are stored to form an lyric-based feature group $\mathbf{G} = [\mathbf{E}_{out_1}, \mathbf{E}_{out_2}, \dots, \mathbf{E}_{out_B}] \in \mathbb{R}^{((4+L_e) \times B) \times C_l}$. Finally, We select the last 70% to 80% of the audio-lyric feature group and the mean across the second dimension is taken to get the audio-lyric feature $\mathbf{X}_l(i) \in \mathbb{R}^{C_l}$. The medium version of the whisper we adopted contains 24 text decoder blocks, and the hidden size is 1024.

In terms of computational efficiency, the introduction of prefix latents enables the Whisper model to generate multiple embeddings in a single forward pass, thereby obviating the need for autoregressive operations during the decoding phase. This can be regarded as a Non-Autoregressive (NAR) method for efficient inference [24]. Despite this, certain studies [24] indicate that NAR performance is generally inferior to that of Autoregressive (AR) methods. To explore the performance upper bound of Whisper in CSI tasks, we also propose an AR-based feature extraction method. Importantly, in this AR approach, there are no modifications required to the Whisper model, and its

parameters are kept frozen throughout the process. The Whisper model transcribes each audio segment and collects the final hidden states from each inference pass. These states are then aggregated using a mean operation to form the lyric-based feature $\mathbf{X}_l(i)$. Since the shape of the embeddings outputted by both NAR and AR methods is consistent, they can be used interchangeably. In section 4, we refer to the strategy using efficient Whisper adaptation as "E" and the original Whisper-based strategy as "AR". Lastly, we introduce a trainable linear projection layer subsequent to the Whisper output to map the embedding dimensions C_l to 512. For clarity, the symbol C_l continues to denote the dimensions of these projected embeddings.

3.3 A Bag of Tricks for Improving ByteCover3

We enhance our model’s performance by incorporating three techniques: Sparse Softmax, Non-local Operations, and Grid Distortion. Due to the crowdsourced nature of the labels in the SHS100k dataset [9], mislabeling of version categories is inevitable. Additionally, the SHS100k dataset contains 8,858 cliques of music, indicating a high number of classes to distinguish when training models using softmax loss. Sun et al. [25] demonstrated that an increase in the number of classes raises the risk of overfitting with softmax loss, particularly when incorrect labels are present, as it may further degrade model performance by fitting these erroneous labels. Therefore, in X-Cover, we have opted to use Sparse Softmax [25] loss instead of the original softmax loss. Sparse Softmax loss retains only the top-K logits and the logits for the ground truth class during probability computation, effectively reducing the number of classes to distinguish to $K + 1$. However, a smaller K value during the initial phase of training might impair the model’s ability to fit. Through tuning, we found that fine-tuning with $K = 1024$ after training with the original softmax loss achieves optimal results.

As demonstrated in [26], capturing global spectrogram information is crucial for understanding the complex compositions in music, characterized by varied spectral characteristics over time. However, the limited receptive field size of conventional CNNs restricts their ability to capture long-range dependencies across different parts of the spectrogram effectively. To address this limitation, we integrate Non-Local modules [27] into the ResNet-IBN architecture. These modules utilize the strength of Non-Local operations to compute interactions directly between any two positions in the input data, irrespective of their physical distance. This feature is particularly advantageous for analyzing music tracks, where distant sections may share thematic but transformed material, a characteristic common in cover songs.

Finally, Grid Distortion is borrowed from computer vision field, involves random scaling transformations in both the frequency and time dimensions of the spectrogram to simulate time-stretching and pitch shift.

4. EXPERIMENTS

We evaluated X-Cover using two publicly available datasets: SHS100K, which consists of 8,858 cover groups and 108,523 individual recordings [9], and Covers80, featuring 160 recordings that include two covers of each of the 80 songs [5]. The training and test division of SHS100K adheres to previous work [8, 11–13], while Covers80 serves exclusively for testing. We convert all audio to CQT and Mel spectrograms before training. For CQT, we set the bins per octave to 12 and use a Hann window during extraction with a hop size of 512. All audio is resampled to 22,050 Hz before CQT conversion. We then downsample the CQT temporally by averaging over 100 adjacent frames to enhance computational efficiency and reduce latency. For Mel spectrograms, we follow the configuration in Whisper [17], resampling audio to 16,000 Hz and computing an 80-channel log-magnitude Mel spectrogram with 25-millisecond windows and a 10-millisecond stride. X-Cover’s training phase uses weights from ByteCover3 for initialization. For the Whisper branch, we adopt configurations from the Whisper-Medium setup [17], and its initial weights are also sourced from pre-trained models.

Model	#Dims. ↓	mAP ↑	MR1 ↓
Covers80			
Me+Ha+Ly [14]	1536	0.993	1.02
ByteCover3 [13]	512	0.927	3.32
X-Cover-E	2560	0.992	1.04
X-Cover-AR	2560	1.000	1.00
SHS100K-TEST			
MOVE [10]	512	0.519	154.5
Me+Ha+Ly [14]	1536	0.794	39.3
ByteCover3 [13]	512	0.824	37.0
Whisper-E	512	0.437	150

X-Cover-AR	2560	0.924	14.9

Table 1. Performance on different datasets.

4.1 Comparison on Performance and Efficiency

As shown in Table 1, we benchmark the performance of various models, including our X-Cover, on two datasets: Covers80 and SHS100K-TEST. Metrics reported include the number of dimensions (Dims.), mean Average Precision (mAP), and Mean Rank 1 (MR1). For comparative analysis, we include MOVE [10], Me+Ha+Ly [14], and ByteCover3 [13]. Our X-Cover incorporate Whisper models trained with LAL loss, with and without efficient adaptation. By integrating these Whisper-based models with ByteCover3.5, we produce two hybrid solutions: X-Cover-E and X-Cover-AR. Notably ByteCover3.5 is an improved version over ByteCover3 which incorporates a series of enhancements described in Section 3.3. Addition-

	ByteCover3.5	Whisper-E	Whisper-AR	X-Cover-E	X-Cover-AR
Feature Extraction(ms)	21	402	10467	452	10522

Table 2. The average inference time per audio

ally, the Me+Ha+Ly model [14] included in the comparison is not a strict replication of the original work which is a composite system comprised with a melody extraction model, the ALR model, and the MOVE [10]. Due to limited information in the original paper and the smaller size of ALR model compared to Whisper, our version of Me+Ha+Ly uses Basic-Pitch [28] and our Whisper-AR, ensuring a more equitable comparison. We will release the implementation publicly. All models are trained with the Adam Optimizer and a batch size of 128. Table 2 presents the average inference time for X-Cover variants on SHS100K-TEST using an NVIDIA A100 GPU.

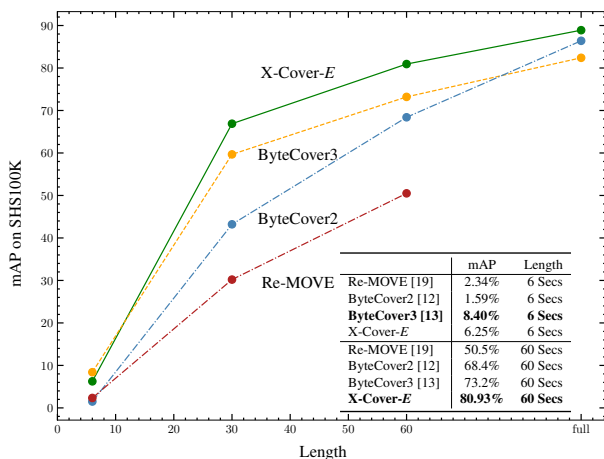

Figure 3. Length of Queries vs. Performance.

Figure 3 displays the mAP results of X-Cover-E for different query lengths on SHS100K-TEST, using Re-MOVE [19], ByteCover2 [12] and ByteCover3 [13] as compared methods. As illustrated in the figure, our X-Cover-E model achieves the best mAPs for all query lengths except for the 6-second length. This clearly indicates the effectiveness of X-Cover-E. The poorer performance at the 6-second scenario is likely due to the shortness of the queries, which may not contain enough meaningful lyric information, thus not highlighting the strengths of X-Cover-E.

Overall, X-Cover-AR consistently outperforms other models on both datasets. Remarkably, X-Cover-AR, X-Cover-E and Me+Ha+Ly achieve nearly 100% accuracy on Covers80. Both methods employ Whisper-AR, making this high accuracy expected given Covers80 which is dataset with a limited size and predominantly consisting of recordings with vocal components. Therefore, we believe SHS100K-TEST is a more robust test of model performance. On this dataset, both X-Cover-AR and X-Cover-E achieve state-of-the-art performance. The performance gap between X-Cover-E and X-Cover-AR can be attributed to the differences in Whisper-AR and Whisper-E. The com-

parable performance and significantly faster speed of X-Cover-E validate our efficient adaptation. Surprisingly, Whisper-AR, cloned from an ASR model except for the final linear layer, shows comparable performance to other SoTA methods on SHS100K, highlighting the potential of large-scale pretrained ASR models in CSI tasks. However, the second-level inference time for individual samples in X-Cover-AR poses a challenge for its practical deployment in real-life scenarios. Finally, we employ the PCA-FC dimensionality reduction module from ByteCover2 to compress X-Cover-AR features from 2560 to 512 dimensions, finding negligible performance loss. This suggests that the performance gains in X-Cover variants are not due to increased feature size.

5. CONCLUSION

This paper has enhanced the robustness and efficiency of the ByteCover3 system in CSI by integrating lyric-related features using a pre-trained Automatic Speech Recognition model, Whisper. This integration addresses the issue of non-musical elements that distort musical characteristics essential for accurate CSI, without the need for training an additional lyrics recognition module from scratch.

The use of Whisper, adapted via prefix-tuning, significantly reduces the computational demands typically associated with large-scale ASR systems, thereby improving efficiency in both training and inference stages. Our results demonstrate improved accuracy and reliability of CSI, particularly in handling short queries against full songs.

In conclusion, our approach contributes to the development of more robust, efficient, and scalable CSI systems, enhancing both intellectual property management and music recommendation systems, especially in social video platforms. Future work will aim to further optimize these methods and explore additional features to increase resilience against noise in practical applications.

HARMONIC AND TRANSPOSITION CONSTRAINTS ARISING FROM THE USE OF THE ROLAND TR-808 BASS DRUM

Emmanuel Deruty

Sony Computer Science Laboratories, Paris, France; Aalborg University, Denmark
emmanuel.deruty@sony.com

ABSTRACT

The study investigates hip-hop music producer Scott Storch’s approach to tonality, where the song’s key is transposed to fit the Roland TR-808 bass drum instead of tuning the drums to the song’s key. This process, involving the adjustment of all tracks except the bass drum, suggests significant production motives. The primary constraint stems from the limited usable pitch range of the TR-808 bass drum if its characteristic sound is to be preserved. The research examines drum tuning practices, the role of the Roland TR-808 in music, and the sub-bass qualities of its bass drum. Analysis of TR-808 samples reveals their characteristics and their integration into modern genres like trap and hip-hop. The study also considers the impact of loudspeaker frequency response and human ear sensitivity on bass drum perception. The findings suggest that Storch’s method prioritizes the spectral properties of the bass drum over traditional pitch values to enhance the bass response. The need to maintain the unique sound of the TR-808 bass drum underscores the importance of spectral formants and register in contemporary popular music production.

1. INTRODUCTION

In popular music, a common practice is to tune the drums to the song’s key [1]. However, in a 2007 interview [2], R&B producer Scott Storch suggests that during the production of music involving a Roland TR-808 drum machine, it may be beneficial to do the opposite and transpose the song’s key to fit the 808 bass drum [3]. The process involves transposing all the tracks but the bass drum. Storch’s motive for undertaking such a potentially time-consuming set of operations is to conserve the characteristic sound of the 808 bass drum.

The present study investigates aspects of the music production process that may explain Storch’s position. In Section 2, we shortly address the issue of drum tuning in popular music. In Section 3, we provide an overview of the importance and usage of the Roland TR-808 in popular music production, focusing on its bass drum voice.

In Section 4.1, we analyze the content of TR-808 bass drum samples. In Section 4.2, we relate spectral features of TR-808 bass drum samples to a diachronic analysis of the power spectrum in popular music. In Section 5, we can understand Storch’s position by involving the frequency response of loudspeakers and the sensitivity of the human ear. Finally, in Section 6, we discuss how the practice suggested by Storch may be a particular case of how properties of the spectrum might be considered more important than pitch values.

2. DRUMS AND TUNING

The musical signal has been divided into two categories: “percussion has a short temporal duration and is rich in noise, while harmonic elements have a long temporal duration with most of the signal energy concentrated in pitch spikes” [4]. “The harmonic and percussive components of music signals have much different structures in the power spectrogram domain, the former is horizontal, while the latter is vertical” [5]. These observations are the basis for source separation methods distinguishing “drums” from “pitched instruments” [6, 7].

Yet, drums can contain pitched content [8]. In drum sounds, relations between eigenfrequencies are not necessarily harmonic [9]. “The tonal elements in drums are usually not structured like partials in a harmonic series. Instead, their frequency relationship can range from inharmonic to chaotic” [10]. From a music producer’s perspective, “drums make several different notes simultaneously” [11].

Recent source separation methods don’t involve prior hypotheses. They’re based on models trained on actual data. Listening to the audio output stemming from such technology indicates that drum stems extracted from popular music do contain pitch. Demonstrations of Steinberg’s SpectraLayers [12], Native Instruments’ iZotope RX 8 [12], iZotope RX 9 [13], and StemRoller [14], provide relevant examples.

If drums contain pitched content, they can be tuned. In popular music, the “[i]ntricate tuning of acoustic drums can have a significant impact on the quality and contextuality of the instrument” [1]. There is no consensus on how to tune drums: “[t]alk to ten different drummers and you’ll get ten different ways to tune drums [...] there’s actually no wrong or right way to tune a drum, or right or wrong pitches to tune it to” [15].

Scott Storch is an American record producer and songwriter. Storch has been referred to as a “producer that changed the R&B game” [16], a “superproducer” [17], *i.e.* a wave of artists “who have established a new degree of visibility for the rap producer, earning star billings virtually equal in prominence to the artists that they produce” [18]. For Scott Storch, drum tuning is an integral part of the music production process:

“I know there’s a lot of producers [who will] put an 808 in the song, and there will be chords and stuff clashing with it, and [...] if [...] your ears are really in tune with that stuff, you realize it’s just like [“not so convincing” kind of gesture]... Sometimes, it actually does something cool to the track, but [...] I like to [...] get into that and tune the kick to match [...] the bass line or whatever the chords are doing [...], I just try different stuff... then... [even when there is] not an incredible amount of tune that carries over regular kicks, like short kicks, and I find myself sometimes at least even trying to tune [...] a regular [...] kick drum sound, and get it close to where most of the chords are in the song...” [2, 0:30]

In the above, Storch mentions the Roland TR-808 bass drum and testifies to tuning bass drums to match the music’s key.

3. THE ROLAND TR-808

The Roland TR-808 Rhythm Composer is an analog drum machine manufactured between 1980 and 1983 [19]. It is “one of the most influential and unique drum machines of its time” [20]. “To this day, the 808 remains a benchmark against which all other analog drum machines are measured” [21]. It can be found in many music genres. The TR-808’s distinctive presets are classic sounds in hip-hop, techno, electro, R&B, and house music [22]. The 808 “play[ed] a central role in the development of acid house” [21]. Pop music star Phil Collins used it throughout his entire career [23, 1:21:28]. It is “a fixture in hip-hop culture, not only as a tool for producers but as a defining sound of the genre” [19]. According to Scott Storch, in modern trap music, producers “live in an 808 world” [24]. One reason for the success of the 808 resides in the fact that “it sounded like nothing else [...] and this is what made it so distinctive” [25]. Perhaps as a result, the 808 has been seen not only as a drum machine but as an “instrument in its own right” [23, 0:06:51].

One notable voice of the 808 is its “long and velvet deep, almost subsonic” bass drum [25], which can be made into a “multi-second-long decaying pseudo-sinusoid with a characteristic sighing pitch” [21]. According to producer Pharrell Williams, the 808 bass drum “filled a massive void in the sound spectrum that wasn’t there [...] once the 808 started to occupy that space, it became like something that you missed if you didn’t have it” [23, 1:20:52].

Over time, the 808 bass drum became used as both kick drum and bass. According to producer Remi Kabaka Jr., “the kick drum would play the bass at the same time [...] there was drums and there was bass, but now the two were sort of fused, so the fill was not just complex and rhythmical, but it was also tonal” [23, 1:11:11]. Musician and writer Alex Lavoie notes that “[i]n most contemporary music genres, especially in trap and hip-hop, the 808 often carries the bassline, providing both the low-end foundation and outlining the harmonic progression of the song” [26]. Musician and producer Charles Burchell writes that the TR-808 “brings a sound closer to a traditional bass line while retaining the power of a drum [...] In many cases, producers will not use a kick drum sample. Instead, they program drum patterns with a tuned 808 as the kick drum” [27].

As a tonal instrument, the 808 bass drum can be tuned: as Lavoie states, “[a]n 808 kick, particularly when it has a long decay, effectively functions as a bass instrument. That’s why tuning your 808s is so crucial” [26]. Lavoie warns that “[i]f the pitch of your 808 kick doesn’t match the key of your song, it can create a dissonant effect” [26].

4. THE 808 BASS DRUM

4.1 Signal analysis of 808 bass drum samples

Figure 1 shows the waveform corresponding to the “TR808 BD Bass Drum Long 01” preset. All samples considered in this paper originate from the TR-808 Trisample library [28]. The waveform confirms that the sample is tonal. The tonal aspect derives from the TR-808 generation technique, during which an oscillator produces a sawtooth wave that is filtered to make it close to a sine wave [29].

Figure 1. “TR808 BD Bass Drum Long 01” sample, waveform.

Figure 2 shows the STFT for the same sample. Harmonics are present near the start of the sample and then fade out. The sample’s pitch value is briefly higher near the beginning, then decreases to a stable value. A study of the 37 “long” samples from the Trisample library shows that the median range for the initial frequency sweep is close to one half-tone.

The Tristar library features “driven” samples (a reference to the slang term “drive” for “overdrive”, *i.e.* “distortion”). Figure 3 shows the STFT for one “driven” sample. The threshold conditioning the display of the partials as red lines is the same as in Figure 2, which indicates that the distortion boosts the level of the overtones.

Figure 2. “TR808 BD Bass Drum Long 01” sample, STFT. The horizontal lines follow the fundamental and harmonics. The blue line stops when the energy of the corresponding bin is lower than 0.7 times the peak energy of all bins. The red lines stop when the energy of the corresponding bin is lower than 0.5 times the peak energy of all bins.

Figure 3. “TR808 BD Bass Drum Driven 01” sample, STFT.

Figure 4 shows the STFT for an extract from the 2017 song “Mask Off”, by the American rapper Future. The track has been described as an example of heavy 808 use [19]. The initial frequency sweep on each bass drum occurrence is similar to the samples shown in Figures 2 and 3. The vertical distribution of high energy values at the beginning of each bass drum occurrence suggests that the 808 is superimposed with a noisier kick drum. The 808 samples are tuned to the song’s tonality (D minor). The pitch values (D1 and B \flat 0) are very low: they stand one minor second and one perfect fourth above the piano’s lowest note. The corresponding frequency range (ca. 40Hz) recalls the “almost subsonic” aspect of the 808 bass drum samples [25].

Figure 4. Future, “Mask Off”, 8 beats from 0’25 to 0’30, STFT. The vertical lines denote the kick drum’s onsets. The horizontal lines follow the TR’s fundamental and harmonics. The corresponding pitch values are shown at the top.

4.2 Sub-bass frequencies and the 808 bass drum

Producers recognize three distinct regions of sub-bass: the “boom” (ca. 30Hz), the “thump” (ca. 50Hz) and the

“punch” (ca. 80Hz) [30, pp. 88–118] [31, p. 282]. Figure 5 confirms that 50Hz (the “thump”) is the “frequency range occupied by the Roland TR-808 analog kick” [31].

Before the advent of digital audio, low frequencies were attenuated to protect amplifiers and speakers from the adverse effects of mechanical noise and harmonic distortion [31, p. 282] [32,33]. Musical information in this frequency range only became possible by using digital audio as a medium. Figure 6 shows the evolution of the power spectrum in popular music. The measures were derived from a dataset containing 30435 tracks released between 1961 and 2022. The choice of the tracks stems from the “Best Ever Albums” website, a review aggregator that proposes the best-rated albums for each year of production [34]. For each year, we select the best-rated albums. The overall spectral profile is consistent with Pestana’s results [35]. The increase of energy in the lower band, also testified by Hove et al. [36], is concomitant to the advent of digital audio.

Figure 5. Distribution of fundamental frequencies of TR-808 bass drum samples. The fundamental frequencies are evaluated on 0.2-second windows. The contribution of each window is weighted according to the energy at the fundamental frequency. In the non-“driven” presets, the maximum of the distribution corresponds to $f_0 = 49.48$ Hz. The f_0 values for the “driven” presets are higher. “Short” presets involve a secondary local maximum ($f_0 = 51.05$ Hz) corresponding to the samples’ earliest windows.

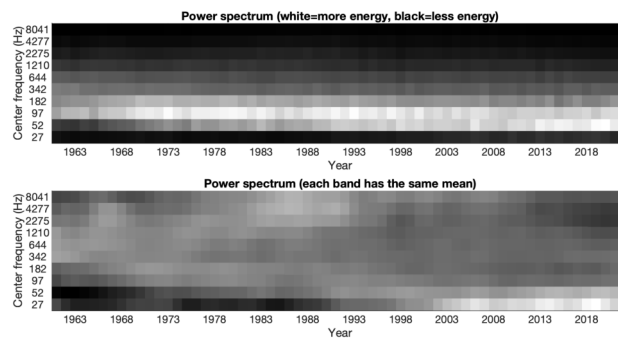

Figure 6. Evolution of the power spectrum in popular music. Top, raw energy values. Bottom, values for each frequency band are normalized to the same mean.

The analysis results shown in Figure 2 indicate that after the initial 0.4s-long attack, “long” 808 samples are based on a single low-frequency sine wave. The sine wave’s frequency is ca. 50 Hz according to Figure 5. The results shown in Figures 3 and 4 suggest that this very low frequency remains an essential component of the 808 bass

drum with added harmonics. Confronting these observations with the power spectrum evolution in popular music (Figure 6), it follows that the sound of the 808 bass drum wasn't fully reproduced before the end of the '90s, even though the machine itself was sold between 1980 and 1983.

After 2009, “the characteristic 808-kick drums [...] started entering mainstream music in general”, and trap music, a “tradition of rap that developed during the 1990s”, an “808 world” according to Scott Storch (see Section 3), “began to reach strong presence on the mainstream Billboard music charts” [37]. So strong is the presence of trap in the charts that this formerly underground genre has been qualified as “pop”, in the sense that “[p]eople’s ears have adjusted” to it [38].

The extended bandwidth provided by the emergence of digital audio made possible the faithful restitution of the entire spectrum of the 808 bass drum, which favored the birth and rise of a music genre that became mainstream and influenced popular music in general.

5. TUNING THE SONG’S KEY TO THE TR-808 BASS DRUM

In Section 2, Scott Storch describes how he tries to tune the bass drum (808 in particular) to the music’s key. Later in the same interview, Storch suggests that instead of tuning the 808 bass drum sample to the song’s tonality, one can do the opposite and adjust the song’s key to the 808 bass drum sample:

“[S]ometimes, producers will program a song in a certain key, and they’ll try to program an 808 under it, and it’s like the key of the song is almost too low to really let speakers do what they need to do with the bass so, I recommend [...] modulating the song up, transposing it up a couple of keys, and you’ll be surprised how much more level you can get out of the song. [Because] anything really below [...] a low E [...], it’s like the speakers are gonna not, let you turn it up, you don’t feel the bass response.” [2, 1:37]

Storch describes a situation in which a producer previously set the key for a song, tunes an 808 bass drum to make it fit the key, and, as a result, the 808 bass drum does not sound “right”.

5.1 Transposition of the TR-808 bass drum: effect on the lowest partial

Let us consider an example where the song’s key is D, as in the extract from Figure 4. We focus on the fundamental, the only lasting component in samples from the “long” type (Figure 2). As seen in Figure 5, the f_0 of an 808 bass drum is ca. 49.5Hz, corresponding to a G1. The producer, therefore, transposes the 808 bass drum one perfect fourth down (5 semitones) to a D1 – one tone below the “low E”

mentioned by Storch. Storch states that the loudspeakers may not reproduce the bass correctly in such a situation.

Professional mixing engineers mainly use near-field monitors [39, p. 3]. With such monitors, they can produce “masters which ‘travel’ well to their use by the record buyers” [40]. The use of near-field monitors extends to producers. Nigel Godrich testifies that during the production of Radiohead’s “OK Computer”, he always used near-field monitors, but never the studios’ main monitors, which “don’t relate to anything” and are “fairly useless” [41]. In the many videos documenting his work, Storch can be seen using near-field monitors.

Newell et al. [40] provide the frequency response for 36 near-field monitoring loudspeakers. Figure 7 graphs the median frequency response for these loudspeakers against the median f_0 for the 808 bass drum samples (49.5Hz / G1) and the TR bass drum median frequency transposed down one perfect fourth (37Hz / D1). The downward transposition results in a gain loss of 6.3 dB. Following Storch’s suggestion and transposing up the song key instead of transposing down the 808 sample would avoid the 6.3dB loss. In Storch’s terms, transposing the song up may “let speakers do what they need to do with the bass”.

Figure 7. near field loudspeaker responses as a function of frequency. The center horizontal line in each box represents the median, and the two surrounding horizontal lines represent the 25th and 75th percentiles. The blue line shows the smoothed median response. The red vertical line represents the median f_0 for the 808 bass drum as shown in Section 4.2, Figure 5. The gray rectangle denotes a -5 semitone transposition of the median f_0 . The textual representation displays the difference in the response that occurs.

Loudspeakers are not the only frequency-dependent transducers involved in the listening process. The human ear is also sensitive to frequency. In particular, as the frequencies get closer to the lower limit of human hearing, a sine wave with the same sound pressure level but a lower frequency will be perceived as less loud. The phenomenon is accounted for by equal loudness contours, representing the sound pressure levels at different frequencies that are perceived as equally loud [42]. Figure 8 graphs the ISO226-2003 [43] equal loudness contours against the median 808 bass drum f_0 , and the same frequency transposed down one perfect fourth. If we choose a loudness of 60 phon, a +5.5dB gain would be required so that the transposed f_0 remains at the same loudness. Therefore, considering the human ear as one of the transducers in the signal path, the gain it applies to the signal when transposing down the original median f_0 is ca. -5.5dB. As a result,

the overall gain loss following the downward transposition originating from both the loudspeakers and the ear can be estimated to be ca. 11.8 dB.

Figure 8. Equal-loudness contours according to [43]. The numbers superimposed on each contour indicate the loudness value corresponding to the contour (in phon). The red vertical line represents the median f_0 for the 808 bass drum as shown in Section 4.2, Figure 5. The gray rectangle indicates a -5 semitone transposition of the median f_0 (one perfect fourth down). The textual representation displays the gain that would be required so that the transposed f_0 remains at the same 60-phon loudness.

If different 808 bass drum notes result in different gains, then a sequence of different 808 bass drum notes will result in gain changes within the sequence. Quoting Storch, “for 808s [...] I try to stay in the comfort zone of the speaker, so I don’t [...] have the volumes jumping out for different notes” [44]. In other words, 808 bass drum parts’ pitch should remain largely static to achieve a stable gain. In turn, largely static bass pitch values may result in a limited variety of chords. The phenomenon illustrates how loudness stability may take precedence over harmonic complexity.

5.2 Transposition of the TR-808 bass drum: involvement of the harmonics

The 808 bass drum samples corresponding to Figures 3 and 4 involve lasting harmonics. Figure 9 shows the combined response deriving from both the near field loudspeakers and the ear’s sensitivity at 60 phon. The lower the frequency, the greater the influence of transposition on the overall gain. The gain loss diminishes with each harmonic. It is almost zero for the fifth harmonic.

We generate a 49.5Hz five-partial harmonic complex tone. The amplitudes of the partials are the same as in the “TR808 BD Bass Drum Driven 01” sample when the frequency values reach a static regime (see Figure 3). The overall power change following a 5-semitone downward transposition is -4.5dB. It is much less than the -11.8 dB gain brought by the downward transposition of the lone fundamental. The result suggests that the issues mentioned by Scott Storch (gain conservation and gain stability) mainly concern the fundamental or, at least, the lowest harmonics. In other words, Storch is specifically concerned with the audibility and stability of the 808 bass drum’s bottom partials.

The phenomenon known as the “missing fundamental” [45] suggests that even if a negative gain is applied to lower

Figure 9. The black line shows the combined response deriving from both the near field loudspeakers and the ear’s sensitivity at 60 phon (Figures 7 and 8). The red vertical lines represent the median values for the 808 bass drum’s fundamental and harmonics. The textual representations display the difference in the response that occurs from a -5 semitone transposition.

harmonics, the perceived pitch remains unchanged due to the auditory system’s temporal pitch processing. Only timbre is affected. In the case of the sub-bass register, *i.e.* frequencies lower than 100Hz according to Fink [31, p. 281], another perceptual aspect may be mentioned. In relation to findings by Takahashi et al. [46], Fink et al. [30, pp. 88-118] suggest that one aspect of the perceptual effects of bass stems from small body surface displacements. According to the author, each sub-bass range can be associated with a body region in which the corresponding frequencies are imaginatively felt. The “boom” (ca. 30Hz) is “the semi-audible vibration in the gut felt during the deepest drops in dancehall and dubstep”. The “thump” (ca. 50Hz) is felt in the stomach, and the “punch” (ca. 80Hz) in the chest. Even when listeners use headphones, bass frequencies may be associated with a “tactile sensation” [47]. Fink [31] and Hove et al. [47]’s views suggest that low frequencies may play a role beyond pitch and timbre, in this case, a haptic role.

A downward transposition and the resulting negative gain applied to these frequencies may affect both the resulting timbre and bodily sensation. As a result, they may be prejudicial to at least some music genres, independently from the presence of upper harmonics.

6. PITCH AND REGISTER

Scott Storch’s advice according to which a song’s key may be adjusted to the 808 bass drum sample is based on the following premise: the transposition of the elements of the music that are not the 808 bass drum is less problematic than the transposition of the 808 bass drum. The change in pitch values doesn’t affect the musical intervals, but the shift in register affects the perceived spectral profile. The change in perceived spectral profile is more important in the case of the TR-808 bass drum due to its low-frequency content.

Following Frisius [48, p. 81], “a [music] theory [that] posits a principle of neutral transposition, according to which groups of pitches essentially do not change their character if one transposes them”, doesn’t take into account the transposition of the sounds themselves. Frisius

remarks that such a theory may not be suited to music from the 20th century. He mentions the composer Luigi Rus-solo, who found it difficult to “transpos[e] sonic gestures into other registers without losing their identity”. According to Frisius, this difficulty is “felt above all when pitch is not clearly definable”. One way to understand the phenomenon is that transposed melodies are only the “same as” each other because they are constructed using a set of pitches whose chromas repeat at the octave. The listener encodes them in terms of pitch sequences. If two sounds are “transpositions” of each other but are not perceived in terms of pitch, then they are just different sounds.

Pitch intervals may be robust to transposition, but the register will change, and so will timbre. The phenomenon has been described in orchestration treatises [49–51]. According to Hector Berlioz, as far as the violin is concerned, C major may be “*grave, mais sourd et terne*” (rich in low frequencies, but dull and muted), and F# minor “*tragique, sonore, incisif*” (tragic, resonant, incisive) [49]. More recently, Reymore et al. [52] have studied the relation between pitch height and timbre in acoustic instruments.

Personal interviews with music producers from the production company Hyper-Music (<https://www.hyper-music.com/>) suggest that in recent popular music, the simultaneous consideration for pitch values and register when considering transposition is paramount. According to one of Hyper-Music producers, Storch prioritizing the register of an instrument over particular pitch values is a “basic rule” of modern music production. Pitch is subservient to spectral formants. Priority is given to the absolute position of the formants in the spectrum. If pitch has to be changed so that the formants of the sound carrying the pitch reach the desired positions, it will be changed. Another producer from the same company claims to be always cautious with transposition, as it may affect timbre. In accordance with Frisius’ point of view, if the pitch content of the part is not too strong, the same producer may simply forego transposition, even if the pitched content of the sample conflicts with other tonal elements.

In productions involving a TR-808 bass drum, Hyper-Music’s producers often set the tonality to D or Eb to take full advantage of the bass drum’s character. Such tonalities neighbor that of the example shown in Figure 4.

7. CONCLUSION

According to Section 2, some authors have previously divided the musical signal into two categories: percussion (rich in noise, short duration), and harmonic elements (long duration, most of the energy concentrated in spikes in the spectrum) [4, 5, 7]. However, other authors have studied the existence of pitch in percussion [8–10]. In music production, drum tuning has been seen as essential [1] but sometimes difficult [8]. Scott Storch, a renowned music producer, has emphasized the importance of fine-tuning drums to match the music’s key despite the inherent challenges in doing so.

In Section 3, we showed that the Roland TR-808 Rhythm Composer has been deemed an influential analog

drum machine [19–21], primarily known for its distinctive and deep bass drum sound [25]. Producers and musicians from various music genres have testified to its efficiency in providing low-end foundation. They use the 808 bass drum not only as a kick drum but also as a tonal instrument that plays basslines, thus emphasizing the importance of its tuning.

Signal analyses of 808 bass drum samples reported in Section 4 show that its fundamental frequency can be found ca. 50Hz and may or may not have lasting harmonics. The measured evolution of the power spectrum in popular music suggests that digital audio technology enabled the faithful reproduction of the 808 bass drum’s extended bandwidth, which played a crucial role in the rise of trap music’s popularity and its subsequent influence on mainstream music [37].

In Section 5, we discussed tuning the song’s key to the 808 bass drum. Producers often try to tune the bass drum to match the song’s key. However, Scott Storch suggests an alternative approach: adjusting the song’s key to fit the 808 bass drum sample. Storch explains that some songs might have a key that is too low for the bass to be correctly reproduced by speakers. Instead, he recommends transposing the music up to achieve a more balanced and powerful bass response. If, for instance, the bass drum is transposed down one perfect fourth to match the song’s key, its fundamental frequency loses ca. 11.8 dB in overall gain, considering the response of near field loudspeakers of the type that producers customarily use [39,40] and the human ear’s sensitivity to frequency [43]. The loss may affect the instrument’s timbre and invalidate the specific bodily sensations the sub-bass range may evoke [30, 31, 47]. The analysis also suggests that the gain loss primarily affects the fundamental frequency and lower harmonics. The discussion emphasizes the importance of controlling the level of bass in music production. It suggests that adjusting the song’s key to the 808 bass drum can indeed be a helpful technique to achieve this goal.

In Section 6, we briefly discussed the relationship between pitch and register in music and how transposition may affect these elements. While classical Western music theory emphasizes the robustness of pitch intervals to transposition, other perspectives [48,52] suggest that transposition has significant consequences on timbre. Orchestration treatises have long associated specific timbral characteristics with different keys, highlighting the importance of considering both pitch and register [49–51]. Recent interviews with popular music producers suggest the approach is significant in modern music production.

An intriguing research direction may stem from the assessment of one of the interviewees, according to which spectral formants have precedence over pitch values in modern popular music. Storch’s handling of the 808 bass drum is an example of this principle. If such a claim proves to have merit, it may have consequences on music analysis and user interaction in generative systems applied to popular music.

8. ACKNOWLEDGMENTS

Many thanks to Yann Macé and Luc Leroy from the music production company Hyper Music for their insights into Scott Storch's work and the subsequent discussions. Special thanks to David Meredith (Aalborg University) for his valuable comments.

ABSTRACT

This study presents FruitsMusic, a metadata corpus of Japanese idol-group songs in the real world, precisely annotated with who sings what and when. Japanese idol-group songs, vital to Japanese pop culture, feature a unique vocal arrangement style, where songs are divided into several segments, and a specific individual or multiple singers are assigned to each segment. To enhance singer diarization methods for recognizing such structures, we constructed FruitsMusic as a resource using 40 music videos of Japanese idol groups from YouTube. The corpus includes detailed annotations, covering songs across various genres, division and assignment styles, and groups ranging from 4 to 9 members. FruitsMusic also facilitates the development of various music information retrieval techniques, such as lyrics transcription and singer identification, benefiting not only Japanese idol-group songs but also a wide range of songs featuring single or multiple singers from various cultures. This paper offers a comprehensive overview of FruitsMusic, including its creation methodology and unique characteristics compared to conversational speech. Additionally, this paper evaluates the efficacy of current methods for singer embedding extraction and diarization in challenging real-world conditions using FruitsMusic. Furthermore, this paper examines potential improvements in automatic diarization performance through evaluating human performance.

1. INTRODUCTION

In Japanese pop culture, an *idol* is a performer who engages in dancing, singing, and entertaining fans [1]. In the culture, idols frequently participate in activities, such as concerts and television programs, as members of idol groups. One of the most renowned contemporary idol groups is AKB48, which has 40 single compact discs (CDs) that are million-sellers, as certified by The Recording Industry Association of Japan¹. FRUITS ZIPPER has

¹ https://www.riaj.or.jp/f/data/cert/gd_search.html

emerged as another notable group comprising seven girls and being awarded the Best New Artist at the Japan Record Awards 2023, the most prestigious accolade in Japanese music culture [2]. Not only can fans attend concerts, but they can also interact with the idols at handshaking events (*Akushukai*) or bonus events (*Tokutenkai*), where the fans can forge deep connections with the idols [3].

Idol-group songs feature several unique characteristics. One notable characteristic is *song division*, also called *utawari* in Japanese [4, 5]. This approach involves a dynamic vocal arrangement where the singing roles shift throughout the song; individual members may take turns singing solo lines, or multiple members may sing together in unison. In particular, the entire group often sings together in the chorus sections, known as *sabi*. Song division is chosen intentionally to maximize the charm and attractiveness of each idol and song. Therefore, the analysis of song division is crucial for understanding the structure and expression of songs, as well as the creators' intentions.

Song division plays a crucial role also in shaping audience participation through chants and shouts, known as *calls* and *mixes*, which are indispensable elements of idol-group concerts [6]. Fans spontaneously create these chants and shouts, reflecting the song's structure, musical intensity, and song division, specifically which member is assigned to sing at any given moment. Furthermore, song division significantly influences music videos and concert recordings produced by idol groups, demonstrating its pivotal role in producing and appreciating idol music content.

As previously described, song division is crucial for understanding and enjoying the musical compositions of idol groups. To aid fans' comprehension, some idol groups release official charts showing how songs are divided among members. For Korean pop groups with similar features to Japanese idol groups, several fans create *line distribution* videos. These videos, widely viewed on platforms like YouTube and TikTok, visualize the structures of song division, facilitating a deeper understanding. Therefore, developing techniques for recognizing song division will help fans enjoy the music compositions and enhance their interaction with idols. In addition, such advancements will support creators in promoting idol groups.

The task to estimate song division, i.e., *who sings when*, within a music signal is known as *singer diarization*. This technique has been inspired by speaker diarization, which identifies *who speaks when* in conversational speech [7–9]. The singer diarization technique was initially introduced

to analyze folk music and has been adapted for Japanese idol-group songs [4]. However, existing research has not examined songs from real-world idol groups but from idol-themed games and anime. These game and anime songs generally belong to narrower genres, feature simpler song division structures, and have vocals that are easier to distinguish, thanks to the distinctive voice qualities of the voice actors. Further research indicates that in-the-wild audio signals can improve diarization performance in real-world settings, even with small datasets [4, 10]. Consequently, compiling a dataset featuring songs from real-world idol groups is critical for developing practical applications targeting pop culture.

This study addresses the demand for a practical dataset in music information retrieval (MIR) by constructing a new corpus, FruitsMusic. This corpus consists of detailed annotations about *who sings what and when* in real-world songs performed by Japanese idol groups from YouTube, enabling the advancement of singer diarization techniques and their assessments. Beyond singer diarization, FruitsMusic also advances various MIR techniques such as lyrics transcription [11, 12], emotion classification [13, 14], singer identification [15, 16], and singer-based music search [17], for not only Japanese idol-group songs but also a wide array of musical pieces featuring single or multiple singers from different cultures. A significant advantage of FruitsMusic is its focus on real idol groups, allowing for evaluations in challenging scenarios and enhancing the applicability of MIR techniques in the real world. This paper details the structure, development methodology, and unique characteristics of FruitsMusic. The paper also demonstrates the applications of evaluating existing methods in two MIR tasks, singer embedding extraction and diarization, in real-world scenarios.

2. STRUCTURE AND CONSTRUCTION METHODOLOGY OF FRUITSMUSIC

In this study, we constructed FruitsMusic (Corpus of Fully Real-World Popular Idol-group Songs from YouTube Videos for Music Information Processing) aimed at developing and evaluating various MIR techniques. This corpus is a collection of annotations for 163 minutes of music video content on YouTube, detailing *who sings what and when*. The corpus includes annotations for 40 songs performed by 18 different groups, featuring a total of 122 unique female singers, all approximately 20 years of age. The corpus is available at <https://huggingface.co/datasets/fruits-music/fruits-music>².

2.1 Related Works

Several corpora derived from YouTube have been constructed across various research fields. The key advantage of this approach is the utilization of a wide range of real-world video and audio content.

For example, ActivityNet and YouTube-8M are benchmark datasets widely used in video processing [18, 19].

² This paper has been written based on FruitsMusic version 1.2.0.

(b) RTTM file

Table 1. An example of JSON and RTTM files.

Similarly, YouTube-ASL, a large-scale American Sign Language corpus, originates from YouTube [20].

In the field of audio processing, several corpora have utilized YouTube videos. AudioSet, for instance, is widely adopted for recognizing and detecting audio events [21]. VoxLingua107 covers 6,628 hours of speech across 107 languages and is helpful to language detection [22]. Further, JTubeSpeech consists of extensive Japanese speech data from YouTube and helps the development of diverse speech processing techniques [23]. Similarly, YODAS consists of 500,000 hours of speech in over 100 languages and makes multilingual speech processing techniques applicable in the wild [23, 24]. Coco-Nut is another corpus with subjective descriptions of voices, designed for controlling speaker identity based on text prompts [25].

These prior works underscore the effectiveness of YouTube-based corpora, which we also adopted in this study. Our corpus focuses especially on accuracy and reliability, which are less emphasized in these prior corpora. In addition, the video-based nature of FruitsMusic facilitates multimodal processing, such as multimodal diarization [26]. Note that these prior corpora have been curated to protect individual privacy rights by excluding personal information, and FruitsMusic also maintains these ethical standards.

2.2 Structure of the Corpus

FruitsMusic includes annotations in JavaScript Object Notation (JSON) format, Rich Transcription Time Marked (RTTM) files for diarization, and text files of lyrics. Table 1 presents an example of JSON and RTTM files.

2.2.1 JSON Files

The JSON files include the following information:

- **Song ID.** This field is formed by combining a two-character idol-group ID, the letter “m”, and a two-digit ID.
- **Video ID on YouTube.**
- **Type of the video.** This field is either of `music_video`, `middle_music_video`, or `dance_practice`. The names of these types are derived from traditions in Japanese idol culture.
- **List of singer IDs.** Each ID is formed by combining a two-character idol-group ID, the letter “s”, and a two-digit ID.
- **Song title.** This field aims at natural language processing (NLP) tasks.
- **Start time and duration of the song.** The videos may contain content beyond songs, such as comments from idols. This information is provided to help filter out such content.
- **Singing states.** This is a list of the start and end times of the segment, the singers assigned to the segment, and the lyrics. The `lyrics` field contains the official lyrics, which may differ from the actual lyrics sung. In such cases, the `realLyrics` field is used.

The time and duration fields are annotated in milliseconds.

2.2.2 RTTM Files

The RTTM format is specially designed for speaker diarization tasks, identifying *who speaks when* [27]. Table 1b presents an example of an RTTM file. Within this format, each line details the start time and duration of the segment, as well as the singer’s ID. For simultaneous singing, the format allocates a separate line to each singer, resulting in multiple lines corresponding to the number of singers.

2.2.3 Text Files of Lyrics

Lyrics lines may be duplicated in the JSON files to precisely represent *who sings what and when* (e.g., DRm03). As a result, extracting lyrics from JSON files is not straightforward. To support the development and assessment of techniques involving lyrics, such as lyrics transcription, FruitsMusic provides separate text files of lyrics.

2.3 Subsets

FruitsMusic is split into Subset A and Subset B. Subset A is designed mainly for training, and Subset B is for evaluation. However, both subsets can be arbitrarily used for various purposes. Subset A contains 32 songs, while Subset B has 8 songs. To ensure unbiased evaluation, Subset B does not contain any singers from Subset A, and each group in Subset B contributes only one song. The songs in Subset B were chosen to cover various genres (dance, rock, synthpop, etc.) and division styles. Also, groups in Subset B are generally less famous than those in Subset A, which helps ensure fairer and less biased human evaluation.

	CHiME-5	FruitsMusic
Average audio length	9031 s	244 s
# Speakers	4	4–9
Average segment length	2.11 s	4.44 s
Total length per speaker	1159.6 s	15.9 s
Segments without speakers	22.3%	23.9%
Solo segments	51.4%	42.6%
Multiple-speaker segments	26.4%	33.5%
Segments with 3+ speakers	6.4%	26.5%

Table 2. Comparison of FruitsMusic with the CHiME-5 dataset [28], a conversational speech dataset. The “Total length per speaker” row indicates the average total duration per speaker in each audio.

2.4 Song Selection

We meticulously selected the songs for FruitsMusic to ensure the corpus’s reliability and usefulness. To achieve accurate annotations, we initially gathered extensive knowledge about the idol groups. We then used reliable sources, including concert recordings and official announcements, for information. Additionally, to support applications like singer diarization, each singer has at least one solo section within the database. Moreover, we assign each singer to only one group in FruitsMusic. While idols may participate in multiple groups or move between groups in reality, we avoid such complexities in this database. FruitsMusic focuses solely on contemporary songs released from 2022 onwards to reflect the latest music trends.

2.5 Rules

This corpus has been constructed using copyrighted materials. Users are required to follow the licensing agreement specified in the corpus documentation to protect the rights of creators and idols. The agreement sets three major rules. First, the copyrighted content of this corpus, such as lyrics texts, is not intended for appreciation or entertainment. Second, the corpus cannot be used to develop or enhance generative artificial intelligence (AI) techniques, such as singing voice synthesis, voice conversion, lyrics generation, and music creation. However, users can utilize the corpus for recognition or information extraction tasks, including lyrics recognition, singer embedding extraction, and assessing the naturalness of lyrics or music. Third, when citing this corpus in any media, including academic works and presentations, users are required to identify both the groups and the singers using the provided IDs and refrain from using their real names. If the mention of song names is not essential for the discussion, users are also required to refer to them by their respective IDs.

3. COMPARISON WITH CONVERSATIONAL DATASET

This section compares FruitsMusic with the CHiME-5 dataset, a conversational speech dataset designed for The

5th CHiME Speech Separation and Recognition Challenge [28], to explore the differences between conversational speech and songs with song division. The CHiME-5 dataset contains 20 conversational speech instances, each from four speakers. Table 2 shows the comparison results, considering all subsets of both CHiME-5 and FruitsMusic.

Initially, the average audio length in FruitsMusic is significantly shorter than in CHiME-5. Unlike conversational speech, which is not limited by specific length constraints, the duration of songs is tightly controlled by the structure of the musical compositions. Furthermore, the average total duration of speech segments per speaker in FruitsMusic is extremely shorter than in CHiME-5. This difference arises from the shorter overall audio length and the larger number of singers in FruitsMusic. Since solo segments play a key role in capturing singer characteristics, developing singer identification techniques under these challenging conditions, different from conversational speech, is essential for improving singer diarization and other MIR systems for songs featuring multiple singers.

The comparison reveals a noteworthy difference in the frequency of simultaneous speakers between CHiME-5 and FruitsMusic. In particular, sections featuring 3 or more singers in FruitsMusic are significantly longer than in CHiME-5. This indicates that the methods that treat overlapping speech as segments with two speakers, often adopted in speaker diarization [29], cannot be directly applied to singer diarization. Furthermore, about 60% of segments with multiple singers feature vocals from only a subset of the entire group. Hence, the assumption that all singers are present in overlapped segments proves ineffective for singer diarization; it is crucial to accurately and independently determine the vocal activity of each singer.

4. APPLICATION 1: SINGER EMBEDDINGS

Singer embeddings are multidimensional vectors that capture each singer’s unique vocal traits. In singing information processing, high-quality singer embeddings are crucial for enhancing the performance of tasks involving singers, such as singer identification, voice matching, and singer diarization. This section evaluates two types of embeddings extracted from song segments by a specific group and discusses the effectiveness of each extraction technique in real-world scenarios. This section visualizes these embeddings to understand their effectiveness in distinguishing singers and provides a numerical analysis of the clustering performance based on singers.

In our evaluation, we compare two types of singer embeddings. The first type involves x-vectors, traditional yet effective speaker embeddings derived from deep neural networks (DNNs) for speaker identification [30]. Specifically, we utilize an x-vector extractor `microsoft/wavlm-base-plus-sv`³, which incorporates WavLM, a large-scale pre-trained model based on self-supervised learning [31]. Second, we evaluated embeddings based on ECAPA-TDNN, an enhanced time de-

lay neural network (TDNN) in x-vector extractors [32]. ECAPA-TDNN-based embeddings have been proven to show remarkable performance in speaker recognition and diarization [32–34]. We used an ECAPA-TDNN model provided by SeechBrain⁴ [35]. In addition, this evaluation considers both mixed and vocal signals, with the latter extracted using Demucs, an open-source music source separation tool [36, 37]. We utilized the `htdemucs_ft` model, a fine-tuned version of the Hybrid Transformer Demucs, renowned for its state-of-the-art performance in music source separation.

We focus on the group KF, which comprises seven members and has eight songs, the most available on FruitsMusic. For this study, we selected segments where a singer performs solo for over 2 seconds. On average, each singer has 20 segments, totaling approximately 101 seconds of solo performance.

As objective evaluation metrics, F values are calculated to benchmark clustering efficacy [38]. Here, the F value is the harmonic mean of two metrics: purity P and inverse purity I . The P and I are defined as follows:

$$P = \frac{1}{N} \sum_i \max_j |C_i \cap S_j|, \text{ and} \quad (1)$$

$$I = \frac{1}{N} \sum_j \max_i |C_i \cap S_j|. \quad (2)$$

In these equations, C_i is the i -th cluster, and S_j is the set of the j -th singer’s samples. High F values indicate superior performance, with a theoretical maximum of 1. For this evaluation, spectral clustering [39] was performed to create 7 clusters, matching the number of singers. All the embeddings were L_2 -normalized in advance.

Figure 1 shows the visualizations of the acquired embeddings by reducing their dimensions into two using t -SNE. The effectiveness of Demucs is confirmed across both extraction methods. Compared to x-vectors, embeddings derived with ECAPA-TDNN provide more expressive singer representations. Specifically, Figure 1d reveals that samples from certain singers, specifically KFs01 (represented in red circles) and KFs06 (in pink stars), tend to gather by singer identity. Hence, ECAPA-TDNN-based embeddings are proved to effectively capture singers’ unique identities even from short singing segments. This shows the advantages of the ECAPA-TDNN methodology over conventional TDNN in x-vector extractors. However, none of the plots show distinct clusters visibly forming, and the highest F value was only 0.64. This indicates that tasks like singer diarization and number estimation remain challenging using any embedding extractor evaluated. Since the ECAPA-TDNN model is trained with speech datasets, fine-tuning it with singing voice datasets will enhance its performance. Note that the separated vocal signals are distorted; therefore, using datasets with both clean and mixed or separated signals from real-world conditions will be effective.

³ <https://huggingface.co/microsoft/wavlm-base-plus-sv>

⁴ <https://huggingface.co/speechbrain/spkrec-ecapa-voxceleb>

Figure 1. *t*-SNE visualizations of singer embeddings from the idol group KF’s songs, where each color and shape represents a different singer. Captions detail the extraction methods and whether Demucs was applied. Values in parentheses represent F values, measuring the clustering performance.

5. APPLICATION 2: SINGER DIARIZATION

To evaluate the efficacy of FruitsMusic in training singer diarization models, we trained several models with Subset A of FruitsMusic and assessed their performance using Subset B. In this comparison, the number of singers was not given to the systems. Furthermore, we engaged a human evaluator to perform the manual diarization of songs in Subset B and discuss the potential advancements in automatic diarization performance.

5.1 Construction of a Synthesized Dataset

To improve the diarization performance, we utilized songs from commercial CDs in addition to FruitsMusic. This dataset consists of 272 songs performed by multiple singers, with a separate recording for each song and singer combination. For example, if three singers perform song A, each of the three singers has solo recordings: one by singer 1, another by singer 2, and a third by singer 3. On average, each song features 4.1 singers, resulting in a total of 1126 recordings. All the songs were sourced from idol-themed games and anime, and the singers were 129 unique female voice actresses. We executed source separation on all 1126 recordings using Demucs to generate isolated vocal and accompaniment signals.

We generated five song division patterns for each song, capping the number of singers to a maximum of seven. We applied voice activity detection (VAD) first and randomly assigned singers to each segment. During the assignment, a single singer was allocated to 60% of the segments, all singers to 23%, and random singers to the remaining 17%. We mixed the vocal signals based on the generated song division and combined the sepa-

rated accompaniment with the mixed vocal tracks to create the final mixture. In these generated songs with song division, singers perform in unison during segments with multiple singers. The VAD process used `pyannote/voice-activity-detection`⁵.

5.2 Evaluated Systems

In this experiment, the following systems are compared.

5.2.1 SA-EEND with EDA

The first approach adopted Self-Attentive End-to-End Neural Diarization (SA-EEND) [10]. Since the number of singers for the evaluated signals was unknown, we used enhanced SA-EEND with Encoder-Decoder-based Attractors (EDA) [40]. The hyperparameters matched those of the CALLHOME dataset, as specified in the original publication [40]. The input signals were downsampled to 8000 Hz and were converted to monaural signals.

5.2.2 `pyannote.audio`

The second method used `pyannote.audio`⁶, an open-source toolkit for speech processing tasks [29, 41]. The diarization workflow is structured as a pipeline process, incorporating PyanNet-based modules. To conduct this experiment, we fine-tuned the publicly available pre-trained model `pyannote/speaker-diarization-3.1`⁷ using the prepared song datasets. This fine-tuning process adapted the segmentation models and optimized the thresholds for both segmentation and clustering. The input signals were downsampled to 16 000 Hz and converted to monaural signals.

5.2.3 Human Evaluator

In addition to the automatic diarization approaches, we also engaged a human evaluator to perform manual singer diarization to gauge the achievable performance. The individual understands Japanese and often listens to Japanese pop music (about 60 hours a month), yet was completely unfamiliar with any of the songs in Subset B of FruitsMusic. To maintain the experiment’s integrity, we presented only the audio signals of the songs without any corresponding videos. The participant was allowed to use any external tool to aid in the diarization process but was explicitly restricted from searching for the songs on the internet.

5.3 Experimental Setup

As a training dataset, Subset A from FruitsMusic was used. The songs DRm01, Kfm01, Rgm01, SBm01, and SYm01 were designated for validation. The remaining songs, excluding three songs featuring nine singers, were allocated for training. Due to the highly extended training time required for SA-EEND with EDA for songs featuring more than seven singers, three songs with nine singers, VYm02,

⁵ <https://huggingface.co/pyannote/voice-activity-detection>

⁶ <https://github.com/pyannote/pyannote-audio>

⁷ <https://huggingface.co/pyannote/speaker-diarization-3.1>

System	Mixed	Separated
SA-EEND with EDA		
Synthesized only	99.5%	101.3%
Synthesized + FruitsMusic	103.2%	83.8%
pyannotate.audio		
Synthesized only	92.9%	69.9%
Synthesized + FruitsMusic	91.3%	50.3%
Human	22.7%	—

Table 3. DER for Subset B in FruitsMusic with the several diarization systems.

VYm03, and XSm02, were excluded from the dataset. The loudness of all songs was normalized to -14 LUFS.

The evaluation metric used was the diarization error rate (DER) [27], defined as:

$$\text{DER} = \frac{\sum_{s=1}^S d_s \left[\max \left(N_s^{(\text{ref})}, N_s^{(\text{hyp})} \right) - N_s^{(\text{correct})} \right]}{\sum_{s=1}^S d_s N_s^{(\text{ref})}}. \quad (3)$$

Here, S is the total number of segments, d_s represents the duration of the s -th segment, and $N_s^{(\text{ref})}$, $N_s^{(\text{hyp})}$, and $N_s^{(\text{correct})}$ correspond to the number of ground-truth singers, estimated singers, and accurately identified singers in the s -th segment, respectively. According to this definition, DER can exceed 100%. The calculation of DER was performed with `dscore`⁸, an open-source tool. Due to the implementation of `dscore`, self-overlapped segments, which contain multiple recordings of the same singer, were normalized in the calculation process. The collar size, the time ignored in DER calculation around segment boundaries, was set to zero.

The model selection criterion was achieving the minimum DER on the validation set. For each condition, we developed two versions of the system: one trained on mixed signals and another trained on extracted vocal signals. The vocal signal extraction was performed using the `htdemucs_ft` model of `Demucs` [36, 37].

5.4 Results

Table 3 shows the DER of all the systems. The performance of the mixed signal systems is significantly inferior to that of the separated signal systems. In other words, across evaluated systems, `Demucs` effectively improved diarization performance; hence, a pipeline system combining source separation and diarization proved more effective than using a single system on mixed signals in the case of this evaluation. In both approaches, `SA-EEND` and `pyannotate.audio`, training with `FruitsMusic` significantly improved the overall performance, particularly for the separated signal systems. The results suggest that `FruitsMusic`, despite its smaller size, can significantly enhance diarization performance rather than relying solely on large-scale synthesized datasets.

⁸ <https://github.com/nryant/dscore>

System	BD	BI	JA	JY	MG	QD	SL	TJ
SA-EEND with EDA								
w/o FruitsMusic	1	3	2	2	4	0	6	2
w/ FruitsMusic	2	2	2	2	2	2	2	2
pyannotate.audio								
w/o FruitsMusic	3	5	3	3	3	3	3	3
w/ FruitsMusic	7	7	7	7	7	6	7	7
Human	8	6	6	5	7	5	6	4
Ground truth	9	4	7	5	7	5	6	4

Table 4. Estimated total number of singers derived from diarization results. All the systems used separated vocal signals using `Demucs`. Each column shows a song in Subset B. The suffixes “m01” of song IDs are omitted.

Table 4 shows the estimated number of singers included in the diarization results. The `SA-EEND`-based systems struggled to distinguish singers accurately. This seems due to the difficulties of naive DNN-based methods in distinguishing singer identities, as discussed in Section 4. On the other hand, `pyannotate.audio` demonstrated an almost invariant estimation of the number of singers. This indicates a potential overfitting to the training datasets, with the most common number of singers in the training set tending to dominate the predictions.

Among the evaluated systems, human performance was remarkably superior to the automatic diarization systems in terms of DER. Notably, a human evaluator accurately estimated the number of singers in 5 out of 8 songs. This demonstrates that humans can effectively distinguish individual singers’ voices even within mixed music signals. Therefore, these results proved a significant potential for improving both automatic singer identification and diarization performance.

6. CONCLUSION

This paper presents `FruitsMusic`, a novel corpus of precise annotations on *who sings what and when* in Japanese idol-group songs. The song selection and subset creation were meticulously conducted to facilitate unbiased evaluation and ensure usefulness across a wide range of genres, song division styles, and idol groups. The corpus can be applied to various MIR tasks, such as singer diarization, singer identification, and lyrics transcription. This paper showcases its applications in evaluating singer embedding extraction and diarization techniques. The results showed that distinguishing singers from short singing segments remains challenging, despite effective methods in speech processing. The paper also suggests potential advancements in automatic diarization performance by assessing human performance. We acknowledge significant existing areas for performance improvement in diverse MIR tasks, and we are confident that `FruitsMusic` has the potential to advance various techniques among them.

7. ACKNOWLEDGMENTS

This work was supported by JSPS KAKENHI Grant Number JP23K20017. This paper is based on results obtained from a project, JPNP20006, commissioned by the New Energy and Industrial Technology Development Organization (NEDO). This study was supported by the BRIDGE program of the Cabinet Office, Government of Japan.

8. ETHICS STATEMENT

The FruitsMusic corpus is derived from YouTube videos of Japanese idol groups and consists of annotations that detail *who sings what and when*. Hence, FruitsMusic has the potential to help develop singing voice synthesis (SVS) or voice conversion (VC) systems that replicate the voices of actual idols. Moreover, analysis of the videos within FruitsMusic enables associating the real names of groups and singers with their IDs. These scenarios raise potential concerns about infringing on the personality rights of the idols. Additionally, using FruitsMusic to construct or trigger other generative AI techniques, such as lyrics and music generation, may violate the rights of composers and creators. In light of these considerations, as described in Section 2.5, FruitsMusic enforces the stringent licensing agreement and requires all users to adhere to it when downloading and using the corpus.

ABSTRACT

Recent advancements in music source separation (MSS) have focused in the multi-timbral case, with existing architectures tailored for the separation of distinct instruments, overlooking thus the challenge of separating instruments with similar timbral characteristics. Addressing this gap, our work focuses on monotimbral MSS, specifically within the context of classical guitar duets. To this end, we introduce the GuitarDuets dataset, featuring a combined total of approximately three hours of real and synthesized classical guitar duet recordings, as well as note-level annotations of the synthesized duets. We perform an extensive cross-dataset evaluation by adapting Demucs, a state-of-the-art MSS architecture, to monotimbral source separation. Furthermore, we develop a joint permutation-invariant transcription and separation framework, to exploit note event predictions as auxiliary information. Our results indicate that utilizing both the real and synthesized subsets of GuitarDuets leads to improved separation performance in an independently recorded test set compared to utilizing solely one subset. We also find that while the availability of ground-truth note labels greatly helps the performance of the separation network, the predicted note estimates result only in marginal improvement. Finally, we discuss the behavior of commonly utilized metrics, such as SDR and SI-SDR, in the context of monotimbral MSS.

1. INTRODUCTION

The task of music source separation (MSS) involves dissecting a musical composition into its constituent sources, typically segregating individual instruments or vocal tracks from a composite audio mixture [1, 2, 3]. Due to the multitude of the co-playing sources, as well as its utility in a variety of applications [1], MSS stands as a significant challenge in the field of Music Information Re-

trieval (MIR) [4]. The majority of research efforts have focused on multi-timbral music source separation [5, 6, 7]. In this case, the goal is the separation of distinct instrumental sources from a mixture, where the sources belong to different instrument families or types such as vocals, bass, drums and others, and as such can be framed as an extension of the task of speech denoising into the music domain [8].

Through the advancement of digital signal processing [9] and deep learning [5, 10], considerable progress has been made in extracting distinct instrumental tracks from complex musical compositions. Most recent, deep-learning based approaches for MSS are divided into spectrogram-domain approaches [11], waveform-domain methodologies [10, 12, 13, 14, 15] and hybrid ones, working simultaneously in both domains [5]. Spectrogram-domain methods typically isolate sources via mask prediction [16], waveform-domain approaches enhance source separation by applying spectrogram techniques in a learned latent space [14, 17], or directly predicting the isolated waveforms [12], with the additional advantage of incorporating phase information, while hybrid architectures [5] leverage the strengths of both. Moreover, recent findings have highlighted the benefits of using static or dynamic activity labels [18, 19, 20, 21, 22], as well as jointly training transcription and source separation modules [23, 24], which enhances task performance, paralleling efforts in simultaneous speech recognition and separation training [25].

However, an area that remains relatively underexplored is monotimbral music source separation. This subfield of MSS focuses on extracting audio components that belong to the same instrument family, or different builds of the same instrument. It can be viewed as the counterpart of the speaker separation problem [31] in the music domain. While this similarity has led to the development of similar methodologies for network training [32], speaker separation, especially within the context of, rarely available in MSS datasets, multi-microphone recordings [33], can also rely on spatial cues. The limited exploration in this area can largely be attributed to the historical focus on isolating the most prominent instruments in popular music, while the demand for separation of instruments with close timbral characteristics is less pronounced. Indeed, there are very few datasets suitable for training algorithms on the task of separating instrumental tracks from the same

instrument family in a polyphonic context [30], with the majority of publicly available datasets covering the case of separating mixtures of multiple singing voices [34, 35, 36].

In this paper, we attempt to bridge this gap by introducing GuitarDuets¹, a dataset consisting of a total of ca. 3 hours of real and synthesized guitar duet recordings, along with partial note-level annotations, which can be leveraged as auxiliary score information. We benchmark GuitarDuets in the tasks of i) unconditional guitar duet separation and ii) score-informed duet separation, using the hybrid Demucs [5] as our separation model. We also examine the possibility of integrating note-level predictions into a joint transcription and separation framework. In more detail, the main contributions of this work are:

- Introduction of GuitarDuets, a dataset for monotimbral music source separation, featuring both real classical guitar duet recordings and synthetic recordings generated from online transcriptions and virtual instruments. The synthetic portion includes MIDI representations for each guitar part, enriching the dataset for algorithm training and detailed analysis.
- Extensive cross-dataset evaluation across various conditions, including real and generated synthetic data, as well as the existence or absence of auxiliary score information in specific Demucs branches.
- Development of a joint transcription and separation framework, which incorporates transcription predictions, by adapting existing architectures [5, 37] to the task of monotimbral source separation with the introduction of a permutation-invariant [32] loss. We show that incorporation of these note-level predictions can improve the separation of real guitar duets.
- Finally, we analyze the behavior of commonly-utilized source separation metrics in the context of classical guitar duets to understand their effectiveness when applied in sources with similar timbres.

¹ The dataset is available at: <https://zenodo.org/records/12802440>

2. DATASETS

2.1 Existing Datasets

Datasets available for music source separation or transcription are primarily divided into multitimbral and monotimbral ones, each offering instrument-specific tracks or stems, often accompanied by transcriptions. Multitimbral datasets such as musdb18 [7], URMP [27], MedleyDB [38], MoisesDB [26] and SLAKH [28] are most prominent, featuring both real and synthesized data from a broad spectrum of instruments; some extend to multimodal forms, including for instance audiovisual elements [27].

In contrast, monotimbral instrumental datasets, notably fewer in number, include focused collections such as GuitarSet [30] and EnsembleSet [29]. GuitarSet provides detailed annotations for acoustic guitar recordings, consisting of pairs of comping and soloing performances, while EnsembleSet targets chamber ensembles with high-quality synthetic reproductions of classical music. Despite their utility, these monotimbral datasets face some limitations, namely: GuitarSet’s structure, with distinct solo and accompaniment parts, oversimplifies the separation task due to the distinct role of each guitar. Also, the lack of timbral differences between the two guitars prevents the networks from focusing on timbral cues for the separation task. On the other hand, EnsembleSet’s reliance on synthetic data introduces a realism gap, underscoring the need for datasets that more accurately capture the dynamics of live musical performances. Moreover, the instruments it contains are largely monophonic, which hinders its use for scenarios with polyphonic co-playing instruments.

2.2 The GuitarDuets Dataset

In this section, we will describe the GuitarDuets dataset, comprising both real recordings of classical guitar duets and synthesized recordings, leveraging virtual instruments and MIDI scores. This approach aimed to provide an original and realistic set of guitar duet recordings for training and evaluating deep learning algorithms on monotimbral MSS, while simultaneously overcoming their limited duration, granting ample training data and enabling analysis between real and synthetic datasets. In total, our dataset comprises 58.6 minutes of real data and 106 minutes of synthesized data, amounting to 164.6 minutes overall. A comparison of the GuitarDuets with the most prominent datasets for MSS in the literature is outlined in Table 1,

whereas detailed statistics about both the real and synthesized subsets of GuitarDuets are given in Table 2.

Real Recordings: For the recordings featuring real classical guitars, we utilized a quiet, acoustically treated room and high-quality condenser microphones (Presonus PM-2), one for each guitar. During the recording process, four different classical guitars were used, with some tracks (16 min.) replayed using different guitars to further enhance timbral diversity. Simultaneous play was crucial for capturing the musical interplay between the two guitarists. The whole recording process resulted in the recording of 27 guitar duets (per-track duration: 123 ± 82 sec.), mostly from the Modern Classical and Nuevo Tango genres and from the Romantic Period. This approach, while essential for the integrity and realism of the dataset, introduced a challenge with cross-microphone sound bleeding. This crossover of sound presented a significant concern, as it compromises the isolation of the individual guitar tracks, impacting the quality of the dataset. In addressing the issue of source bleeding in microphones, we recorded a specialized test set that is free from such leakage. This set, consisting of 7 tracks (per-track duration: 39 ± 13 sec.), was created to ensure the absence of cross-feed between microphones. Each guitar track was exported as a 44,100 Hz, 16-bit WAV file in stereo format, with mixed audio files created by averaging individual guitar performances.

Synthetic Recordings: Despite the inherent realism of the real recordings, their small duration could prove problematic for network training, whereas the single recording setup utilized could import biases. A commonly utilized shortcut to increase the duration of real recordings is to virtually augment them, by synthesizing additional pieces based on note-level transcriptions and virtual music instruments, which has proven effective not only in generating multitrack datasets [28, 29], but also in tasks such as tablature generation [39, 40]. In our case, “Session Guitarist - Picked Nylon”², a sample-based virtual instrument, was utilized to generate classical guitar sounds. It offers a wide range of playing styles, capturing the nuances of nylon-stringed guitars. We selected guitar duet MIDI scores from the MuseScore community³, representing a broad spectrum of pieces. Logic Pro X⁴ served as the digital audio workstation (DAW) for transforming MIDI scores into realistic guitar performances. By configuring multiple instances of the PICKED NYLON plugin with distinct timbral settings, we produced different guitar sounds. The final dataset was exported as 44,100 Hz, 16-bit WAV files in both stereo and mono formats for mixed audio file creation.

3. METHODOLOGY

3.1 Separation Architecture

In this work the Hybrid Transformer Demucs [5] was used as the separation backbone, consisting of dual U-Nets [16], operating in both time and spectrogram domains, each

² <https://www.native-instruments.com/en/products/komplete/guitar/session-guitarist-picked-nylon/>

³ <https://musescore.com/>

⁴ <https://www.apple.com/logic-pro/>

Figure 1: Overview of the incorporation of note-level annotations into the Demucs Architecture.

featuring four encoder and decoder layers. The temporal encoder (TEncoder) downsamples the input waveform through a series of 1D convolutions, whereas the spectral encoder (ZEncoder) gradually compresses the STFT magnitude of the input by applying convolutions across the spectral axis. The traditional convolutional layers, positioned between the encoder and decoder in previous iterations of the Demucs architecture [41] are replaced with a cross-domain Transformer Encoder, composed of interleaved self-attention and cross-attention Encoder layers, each equipped with Layer Scale [42]. The attention mechanism operates with eight heads, and the hidden state size of the feedforward network is four times the dimension of the transformer. The primary decoder layer is shared, branching into both temporal and spectral domains, with the respective decoders built symmetrically to the encoders. The spectral output, post an inverse Short Time Fourier Transform (ISTFT), is merged with the temporal output, producing the model’s prediction. We note that in our experiments, the input length is set to 4 seconds.

3.2 Score-Informed Separation

In the context of Score-Informed Separation, the separation network is conditioned on the note-level transcripts of the recordings. To this end, binary vectors indicating the presence or absence of each of the 128 MIDI notes during small temporal frames are concatenated with the intermediate feature maps in each branch, as indicated in Fig. 1. In particular, in the temporal branch, the activity labels of each guitar are inserted after the third TEncoder layer. The binary vector for each guitar has a dimensionality of $128 \times N_s$, where N_s corresponds to the number of samples for each 4-second segment, yielding a combined shape of $256 \times N_s$ for both guitars. Thus, the activity labels have to be downsampled across the temporal axis, to match the resolution of the encoder at this stage. In a parallel manner, within the frequency branch, these binary vectors are introduced following the second ZEncoder

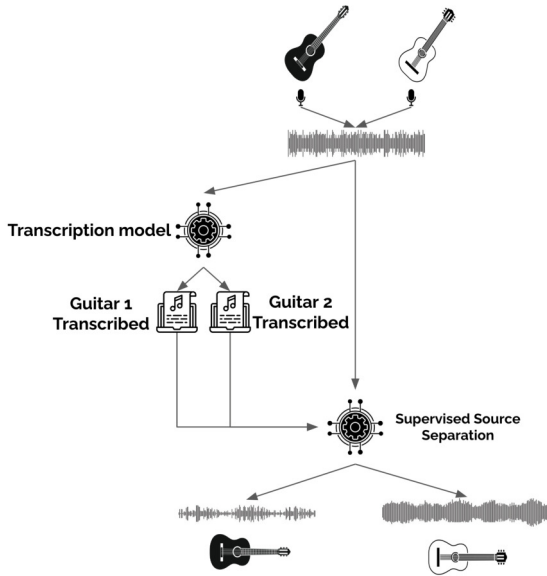

Figure 2: Overview of the proposed methodology for joint transcription and separation of guitar duets.

layer. The shape of the activity labels for concatenation is $2 \times 128 \times N_s$, aligning with the two guitars’ MIDI notes. In this case, the activity labels are concatenated with the feature maps across the channel dimension; since the frequency resolution of the ZEncoder, at this stage, matches the number of MIDI notes, resampling occurs only across the temporal axis, by downsampling the note activity labels to the respective temporal resolution of the ZEncoder.

If transcriptions are not available, we use a separate transcription network to generate them creating a joint transcription-separation framework. The first network would intake the combined sounds of the two guitars and generate a binarized piano roll representation for each individual guitar. Afterward, the second model combines the mixed audio and the generated piano rolls to create separate estimates for each guitar as depicted in Figure 2. From a musical endpoint the transcription network could potentially capture note interdependencies and guitar duet patterns through binarized vector features, aiding in note prediction. This transcription informs the separation model, which refines the output by focusing on timbre.

For the transcription architecture, we utilize the Residual Shuffle-Exchange Network (RSE) [37], which has achieved state-of-the-art results in MusicNet [43]. This network enhances the neural Shuffle-Exchange network [44] by employing both Switch and Shuffle layers to capture sequence dependencies effectively, as well as reducing its computational overhead by incorporating strided convolutions. For further details about the architecture we refer to [37, 44]. In our implementation, the RSE’s output layer is modified to produce a binarized 2×128 -dimensional representation, to assign activity labels for each of the 128 MIDI notes to the corresponding instrument.

4. EXPERIMENTAL EVALUATION

4.1 Experimental Setup

For the separation experiments, we used both the real and synthesized subsets of GuitarDuets, which we will further denote as GuitarDuets(R) and GuitarDuets(S), respectively, as well as the GuitarSet, for which mixtures were generated via addition of the available comping and solo excerpts. We adapted the backbone Demucs model for classical guitar duet separation, modifying it to output two stereo signals, one for each guitar. Data augmentation techniques including channel swapping, time cropping, amplitude scaling and remixing individual guitar parts from different performances were employed during network training to improve generalization. As our loss function we used the quantity:

$$\alpha \cdot \min(|\hat{g}_1 - g_1| + |\hat{g}_2 - g_2|, |\hat{g}_2 - g_1| + |\hat{g}_1 - g_2|) + \beta \cdot |(\hat{g}_1 + \hat{g}_2) - (g_1 + g_2)|, \quad (1)$$

where the first term corresponds to the traditional permutation-invariant L1 loss between the ground truth signals g_1, g_2 and the output sources \hat{g}_1, \hat{g}_2 , and the second term models the similarity between the sum of the guitar estimates and the input mixtures, encouraging the network to provide separate guitar tracks which neither discard nor duplicate note instances, whereas the weight values were set, after preliminary experiments, to $\alpha = 0.8, \beta = 0.2$.

For the transcription architecture experiments, we employed GuitarSet and the GuitarDuets(S) dataset, which contain note-level annotations for individual guitar parts. We transformed labels from GuitarSet (.jams files) and the MIDI files from our dataset to CSV format. All audio files, initially sampled at 44,100 Hz, were resampled to 11,000 Hz and converted to mono, to render them compatible with the RSE backbone [37]. Similar to the separation case, the loss function—in this case, the binary cross entropy—was employed within a permutation invariant framework.

4.2 Cross-Dataset Analysis

For the purposes of the cross-dataset analysis, we consider the GuitarDuets(R) and GuitarDuets(S) subsets as separate datasets, and train the Demucs backbone on various combinations of GuitarSet, GuitarDuets(R) and GuitarDuets(S), using the same experimental protocol and an 80-20 training-validation split; all networks are evaluated on the bleeding-free testing set of GuitarDuets(R). Upon inspection of the results, presented in Table 3, several key insights emerge. Namely, the complete GuitarDuets dataset yielded the highest SDR values for the first guitar. The inclusion of the synthesized subset likely provided additional information that enhanced the model’s performance with regards to the SDR. On the other hand, the inclusion of these synthetic parts made the model prone to auditory artifacts, since the highest SAR scores were achieved for the combination of GuitarDuets(R) with the GuitarSet. Finally, we observe that the combination of the complete GuitarDuets dataset with GuitarSet leads in diminished performance, probably due to the structural differences between the training subsets.

Source Datasets			Metrics

Table 4: Separation results on the testing sets of GuitarDuets(S), GuitarDuets(R), when using solely the respective training sets for training, depending on the availability of note-level annotations and the Demucs branches conditioned on them. G1 corresponds to the 1st guitar, G2 to the 2nd. Higher is better for all metrics.

In our analysis, we observed a consistent discrepancy in the Signal-to-Distortion Ratio (SDR) between the two guitars, where the first guitar exhibited a decent SDR, while the second often fell below a threshold of 1 dB. This pattern suggests that the algorithm may be effectively separating the first guitar by identifying it as the primary source, whereas it perceives the second guitar as background noise, or merely an auditory artifact. It is important to note that the average amplitude of both guitars is on the same scale, so this observation is not attributed to amplitude differences. Notably, we observe that the most consistent SDR values for G2 were achieved when GuitarSet was included in the training set, which we attribute to its relatively noise-free structure.

4.3 Score-Informed Separation Approaches

For the experiments concerning score-informed separation, we investigated the integration of activity labels into our network, considering Demucs’ operation across frequency

and temporal domains, by using the GuitarDuets(S) as our dataset since it contains note-level annotations. We also investigate, using both GuitarDuets(R) and GuitarDuets(S), whether the joint transcription-separation architecture can aid in effective separation in scenarios where no ground truth data is available. In both cases, a part of the dataset (the bleeding-free subset of GuitarDuets(R), and 10% of GuitarDuets(S)) was used for performance evaluation; the rest were used for training and validation, at an 80:20 ratio.

The analysis, as detailed in Table 4, reveals that while using the temporal branch for note label integration leads to slightly improved results compared to the spectral branch, the hybrid approach achieves the most promising outcomes. This performance can be attributed to the inherent design of the Demucs architecture, which has historically shown improved efficiency when leveraging both domains concurrently [41]. It is also noteworthy that while the integration of ground-truth labels leads to higher SIR values, presumably due to the guidance that these labels

Figure 3: Comparison of spectrogram estimates with estimated (top) note-level annotations, and without those (bottom), for an instance from GuitarDuets (R).

provide to the separation network about the identity of each guitar, the improvement in SAR is marginal.

Regarding the joint transcription and separation framework, the performance does not reach the levels achieved when ground-truth note-level annotations are available, as measured in GuitarDuets(S). On the other hand, while in the case of GuitarDuets(R), the performance is slightly improved when these pseudo-annotations are available, GuitarDuets(S) achieves better results in their absence. A comparison of guitar estimates for the models trained with and without predicted note label information, for an instance of the GuitarDuets(R) test set, can be depicted in Figure 3; we assume that the incorporation of note activity labels enables the separation model to more accurately sustain notes, enhancing the quality of the isolated melodic and accompanying parts. On the other hand, we attribute the performance drop, when using GuitarDuets(S), to the reduced generalization of the transcription network. Since the training set of GuitarDuets(S) was used for its training, the separation network was trained using mostly correct labels, but evaluated with note-level annotations of pieces the transcription network did not use for training.

4.4 Comparative Metric Analysis

In the field of MSS, the evaluation of separation quality is often quantified using metrics such as SDR [45] and SI-SDR [46]. While they have been extensively used in studies focusing on separating different instruments, their behavior on sources with similar timbral characteristics remains less explored. Given that most prior work involves instruments with distinct timbres, direct comparison of our results with SDR values achieved across different datasets may not be appropriate for our study, which focuses on two classical guitars with similar timbral properties.

Figure 4: Comparison of the behavior of SDR (left) and SI-SDR (right) when assessing the separation of monotimbral (blue line) or multitimbral (orange line) duets.

In order to identify potential disparities in the behavior of the metrics that can be attributed to timbral similarities in the mixture components, we simulated imperfect estimates of a reference signal x_1 by creating additive synthetic mixtures of the signals x_1, x_2 as:

$$m = \alpha x_1 + (1 - \alpha)x_2, \quad (2)$$

with $\alpha \in (0, 1)$, and measured the values of the SDR, SI-SDR metrics between these mixtures and x_1 . We examined two cases using signals derived from Track 29 of the GuitarDuets(S): i) a monotimbral mixture, where both x_1 and x_2 constitute guitar signals, and ii) a multitimbral mixture, where x_2 was synthesized from the second guitar’s notes using a piano virtual instrument plugin. To guarantee a fair comparison across all tests, we performed amplitude normalization between the two tracks for each experiment.

The results, displayed in Figure 4, indicate that both metrics for the guitar mixtures are consistently higher than those obtained from mixtures of different instruments. For instance, the mixing ratio α required to reach an SDR value of 5 approaches 0.8 for the multi-timbral case, while 0.6 for the mono-timbral case. This suggests that the timbral similarity between the two guitars introduces a challenge for the metrics to accurately assess the quality of separation.

5. CONCLUSIONS

In this paper, we introduced GuitarDuets, a dataset consisting of both real and synthesized classical guitar duets. We exhibit that our dataset can be utilized for developing monotimbral source separation algorithms within both traditional and score-informed frameworks. We further developed a joint permutation-invariant framework for transcription and separation of monotimbral mixtures, which we show that can lead to improved performance in separation of real guitar duets. In the future, we plan to extend the recordings of both the real and synthesized subsets of GuitarDuets, and provide note-level annotations for its real subset. Furthermore, regarding the joint transcription-separation architecture, we intend to explore more sophisticated ways for integrating the predicted guitar transcripts into the separator [47, 48]. Finally, we aim to conduct extensive listening tests, which will help in further shedding light into both the performance of the various approaches we compare, and the significance of objective metrics within the context of monotimbral audio source separation.

ABSTRACT

Symbolic Music, akin to language, can be encoded in discrete symbols. Recent research has extended the application of large language models (LLMs) such as GPT-4 and Llama2 to the symbolic music domain including understanding and generation. Yet scant research explores the details of how these LLMs perform on advanced music understanding and conditioned generation, especially from the multi-step reasoning perspective, which is a critical aspect in the conditioned, editable, and interactive human-computer co-creation process. This study conducts a thorough investigation of LLMs' capability and limitations in symbolic music processing. We identify that current LLMs exhibit poor performance in song-level multi-step music reasoning, and typically fail to leverage learned music knowledge when addressing complex musical tasks. An analysis of LLMs' responses highlights distinctly their pros and cons. Our findings suggest achieving advanced musical capability is not intrinsically obtained by LLMs, and future research should focus more on bridging the gap between music knowledge and reasoning, to improve the co-creation experience for musicians.

1. INTRODUCTION

Large language models (LLMs), such as GPT-4, harness the power of deep learning to produce human-like text. These models, trained on vast datasets of textual content, have notably propelled advancements in natural language processing (NLP). They excel in complex language understanding and generation tasks including translation, sentiment analysis, question answering, and summarization, showcasing their reasoning capability with sophistication.

Large language models (LLMs), initially pre-trained on

extensive textual corpora, can assimilate general linguistic patterns and structures. They are subsequently fine-tuned with domain-specific data, such as code and mathematical symbols, to enhance the adaptation to specific tasks. This refinement allows LLMs' proficiency to more accurately manage domain-specific terminology and complicated challenges like multi-step reasoning. Music Reasoning refers to the ability to estimate the varying harmonies, keys, rhythms, and other musical elements that are not explicitly annotated in a piece of music and are significant for music themes, progression, and styles [1]. The analogy between the reasoning process in music and mathematics suggests their structural similarities. Both disciplines fundamentally rely on patterns: music in rhythms, scales, and chord progressions, while mathematics involves sequences, symmetries, and geometric configuration. Moreover, music theory utilizes mathematical concepts to articulate intervals between pitches, chord structures, and the rhythmic temporal division [2,3], underscoring the intrinsic reasoning nature of the musical components.

Music can be represented as sequences of symbols such as MIDI or ABC notation, rendering it suitable for processing by LLMs, which excel in long-context understanding and multi-step reasoning. These models are capable to dissect and generate intricate musical patterns encompassing melodic, harmonic, and rhythmic structures. LLMs also play a pivotal role in enhancing interactive music generation systems, where user inputs tailor the model's output, enriching the composing experience. While previous studies [1,4,5] have investigated LLMs in music tasks, detailed interpretations of the process remains less explored. This paper conduct an evaluation of four LLMs, GPT-4 [6], Gemma-7B-it [7], Llama2-7B-chat [8], and Qwen-7B-chat [9], assessing their capabilities on tasks related to symbolic music understanding and generation:

- Music Understanding: 1) Music theory exercise; 2) Motif extraction; 3) Musical form extraction.
- Music Generation: 1) Chord-conditioned music generation; 2) Melody harmonization; 3) Musical-form-and-motif-conditioned music generation

© Z. Zhou, Y. Wu, and Z. Wu. Licensed under a Creative Commons Attribution 4.0 International License (CC BY 4.0). **Attribution:** Z. Zhou, Y. Wu, and Z. Wu, "Can LLMs "Reason" in Music? An Evaluation of LLMs' Capability of Music Understanding and Generation", in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

The task of "Musical Form & Motif Conditioned Music Generation" as described in Chatmusician [1] involves generating music that adheres to detailed prescribed conditions like form and motif. Figure 1 illustrates this process: The prompt's green text specifies conditional constraints including the musical form, motif, and some musical elements (key, time signature, etc.). Under the prompt, the left sheet presents the human composer's work. The right sheets show ABC notations from different models alongside the reference. The Gemma-7B-it model merely replicates the provided motif, adding no new elements. Similarly, GPT-4 simply repeats the given condition. Qwen-7B-chat and Llama-7B-chat include correct musical elements and the motif but fail to capture the musical form "AB" and maintain the duration of a measure.

The main contributions of our paper are as follows: (1) we provide multi-step prompt engineering and explore how LLMs exhibit their reasoning capabilities with multi-step instructions in music understanding and generation tasks. (2) we assess four major LLMs on various symbolic music tasks, analyzing their reasoning in ABC sequences through quantitative statistical results and qualitative human assessment, including error analysis. The examples, hand-crafted prompts, and codes of data preprocessing are available at [github](#).

2. RELATED WORK

In this section, we summarize related works from two perspectives. First, we introduce previous studies on LLMs in the symbolic music domain, explaining their performance and evaluation methods in music understanding and generation tasks. Then, we discuss the application of LLMs in reasoning math problems and controllable creative text generation, highlighting similarities between the reasoning processes in music and math and the conditioned, open-ended nature of both music and text generation.

2.1 LLMs in Symbolic Music Domain

This subsection reviews the application of LLMs in the symbolic music domain. Previous studies have focused on adapting LLMs for music understanding and generation. Chatmusician [1] uses continual pre-training and fine-tuning on LLaMA2 to understand and generate ABC notation music, without specialized music structures or tokenizers. SongComposer [4] collects a song pretraining dataset including lyrics, melodies and paired lyrics-melodies, employing 10K crafted QA pairs to enable LLMs to perform multiple music-related tasks such as lyric-to-melody conversion and song continuation. MusicAgent [10] integrates various music tools into a single system, though it lacks interaction among these tools. Most approaches view music creation as a linear process, which diverges from the multi-step approach humans use, limiting their applicability for generating creative works. To mimic human creative processes, ByteComposer [5] employs a four-step method to replicate the creative workflow of human composers: conception analysis, draft Com-

position, self-evaluation and modification, and human aesthetic selection. And designs an interactive agent system consisting of expert, generator, voter, and memory modules. What's more, they construct supervised fine-tuning data covering tasks of basic music theory conception, control code generation, music score evaluation and next-step planning. Despite being a significant step towards multi-step music creation with LLMs, it lacks a detailed discussion on the limits of LLMs at each stage.

2.2 Reasoning and Controllable Generation with LLMs

"Reasoning" in NLP involves integrating various knowledge sources or contexts to generate new assertions, events, or actions [11]. This process often breaks complex questions into sequential steps [12]. Techniques such as Chain-of-Thoughts (CoT) [13, 14] have shown effectiveness in addressing complex reasoning tasks, particularly in mathematics. The Program-of-Thoughts approach improves upon CoT by using language models to generate text and code, enhancing math problem-solving performance [15]. Plan-and-Solve (PS) Prompting, a zero-shot technique, outperforms zero-shot CoT significantly, exceeds Zero-shot Program-of-Thoughts, and matches 8-shot CoT in math reasoning [16].

While music and mathematics share similarities, it is crucial to recognize that music is not as deterministic. In controllable music generation, despite given chords, motifs, and forms, unpredictable elements still significantly affect the quality of the music, similar to controllable text generation. Zhang et al. [17], identify three types of control conditions: semantic, structural, and lexical. Semantic controls refer to content control such as sentiment [18, 19] or topic [20, 21], resembling style and emotion in music. Structural control involves shaping the structure of the generated text, such as setting a story's framework or using data from tables or graphs as input, similar to specifying musical forms for generation [22, 23]. Lexical controls manage vocabulary usage, ensuring specific keywords appear, akin to using musical chords and motifs as guidelines. LLMs are extensively applied in diverse controllable and creative generation tasks [24–26]. These systems' abilities in long-context and multi-step generation under predefined conditions are examined, though such analyses are rarely applied in the music domain.

3. METHODOLOGY

3.1 Datasets

In this paper, we incorporate six tasks covering from music understanding to generation. The data is collected from *MusicPile* and *MusicBench* in ChatMusician [1]. The statistics of the dataset we use are shown in Table 1. Each model can support the maximum length of tokens of each task.

Figure 1. A comparison of different LLMs’ responses with the same instruction of the musical-form-and-motif-conditioned task as the input. The ABC notation contained in the response is extracted and displayed as scores the quality of all responses is marked with diverse symbols.

Tasks	Numbers	Max/Avg. tokens
Music theory exercise	367	733/103.56
Motif extraction (ME)	2470	1165/194.28
Musical form extraction (MFE)	483	650/187.35
Chord-conditioned generation (CCG)	1721	283/94.83
Melody harmonization (MH)	355	551/166.03
Musical-form-and-motif-conditioned generation (MFMC)	4881	285/53.82

Table 1. Statistics of each task. The number of items and the max and average length of tokens are provided.

3.2 Prompt Engineering

Before examining each LLM’s task performance, we conducted preliminary tests to verify their understanding of the relevant musical concepts. These tests confirmed that all models possess foundational knowledge of the six music tasks assessed in this study.

We employed two prompt modes in our experiments of all tasks, **Default** and **Chain-of-Thoughts (CoT)**. Default mode means forcing the model to respond without any analysis. Additionally, for music theory exercises, to make the model better understand the questions and options, and return the answer in a unified format, we also include the **In-Context-Learning (ICL)** mode by adding some question-answer pairs as examples shown to the models in the prompt. Taking the task of music theory exercises understanding as an example, three modes of prompts as the prefix of inputs followed by each item in the datasets are shown in Figure 2. Different from the music theory exercise, we specifically design prompts to support a multi-round chat conversation with LLMs for the generation tasks. Figure 3 shows an example of a four-round prompt set of chord-conditioned generation. We invite graduates who majored in music composition to write down their multi-step thoughts when completing the generation tasks involved in this paper. We summarize the common steps of all answers, adapt them to the prompt set, and make sure LLMs can understand or at least intend to follow the instructions. An example of GPT-4’s response to the instruction in Figure 3 is shown on the website¹.

Music Theory Exercise

Default: "You will see JSON-formatted instruction data followed by questions. Your responses should only indicate the selected option (using uppercase letters), without providing any analysis."

CoT: "You will see a JSON-formatted instruction data followed by questions. Your responses should include an analysis step by step. The returned JSON format is as follows: {\"reason\": \"**Let’s think step by step**\", \"answer\": \"A\"}"

ICL: CoT + "Here is an example of a question and its answer:
Read the following questions from the four options (A, B, C and D) given in each question. Choose the best option. Which of the following is the name of the note in the example?",

"L:1/4 M:4/4 K:Cb, D,4 |]",
Options: {"A": "B-flat", "B": "D", "C": "B", "D": "D-flat"},
Answer: "D".

Figure 2. A prompt example of the music theory exercise in different modes.

3.3 Pre-processing Responses

The responses of models are supposed to have correct ABC notations, but it may have certain syntax or formatting issues, and some outputs may even contain a large amount of natural language. We select the main features of ABC notation including field names and bar line symbols to help us extract the ABC sequence. If the extracted ABC sequence can be rendered into MIDI files using Music21² successfully and can be later rendering into audio file using midi2audio³, we consider it capable of producing valid ABC notation.

¹ https://github.com/SylviaZiyazhou/LLMs_music_reasoning/blob/main/CoT_music_generation_GPT4_response.pdf

² <https://web.mit.edu/music21>

³ <https://pypi.org/project/midi2audio>

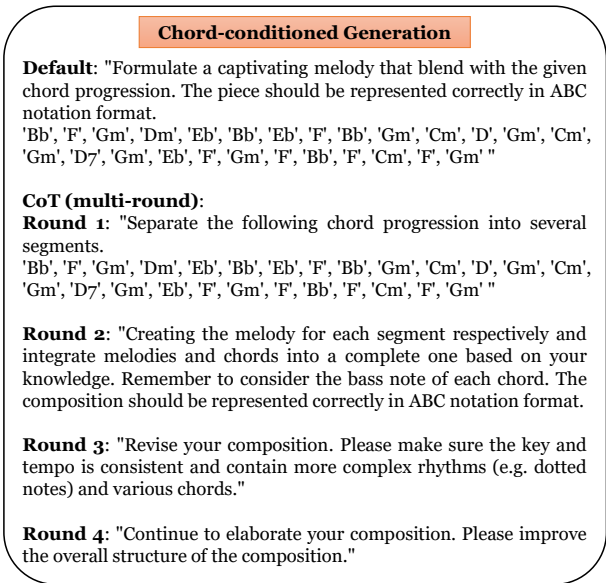

Figure 3. A prompt example of the chord-conditioned generation in different modes.

3.4 Multi-step Reasoning Analysis

In order to compare each model’s reasoning capability on both understanding and generation tasks, we first conduct a subjective assessment to evaluate how different models’ reasoning processes influence their performances. Participants are all familiar with basic music theory and can understand each task as well as the ABC notation. Secondly, based on the results of the subjective assessment, we further perform an error analysis in detail to show the intermediate answers during the reasoning process of each model.

3.4.1 Human Assessment Pipeline

In this section, we will provide a detailed description of our subjective experiments on four popular and open-source LLMs, including Gemma-7B-it, Llama2-7B-Chat, GPT-4, and Qwen-7B-chat. We ask the participants to evaluate to what extent the model understands the instructions and correctly answer the questions in the understanding tasks, and to what extent the responses contain the conditions and make creative works in the generation tasks. Specifically, the questions in the human assessment are as follows:

- For both understanding and generation tasks: 1) To what extent does the model understand and follow the instructions?
- Specifically for the understanding tasks: 1) To what extent does the model correctly answer the question? 2) To what extent does the model reason like human beings?
- Specifically for the generation tasks: 1) AB test: please choose the better one between a pair of music excerpts by considering their "Musicality"; 2) To what extent does the model contain the conditions?

Except for the AB test in the generation task, each question should be rated in a scoring range from 0 to 10 points. We invited music experts who are familiar with ABC notations as the participants in the human assessment, ensuring that each item was evaluated by at least two experts.

4. EVALUATION RESULTS

In this section, we provide the evaluation results based on the methodology we discussed in the last section. The quantitative results include the correctly parsing rate of ABC notation in the generation tasks, and the accuracy of music theory exercises. The qualitative results include the statistical analysis of human assessment and the detailed error analysis. Due to space limitation, we provide the examples at [github](#) and the online links of the corresponding files will be attached in the illustration.

4.1 Quantitative Results

Figure 4 shows the success rate of rendering valid audio from each LLM’s responses under different generation tasks. The pre-processing methodology is introduced in Section 3.3. Except for GPT-4, the other three models all have an audio generation rate of less than 50%, finding it difficult to generate the correct ABC notation format to be converted into audio.

Table 2 displays the accuracy of the music theory exercises in three modes. The reason why some models have an accuracy rate below 25% in multiple-choice questions with four options is that most of their responses seek additional information about the questions rather than answering them. Gemma-7B-it has a comparable performance with GPT-4 in the *Reason*. subset in the *Default* mode even with a much smaller model size. However, CoT and ICL modes, which significantly improve the GPT-4’s performance, show very limited effect or even deficiency in other models. This may inspire us to reconsider the utilization of classical CoT and ICL approaches in solving music tasks.

Figure 4. The success rate of rendering audio from each LLM’s responses in the music generation tasks.

Model (and Mode)	Know. (%)	Reas. (%)
GPT-4 (Default)	58.2	25.6
GPT-4 (CoT)	68.4	36.7
GPT-4 (ICL)	69.9	34.9
Llama2-7B-chat (Default)	11.9	10.2
Llama2-7B-chat (CoT)	29.8	16.3
Llama2-7B-chat (ICL)	10.4	15.3
Gemma-7B-it (Default)	45.7	31.6
Gemma-7B-it (CoT)	36.1	17.3
Gemma-7B-it (ICL)	33.1	31.6
Qwen-7B-chat (Default)	42.0	17.4
Qwen-7B-chat (CoT)	40.2	22.4
Qwen-7B-chat (ICL)	35.7	24.5

Table 2. Accuracy of the music theory exercises of each model. All three modes of results are provided. *Know.* means the music knowledge part and *Reas.* means the music reasoning part. They are two subsets of which the former tests the models’ memory of basic music concepts and the latter needs further reasoning and calculation to be completed. GPT-4’s results come from [1].

Type	Model	Inst. Fl.		Correct.		Reason.	
		μ	σ	μ	σ	μ	σ
ME	GPT-4	10.0	0.0	6.5	2.6	7.8	1.3
	Gemma	8.2	2.1	5.1	2.8	7.4	3.2
	Llama2	7.8	1.9	4.7	2.8	4.7	2.4
	Qwen	7.6	0.7	3.8	1.5	2.1	1.3
MFE	GPT-4	10.0	0.0	5.0	2.5	5.6	2.0
	Gemma	3.5	3.6	2.1	2.2	2.9	2.1
	Llama2	5.4	1.8	3.2	2.8	4.3	2.3
	Qwen	2.6	1.5	2.3	1.9	3.3	2.0

Table 3. The human assessment results of different LLMs on the understanding task. *Inst. Fl.*, *Correct.* and *Reason.* respectively indicate to what extent the model follows the instructions, correctly answers the questions, and reasons like humans. μ and σ respectively denote the average scores and the standard variance.

Type	Model	Inst. Fl.		Condi.	
		μ	σ	μ	σ
MFMC	GPT-4	5.7	1.4	6.3	1.5
	Gemma	4.0	1.8	4.6	2.2
	Llama2	4.3	1.6	4.3	2.3
	Qwen	4.9	2.1	2.9	2.2
MH	GPT-4	6.5	3.5	5.5	2.5
	Gemma	3.0	1.0	4.5	2.5
CCG	GPT-4	5.2	3.3	5.8	3.8
	Gemma	1.6	1.0	1.3	0.8

Table 4. The human assessment results of different LLMs on the generation task. *Condi.* indicates to what extent the model contains the condition given in the instructions and ABC format.

4.2 Qualitative Results

For human assessment, Table 3 shows LLMs on ME and MFE tasks under the *CoT* mode. We randomly sampled 40 examples of each task. In the instruction following question, GPT-4 demonstrates very good results, while other LLMs more or less can accomplish the tasks, indicating a certain level of capability. However, when it comes to the correctness, even GPT-4 finds it challenging to provide satisfactory answers to the prompts. When testing the logical reasoning of LLMs, the average scores indicate that all LLMs encounter difficulties in applying logical reasoning when answering questions step by step, leading to fundamental errors in music theory or illogical conclusions. This highlights the LLMs’ limitation of involving music background knowledge.

Table 4 presents the results of human assessment we conducted on generative tasks. In addition to the results shown in the table, we also conducted an AB test based on Musicality. We find that the GPT-4 and Gemma-7B-it achieve comparable results in MFMCG task, while in other tasks GPT-4 always wins. This means Gemma-7B-it has a potential in creating high-quality symbolic music with limited model size.

As depicted in Figure 4, on MH and CCG tasks, Qwen-7B-chat and Llama2-7B-chat struggled to effectively output correct ABC sequences to be rendered into audios. Therefore, for MH and CCG tasks, we only include the AB test results for GPT-4 and Gemma-7B-it. Despite GPT-4 achieving relatively better scores in generative tasks, it still falls far away from humans’ expectations. Interestingly, beyond the data, LLMs’ generative results occasionally exhibit instances of copying motifs provided in the prompt, as well as displaying unstructured harmonic repetitions or completely off-key notes. We believe that although LLMs can adhere to the ABC format condition provided in the prompt, their lack of musical information and knowledge makes it challenging to understand the high-level information within the condition, resulting in less satisfactory generated outcomes.

In terms of the results from subjective experiments, we identified a common issue prevalent in LLMs. Firstly, LLMs, apart from GPT-4, struggle to generate data in the correct ABC format with high probability, despite being able to provide a perfect answer when asked what ABC notation is. This phenomenon led us to speculate that while LLMs are trained extensively and comprehensively, LLMs can hardly understand all the information they have been exposed to and utilize them in different scenarios. Besides, LLMs can generate music in a seemingly appropriate ABC format in generative tasks, but what appears to be a correctly-formatted response is merely copying the prompt without grasping the semantic and structural information in the given condition.

4.2.1 Multi-step Reasoning Analysis

To better illustrate each model’s reasoning capability when it is used to complete the music theory exercises, we provide an example of a question in the music theory exer-

Figure 5. Human composer’s work for the chord-conditioned generation task.

cises subset and step-by-step responses of the four models⁴. The question is about recognizing the interval property of an ABC sequence referring to a compound in a music sheet. From the responses, we can see that GPT-4 is the only model which can actually perform the calculation but still unable to understand the musical notes in the ABC notation. In the GPT-4’s responses in the *CoT* mode, “4”, which is mistaken as “a fourth apart”, should be a note duration. Accordingly, this mistake influences the whole reasoning process of the calculation of intervals. The response of Llama2-7B-chat also shows its incapability of involving correct music knowledge understanding of notes intervals in the reasoning process. What’s more, Qwen-7B-chat even accidentally contains Chinese in the English text and Gemma-7B-it failed to recognize musical notes in the ABC sequence (see in the supplementary materials), although they can return the correct answer if they are merely asked about “the definition of note intervals”.

Besides, the responses of generation tasks such as MFMC generation also have similar problems. In the *CoT* mode, we find all LLMs except GPT-4, are hard to follow the multi-step instructions and output music in a correct ABC format, so we only provide a GPT-4 response respectively in the raw text⁵ and music sheet⁶ form given the prompt in Figure 3. Although GPT-4 can well understand the instructions in every step, it generates repetitive and simple rhythm without enough progression and variation, compared to the human composer’s work in Figure 5.

5. CONCLUSION AND DISCUSSION

In conclusion, our experimental analysis highlights current LLMs’ limitations in the realm of music understanding and generation, particularly from the perspective of song-level multi-step reasoning. These findings are crucial as they underline the challenges LLMs face when tasked with generating coherent and contextually rich musical compositions,

⁵ https://github.com/SylviaZiyaZhou/LLMs_music_reasoning/blob/main/CoT_music_generation_GPT4_response.pdf

⁶ https://github.com/SylviaZiyaZhou/LLMs_music_reasoning/blob/main/Music_Sheet_of_music_generation_GPT4_response.pdf

which often require both complex sequential processing and creative fineness. From the human assessment results and the error analysis, we find that all these models failed to inject correct music theory and knowledge in the music understanding, reasoning and generation process. This knowledge generalization gap is analogous to the reversal curse problem illustrated in [27] where LLMs trained on “A is B” fail to learn “B is A”. Without making sure the fundamental concepts are correctly mentioned in the generated responses, it is hard to alleviate the LLMs’ hallucination and guarantee the responses’ quality. Therefore, it is significant to implement the knowledge augmentation module in the Supervised Fine-Tuning (SFT) stage to ensure the LLMs can reason based on correct music knowledge by curating more SFT data with enough knowledge-based contexts and practical reasoning processes.

Specifically, several insights for the multi-step SFT dataset construction can be concluded from the process where professional musicians are asked to create music following the instructions. Firstly, more expert knowledge should be involved in the dataset construction to guarantee its quality. For example, in the chord-conditioned generation task in Chatmusician’s dataset, the bass note sequence of the given chords does not conform to the musicians’ expectation of the progression generally. Secondly, some conditions in the old one-step form are too lengthy and informative with limitations that the human composers feel difficult to follow. For example, when they are given an “AB” structure with two different motives in the MFMC task, all of them find hard to integrate two segments with different motives into a complete piece of music in an “AB” form. Therefore, it might not be reasonable to ask the LLMs to output a completely and well composed music in a one-step approach.

What’s more, although four models are all claimed to be able to handle the input size from 4K to 8K tokens, which is much longer than the instructions in the dataset we used, they do not show their long-context processing advantages in the symbolic music domain. Our experimental results show that the widely-used *CoT* and *ICL* approaches are not always effective in improving the model’s performance. In this way, more step-by-step learning strategies should be specifically developed for instruction-based symbolic music tasks by focusing on correctly answering music theory exercises, explicitly extracting motifs and implicitly extracting musical forms, and consistently following the conditions in the instructions.

ABSTRACT

Efficient audio representations in a compressed continuous latent space are critical for generative audio modeling and Music Information Retrieval (MIR) tasks. However, some existing audio autoencoders have limitations, such as multi-stage training procedures, slow iterative sampling, or low reconstruction quality. We introduce Music2Latent, an audio autoencoder that overcomes these limitations by leveraging consistency models. Music2Latent encodes samples into a compressed continuous latent space in a single end-to-end training process while enabling high-fidelity single-step reconstruction. Key innovations include conditioning the consistency model on upsampled encoder outputs at all levels through cross connections, using frequency-wise self-attention to capture long-range frequency dependencies, and employing frequency-wise learned scaling to handle varying value distributions across frequencies at different noise levels. We demonstrate that Music2Latent outperforms existing continuous audio autoencoders in sound quality and reconstruction accuracy while achieving competitive performance on downstream MIR tasks using its latent representations. To our knowledge, this represents the first successful attempt at training an end-to-end consistency autoencoder model. Pretrained weights are available under [this link].¹

1. INTRODUCTION

The ability to faithfully and efficiently represent high-dimensional audio data in a compressed latent space is crucial for a variety of applications, including generative modeling, music information retrieval (MIR), and audio compression. Generative models trained on latent representations of audio can be significantly more efficient than models trained directly on the data space, especially considering the high dimensionality of high-sample rate waveform samples. Additionally, a well-designed latent space can facilitate downstream MIR tasks by including musically relevant features in low-dimensional embeddings. However,

existing state-of-the-art audio autoencoders often present limitations, such as a multi-stage training process, the use of an unstable adversarial objective that requires multiple discriminators, and slow iterative sampling to reconstruct audio waveforms.

In this work, we introduce Music2Latent, a novel consistency autoencoder that encodes audio samples into a continuous latent space with a high compression ratio. Music2Latent is trained fully end-to-end using a single consistency loss function, making it easier to train than many existing audio autoencoders that require a careful balance between multiple competing loss terms [1–4]. Additionally, considering the underlying consistency model [5, 6], Music2Latent can reconstruct samples with high fidelity in a single step, enabling fast and efficient decoding. We evaluate Music2Latent on audio compression metrics, that measure the discrepancy between input and reconstructed samples, and on audio quality metrics, that establish the general audio quality of the reconstructions. Despite not being the primary focus of our model, we also investigate the downstream performance of encoded representations on standard Music Information Retrieval (MIR) tasks. Our experiments demonstrate that Music2Latent reconstructs samples more accurately and with higher audio quality compared to existing continuous autoencoder baselines while providing comparable or better performance on downstream tasks. Our contributions are as follows:

- We introduce Music2Latent, a consistency autoencoder that encodes waveforms into a continuous latent space with a 4096x time compression ratio.
- We show how it is possible to achieve high-quality reconstructions with a fully end-to-end training process relying on a single loss function.
- We introduce a frequency-wise self-attention and a frequency learned scaling mechanism, and demonstrate how they improve audio quality.
- We demonstrate that Music2Latent surpasses existing continuous autoencoder models in terms of reconstruction accuracy and audio quality while achieving competitive performance on downstream MIR tasks.

To the best of our knowledge, we are the first to successfully use consistency training in the music and audio field, and we are the first across all fields to successfully train an end-to-end consistency autoencoder model.

2. RELATED WORK

2.1 Autoencoders for Latent Generative Modeling

Several autoencoder approaches have been explored in both the image and audio domains.

Image Domain: Vector Quantized Variational Autoencoders (VQ-VAE) [7] introduced the concept of learning discrete latent representations of images through vector quantization. VQ-VAE-2 [8] extended this approach to hierarchical codebooks, enabling the generation of realistic images using autoregressive models trained on the learned discrete latent codes. Vector Quantized Generative Adversarial Networks (VQGAN) [9] combine the VQ-VAE framework with adversarial training, incorporating a discriminator network to improve the perceptual quality of generated images. Latent Diffusion Models (LDMs) [10] leverage diffusion models trained on the latent space of a pre-trained autoencoder. By operating on a compressed representation of the data, LDMs achieve high-quality image synthesis with reduced computational requirements compared to pixel-based diffusion models. Diffusion autoencoders [11] combine a learnable encoder with a diffusion model as the decoder, aiming to learn a meaningful and decodable representation of images in a fully end-to-end manner. However, they still require a slow iterative sampling process to reconstruct samples.

Audio Domain: The audio autoencoder proposed in the Musika music generation system [1] encodes audio into a continuous latent space by reconstructing the magnitude and phase components of a spectrogram. While Musika achieves fast inference, it requires a two-stage training process combined with an unstable adversarial objective. Moûsai introduces a diffusion autoencoder [12] to learn a compressed invertible audio representation. However, it requires multiple sampling steps for reconstruction. Several audio autoencoders employ Residual Vector Quantization (RVQ) to learn discrete latent representations. Examples include SoundStream [2], EnCodec [3], and Descript Audio Codec (DAC) [4]. These models are well-suited for training autoregressive models on the latent representations but are less suitable for other generative models such as diffusion, consistency, or GAN-based methods. They also generally produce (discrete) representations at a significantly lower time compression ratio than continuous models, and are thus not directly comparable to our work.

2.2 Consistency Models

Consistency models [5, 6] offer a novel approach for efficient generative modeling by learning a mapping from any point on a diffusion trajectory to the trajectory’s starting point. They have been successfully applied to image generation tasks [13], achieving high-quality results with single-step sampling. The application of consistency models to audio generation is still relatively unexplored. CoMoSpeech [14] explores consistency distillation for speech synthesis, but it requires a pre-trained diffusion model to be trained.

3. BACKGROUND

3.1 Consistency Models

Consistency models represent a novel family of generative models capable of producing high-quality samples in a single step, without the need for adversarial training or iterative sampling. They are grounded in the probability flow ordinary differential equation (ODE) introduced by [15]:

$$\frac{dx}{d\sigma} = -\sigma \nabla_x \log p_\sigma(x), \quad \sigma \in [\sigma_{\min}, \sigma_{\max}] \quad (1)$$

Here, $p_\sigma(x)$ represents the perturbed data distribution obtained by adding Gaussian noise with zero mean and standard deviation σ to the original data distribution $p_{\text{data}}(x)$. The term $\nabla_x \log p_\sigma(x)$ is known as the score function, which plays a crucial role in score-based generative models [16–18]. The probability flow ODE establishes a bijective mapping between a noisy data sample $x_\sigma \sim p_\sigma(x)$ and $x_{\sigma_{\min}} \sim p_{\sigma_{\min}}(x) \approx x \sim p_{\text{data}}(x)$. This mapping, denoted as $f(x_\sigma, \sigma) \mapsto x_{\sigma_{\min}}$, is termed the consistency function, which satisfies the boundary condition $f(x_{\sigma_{\min}}, \sigma_{\min}) = x_{\sigma_{\min}}$. A consistency model $f_\theta(x_\sigma, \sigma)$ is a neural network trained to approximate the consistency function $f(x_\sigma, \sigma)$. To meet the boundary condition, consistency models are parameterised as:

$$f_\theta(x_\sigma, \sigma) = c_{\text{skip}}(\sigma)x_\sigma + c_{\text{out}}(\sigma)F_\theta(x_\sigma, \sigma) \quad (2)$$

where $F_\theta(x_\sigma, \sigma)$ is a free-form neural network, and $c_{\text{skip}}(\sigma)$ and $c_{\text{out}}(\sigma)$ are differentiable functions such that $c_{\text{skip}}(\sigma_{\min}) = 1$ and $c_{\text{out}}(\sigma_{\min}) = 0$.

Consistency models can be trained using either consistency distillation (CD) or consistency training (CT). CD requires pre-training a diffusion model to estimate the score function $\nabla_x \log p_\sigma(x)$ via score matching [19]. CT, on the other hand, allows training consistency models in isolation and is the method that is considered in this work.

3.2 Consistency Training

In consistency training, the probability flow ODE is discretised using a sequence of noise levels $\sigma_{\min} = \sigma_1 < \sigma_2 < \dots < \sigma_N = \sigma_{\max}$. The consistency model $f_\theta(x_\sigma, \sigma)$ is then trained by minimising the following consistency training loss over θ :

$$\mathcal{L}_{\text{CT}} = \mathbb{E} \left[\lambda(\sigma_i, \sigma_{i+1}) d \left(f_\theta(x_{\sigma_{i+1}}, \sigma_{i+1}), f_{\theta^-}(x_{\sigma_i}, \sigma_i) \right) \right] \quad (3)$$

where $d(x, y)$ is a metric function such as mean squared error and $\lambda(\sigma_i, \sigma_{i+1})$ is a noise level-dependent loss scaling. In the above equations, f_θ and f_{θ^-} are referred to as the student network and the teacher network respectively. The teacher’s parameters θ^- are obtained by applying a stop-gradient operation to the student’s parameters θ during training:

$$\theta^- \leftarrow \text{stopgrad}(\theta) \quad (4)$$

After training, the consistency model $f_\theta(x, \sigma)$ can directly generate a sample x by starting with $z \sim \mathcal{N}(0, I)$ and computing $x = f_\theta(\sigma_{\max}z, \sigma_{\max})$. This enables efficient one-step sampling, a key advantage of consistency models over diffusion models.

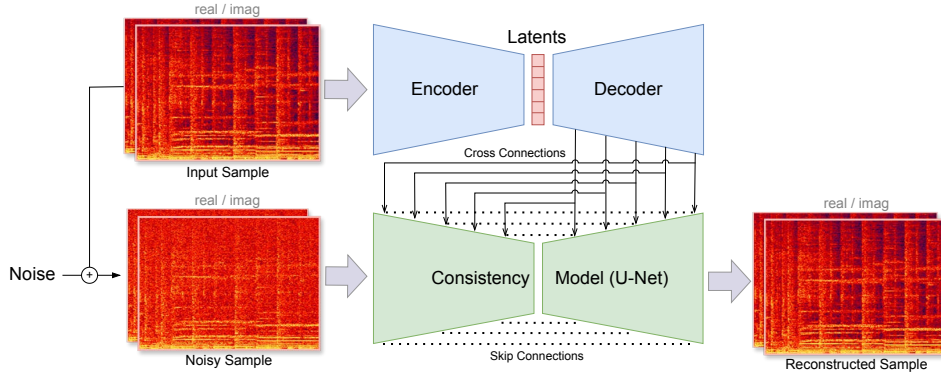

Figure 1. Training process of Music2Latent. The input sample is first encoded into a sequence of latent vectors. The latents are then upsampled with a decoder model. The consistency model is trained via consistency training, with an additional information leakage coming from the cross connections.

4. MUSIC2LATENT

In the following sections, we provide a detailed explanation of the audio representation, architecture, and training framework underlying Music2Latent.

4.1 Audio Representation

Music2Latent utilises complex-valued STFT spectrograms as the representation of waveform audio. This choice is motivated by several factors. First, previous works [20, 21] have demonstrated the effectiveness of complex spectrograms in capturing the intricate structure of audio signals and enabling the generation of high-fidelity audio. Second, 2-dimensional spectrograms allow for the direct application of UNet architectures [22] that have been successfully used in the image domain with diffusion and consistency models. However, the distribution of values across different frequencies in a STFT spectrogram can vary significantly, with substantially higher magnitudes in low frequencies compared to high frequencies. This can hinder the ability of the model to accurately reconstruct all frequency components, as the learning signal for high frequencies may be overshadowed by the stronger signal from lower frequencies. To address this issue, we apply the amplitude transformation proposed in [23] and later used in [24] which scales up lower energy components in the spectrogram:

$$\tilde{c} = \beta |c|^\alpha e^{i\angle(c)} \quad (5)$$

where c is the original complex STFT coefficient, \tilde{c} is the transformed coefficient, $\alpha \in (0, 1]$ is a compression exponent that emphasizes lower-energy frequency components, $\angle(c)$ represents the phase angle of c , and $\beta \in \mathbb{R}^+$ is a scaling factor to normalize amplitudes within a desired range (e.g., $[0, 1]$). This transformation ensures that the model receives a more balanced representation of the audio signal, facilitating accurate reconstruction across all frequencies. We consider the complex STFT spectrogram as a 2-channel representation, with each channel representing real and imaginary components respectively.

4.2 Architecture

The architecture of Music2Latent consists of an encoder, a decoder, and a consistency model.

Encoder: The encoder receives as input the audio sample in the form of an STFT spectrogram with real and imaginary components in each channel. It then gradually down-samples the feature maps along the time axis and outputs a sequence of latent vectors with dimensionality d_{lat} . Instead of being trained with a VAE objective [10, 25] to keep the distribution of latent values under control, the latent encodings of the model are kept in the $(-1, 1)$ range using a \tanh activation function, which was proven to be a successful approach in previous works for downstream latent generative modeling tasks [1, 12].

Decoder: The decoder mirrors the encoder architecture but performs upsampling instead of downsampling. The decoder takes as input a sequence of latent vectors from the encoder and progressively upsamples them to match the dimensionality of the feature maps of the consistency model. The only purpose of the decoder is to ensure that the conditioning information from the latent encodings is available to the consistency model at all levels of its architecture (the reason for this architectural choice is provided in the next section).

Consistency Model: The consistency model uses a UNet architecture with a downsampling branch and an upsampling branch connected via additive skip connections. The output of the decoder at each upsampling layer is also added to the corresponding layer of the consistency model. This provides cross connections that allow the consistency model to directly access the conditioning information about the sample it is attempting to reconstruct at all levels of its architecture. This design choice is crucial for single-step reconstruction, as it ensures that the model has access to the necessary information to accurately reconstruct the target sample from the very beginning of the UNet architecture.

Adaptive Frequency Scaling: The distribution of values along the frequency axis in the input spectrograms changes

significantly with respect to the noise level σ . Specifically, when σ is close to σ_{min} , the magnitudes at low frequencies are on average much higher than the ones at high frequencies, while with σ approaching σ_{max} , there is an equal distribution of values across all frequencies since the sample is pure noise. To address this, we introduce a frequency-wise scaling mechanism that adaptively scales the input and output of the consistency model based on the current noise level. Specifically, we employ a Multi-Layer Perceptron (MLP) that takes as input the noise level σ in the form of a sinusoidal embedding [26] and outputs a scaling factor for each frequency bin:

$$s_f(\sigma) = \text{MLP}(\sigma), \quad (6)$$

where $s_f(\sigma) \in \mathbb{R}^F$ is a vector of scaling factors, one for each of the F frequency bins of the noisy spectrogram. We calculate different scaling factors to scale both the input x_σ and the output of the consistency model $F_\theta(x_\sigma)$ as follows:

$$\tilde{x}_\sigma = x_\sigma \odot s_{f,\text{in}}(\sigma) \quad \tilde{F}_\theta(x_\sigma) = F_\theta(x_\sigma) \odot s_{f,\text{out}}(\sigma) \quad (7)$$

where \odot denotes element-wise multiplication.

Frequency-wise self-attention: To capture long-range dependencies within the frequency domain while keeping a memory footprint that scales linearly with the time axis, Music2Latent employs frequency-wise self-attention. This mechanism allows the model to attend to information from all frequency bins at a given time step, enabling it to learn complex relationships between different frequency components. Considering that only the time dimension of the input can vary at inference time, using frequency-wise attention compared to full self-attention does not incur in a memory requirement that scales quadratically with time. After computing the query Q , key K , and value V via linear projections of the input features, we calculate the attention matrix A by performing an outer product on individual timesteps t :

$$A_t = \text{softmax} \left(\frac{Q_t K_t^T}{\sqrt{d}} \right) \quad (8)$$

where d is the channel dimension, and after concatenating the attention weights from all timesteps together we have $A \in \mathbb{R}^{T \times F \times F}$. The softmax operation is then applied across the frequency dimension, ensuring that the attention weights for each frequency bin sum to one.

4.3 Training Process

Music2Latent is trained using the consistency training (CT) objective [5, 6]. As described in Sec. 3.2, the objective minimizes the discrepancy between the outputs of the consistency model at adjacent noise levels σ_i and σ_{i+1} . As for the distance metric in the consistency training loss function (Eq. 3), we use the Pseudo-Huber loss function [27] which smoothly transitions from the ℓ_1 to the squared ℓ_2 metrics:

$$d(x, y) = \sqrt{|x - y|^2 + c^2} - c, \quad (9)$$

where c is a hyperparameter that controls the transition. In [6], it was shown that for image generation with consistency models, this loss provides smoother gradients during training and performs substantially better compared to the more common squared ℓ_2 loss. The consistency model is parameterised as described in Eq. 2, with the exception that in addition to providing as input the noisy sample x_σ , we allow for information leakage of the clean sample x through the features \mathbf{y}_x provided by the decoder via cross connections:

$$\begin{aligned} \text{lat}_x &= \text{Enc}_\theta(x) & \mathbf{y}_x &= \text{Dec}_\theta(\text{lat}_x) \\ f_\theta(x_\sigma, \sigma, \mathbf{y}_x) &= c_{\text{skip}}(\sigma)x_\sigma + c_{\text{out}}(\sigma)F_\theta(x_\sigma, \sigma, \mathbf{y}_x) \end{aligned} \quad (10)$$

which results in the following consistency loss that is used to train the system fully end-to-end:

$$\mathcal{L} = \mathbb{E} [\lambda(\sigma_i, \sigma_{i+1})d(f_\theta(x_{\sigma_{i+1}}, \sigma_{i+1}, \mathbf{y}_x), f_{\theta^-}(x_{\sigma_i}, \sigma_i, \mathbf{y}_x))] \quad (11)$$

With respect to the noise level-dependent loss scaling $\lambda(\sigma_i, \sigma_{i+1})$, we follow [6] and use:

$$\lambda(\sigma_i, \sigma_{i+1}) = \frac{1}{\sigma_{i+1} - \sigma_i} \quad (12)$$

which assigns a higher weight to the loss when there is a small gap between consecutive noise levels. We also adopt the lognormal sampling of σ introduced by [28] and adopted for consistency training by [6] to focus training on a more relevant range of noise levels.

Continuous Noise Levels: Unlike the formulation presented in previous consistency model literature [5, 6], which use a discrete set of noise levels for training, Music2Latent employs a continuous noise schedule. This change is inspired by recent state-of-the-art diffusion models which notably sample noise levels from a continuous distribution [28]. Parallel work on improving the performance of consistency models also demonstrates how employing a continuous noise schedule improves results compared to the original discrete schedule [29]. Specifically, we use an exponential schedule during training to determine the step size between consecutive noise levels used for the consistency loss:

$$\Delta t_k = \Delta t_0^{\frac{k}{K}(e_K - 1) + 1} \quad (13)$$

where Δt_k is the step size at training iteration k , Δt_0 is the initial step size at iteration 0, and e_K is the exponent at final iteration K . This schedule ensures that the step size decreases exponentially as training progresses, allowing the model to gradually learn finer details of the data distribution. In order to calculate σ_i and σ_{i+1} , we first sample a timestep $t_{i+1} \in [0, 1]$ with the sampling weights given by the lognormal distribution, and calculate the adjacent timestep $t_i = \max(t_{i+1} - \Delta t_k, 0)$. Finally we calculate σ_i using the time step-to-noise level mapping from [28]:

$$\sigma_i = \left(\sigma_{\min}^{\frac{1}{\rho}} + t_i \left(\sigma_{\max}^{\frac{1}{\rho}} - \sigma_{\min}^{\frac{1}{\rho}} \right) \right)^\rho \quad (14)$$

where $\rho = 7$. We use the same mapping to calculate σ_{i+1} .

4.4 Implementation Details

With respect to the UNet architecture of the consistency model, we use the NCSN++ architecture introduced in [17], which consists of convolutional residual blocks with 3x3 kernels, Swish activation function [30] and Group Normalisation layers. The same residual blocks are used in both the encoder and decoder. We use sinusoidal embeddings to encode the noise level, using $\frac{\log(\sigma)}{4}$ as the input. The skip connections between the downsampling and the upsampling branches of the UNet are added instead of being concatenated, as recent works on diffusion models [31] show that addition provides better performance. Consequently, the cross connections from the decoder are also added to the corresponding UNet features, following a linear projection layer. In the encoder, before the final bottleneck layer with a \tanh activation function, used to constrain the latent encodings to the $(-1,1)$ range, the 2D features are reshaped into 1D features by flattening the frequency dimension into the channel dimension, and a series of 4 residual blocks with 1D convolutions with kernel size of 3 are used. We choose $d_{lat} = 64$, which results in a $4096x$ time compression ratio and a $64x$ total compression ratio. The decoder perfectly mirrors the architecture of the encoder, while not receiving any incoming skip connections, since all the information necessary to reconstruct the clean input sample must be contained in the latent encodings. For the consistency model and encoder/decoder models we use 5 levels corresponding to 4 upsampling/downsampling operations, and in each level we use 2 residual blocks for the consistency model, and 1 residual block for the encoder and decoder. The base channels for all models are set to 64 and the channel multiplier for each of the 5 levels is set to $[1, 2, 4, 4, 4]$ for all models. We use 512 channels for the 1D convolutional blocks in the encoder and decoder. We use frequency-wise self-attention layers with 4 heads in the 3 last levels for all models, in order not to use it with higher frequency dimensions. The channels used for sinusoidal embeddings and the MLPs used for both noise level embeddings and frequency scalings are set to 256. The model has ~ 58 million parameters. The consistency training framework follows the same implementation of [6] with respect to the scaling factors $c_{in}, c_{skip}, c_{out}$, the parameter c for the pseudo-Huber loss function, the minimum and maximum noise parameters $\sigma_{min}, \sigma_{max}$, the standard deviation of the data samples σ_{data} , and the lognormal distribution values

of P_{mean}, P_{std} . Regarding the input STFT spectrograms, we extract them using $hop = 512$, $window = 4 \cdot hop$ and we transform them using the formula presented in Sec. 4.1, with $\alpha = 0.65, \beta = 0.35$. Regarding the step size schedule for the continuous noise levels, we choose $\Delta t_0 = 0.1$ and $e_K = 3$. We train the model on waveforms of 34, 304 samples, which correspond to ~ 0.78 s of 44.1 kHz audio. The model thus produces latent representations of 44.1 kHz audio at a sampling rate of ~ 11 Hz. We use a batch size of 16 and train for $K = 800k$ iterations using the RAdam optimizer [32] with $lr_0 = 1e^{-4}, \beta_1 = 0.9, \beta_2 = 0.999$. We use a cosine learning rate decay with $lr_K = 1e^{-6}$ and we keep an Exponential Moving Average (EMA) of the parameters of all models with a momentum of 0.9999. Training takes ~ 5 days on a single RTX 3090 GPU.

Figure 2. Audio quality of reconstructed samples with respect to the number of denoising steps of the consistency model.

5. EXPERIMENTS AND RESULTS

5.1 Datasets

We train the model on MTG Jamendo [33] and on the clean speech segments from DNS Challenge 4 [34], sampling from each dataset with equal probability. We keep the original sample rates of 44.1 kHz and 48 kHz. We include speech in the training data to both improve the reconstruction of vocal content in music samples, and to make Music2Latent useful also for speech-related tasks. We use MusicCaps [35] as our evaluation dataset.

5.2 Baselines

We compare Music2Latent to different audio autoencoders that encode audio samples into a continuous latent space to enable downstream latent generative modeling. We include the autoencoder introduced in Musika [1] and the

autoencoder introduced by [36] to train a latent diffusion model for music accompaniment generation (we name this model LatMusic in our comparison). Both models encode audio samples with the same compression ratio of $64x$ as Music2Latent. We also include the diffusion autoencoder introduced in Moûsai [12], which has a compression ratio of $32x$ (Moûsai_v3), and a different autoencoder model that is made available by the authors of Moûsai² with a comparable compression ratio of $64x$ (Moûsai_v2).

5.3 Audio Compression and Quality

	SI-SDR \uparrow	ViSQOL \uparrow	FAD _{clap} \downarrow	FAD \downarrow
Musika	-25.81	3.80	0.103	2.308
LatMusic	-27.32	3.95	0.050	1.630
Moûsai_v2	-21.44	2.36	0.731	4.687

Music2Latent	-3.85	3.84	0.036	1.176
DAC	9.48	4.21	0.041	0.966

Table 2. Audio compression and quality results.

We adopt the same objective evaluation metrics as in [3] and use Scale-Invariant Signal-to-Noise Ratio (SI-SDR) [37] and ViSQOL [38–40]. SI-SDR is a distance calculated between input and reconstructed waveforms, while ViSQOL estimates a MOS-like score on perceptual quality from the difference between the two signals. Considering that Music2Latent is trained as a generative model, we also use Fréchet Audio Distance (FAD [41]) to evaluate the general audio quality of reconstructed samples without relying on paired samples. In addition to the original FAD implementation, we also evaluate on FAD_{clap} using CLAP [42] features, which was shown to correlate significantly better with perceived audio quality [43]. In Tab. 2 we show that Music2Latent is competitive with respect to ViSQOL to Musika and LatMusic, while vastly outperforming all baselines on the remaining metrics. Note that all four baselines discard phase information from the input of the autoencoder, which may explain the poor SI-SDR performance. DAC, while not being directly comparable, scores favourably in reconstruction metrics, while matches Music2Latent in terms of audio quality. In Fig. 2 we also show that the audio quality of reconstructions remains almost constant when using more than a single denoising step. We provide audio samples and additional supplementary material on the accompanying website³.

5.4 Ablation Study

	FAD _{clap} \downarrow	FAD \downarrow

+ Freq-wise Attention	0.0547	1.710
+ Adaptive Freq Scaling	0.0537	1.665

Table 3. Ablation study. *Base Model* is trained without frequency-wise attention and adaptive frequency scaling.

² <https://github.com/archinetai/archisound>

³ <https://sonyyslparis.github.io/music2latent-companion/>

To demonstrate the effectiveness of both frequency-wise attention and learned frequency scaling, we perform an ablation study and report the FAD and FAD_{clap} results in Table 3. With respect to the model with no attention and no scaling, we use channel multipliers [1, 2, 4, 4, 5] to roughly match the number of parameters that are lost. All ablated models are trained for 200k iterations. The remaining training details are the ones described in Sec. 4.4.

5.5 Downstream Performance

Since training representation learning models on compressed audio representations instead of raw data was shown to be a promising approach [44–47], our goal is to investigate whether there are well disentangled audio features in the feature space of audio autoencoders. We evaluate downstream performance on MagnaTagATune [48] for auto-tagging, Beatport [49] for key estimation, and TinySOL [50] for instrument and pitch class classification. For each dataset, we extract the encoder features from the layer with the highest number of output channels from each of the models (after flattening the 2D features for Music2Latent and before the last linear layer for the remaining models), average them along the time axis, and train a 2-layer MLP with [256, 128] units. We also show the results obtained by performing the same evaluation on features from the classification model MusiCNN-MSD [51] and well-established representation learning models CLMR [52] and MERT-v1-95M [47] (with averaged features from layers 9 to 12). We extract features from these models following [53] and perform all evaluations using the `mir_ref` library⁴ [54]. In Tab. 1 we show how Music2Latent outperforms autoencoder baselines in almost all tasks, and in the case of key and pitch classification it even outperforms state-of-the-art representation learning models. We hypothesize that the loss is more sensitive to pitch information than timbre content (explaining the weak comparison on TinySOL-instrument to the representation learning models).

6. CONCLUSION

In this work we introduced Music2Latent, a consistency autoencoder that efficiently compresses high-dimensional audio waveforms into a continuous latent space. By leveraging consistency training, Music2Latent achieves high-fidelity single-step reconstruction, and enables efficient downstream latent generative modeling. We propose a learned frequency scaling mechanism to handle varying frequency distributions across diffusion noise levels. Experiments show Music2Latent matches or outperforms baselines in reconstruction accuracy and audio quality, while having comparable or better performance on downstream tasks. To our knowledge, Music2Latent represents the first successful end-to-end consistency autoencoder. Future work could explore extensions to other modalities and higher compression ratios. Overall, we believe Music2Latent is a significant contribution to audio generative modeling and representation learning.

ROBUST AND ACCURATE AUDIO SYNCHRONIZATION USING RAW FEATURES FROM TRANSCRIPTION MODELS

{johannes.zeitler, ben.maman, meinard.mueller}@audiolabs-erlangen.de

ABSTRACT

In music information retrieval (MIR), precise synchronization of musical events is crucial for tasks like aligning symbolic information with music recordings or transferring annotations between audio versions. To achieve high temporal accuracy, synchronization approaches integrate onset-related information extracted from music recordings using either traditional signal processing techniques or exploiting symbolic representations obtained by data-driven automated music transcription (AMT) approaches. In line with this research direction, our paper introduces a high-resolution synchronization approach that combines recent AMT techniques with traditional synchronization methods. Rather than relying on the final symbolic AMT results, we show how to exploit raw onset and frame predictions obtained as intermediate outcomes from a state-of-the-art AMT approach. Through extensive evaluations conducted on piano recordings under varied acoustic conditions across different transcription models, audio features, and dynamic time warping variants, we illustrate the advantages of our proposed method in both audio–audio and audio–score synchronization tasks. Specifically, we emphasize the effectiveness of our approach in aligning historical piano recordings with poor audio quality. We underscore how additional fine-tuning steps of the transcription model on the target dataset enhance alignment robustness, even in challenging acoustic environments.

1. INTRODUCTION AND RELATED WORK

Aligning different versions of a musical piece is a common task in music information retrieval (MIR). For example, score–audio synchronization with the objective to align score-based note information with time positions of an audio recording is used in automatic score following [1, 2], score-informed audio decomposition techniques [3], or the derivation of note labels for the training and evaluation of automated music transcription (AMT) systems [4]. Aligning different audio recordings of the same musical piece (audio–audio synchronization) enables applications

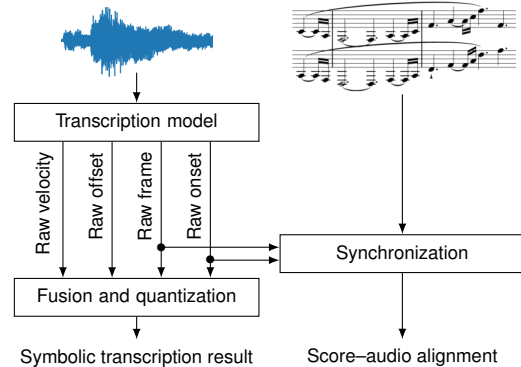

Figure 1: Schematic overview of the proposed audio–score synchronization pipeline using raw features from a transcription model.

like track switching [5], cross-version analysis [6], automated accompaniment of instrumentalists using existing backing tracks [7, 8], and the transfer of annotations from one recording to another [9, 10].

Alignment pipelines based on dynamic time warping (DTW) typically use chroma or onset features, or a combination of both [11, 12]. While such features can easily be obtained from symbolic score information, they need to be estimated from audio recordings. Traditionally, many alignment pipelines rely on features estimated with classical signal processing methods, e.g., using a constant-Q transform [13] or a multirate filterbank [11, 14]. With the advancements in deep learning (DL) techniques, several systems for multi-pitch estimation (MPE) [15–20] as well as learning-based methods for onset estimation [21–24] have been introduced. Along with the creation of large datasets of pairs of audio recordings and note labels such as MAESTRO [25] or MusicNet [16], modern transcription models precisely estimate note on- and offset, as well as velocity and pedaling information [26–28].

In this work, we investigate the advantages of using features estimated by AMT systems for audio–audio and audio–score alignment tasks. We demonstrate how to leverage intermediate predictions from transcription models for aligning audio recordings and symbolic representations, as illustrated in Figure 1. In particular, we investigate alignments within a carefully curated dataset of the first movements of the 32 piano sonatas by Ludwig van Beethoven, with all sonatas performed by eleven artists, encompassing live performances, historic recordings with low audio quality, performances on historic instruments,

Figure 2: Chroma (left) and DLNCO (right) features for Beethoven’s Appassionata (Op. 57-1) played by F. Dupree. (a) FB_RAW. (b) T1_RAW. (c) T1_SYM. (d) DK_SYM.

and modern studio-quality recordings. By analyzing the alignment precision and robustness across different feature extractors and representations, synchronization algorithms, and audio versions, we demonstrate that our approach allows for robust synchronization of real-world data.

The outline of this paper is as follows. First, in Section 2, we describe the synchronization pipeline and discuss its components, followed by an introduction to our dataset of Beethoven’s piano sonatas in Section 3. Since there are no reference alignments available for the audio recordings in this real-world dataset, we rely on heuristics for evaluation, see Section 4. In Section 5, we experimentally show how using raw intermediate features from transcription models increases the alignment stability, as compared to using the final symbolic transcription results. Furthermore, we give detailed insights into the peculiarities of aligning datasets encompassing historic music recordings and demonstrate how to adapt to such data. We conclude in Section 6 with an outlook on future work.

2. SYNCHROZINATION PIPELINE

In this section, we provide an overview of the synchronization pipeline. First, we describe the feature extractors and types of feature representations, before we outline the DTW-based alignment step. An overview of all elements in the pipeline and their abbreviations is provided in Table 1. Following the notation in [26], we distinguish between two types of features: *frame* features encode when a note is active (in the piano case, this corresponds to the time until a key is released, or until the sustain phase ends), and *onset* features encode only the beginning of a note (in the piano case when a key is pressed).

2.1 Feature Extraction Model

Filterbank. Before the advent of today’s DL-based feature extraction models, traditional signal processing techniques were a common way to extract features from audio recordings. For example, the standard implementation of Sync Toolbox [14] uses a multirate filterbank (FB) to estimate frame-wise note activity and onsets.

Transcription Model. In recent years, AMT systems based on DL have shown significant improvements in performance [29]. One of the ground-breaking architectures is the *Onsets and Frames* architecture by Hawthorne et al. [26], which has separate prediction heads to estimate onsets and frames. Maman et al. [4] proposed a strategy to train a model based on the onsets and frames architecture on diverse and unaligned pairs of audio data and musical scores. This has led to improved performance on unseen datasets, generalizing across instrumentations, acoustic conditions, and styles. In the following, we refer to the transcription model from [4], trained on MusicNet [16] with re-aligned labels, as T1. Kong et al. [27] extend the onsets and frames architecture by additionally modeling sustain pedal activity, therefore providing more robust training in the presence of misaligned offset information. We refer to the transcription system from [27], trained on MAESTRO [25], as T2.¹

Disklavier. Certain datasets such as MAESTRO [25] include pairs of audio recordings and reference note information by having the pieces performed on a Disklavier. We refer to features directly extracted from the symbolic Disklavier track as DK, and use them as an upper bound for the performance of an MPE feature extractor.

2.2 Feature Representation

Raw features. For each sequence of input audio, the feature extractors FB, T1, and T2 predict continuous pitch- and frame-wise probabilities $\mathbf{P}_{raw}^{frame}, \mathbf{P}_{raw}^{onset} \in [0, 1]^{88 \times N}$ for frame activity and note onset, respectively. These feature matrices can be thought of as RAW features and are commonly stored in a pianoroll-like representation for 88 pitches and N time frames (T1 and T2 additionally predict

¹ Note that we do not include transcription models that directly output a tokenized sequence of MIDI messages (where we can not access raw pitch probabilities), such as the MT3 model by Hawthorne et al. [30].

such probabilities for note velocity and offset). Figure 2a/b illustrates RAW features for a piece from the ASAP dataset [31], computed by the FB and T1 feature extractors .

Symbolic features. In AMT, the raw predictions for frames, onsets, and offsets are fused and quantized in a postprocessing step, yielding binary estimates about which keys have been pressed. In particular, note sustain (frame activity) is conditioned on a previously occurring note onset [26,27]. This postprocessing step outputs a sequence of symbolic control messages for note onset and offset events, with additional control messages for pedal information in the case of T2. We denote these binary and symbolic-like features as SYM features and, for usage in our synchronization pipeline, store these in the form of two discretized pianorolls $\mathbf{P}_{\text{sym}}^{\text{frame}}, \mathbf{P}_{\text{sym}}^{\text{onset}} \in \{0, 1\}^{88 \times N}$ for frame activity and onset events, respectively. Note that in the case of Disklavier (DK), no RAW features are available and thus only SYM features are used. Figure 2c/d illustrates SYM features for T1 and DK.

Comparison. In Figure 2 we qualitatively compare RAW features from FB and T1 as well as SYM features from T1 to the DK reference. While FB_RAW in Figure 2a shows many false positive chroma events and misses many onsets compared to DK in Figure 2d, the chroma features of T1_RAW in Figure 2b are relatively stable and onsets perfectly coincide with DK. Thresholding the RAW transcription results to T1_SYM features (Figure 2c) yields varying and often shortened note durations in the chroma representation compared to DK, indicating possible instabilities when using these features for computing an alignment.

2.3 Alignment Technique

We use two variants of DTW to compute the optimal alignment between two feature sequences.

Onset features. As a first approach and in line with previous work [4, 32], we use only onset features and convert them to a twelve-dimensional pitch class representation. Using the Euclidean distance function, we compute the cost matrix between the onset feature sequences of the two versions to be aligned. We use standard DTW with unit steps in the horizontal, vertical, and diagonal direction with step weights (1.5, 1.5, 2) to compute the minimum cost path between the two sequences [12]. We refer to this approach, using only onset features, as \circ .

Onset and frame features. As a second alignment variant, we choose a high-resolution approach [11] that combines frame and onset features. Using frame features yields robustness on the coarse temporal level, while onset features provide precision on the fine level by precisely aligning note onsets [24]. In this approach, we again convert frame and onset features into pitch class representations and additionally add a decay to the onset features. We refer to [11] for a description of these decaying locally normalized chroma onset (DLNCO) features. Next, we compute separate cost matrices for frame features (using the cosine distance) and for onset features (using the Euclidean distance). Afterward, we add the two cost matrices for frame and onset features and use DTW with step weights

(1.5, 1.5, 2) to compute the optimum alignment path on the combined cost matrix. We refer to [14, 33] for an efficient multi-resolution and multi-scale implementation of DTW. We denote the described approach, using a combination of onset and frame features, as $\circ\text{F}$. Note that we do not consider using only frame features (commonly called chroma features), as previous work has shown a lack of precision in this case. For example, Ewert et al. observe a 100% increase of the alignment error when using frame features instead of combined frame and onset features for the case of piano music, where onsets are clearly defined [11].

3. DATASETS

In our experiments, we consider the case of piano music, as there are large-scale datasets available [25, 31, 34], note onsets are well-defined, reference note information can be obtained from performances on a Disklavier, and many transcription models are primarily trained on piano music [26, 27]. To this end, we evaluate alignment accuracy not only in acoustically controlled scenarios such as MAESTRO. Instead, we consider a much more challenging scenario using real-world piano recordings under complex acoustic conditions, which we find in a dataset of Beethoven’s piano sonatas [35]. The 32 piano sonatas by Ludwig van Beethoven are recognized as pivotal works in Western classical music and hold a significant place in cultural history. Being one of the most performed and recorded corpus of classical music, alignments between a multitude of different versions can be studied.

3.1 Beethoven Piano Sonata Dataset

As a main evaluation corpus, we choose the Beethoven Piano Sonata Dataset (BPSD) [35], which comprises eleven complete audio recordings of the first movements of all 32 piano sonatas, along with sheet music in machine-readable format. An aspect of central importance is the coherent structure of the dataset: all audio versions and the symbolic sheet music share the same musical timeline, which was enforced by manually editing the score and audio versions. Thus, there is no incoherence due to, e.g., additional

or missing repetitions. The BPSD includes over 41 h of audio recorded under various acoustic conditions, being far more diverse than common piano datasets [25, 34]. For example, MAESTRO was entirely performed on Yamaha Disklaviers, and training on MAESTRO does not provide good generalization on other datasets [4, 32, 36]. In contrast, the BPSD comprises modern studio recordings in high audio quality, vintage recordings published on vinyl, including pitch drift due to wobbling of the vinyl records, performances on historical instruments such as the fortepiano, and significant deviations from today’s standard tuning frequency of 440 Hz (A4). Measure positions were annotated manually for all 32 sonatas recorded by Wilhelm Kempff in 1964 (WK64). An overview of the eleven audio versions in the BPSD is provided in Table 2.

3.2 ASAP

To be able to use reference note information from Disklavier recordings in our experiments, we additionally leverage the ASAP dataset [31]. To achieve consistency across all experiments, we identify the performances of the first movements of Beethoven’s piano sonatas in ASAP which share the same structure as recordings in the BPSD. This subset consists of 13 individual recordings with a total length of 103 min.

4. QUANTIFYING SYNCHRONIZATION ACCURACY

In this section, we describe the heuristics used to assess the accuracy of our score–audio and audio–audio synchronization pipelines. We refer to [37] for a detailed discussion about the analysis of synchronization accuracy without ground-truth annotations.

4.1 Notation

We first introduce some notation for aligning time points between two different versions V_1 and V_2 of a piece. We assume that these versions have continuous time axes $[0, T_1]$ and $[0, T_2]$, which can either be in physical time (for audio recordings, in seconds) or in musical time (for score-related data, in measures). From the alignment algorithms described in Section 2.3, we obtain a monotonous mapping function $\mathcal{M}^{V_1 \rightarrow V_2} : [0, T_1] \rightarrow [0, T_2]$ to transfer time instants from the timeline of one version to the other. Note that even though the alignment result obtained from DTW maps discrete time axes, our assumption of having continuous time axes can be obtained by using suitable interpolation techniques, see [37].

4.2 BPSD: Measure Transfer

In the following, we consider three versions: $V_1 = S$ being a score, and $V_2 = A_1$ and $V_3 = A_2$ being different audio versions of the same piece. We choose A_2 to be the recordings by Wilhelm Kempff (WK64), for which we have access to manually annotated measure positions t_{A_2} . Using audio–audio synchronization, we obtain a mapping $\mathcal{M}^{A_2 \rightarrow A_1}$ to transfer these measure positions to the first

Figure 3: Schematic illustration of (a) measure transfer and (b) note onset transfer heuristics.

audio version A_1 . Similarly, we transfer measure positions t_S obtained from the score S to the first audio A_1 using a mapping $\mathcal{M}^{S \rightarrow A_1}$. In a last step, as illustrated in Figure 3a, we calculate the absolute error of the measure positions transferred from S and A_2 :

$$\epsilon = \left| \mathcal{M}^{S \rightarrow A_1}(t_S) - \mathcal{M}^{A_2 \rightarrow A_1}(t_{A_2}) \right|. \quad (1)$$

4.3 ASAP: Note Onset Transfer

In order to evaluate score–audio synchronization on the ASAP dataset, we can not resort to the heuristic described in Section 4.2, as there are no reliable manual measure annotations available. Therefore, we use an approach that transfers note onsets, illustrated in Figure 3b, to assess the synchronization accuracy.

First, we obtain audio features for two different audio recordings A_1, A_2 of the same piece, as well as features for the score S . For each version, we perform score–audio synchronization to obtain alignment functions $\mathcal{M}^{S \rightarrow A_1}$ and $\mathcal{M}^{S \rightarrow A_2}$ from musical to physical time. Using these mapping functions, we map note event onsets t_S in musical time from the score to the physical time of the audio recordings. In a second step, we transfer the aligned onset positions from the first to the second audio using audio–audio synchronization via the mapping function $\mathcal{M}^{A_1 \rightarrow A_2}$ and compute the absolute error

$$\epsilon = \left| \mathcal{M}^{S \rightarrow A_2}(t_S) - \mathcal{M}^{A_1 \rightarrow A_2}(\mathcal{M}^{S \rightarrow A_1}(t_S)) \right| \quad (2)$$

between these transferred time points and the ones obtained from score–audio synchronization.

In both heuristics, we assume that the synchronization accuracy is high if the time instances transferred via two different branches have small deviations. Note that this is only a *necessary* and not a *sufficient* condition for alignment quality; nevertheless, this metric gives a good indicator of the alignment performance (see also [37]).

5. EVALUATION

While our main focus is on the BPSD due to its realism and diversity, we first analyze synchronization accuracy on the ASAP dataset in order to compare features estimated from audio recordings to those derived from the Disklavier reference. In the next step, we evaluate the alignment performance on the BPSD across all audio versions. Finally, we

Feature	Mean	Median	Conf. 90	Conf. 95
T1_SYM_O	89	0	281	467
T1_SYM_OF	66	12	153	293
T1_RAW_OF	29	8	64	146
T2_SYM_O	31	0	102	192
T2_SYM_OF	22	2	49	111
T2_RAW_OF	21	7	43	99
DK_SYM_O	37	0	130	216
DK_SYM_OF	25	2	57	123
FB_RAW_OF	64	20	146	268

Table 3: ASAP: Absolute error in milliseconds for note onset transfer heuristic.

conduct a detailed analysis of the performance on individual versions, identify problematic recordings, and illustrate how to improve alignment robustness by adapting a transcription model to the target data.

5.1 ASAP: Estimated Features vs. Reference Notes

First, we evaluate synchronization accuracy on the ASAP dataset using our note onset transfer approach described in Section 4.3. For each pair of audio files, we calculate the mean, median, 90 and 95 percentiles of the absolute alignment error in ms, and report averaged results in Table 3.

Analyzing the median absolute error, which we consider an indicator for the achievable accuracy under average conditions, we find perfect alignments ($\epsilon = 0$ ms) for at least 50% of all note onsets when using only symbolic onset features (SYM_O) for the transcription models T1 and T2, as well as the Disklavier DK. To assess the methods’ robustness and the severeness of outliers, we next investigate the 95% quantiles of the absolute alignment error. Using only symbolic onset features and standard DTW (SYM_O) yields the highest errors for all T1 (467 ms), T2 (192 ms), and DK (216 ms) variants, indicating a lack of robustness despite excellent median accuracy.

In the next step, we jointly use the frame and onset information from the symbolic features (SYM_OF) and observe a slight rise in the median error to 12 ms for T1, and to 2 ms for T2 and DK, respectively. While this indicates that the best achievable precision slightly deteriorates, we monitor a significant reduction of the 90% and 95% confidence intervals by approximately 50% for all SYM_OF variants, indicating a vastly improved robustness towards outliers when combining frame and onset features in the computation of the alignment.

Lastly, we directly use the intermediate predictions for frames and onsets (RAW_OF) in our alignment pipeline. While the median absolute error is comparable to the one based on symbolic features, we again observe a significant decrease in the 90% and 95% confidence intervals. Using RAW_OF features in the T2 transcriber yields the lowest mean (21 ms) and confidence intervals (43 and 99 ms), even outperforming the usage of reference note informa-

Feature	Mean	Median	Conf. 90	Conf. 95

tion obtained from the Disklavier.² We illustrate this finding with the intuitive example of a chord where notes are not played simultaneously, either due to a playing mistake or as a stylistic element, leading to a deviation of symbolic and actually performed note order. While the DK features strictly assign each note onset to one particular time frame and thus cause alignment instabilities in the given example, the continuous RAW predictions can smoothly cover neighboring time frames and thus allow for a robust alignment.

5.2 BPSD: General Performance

Next, we analyze the overall matching of score–audio and audio–audio synchronization on the more realistic and more diverse BPSD by using the measure-transfer heuristic as described in Section 4.2. In Table 4, we again report the mean, median, 90 and 95% confidence intervals for the absolute error between measure positions obtained from score–audio and audio–audio transfer.

Analyzing the median absolute error in Table 4, all features yield a precision between approximately 12 ms and 20 ms, without a clear tendency towards one particular method. However, it is the robustness (measured by the 90% and 95% confidence intervals) where we find a clear trend: using only onsets from symbolic features (SYM_O) yields large alignment outliers, with the 95% confidence interval of the absolute error being 234 ms for T1 and even 466 ms for T2. Using additional frame features (SYM_OF) lowers the 95% confidence interval to 160 ms and 251 ms, respectively. In line with our observations on the ASAP dataset, using intermediate transcription results (RAW_OF) further reduces the mean as well as the confidence intervals for both transcription models. The T1 transcriber, which was trained on audio from the acoustically diverse MusicNet [16] dataset, exhibits significantly lower errors than T2 (121 ms vs. 207 ms for the 95% conf. interval), which was trained only on MAESTRO. While using filterbank features (FB) resulted in relatively high errors on ASAP, on the BPSD we observe metrics that are similar to those of the T1 transcriber, and considerably better than those of the T2 model. This indicates a lack of robustness of the DL-based transcription models on the diverse acoustic conditions of the BPSD, which we will investigate and mitigate in the following section.

² We note that the T2 model was trained on MAESTRO [25], which is the basis of ASAP [31]. Therefore, a separation for train and test data is not guaranteed for T2 in the experiments on ASAP. However, the DK features nevertheless are the upper limit of the achievable transcription accuracy.

5.3 BPSD: Detailed Analysis and Finetuning

To further investigate why the alignment pipelines using transcription features ($T1, T2$) do not yield significantly better results on the BPSD than those features using the filterbank baseline (FB), we further break down the investigation to the BPSD’s individual audio versions. Transcription models (and DL systems in general) are known to exhibit a degraded performance when there is a domain shift between the test data and the training data [32, 36]. Such effects can be caused by poor audio quality in general, or, for music data, by a difference in timbre or tuning.

Identifying problematic versions. We restrict our analysis to raw frame and onset features (RAW_OF) from the filterbank (FB) and the $T1$ transcriber, as these showed the overall most robust results on the complete BPSD (see Section 5.2) and illustrate the median and 95% confidence intervals for all audio versions of the BPSD in Table 5. Analyzing the 95% confidence values for $T1_RAW_OF$ in Table 5, we identify two problematic versions, namely the 1958 recordings by Friedrich Gulda (FG58) with 788 ms and the 1997 recordings by Malcolm Bilson et al. (MB97) with 146 ms. By inspection of the recorded pieces, we find two different reasons for the alignment instabilities.

Musical and acoustic reasons for instabilities. Friedrich Gulda recorded his first cycle of Beethoven’s Piano Sonatas (FG58) over a relatively long time span between 1950 and 1958, playing different pianos in different environments. Among the FG58 recordings, we identify Sonata No. 26 (“Les adieux”) and No. 29 (“Hammerklavier”) as especially problematic, showing large differences in tuning, along with high background noise.

The pianist Malcolm Bilson (MB97) is committed to historically informed performance practice. His interpretations on historical instruments introduce a novel approach to performance in an era predominantly defined by the use of modern instruments. Malcolm Bilson and colleagues recorded their 1997 cycle of Beethoven’s Piano Sonatas on nine fortepianos, including original historical instruments. Compared to modern pianos, the overall sound of fortepianos is significantly different, due to different mechanics, strings, and resonance bodies. Furthermore, the timbre varies across registers, e.g., bass notes sound fundamentally different compared to high-octave notes, and the reference pitch deviates from today’s standard of 440 Hz (A4). In summary, these deviations in timbre, tuning, and recording noise lead to a so-called “domain shift”, i.e., the FG58 and MB97 recordings are not close enough to the transcriber’s training data. As a result, the model’s predictions are highly unstable and do often not correspond to the actually played notes.

Fine-tuning the transcriber. Despite the aforementioned issues, our goal is to obtain highly accurate alignments on the BPSD. Therefore, we choose to adapt the $T1$ transcriber to the BPSD’s audio versions by fine-tuning the model on the target data itself. Note that this is a valid procedure for the purpose of this study, as we do not evaluate the transcription accuracy itself, and we only use unaligned pairs of audio and score data for finetuning (see [4] for a

detailed description of the training process using unaligned pairs of audio and score data). Therefore, we do not overfit the model towards a reference alignment. We denote the fine-tuned transcriber as $T3$.

Results with fine-tuned transcriber. After fine-tuning on the BPSD, the $T3$ model significantly improves the 95% confidence interval for the two problematic versions FG58 and MB97 from 788 ms to 80 ms and from 146 ms to 103 ms, respectively. For all other audio versions, the median absolute error and the 95% confidence interval of the fine-tuned transcriber $T3$ remain in a similar range as the original model $T1$. We note that the averaged 95% confidence interval of 62 ms for the fine-tuned transcriber $T3$ is in the range of the typical tolerance in beat-tracking applications (70 ms), making the proposed synchronization approach with raw features even useful for the creation of datasets with high demands regarding timing.

6. CONCLUSION AND OUTLOOK

In this paper, we analyzed audio synchronization using raw features from transcription models. By conducting quantitative analysis on two different datasets of piano music, we show that the amount of alignment outliers is vastly reduced when using raw instead of symbolic features. We put a particular emphasis on the analysis of synchronization robustness of real-world audio recordings including historic instruments and recordings of low quality, and outline which acoustic conditions lead to alignment mismatch. By fine-tuning a transcription model on the target dataset and using the predicted raw features, we achieve synchronization accuracy that enables usage of the datasets even in time-critical applications such as beat tracking. As the raw features are computed anyway when using transcription models, we propose to use these raw features by default in synchronization pipelines. While raw features from transcription models yield excellent synchronization robustness for piano music, a yet unanswered question that we plan to address in future work is the performance in other genres, e.g., vocal or orchestral music.

HARNESSING THE POWER OF DISTRIBUTIONS: PROBABILISTIC REPRESENTATION LEARNING ON HYPERSPHERE FOR MULTIMODAL MUSIC INFORMATION RETRIEVAL

ABSTRACT

Probabilistic representation learning provides intricate and diverse representations of music content by characterizing the latent features of each content item as a probability distribution within a certain space. However, typical Music Information Retrieval (MIR) methods based on representation learning utilize a feature vector of each content item, thereby missing some details of their distributional properties. In this study, we propose a probabilistic representation learning method for multimodal MIR based on contrastive learning and optimal transport. Our method trains encoders that map each content item to a hypersphere so that the probability distributions of a positive pair of content items become close to each other, while those of an irrelevant pair are far apart. To achieve such training, we design novel loss functions that utilize both probabilistic contrastive learning and spherical sliced-Wasserstein distances. We demonstrate our method’s effectiveness on benchmark datasets as well as its suitability for multimodal MIR through both a quantitative evaluation and a qualitative analysis.

1. INTRODUCTION

Multimodal representation learning of music content, such as music audio and a video [1] and music audio and text [2], has been an important topic of research, given its wide applications to Music Information Retrieval (MIR) tasks. Previous studies have typically used a deterministic approach to train encoders, where the trained encoders are utilized to map each content item to a latent space as a single vector. However, representing an arbitrary content item as a vector has various drawbacks. For example, one-to-many and many-to-many relationships need to be handled in multimodal content, such as those between an album cover image and a set of songs in that album, and between different songs that have the same title and their title text. It is difficult to represent such complex relationships in vectors. To address this challenge, *probabilistic representation learning*,

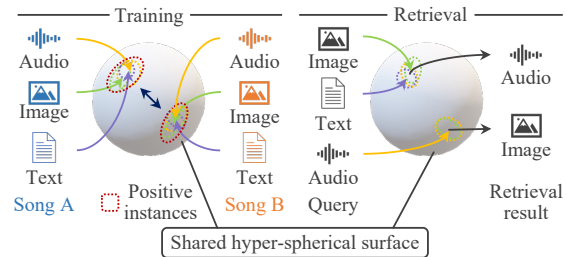

Figure 1. Probabilistic representation learning on hypersphere. **(Left)** Encoders are trained so that the probability distributions of the positive instances (music audio, an image, and text for the same song) are close to each other on the shared hyper-spherical surface, while those of irrelevant instances (different songs, artists, etc.) are far apart. **(Right)** The trained encoders are helpful for multimodal MIR. Given a single-modal query or a multimodal query such as a query that combines an image and text, our method can retrieve content items that match the query by calculating the distance between their probability distributions.

in which each content item is represented as a probability distribution in a latent space, has been studied [3–5].

Probabilistic representation learning (Figure 1) is a promising approach that can provide intricate and diverse representations by characterizing each content item as a probability distribution. This approach requires training encoders that estimate the optimal distribution for each content item. The key here is how to design an appropriate loss function for that training. In the literature, three approaches have been proposed, and in this paper, we propose a fourth approach. The first approach uses the probability product kernel [6], which calculates the expected value between distributions. This is used in probabilistic word embedding [7], face recognition [8], and image classification [9]. The second approach uses Hedged Instance Embeddings (HIB) [10]. It formulates a contrastive loss of the match probability, which calculates the distance between a pair of vectors randomly sampled from each distribution. This is used in cross-modal retrieval of text and images [3, 4], as well as in self-supervised video representation learning [11]. The third approach is to replace variables in an existing loss function (e.g., triplet loss) with probability distributions. For example, a loss function designed for deterministic methods can be calculated by using samples obtained from a Gaussian distribution [5, 12, 13] or a von Mises-Fisher distribution [14–16] via a reparameterization trick [17, 18].

Figure 2. Advantage of optimal transport. **(Left)** To match two positive instance pairs of distributions, A and B, existing approaches ([4, 5, 16], etc.) simply calculate distances between randomly sampled pairs and cannot precisely match distributional shapes, possibly resulting in an undesirable single point when distances of positive sample pairs are minimized for probabilistic representation learning. **(Right)** Optimal transport can select optimal sample pairs to appropriately match their distributional shapes, thereby harnessing the power of rich probability distributions.

These approaches have been applied to text-to-image (or vice versa) cross-modal retrieval [3, 4], and more recently, to multimodal image retrieval [5]. Chun et al. [4] proposed Probabilistic Cross-Modal Embedding (PCME), which is a pioneering work on probabilistic representation learning for cross-modal retrieval. Li et al. [3] proposed Average Semantic Precision (ASP), which can calculate the semantic correlation scores of a dataset, and differentiable ASP approximation, which utilizes ASP as a loss function. Neculai et al. [5] proposed Multimodal Probabilistic Composer (MPC), which can use a multimodal query combining image and text for image retrieval. However, these approaches calculate distances based on sample-wise similarity, with an arbitrary sample pair randomly selected from each distribution (left side of Figure 2). This manner often results in most sample pairs being non-optimal, and as a result, the details of the distributional properties are lost. This disadvantage leads to a decrease in performance.

In light of this background, we propose two novel loss functions, one based on contrastive learning and the other on optimal transport, to be used together for multimodal MIR on a hypersphere. Contrastive learning is an effective tool to jointly map each content item of multiple modalities to a shared latent space [19, 20]. In the context of probabilistic representation learning, utilizing the angular distance between distributions has proven more effective than using their Euclidean distance [15]. Furthermore, the von Mises-Fisher (vMF) distribution (i.e., the distribution on a hypersphere) exhibits a better performance than the Gaussian distribution since vMF-based methods simplify the variance estimation by using a single scalar κ , thereby avoiding the dimension-wise estimation in Gaussian-based methods [14]. Given these insights, we propose a contrastive loss function on a hypersphere for multiple modalities based on probabilistic contrastive learning [16]. In addition, optimal transport [21] offers a robust and effective tool for calculating distances between probability distributions. It allows encoders to bring the probability distributions of a positive pair closer together, thus ensuring a more accurate representation learning (right side of Figure 2). This

unique attribute of optimal transport can benefit multimodal MIR tasks. Hence, we propose a loss function based on a Spherical Sliced-Wasserstein (SSW) [22] p -distance, contemplating the compatibility between contrastive learning and optimal transport on a hypersphere.

By using the proposed loss functions, we can train encoders that map each content item to a hypersphere, as shown in Figure 1. During training, we assume that pairwise combinations of music audio of a song, a cover image for the song, and text generated from the song’s metadata are positive, and that those for irrelevant ones (different songs, music genres, or artists, etc.) are negative (left side of Figure 1). Once the encoders are trained, we can utilize them to obtain the probabilistic representation of each content item for multimodal MIR (right side of Figure 1). The main advantage of probabilistic representation lies in its ability to seamlessly integrate multiple content items in a latent space as a *multimodal query*, which is a great benefit in retrieval tasks. We conduct both a quantitative evaluation and a qualitative analysis on the public YT8M-MusicVideo dataset and a private dataset to demonstrate the effectiveness of our proposed method.

2. PRELIMINARY

2.1 Problem Specification

We use a mel spectrogram of music audio as the input of an audio encoder, an RGB image as the input of an image encoder, and a tokenized text as the input of a text encoder. We follow previous studies [19, 20] regarding the setup of the input representations.

Let $\mathbf{A} = \{\mathbf{a}_n \in \mathbb{R}^{D^a}\}_{n=1}^N$, $\mathbf{I} = \{\mathbf{i}_n \in \mathbb{R}^{D^i}\}_{n=1}^N$, and $\mathbf{T} = \{\mathbf{t}_n \in \mathbb{R}^{D^t}\}_{n=1}^N$ be a set of spectrograms, a set of images corresponding to \mathbf{A} , and a set of tokenized texts corresponding to \mathbf{A} , respectively, where D^a is the number of dimensions of each spectrogram, D^i is the number of dimensions of each image, D^t is the number of dimensions of each tokenized text, and N is the number of songs.

Next, let $\mathbf{Z}^A = \{\mathbf{z}_n^a \in \mathbb{R}^d\}_{n=1}^N$, $\mathbf{Z}^I = \{\mathbf{z}_n^i \in \mathbb{R}^d\}_{n=1}^N$, and $\mathbf{Z}^T = \{\mathbf{z}_n^t \in \mathbb{R}^d\}_{n=1}^N$ be sets of the latent variables of spectrograms, images, and tokenized texts, respectively, where d is the number of dimensions of each latent variable.

We train the audio encoder f_A that maps \mathbf{A} to \mathbf{Z}^A , the image encoder f_I that maps \mathbf{I} to \mathbf{Z}^I , and the text encoder f_T that maps \mathbf{T} to \mathbf{Z}^T so that probability distributions $p(\mathbf{z}_n^a | \mathbf{a}_n)$, $p(\mathbf{z}_n^i | \mathbf{i}_n)$, and $p(\mathbf{z}_n^t | \mathbf{t}_n)$ are close to each other on a shared hyper-spherical surface $S_{\text{shared}}^{d-1} = \{\|\mathbf{z}_n\| = 1\}$.

2.2 Probabilistic Contrastive Learning

Contrastive learning is an established deep learning technique widely utilized in recent research [23]. In particular, methods like N -pairs loss [24], InfoNCE loss [25], and MoCo [26], which calculate the loss based on N -pairs of instances (i.e., one positive pair and $N - 1$ negative (or irrelevant) pairs), serve as powerful tools for multimodal representation learning [1, 2, 19, 20]. However, these contrastive loss functions are designed for deterministic methods and cannot be directly applied to probabilistic approaches.

Recently, Kirchof et al. [16] introduced MCInfoNCE, an adaptation of InfoNCE for probabilistic contrastive learning that uses Monte-Carlo samples from each distribution. The MCInfoNCE loss \mathcal{L}_{MC} is defined as follows:

$$\mathcal{L}_{MC} = -\frac{1}{m} \sum_{j=1}^m \sum_{l=1}^L \log \frac{e^{\text{sim}(\mathbf{z}_j^l, \mathbf{z}_+^l)/\tau}}{e^{\text{sim}(\mathbf{z}_j^l, \mathbf{z}_+^l)/\tau} + \sum_{\mathbf{z}_-} e^{\text{sim}(\mathbf{z}_j^l, \mathbf{z}_-^l)/\tau}}, \quad (1)$$

where m is a mini-batch size, L is the number of samples, τ is a hyperparameter called temperature scaling, which controls the scale of the loss function, $\mathbf{z}_n \sim p(\mathbf{z}_n)$ is an anchor, $\mathbf{z}_+ \sim p(\mathbf{z}_+|\mathbf{z}_n)$ and $\mathbf{z}_- \sim p(\mathbf{z}_-|\mathbf{z}_n)$ respectively indicate positive and negative samples of the anchor, and $\text{sim}(\cdot, \cdot)$ is a function that calculates the similarity (such as cosine similarity) between two distributions. Since MCInfoNCE is originally designed as the single-modal loss, we are the first to modify it for our multimodal loss in Section 3.1.

2.3 Optimal Transport

Optimal transport has been gaining popularity for a variety of computer vision tasks [27–29], but calculating the optimal transport distance between distributions is known to be computationally intensive [30]. This problem can be solved when the distributions are on a particular manifold [22, 30].

We therefore delve into a recent powerful innovation, the Spherical Sliced-Wasserstein (SSW) [22] p -distance, which is specialized on a hypersphere and is highly efficient and useful, but has not yet been used for representation learning.

2.3.1 Definition of Spherical Sliced-Wasserstein (SSW)

The SSW p -distance for $p \geq 1$ is defined between two probability measures $\mu, \nu \in \mathcal{P}_{p,ac}(S^{d-1})$, the set of absolutely continuous probability measures on a hypersphere S^{d-1} with a finite p -th moment, as follows:

$$SSW_p(\mu, \nu) = \int_{\mathbb{V}_{d,2}} W_p(\mu \circ P^{U^{-1}}, \nu \circ P^{U^{-1}}) d\sigma, \quad (2)$$

where $\mathbb{V}_{d,2} = \{U \in \mathbb{R}^{d \times 2}, U^\top U = I_2\}$ is the Stiefel manifold [31], σ is the uniform distribution over $\mathbb{V}_{d,2}$, P^U is the function that projects a point $\mathbf{z} \in S^{d-1}$ onto a great circle S^1 generated by U (for *a.e.* $\mathbf{z} \in S^{d-1}$, P^U can be written in a practical form of $P^U(\mathbf{z}) = \frac{U^\top \mathbf{z}}{\|U^\top \mathbf{z}\|_2}$ [22]), and W_p is the optimal transport distance on S^1 [32, 33]. To avoid any effects stemming from the choice of U , Bonet et al. [22] calculated the SSW distance several times for a set of random U , and we also calculate it in the same way.

2.3.2 Optimal Transport Distance on Great Circle

We focus on the simplest $p = 1$ in Equation (2) to calculate $W_p|_{p=1}$ between two probability measures $\mu', \nu' \in \mathcal{P}(S^1)$ that are after being projected from a hypersphere S^{d-1} onto one of the generated great circles S^1 . The W_1 is defined as

$$W_1(\mu', \nu') = \int_0^1 |F_{\mu'}(t) - F_{\nu'}(t) - \text{LevMed}(F_{\mu'} - F_{\nu'})| dt, \quad (3)$$

where $F_{\mu'}, F_{\nu'}$ are the cumulative distribution function of μ', ν' , respectively, and $\text{LevMed}(\cdot)$ is the level median [34],

defined as follows:

$$\text{LevMed}(f) = \min \left\{ \arg \min_{\alpha \in \mathbb{R}} \int_0^1 |f(t) - \alpha| dt \right\}, \quad (4)$$

where α is a shift parameter. The SSW_1 , which is utilized in our proposed loss functions (Section 3), can thus be calculated by using Equations (2)–(4). Surprisingly, we can approximate the integral in Equation (3) simply by sorting the samples on S^1 in order to calculate $F_{\mu'}, F_{\nu'}$, and $\text{LevMed}(\cdot)$. To illustrate this intuitively, the optimal sample pairing on the right of Figure 2 is dramatically expedited by this sorting on the *one-dimensional* great circle without examining many pairings. We present the algorithm and pseudocode of SSW_1 in our supplementary materials¹.

3. PROPOSED METHOD FOR MULTIMODAL MIR

We design two novel loss functions for probabilistic representation learning: a *multimodal probabilistic contrastive loss function* for multiple modalities (Section 3.1) and an *SSW-based loss function* (Section 3.2) based on optimal transport. To train the encoders as shown in Figure 1, we assign them different roles. The former loss is designed for distancing irrelevant instance pairs of probability distributions on S_{shared}^{d-1} , resulting in closer positive instance pairs. The latter loss focuses on placing positive instance pairs close to each other by matching their distributional shapes, and does not deal with irrelevant pairs at all. Their integration is therefore important. The trained encoders can be applied to multimodal MIR (Section 3.3).

The standard approach for probabilistic representation learning assumes that the latent variables of each content item have a probability distribution of a given form, such as a Gaussian distribution [5, 12, 13] or a von Mises-Fisher (vMF) distribution [14–16]. We use the vMF distribution as the probability distribution on S_{shared}^{d-1} as follows:

$$p(\mathbf{z}_n^{\mathbf{a}}|\mathbf{a}_n) = \text{vMF}(\mathbf{z}_n^{\mathbf{a}}; \mu(\mathbf{a}_n), \kappa(\mathbf{a}_n)), \quad (5)$$

$$p(\mathbf{z}_n^{\mathbf{i}}|\mathbf{i}_n) = \text{vMF}(\mathbf{z}_n^{\mathbf{i}}; \mu(\mathbf{i}_n), \kappa(\mathbf{i}_n)), \quad (6)$$

$$p(\mathbf{z}_n^{\mathbf{t}}|\mathbf{t}_n) = \text{vMF}(\mathbf{z}_n^{\mathbf{t}}; \mu(\mathbf{t}_n), \kappa(\mathbf{t}_n)), \quad (7)$$

where the variables are as defined in Section 2.1. Using the proposed loss functions, we train three encoders so that they can estimate the appropriate parameters, the mean direction $\mu(\cdot)$ and the concentration $\kappa(\cdot)$, of each vMF distribution.

During training, we utilize L samples taken from each vMF distribution via a rejection-sampling reparameterization trick [18] in practice. Our proposed loss functions in Sections 3.1 and 3.2 use the following notations:

$$\zeta_n \sim \text{vMF}(\mathbf{z}_n^*; \mu(\star_n), \kappa(\star_n)), \quad (8)$$

$$\eta_n \sim \text{vMF}(\mathbf{z}_n^*; \mu(\star_n), \kappa(\star_n)), \quad (9)$$

where ζ_n and η_n ($\star, \star \in \{\mathbf{a}, \mathbf{i}, \mathbf{t}\}, \star \neq \star$) are L samples from the vMF distribution of respective content items.

3.1 Multimodal Probabilistic Contrastive Loss Function for Probabilistic Contrastive Learning

Contrastive learning is an effective approach to jointly train encoders for the representation learning of multiple modal-

¹ <https://github.com/T39Nakatsuka/ISMIR2024>

ities [1, 2, 19, 20]. By modifying Equation (1), we design our own multimodal loss function \mathcal{L}_C for all pairwise combinations of multiple modalities (we name this *multimodal probabilistic contrastive loss*) as follows:

$$\mathcal{L}_C = -\frac{1}{m} \sum_{\langle \zeta, \eta \rangle} \sum_{j=1}^m \log \frac{e^{\text{sim}(\zeta_j, \eta_+)/\tau}}{\sum_{k=1}^m e^{\text{sim}(\zeta_j, \eta_k)/\tau}}, \quad (10)$$

where m is a mini-batch size, τ is a temperature scaling, $+$ indicates a positive sample of an anchor, and $\text{sim}(\cdot, \cdot)$ is a function that calculates the similarity between two distributions by leveraging the L samples as follows:

$$\begin{aligned} \text{sim}(\zeta_j, \eta_k) &\simeq \text{sim} \left(\left\{ \mathbf{z}_j^{*,l} \right\}_{l=1}^L, \left\{ \mathbf{z}_k^{*,l} \right\}_{l=1}^L \right) \\ &= \frac{1}{L} \sum_{l=1}^L \frac{\mathbf{z}_j^{*,l\top} \mathbf{z}_k^{*,l}}{\|\mathbf{z}_j^{*,l}\| \|\mathbf{z}_k^{*,l}\|}. \end{aligned} \quad (11)$$

This loss \mathcal{L}_C can thus distance the centroids of the distributions of irrelevant instance pairs for the contrastive learning.

3.2 SSW-based Loss Function for Optimal Transport

We formulate our SSW-based loss function \mathcal{L}_S using the SSW_1 distance (Equations (2)–(4)) as follows:

$$\mathcal{L}_S = \frac{1}{m} \sum_{\langle \zeta, \eta \rangle} \sum_{j=1}^m SSW_1(\zeta_j, \eta_j). \quad (12)$$

Intuitively, both the L samples from ζ_j and the L samples from η_j on S_{shared}^{d-1} are projected onto S^1 , sorted (paired), and used to calculate the cumulative distribution functions, resulting in the optimal transport distance between those positive instance pairs. This loss \mathcal{L}_S can thus make the distributions of positive instance pairs closer.

To leverage the advantages of both \mathcal{L}_C and \mathcal{L}_S , our method uses a loss function that integrates them as follows:

$$\mathcal{L} = \mathcal{L}_C + \lambda_S \mathcal{L}_S, \quad (13)$$

where λ_S is a weight.

3.3 Probabilistic Multimodal MIR

Once the encoders have been trained, we can leverage them to map each content item as a probability distribution on S_{shared}^{d-1} and calculate the distances between their distributions. For a single-modal query, we calculate the cosine similarity between the mean (i.e., Fréchet mean [35, 36]) over samples obtained from the distribution of a query and that of each content item in a dataset. For a multimodal query, we calculate the Fréchet mean over all samples obtained from the distribution of each query and use it like a single-modal query. When the similarity score between a pair of content items is high, it indicates that they are matched. We thus sort the similarity scores in descending order and retrieve the content item in the dataset that scored higher with respect to the query.

4. EXPERIMENTS AND RESULTS

This section describes comparison experiments to quantitatively evaluate how closely the probability distributions of

positive instances were located on S_{shared}^{d-1} , and a qualitative analysis of the proposed method to further investigate the nature of the learned representation of each content item.

4.1 Experimental Setup

4.1.1 Dataset

For the experiments, we used the following two benchmark datasets with different characteristics. We determined the size of each test set by following the setup in [1, 37].

YT8M-MusicVideo dataset [1] is a subset of the YouTube-8M dataset [38], comprising videos tagged as “music video.” We collected 73,113 triplets consisting of music audio (average length of 4 min with a 48 kHz sampling rate), its thumbnail image (an RGB image with an aspect ratio of 16:9), and its metadata including title, channel name, and upload date from 60,785 YouTube channels. We randomly split the dataset into training (64,001 songs), validation (7,112 songs), and test (2,000 songs) sets with no YouTube channels overlapping across these sets. For evaluation, we conducted our experiments three times with different seed values when training the encoders.

AS5M dataset (Album Songs 5 Million dataset) is a private dataset that contains triplets of a music audio excerpt (a 30 s audio preview for trial listening, with a 44.1 kHz sampling rate), its cover image (a square RGB image), and its metadata including song title, artist name, collection name, music genre, and release date. The dataset contains 5,920,828 audio excerpts and their metadata by 174,629 artists, and 1,115,668 cover images. Because multiple excerpts from a music album are associated with a single cover image, each image corresponds to about 5.3 excerpts on average. The songs encompass a variety of music genres (over 250). We randomly split the dataset into training, validation, and test sets with an eight-one-one ratio and with no artists or images overlapping across these sets. For evaluation, we constructed ten folds of test subsets by randomly selecting 2,000 triplets of an audio excerpt, a cover image, and a text prompt for each fold from the test set.

4.1.2 Implementation Details

Encoder architecture: We used an audio model of contrastive language-audio pretraining (CLAP) [20] as the backbone network for the audio encoder, and used image and text models of contrastive language-image pretraining (CLIP) [19] as the backbone network for the image and text encoders. Before training, we set the parameters of the pre-trained models available at Transformers [39] (i.e., “laion/clap-hsat-fused” for CLAP (audio model) and “vit_base_patch16_224” for CLIP (vision and text models)) to the encoders. During training, we updated the projection layers of the encoders.

Audio: The music audio of each song was converted to a mel spectrogram through a CLAP feature extractor available at Transformers [39], and the audio encoder was trained using the spectrogram as input. In training the audio encoder, we applied a masking technique including frequency masking and time masking [40] and a random crop

technique regarding the time domain to the spectrogram for data augmentation [41].

Image: We used an RGB image resized to $224 \text{ px} \times 224 \text{ px}$ as the input of the image encoder. In training the image encoder, we applied a random resized crop (scale=[0.08, 1.0], ratio=[0.75, 1.33]), random horizontal flip (probability=0.5), and random erasing (probability=0.2) [42] to all images for data augmentation.

Text: We tokenized text generated by using a keyword-to-caption augmentation technique [20]² with a maximum length of 77, which is the same setup as CLIP [19]. In training the text encoder, words corresponding to metadata are randomly dropped [43] at a ratio of 0.05 for each metadata.

Training: We used 16 NVIDIA A100 GPUs under each experimental condition, and each GPU computed 64 triplets of audio, images, and text per iteration. Our implementation was based on PyTorch [44]. In training the encoders, we used the Adam optimizer [45] with a learning rate of 1.0×10^{-4} . We used $d = 512$ (dimensions of latent variables) following the setup in [5]. For the vMF distribution, we set $\kappa(\cdot) \in (64, 128)$ to obtain a clear distribution following the setup of [16]. We empirically set the number of samples L to 16. For \mathcal{L}_C , we set the temperature-scaling value (Equation (10)) to $\tau = 0.07$, which was originally used in MoCo [26]. For \mathcal{L}_S , we calculated the SSW_1 distance 100 times for a set of random U , following [22] (i.e., 16 samples from ζ_j and 16 samples from η_j were projected onto 100 different great circles to match distributional shapes from 100 different views). On the basis of preliminary studies, we set the weight λ_S to 1.0.

4.1.3 Ranking-Based Evaluation Metrics

We used three standard evaluation metrics for retrieval tasks: the mean reciprocal rank (MRR) [46], the recall@ k ($R@k$), and the median rank (MR) [1]. MRR is a statistic measure utilized to evaluate the quality of retrieval results. Given a set of queries, MRR calculates the average of reciprocal ranks of the first correct (i.e., original) content item. A higher MRR value indicates a more accurate and efficient retrieval method. $R@k$ evaluates how correctly content items are retrieved in the top results. For retrieval tasks, a higher $R@k$ means that the retrieval method is more practical. We set $k = 1$ for the $R@k$ and displayed $R@1$ as a percentage. MR represents the median value of the ranks of the retrieved correct content item. In our context, a lower MR is desirable because it indicates that the correct content item is ranked closer to the top of the retrieval results.

4.2 Conditions

We compared our method (**Proposed** based on \mathcal{L}) with two competitive methods that utilize probabilistic representation learning for text-image retrieval, **PCME** [4] and **MPC** [5].

² Since the text prompt generation using a template sentence with metadata is known to be effective for retrieval tasks [19], for the YT8M-MusicVideo dataset, we generated a text prompt using: “title” is a music video uploaded by “channel name” on “upload date.” For the AS5M dataset, we generated a text prompt using: “song title” is a(n) “music genre” song by “artist name”, released on “release date.” “song title” is collected to “collection name.”

Figure 3. Visualization of the learned representations of audio, images, and text in the test subsets of the AS5M dataset with respect to music genre tags using t-SNE [51].

For music audio and other modalities, probabilistic representation learning for multimodal MIR has not yet been investigated, so we solely used the multimodal probabilistic contrastive loss \mathcal{L}_C (Section 3.1) as a baseline method (**Baseline**) in order to investigate the effectiveness of \mathcal{L}_S .

4.3 Results

As shown in Tables 1–6, our method outperformed PCME [4] and MPC [5], which are competitive methods for text-image retrieval, in all the retrieval tasks on both datasets. Likewise, our method was superior to the baseline method based on the modified MCInfoNCE [16] in nearly all retrieval tasks. We thus confirmed that \mathcal{L}_S was effective in achieving better performances. The results also showed that a multimodal query outperformed a single-modal query for most tasks. Our method can seamlessly create multimodal queries from multiple probability distributions, bringing benefits to multimodal MIR.

The performance differences between the datasets can be partly explained by their sizes since our method uses transformer models as the encoders. Several studies have shown that the performance of transformer models follows a scaling law [47–50]. This scaling law has been confirmed in experiments with data from various modalities [47–49] and in transfer learning [50]. In practice, the YT8M-MusicVideo dataset is two orders of magnitude smaller than the AS5M dataset, resulting in a decrease in performance. The performance differences between the tasks, as well as between the datasets, can also be explained on the basis of the scaling law. In our experiments, we used the CLAP audio model, which was trained on the LAION-Audio-630K dataset [20]. This dataset is several orders of magnitude smaller than the one used for training the CLIP models, which can lead to the decreased performance in audio-related retrieval tasks.

We provide additional comparison experiments that demonstrate the effectiveness of our proposed method in our supplementary materials¹.

4.4 Qualitative Analysis

We investigated the nature of the learned representations of music audio, images, and text by visualizing them regarding music genres. We utilized music audio, images, and text for 12,180 songs for the top 10 most popular genres in test subsets of the AS5M dataset. We calculated the Fréchet mean over all samples obtained from the distribution of each content item and mapped each of them to a two-dimensional

space using t-SNE [51]. Figure 3 shows that their learned representations form clusters regarding music genres. That is, audio, images, and text in each of these genres are closely associated with each other.

5. CONCLUSION

We proposed a method for multimodal MIR that leverages the probabilistic representations of content items. Our contributions can be summarized as follows. First, we leveraged the von Mises-Fisher (vMF) distribution, which has been used for single-modal tasks [14–16] but has not been used for multimodal retrieval tasks. In addition, the recently-invented spherical sliced-Wasserstein (SSW) [22] p -distance for optimal transport is surprisingly computationally efficient and useful, but has not yet been used in the MIR community. Moreover, we designed the two novel loss functions, \mathcal{L}_C and \mathcal{L}_S , using both probabilistic contrastive

learning and optimal transport to facilitate probabilistic multimodal representation learning. To our knowledge, this is the first work to utilize these reusable insights for probabilistic representation learning. Second, we confirmed the effectiveness of integrating the contrastive loss function \mathcal{L}_C with the loss function \mathcal{L}_S based on the optimal transport distance through quantitative evaluations, and showed that the proposed method can retrieve more appropriate content items for single-modal and multimodal queries. Third, we conducted a qualitative analysis, showing that music audio, images, and text for the same music style are located close to each other on S_{shared}^{d-1} . These results demonstrated that the proposed method is effective for multimodal MIR.

The underlying principles of the proposed method can work for any retrieval tasks regardless of modalities, which will lead to a broader scope of application. As such, we believe that the proposed method will shed light on other challenging retrieval tasks and usher in practical solutions.

ABSTRACT

Most music widely consumed in Western Countries contains song lyrics, with U.S. samples reporting almost all of their song libraries contain lyrics. In parallel, social science theory suggests that personal values - the abstract goals that guide our decisions and behaviors - play an important role in communication: we share what is important to us to coordinate efforts, solve problems and meet challenges. Thus, the values communicated in song lyrics may be similar or different to those of the listener, and by extension affect the listener's reaction to the song. This suggests that working towards automated estimation of values in lyrics may assist in downstream MIR tasks, in particular, personalization. However, as highly subjective text, song lyrics present a challenge in terms of sampling songs to be annotated, annotation methods, and in choosing a method for aggregation. In this project, we take a perspectivist approach, guided by social science theory, to gathering annotations, estimating their quality, and aggregating them. We then compare aggregated ratings to estimates based on pre-trained sentence/word embedding models by employing a validated value dictionary. We discuss conceptually 'fuzzy' solutions to sampling and annotation challenges, promising initial results in annotation quality and in automated estimations, and future directions.

1. INTRODUCTION

Popular music in Western countries almost always contains lyrics, making song lyrics a widely, repeatedly consumed [1] form of text. Over 616 million people subscribe to streaming services worldwide¹, many of whom stream more than an hour of music every day². Lyrics have been shown to be a salient component of music [2], and out

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

Figure 1. Distribution of self-reported percentage of music library containing lyrics from two representative US samples, $n=505$ and $n=600$ respectively.

of over 1400 number-1 singles in the UK charts, only 30 were instrumental³. The two representative US population samples that were our annotators indicate a median 90% of songs in their libraries contain lyrics (Figure 1).

It is thus not surprising that informative relationships between popular songs and their lyrical content have been shown: e.g., country music lyrics rarely include political concepts [3], and songs with more typical [4] and more negative [5] lyrics appear to be more successful. [6] showed that patients are more likely to choose music with lyrics when participating in music-based pain reduction interventions, although melody had an overall larger effect [7] showed that lyrics enhance self reported emotional responses to music, and [8] showed a number of additional brain regions were active during the listening of sad music with lyrics, vs. sad music without lyrics. In fields closer to MIR, [9] show that estimating psychological concepts from lyrics showed a small benefit in a number of MIR tasks, and [10] showed a correlation between moral principles estimated from song lyrics and music preferences.

A connection between music lyrics and music preferences anticipated by theory involves the personal values perceived in the lyrics by listeners. Prior work has shown correlations between an individual's values, and the music they listen to [10–13], suggesting that we seek music in

³ https://en.wikipedia.org/wiki/List_of_instrumental_number_ones_on_the_UK_Singles_Chart

line with our principles. Yet we have not seen an attempt to measure perceived personal values expressed in the lyrics themselves via human annotation or automated methods.

In this work we take a first step towards the automated estimating the values perceived in song lyrics. As artistic and expressive language, lyrics are ambiguous text: they contain different forms of analogy and wordplay [14]. Thus we take a perspectivist approach to the annotations: because we expect that perceptions will vary substantially more than in other annotation tasks, we aim to represent the general perceptions of only one population. We account for the subjectivity by gathering a large number of ratings (median 27) per song from a targeted population sample (U.S.), of 360 carefully sampled song lyrics, using a psychometric questionnaire that we adjust for this purpose. We treat values in line with theory: as ranked lists, using Robust Ranking Aggregation (RRA) to arrive at our 'ground truth'. We then gather estimates from word embedding models, by measuring semantic similarity between the lyrics and a validated dictionary. We show that ranked lists from estimates correlate moderately with annotation aggregates. We then discuss the implications of our results, the limitations of this project, and anticipated future work.

2. PERSONAL VALUES

The modern study of human values spans over 500 samples in nearly 100 countries over the past 30 years, and has shown a relatively stable structure [15], as illustrated in Figure 2. Personal values are a component of personality, defined as the hierarchy of principles that guide a person's thoughts, behaviors, and the way they evaluate events [16, 17]. Basic human values can be used to describe people or groups: social science theory suggests that each person uses a hierarchical list of values as life-guiding principles [18], such that we prioritize some values over others as we make decisions. Schwartz's theory is the most widely used in social and cultural psychology, and has shown correlations with important behaviors, ranging from political affiliation to personal preferences [15].

We communicate our values in order to gain cooperation and coordinate our efforts, according to Schwartz [19]. Thus our values will manifest in the words that we use [20]. Although personal values are traditionally measured by having individual people complete validated psychological questionnaires, it has been argued that values may be clearly expressed in the speech and text that we produce [20].

A common approach to measuring psychological aspects in text is to validate dictionaries: curated sets of words, with subsets aimed at measuring each component of the psychological aspect in question [22–25]. Some work estimating the values of the authors of text has been conducted on individuals who have written personal essays and social media posts e.g. [25, 26], and in arguments abstracted from various forms of public facing text [27]. However, we have not seen work aimed at measuring values *perceived* in text, measuring them along a scale as in

Figure 2. Visualization of the Schwartz 10-value inventory from [19] used in this paper, such that more abstract values of Conservation, vs. Openness to Change, and Self-transcendence vs. Self-enhancement form 4 higher-order abstract values. Illustration adapted from [21].

prior work [19], or ultimately treating them as a hierarchical list in line with theory [18].

3. PRIMARY LYRICS DATA

We aim to collect a sample of lyric data where the lyrics are as accurate as possible, and our sample is as representative as possible. We sampled from the population of songs in the Million Playlist Dataset (MPD)⁴ as it is large and recent compared to other similar datasets. The lyrics themselves were obtained through the API of Musixmatch⁵, a lyrics and music language platform. Musixmatch lyrics are crowdsourced by users who add, correct, sync, and translate them. Musixmatch then engages in several steps to verify quality of content, including spam detection, formatting, spelling and translation checking, as well as manual verification by over 2000 community curators, and a local team of Musixmatch editors. Via their API, Musixmatch provided us with an estimated first 30% of the lyrics of each song.

Using the 'fuzzy' stratified sampling method described below, we sampled 2200 songs. Three members of the research team manually screened approximately 600 of the 2200 songs for inclusion. Each set of lyrics was confirmed to be a match to the actual song, and for suitability⁶. Lyrics were unsuitable if they were: 1) not English, 2) completely onomatopoeic, 3) repetitions of single words or phrases, 4) too few words to estimate values present or, 5) were not a match to the meta-data of the song, e.g. artist title, song name. This resulted in 380 songs, 20 of which were used in a pilot study to determine the number of ratings to gather per song, and 360 were used for annotation.

⁴ <https://research.atspotify.com/2020/09/the-million-playlist-dataset-remastered/>

⁵ <https://www.musixmatch.com/>

⁶ Each member independently screened each lyric and the screening process overall was discussed at length.

3.1 Fuzzy Stratified Sampling

An initial challenge is determining how to represent a corpus. In our case, the population of songs is known to be very large⁷. An ideal scenario would be one in which we aim for a known number of songs, randomly sampled from within clearly defined strata, i.e. relevant subgroups, also known as *stratified random sampling* [28]. However, for music, we do not know how many songs we would need to sample in order to reach saturation, what the relevant strata to randomly sample within should be, and how to measure relevant parameters from each stratum.

Some measurable strata that affect the use of language in song lyrics are clear: e.g., the year of release, which may reflect different events or time-specific colloquial slang. Others are less clear: e.g., there is no single metric of popularity for music, although it can be estimated from various sources such as hit charts. Some may be very subjective, such as genre, for which there may be some overlap of human labelling, but no clear taxonomy exists in the eyes of musicological domain experts [29].

Based upon these considerations, we aimed for a stratified random sampling procedure, based on strata that we acknowledge to be justifiable given our purpose, yet in some cases conceptually ‘fuzzy’: (1) release date; (2) popularity, operationalized as artist playlist frequency from the MPD [30]; (3) genre, estimated from topic modeling on Million Song Dataset artist tags [31]; (4) lyric topic, through a bag-of-words representation of the lyrics data. Popularity and Release date were divided into equally spaced bins; e.g. we divided release year into decades (60s, 70s, 80s, and so on), and genre and lyric topic were divided into categories.

Release date was quantized into 14 bins in 10-year increments from 1890-2030. Popularity was exponentially distributed, and thus manually binned, to make the quantiles per each of the 7 bins as similar as possible. Thus, the first bin contained the lowest 40% of the population in terms of popularity, while the 7th bin contained the highest 9%. Topic modelling was applied on a bag-of-words representation of the lyrics data and artist-tag data to yield 25 estimated genres and 9 lyrics topic strata, respectively.

We observed a skewness of data concentration with regard to several of our strata, e.g., songs that are recent and widely popular are most likely to be drawn. To correct for this and thus get a more representative sample of an overall song catalogue, we oversample from less populated bins. For this, we use the maximum-a-posteriori (MAP) estimate of the categorical distribution of each stratum. The oversampling is controlled by concentration parameter a of the symmetric Dirichlet distribution. We heuristically set this parameter such that songs in underpopulated bins still will make up 5-10% of our overall pool⁸. Through this method, we subsampled our initial 2200 songs lyrics.

⁷ e.g., Spotify reports over 100 million songs in its catalogue <https://newsroom.spotify.com/company-info/>

⁸ Full code of our sampling procedure is at https://anonymous.4open.science/r/Lyrics-value-estimators-CE33/1_stimulus_sampling/stratified_sampling.py

Figure 3. MDS plots derived from the correlation plot reported in [32], and our participant responses as confidence-weighted means

4. GROUND-TRUTHING PROCEDURE

We chose to obtain our annotations from samples of the US population, representative in terms of self-reported sex, ethnicity and age, through the Prolific⁹ platform. Annotator pools comprised of two samples, the first $n=505$ wave participated in a pilot study to estimate the number of ratings per song needed on average, and the second $n=600$ wave comprised our main data collection. Participants completed the survey on the Qualtrics¹⁰ platform.

We clearly differentiate between the Author and the Speaker of lyrics by explaining to participants that the Author of song lyrics may write from the perspective of someone or something else (the Speaker). 17 randomly selected sets of lyrics were then shown to each participant along with instructions to annotate each with the values of the Speaker. We adapted the 10-item questionnaire used in [33] for the value annotations, as it is the shortest questionnaire for assessing personal values whose validity and reliability have been assessed¹¹. As in [33], each questionnaire item is a specific value along with additional descriptive words e.g. POWER (social power, authority, wealth). We adjusted it by asking participants to indicate the values of the Speaker of the lyrics, and by having them indicate on a bar with -100 (opposed to their principles) on one end, and +100 (of supreme importance) on the other end instead of a likert scale. In addition, we asked participants to indicate how confident they were in their ratings, on a scale of 0 (not at all confident) to 100 (extremely confident), inspired by work that has shown that self-reported confidence in ratings can be used to estimate the accuracy of individual ratings [34].

We used a procedure similar to [35] in order to determine the number of raters. Specifically, we recruited a representative 500+ participant sample of the US using the Prolific platform, who completed our survey for 20 songs. We then computed canonical mean ratings of each of the 10

⁹ <https://prolific.co>

¹⁰ <https://qualtrics.com>

¹¹ It has shown correlations ranging from .45-.70 per value with longer more established procedures, test-retest reliability, as well as the typical values structure shown in Figure 2

values per song, and inter-rater reliability using Cronbach’s Alpha. We then estimated Cronbach’s alpha for a range of subsample sizes (5 to 50 participants in increments of 5), for each of the 10 values. We repeated this procedure 10 times per increment, separately for each of the 10 values, and examined the distribution of Cronbach’s Alpha. We specifically looked for the sample size with which Alpha exceeded .7¹². We arrived at a conservative estimate of 25 ratings per set of lyrics, with songs receiving a median 27 ratings (range 22-30).

4.1 Reliability, Agreement and Initial Validation

The rater reliability was estimated via intra-class correlation for each personal value, (type 2k: see [36]) using the ‘psych’ package in R [37], all of which exceeded .9 (excellent reliability). As an initial validation, we compare data simulated from values in the upper triangle of a correlation matrix reported in [32] to those derived from our study. To aggregate our participants rankings for this purpose, we compute confidence-weighted means inspired by [34]: we estimate confidence-weights by dividing participant’s self-reported confidence of a given rating by the highest possible response (100), and then compute aggregated means weighted by these. For both the simulated data and confidence-weighted mean scores, we generate a multi-dimensional scaling plot (MDS) [38] for visual comparison, which has previously been used as method to assess measurements conform to theory [25, 33]. Note: the interpretation is to observe whether each of the values appears next to expected neighboring values, and not each value’s orientation. From these plots (Figure 3), in as little as our 360 annotated lyrics, we surprisingly see similar clusters and relative positioning relations emerging as those obtained from a formal cross-cultural study.

We coerced the annotated scores to ranked lists of values, such that the highest scoring value was at the top. We derived ranked lists per participant per song, and then used Robust Ranking Aggregation (RRA) to extract a single ranked list per song. Aggregation was conducted using R version 4.2.2. [39], and the `RobustRankAggreg` package [40]. Briefly, RRA produces a ranked list by comparing the probability of the observed ranking of items to rankings from a uniform distribution. Essentially, scores are determined by comparing the height of an item on a set of lists to where it would appear if its rank were randomly distributed across lists. These scores are then subjected to statistical tests, where the resulting p value is Bonferroni corrected by the number of input lists [41]. Thus, when an item appears in different positions on a list, the resulting p value is high, as its position appears randomly distributed.

As lyrics are ambiguous, we expect that some songs’ values are completely subjective. We operationalize these as randomly distributed rankings for all personal values for completely subjective songs, i.e. p values above .05 for all 10 items on the ranked list. Results from the RRA show 62 songs with p values above .05 for all 10 values, and 96

Figure 4. Rank correlations between NLP systems / word counts and Robust Ranking Aggregation lists, by normalization scheme.

songs with only 1 value ranked. At most, 5 values were ranked, which occurred for 35 songs. Thus, we confirm that although there was correspondence in the scores that participants assigned per value per song, ranked lists did not always agree.

5. AUTOMATED SCORING

For automated scoring, we use a dictionary of words associated with the 10 Schwartz values [25]. With this dictionary as reference, we computationally estimate the degree to which each value is reflected in the lyrics text according to traditional word counting [25], as well as by assessing cosine similarity between dictionary words and lyrics texts using four classes of pre-trained word embeddings: `word2vec`, a generic English word embedding trained on Google News dataset [42]; `glove`, another generic English word embedding trained on Common Crawl dataset [43]; `mxm-far-[1~10]`, trained on the collected initial lyrics candidate pool, employing the Glove model [43] (using ten models populated from ten cross-validation folds, whose parameters are tuned based on English word similarity judgement data [44].); `mxm-cv-[1~10]`, ten variants of lyrics based word-embeddings from cross-validation folds selected by Glove loss values on the validation set; and finally, `sent-bert`, a transformer model that encodes sentence into a embedding vector, fine-tuning of a generic self-supervised language model called MPNet, which is trained on a large scale English corpus [45]. Our process thus resulted in 24 sets of scores: 5 from models and one from word-counting, normalized using four methods.

We take the perspective from theory that that value assessments should be seen as ranked lists, and thus coerce scores to ranked lists per model per song. We then compute rank correlations between ranked lists derived from model scores and RRA lists from participants. As RRA lists assess lack of consensus on rankings, personal values with high p values received tied rankings, at the bottom of the list. Correlations were computed using Kendall’s τ which is robust to ties (Figure 4).

¹² .7 is a commonly considered an acceptable level of reliability in the form of internal consistency

Figure 5. Rank correlations between word2vec scores Robust Ranking Aggregation lists, per genre grouping operationalized as Artist Tag Topic.

In earlier work [25, 46], Pearson correlations of 0.1-0.2 were considered as moderate evidence of the validity of a proposed dictionary in relation to a psychometrically validated instrument. Although we are using a different metric, we observe several models whose mean rank correlations exceed the .10 mark. The mean Kendall’s τ values were highest for the word2vec, sent-bert, and wordcount models with null normalization ($SD=.24$, $.30$, and $.34$ respectively). We further observe that 76% of the rank correlations for word2vec exceed the .10 mark, followed by 56.1% from sent-bert, and 47.8% from wordcounts. Although none of these models had been thoroughly optimized and thus this cannot be interpreted as a thorough benchmark, we do see evidence of higher than expected correlations.

We also explored whether our fuzzy strata might hint towards more or less automatically scorable lyrics. We found most strata to be uninformative. However, when examining the rank correlations for our overall best performing model, word2vec, we did observe higher mean correlations for some artist tag topics than others (Figure 5). In particular, topics 10 (which included the tags: ‘jazz’, ‘chillout’, ‘lounge’, ‘trip-hop’, ‘downtempo’), 11 (which included the tags like: ‘metal’, ‘celtic’, ‘thrash metal’, ‘dutch’, ‘seen live’), and 16 (which included tags like: ‘country’, ‘Soundtrack’, ‘americana’, ‘danish’, ‘Disney’). Although speculative, we do expect that certain genres are more difficult to interpret than others, in particular for people who are generally unfamiliar with such music.

6. DESCRIPTIVE ANALYSES

We conduct a further exploratory data analysis by examining the gathered value annotations with respect to the song strata introduced in Section 3.1. To better understand the overall patterns of value rankings in songs we visualize the average ranking of each value for each level of each stratum. To reflect the uncertainty of aggregated ranking from RRA, we employ ‘truncated’ rankings: the values within each aggregated ranked list are considered ties if their p-values higher than the threshold ($p = 0.05$), hence with

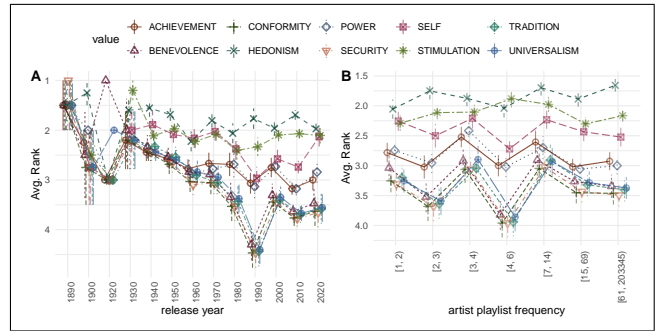

Figure 6. Average value ranking from ‘release year’ (A) and ‘artist-playlist frequency’ (B). x and y axis represent the strata and average ranking measure from RRA, respectively. Each point in different point shapes and vertical bars denote the average ranking value and its confidence interval (at 95% level). For visual convenience, we connected the same values with lines.

high uncertainty in their ranking positions.¹³

In all results, we observe that there is a tendency of overall value ranking: 1) a generally strong presence of HEDONISM in higher ranks in all cases, followed by STIMULATION and SELF (SELF-DIRECTION). 2) ACHIEVEMENT and POWER generally follow next across all figures, and 3) the rest of the values, including BENEVOLENCE, UNIVERSALISM, SECURITY, CONFORMITY, and TRADITION overall rank lower, but show higher variability across strata. We refer to these three groups of values as *Group1* (HEDONISM, STIMULATION and SELF), *Group2* (ACHIEVEMENT and POWER), and *Group3* (the rest) for the rest of the section.

Zooming in each to stratum, in Figure 6, we observe that the ‘release year’ (sub-figure A) strata show the most consistent and visible trend especially for Group3, which generally declines over time. Such a trend is not as obvious in Group1 and only partially observed in Group2. The low presence of Group3 is especially noticeable in the 1990s, although it regained its presence to some degree, a pattern which the SELF value from Group1 partially shares. Such visible movements suggest that the rank of specific values may evolve over time. In sub-figure B, we observe the most flat response across all strata considered: beyond the fluctuation pattern that is shared by all groups, there is no substantial variability among groups, which implies that popularity might not be as correlated as the ‘release year’.

Moving onto Figure 7, we discuss the value presence pattern in two ‘topic’ strata. First, in sub-figure C, we observe that Group3 values show overall higher variability than ‘artist playlist frequency’. It is notable that there are a few distinct topics in which Group3 values show a significant difference; the sixth, seventh and fourteenth topics, which correspond to the ‘under 2000 listeners/musical’, ‘folk/singer-songwriter’, and ‘Hip-Hop/rap’ topics when represented in primary topic terms. Specifically, we see

¹³ We assume that the adjusted exact p-value from RRA monotonically decreases as the rank position ascends (i.e., the lower the p-value is, the higher the ranking position is).

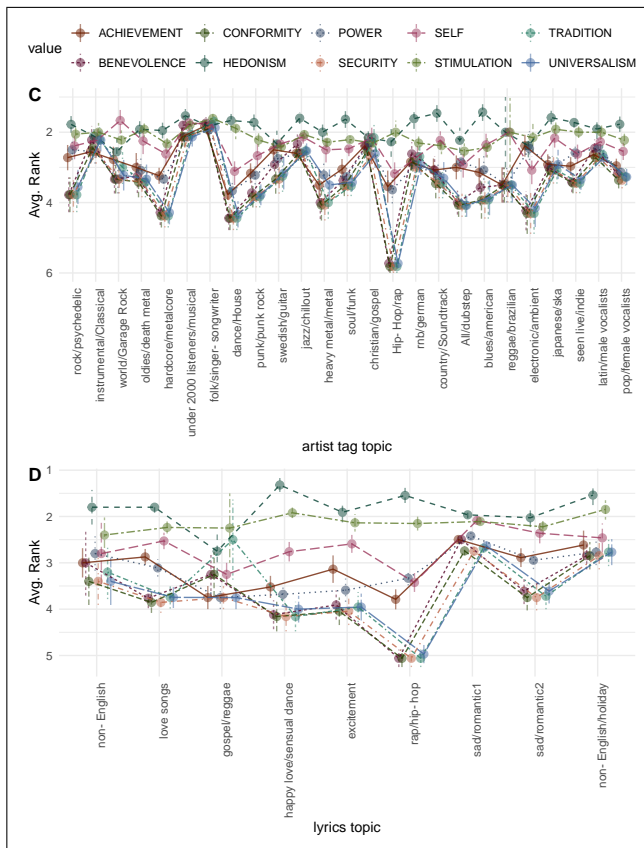

Figure 7. Average value ranking from ‘artist-tag topic’ (C) and ‘lyrics topic’ (D).

that first two topics show a high presence of Group3 values, while the latter topics show the least presence of Group3 values. It suggests that the artists in these styles/genres were perceived on average to present clearly different sets of values through their lyrics, distinguished by the inclusion/exclusion of values such as BENEVOLENCE or UNIVERSALISM.

Finally, considering sub-figure D, we observe a similar pattern as ‘artist playlist frequency’ in 6, albeit with relatively more variability in Group3 values. Notably, the ‘rap/hip-hop’ lyrics topic shows the least presence of Group3 values, which aligns to the observation from previous sub-figure. The ‘sad/romantic1’ topic, on the other hand, shows the highest ranking of Group3 values. Another remarkable topic is ‘gospel/reggae’ topic, where HEDONISM value is least present, which semantically aligns well with the typical lyrical theme of those songs.

7. LIMITATIONS AND FUTURE WORK

In this work we attempt to ground-truth perceptions of ambiguous song lyrics for perceived human values. We adopt a validated questionnaire from the social sciences for this purpose, in addition to a purposeful, if conceptually ‘fuzzy’, stratified sampling strategy, and estimate the average number of ratings needed to estimate the average perception of values in a song. We acknowledge our current sample of 360 lyrics is small and may need expansion

for more typical work, and that, while we had a representative population sample, not every member of the sample rated every song. We thus did gather diverse opinions, but cannot claim they fully represent the target population. In addition, the small sample of songs allowed for only limited observation of patterns that might emerge in larger samples with relation to our defined strata, and indefinite conclusions given the overall massive population of songs in existence. We also did not assess whether variations on the annotation instrument might result in substantial differences in the annotations we received [47], nor did we repeat our procedure [48]. In addition, we acknowledge that participants from different groups will perceive and thus annotate corpora differently [49, 50]. Thus, we expect that lyrics may be especially sensitive to varying perceptions, which we did not explore in this work. Finally, we only provide a preliminary comparison to automated scoring methods, and did not leverage the most contemporary tools for this purpose (e.g. Large Language Models). All of these are rich and promising avenues for future work.

The most interesting avenues are potential relationships that could be revealed with more annotated songs, and eventual automated scoring methods. In particular, we see potential in understanding music consumption more broadly from patterns revealed in the dominant value hierarchies in specific music genres, popularity segments, lyrical topics, and even release year. And for understanding music consumption more narrowly, from patterns revealed in an individual’s music preferences, and the degree to which they conform with their own value hierarchy.

8. CONCLUSION

Song lyrics remain a widely and repeatedly consumed, yet ambiguous form of text, and thus a promising and challenging avenue for research into better understanding the people that consume them. We observe promising initial results for the annotation of personal values in songs, despite our limitations. MDS plots of aggregated ratings showed the beginnings of the expected structure of values, conforming more closely than might be expected from as little as 360 songs. We also observed high inter-rater reliability in the raw scores, suggesting a sufficiently reliable annotation procedure with 25 ratings. Thus, we see promise on our method for ground-truthing lyrics despite their ambiguity. A post-hoc procedure revealed that 15 ratings may be enough on average: we repeatedly subsampled 5, 10, 15 and 20 ratings for each value within each song, and calculated pearson correlations between subsample means and canonical means. From this, we see Pearson correlations to the canonical mean exceed 0.9 for all values from 15 subsampled ratings. Further lyric annotation may thus require fewer annotations per song than what was gathered in this work. In addition, we observe promising rank correlations between ranked rater scores and our automated methods, with over 75% of the rankings in our best performing model above a minimal threshold of .10. Despite inherent challenges in the task, our method shows initial promise, and multiple fruitful avenues for future work.

9. ETHICS STATEMENT

Our study includes data gathered from people, and was approved by the Human Research Ethics board of our university. We follow Prolific’s guidelines on fair compensation to set our compensation rates. Survey design and data handling were pre-discussed with our institutional data management and research ethics advisors, we obtained formal data management plan and human research ethics approval. Participants gave informed consent before proceeding with the survey, which informed them of the intentions of use for their data, and that it could be withdrawn at any time.

ABSTRACT

While most music generation models use textual or parametric conditioning (e.g. tempo, harmony, musical genre), we propose to condition a language model based music generation system with audio input. Our exploration involves two distinct strategies. The first strategy, termed textual inversion, leverages a pre-trained text-to-music model to map audio input to corresponding "pseudowords" in the textual embedding space. For the second model we train a music language model from scratch jointly with a text conditioner and a quantized audio feature extractor. At inference time, we can mix textual and audio conditioning and balance them thanks to a novel double classifier free guidance method. We conduct automatic and human studies that validates our approach. We will release the code and we provide music samples on musicgenstyle.github.io in order to show the quality of our model.

1. INTRODUCTION

In the field of music generation, prior research has predominantly focused on producing brief musical segments [1,2], MIDI generation [3], while generating long and coherent waveforms (around 30 seconds) has only recently been tackled [4–6]. Specifically, most of these recent models have been designed to perform text-to-music generation, providing a fascinating tool for creators. Other types of high-level conditioning have been used in previous work such as tempo, harmony [7]. For lower-level and aligned conditioning, the authors of [5] use melody, while [8] uses chords, piano rolls, or the drum stem. However, music is hard to describe textually and the scarcity of text-music pair datasets makes it challenging to generate music in the style of a specific artist or song, since the artist is probably not represented in the training dataset. Then a common use case would be to generate music in the style of a reference segment. This gives more control to the user since they do not have to find a textual prompt that describes the music they want to generate.

In the computer vision domain, the authors of [9] introduced textual inversion to extract visual concepts that can then be used to generate new images with a text-to-image model. Given a few images (3-5) of a concept or object, one sets them as outputs of a frozen text-to-image model with a randomly initialized learnable text embedding. Backpropagating the generative model loss on the text allows to learn new "pseudowords" in the textual embedding space of the model that match the common concept depicted on the images. One can then compose this learnt pseudoword S^* in a textual prompt to generate an image of the learnt concept (for instance "a painting of S^* in the style of Picasso").

We first adapted this method by using the text-to-music model MusicGen [5], using crops of a song to depict a concept, and optimizing the cross-entropy loss of the music language model. This approach does not need to retrain a model from scratch. However, its inference is very slow since it requires hundreds of optimization steps of the textual prompt, including gradient computation through the language model, before generating music.

To tackle this issue, we present another method where we design a style conditioner module that we jointly train with a text-to-music MusicGen model [5]. This style conditioner takes a few seconds of audio and extracts features out of it. As a result this new model can generate music using two modalities as input: waveforms and textual descriptions. Our conditioning is high level even if it can retain some lower level content such as melodic patterns or rhythm. Designing this style conditioner is challenging as we need to extract enough features to have a meaningful conditioning but not too much, to prevent the generative model to copy and loop the conditioning audio. We thus need to introduce and tune information bottlenecks in our conditioning module. Our contributions are the following:

1) We adapt the textual inversion method of [9] to a pretrained text-to-music MusicGen model. This allows to perform audio conditioning for music generation without training a model from scratch.

2) We present our style conditioner method which is based on a frozen audio feature extractor (Encodec [10], MERT [11] or MusicFM [12]) followed by a transformer encoder [13], Residual Vector Quantizer (RVQ) [14] and temporal downsampling. The number of residual streams used by RVQ is adjustable at inference time which gives the user the ability to change the strength of the style conditioning. To our knowledge, we are the first to explore

this approach for music generation.

3) Since the model is trained with both textual and audio conditioning inputs, we can combine both to generate music. However, audio contains much more information, so that text is ignored by the model at inference. We propose to balance them with a new double classifier free guidance [15] which is a general method for merging conditions with various degrees of information.

4) We introduce novel objective metrics for style conditioning, based on nearest neighbors search in the latent space, validated with human evaluations.

We compare our method to baselines which are: a MusicGen trained with CLAP embeddings [16] as conditioning, a text-to-music MusicGen used with text prompts, and a MusicGen model without conditioning used in continuation mode. We perform as well some ablation studies in order to justify the architecture of our style encoder. Based on results, we show the practicality of our methods and the musical quality of the generated music.

2. RELATED WORK

2.1 Generative models for music

Music generation models can be categorized into two types: autoregressive models and non autoregressive ones. **Autoregressive** ones are motivated by the successful work done in natural language modeling. Recent successful models use a compression model taking the form of a multi stream quantized autoencoder [10, 14] in order to convert audio into K parallel discrete streams of tokens. The K streams are obtained by performing Residual Vector Quantization (RVQ) [14] on the latent space of an autoencoder, making the first stream contain coarse information and following ones refine the approximation of the latent space. Then, an autoregressive transformer [13] is used to model these audio tokens. MusicLM [4] and MusicGen [5] are built on this principle. MusicLM uses a multi-stage approach with different models to predict the K streams, while MusicGen models them in parallel using a delay pattern [5, 17].

Non-autoregressive models such as AudioLDM2 [18], MusicLDM [19], and Stable Audio [6], are latent diffusion models operating in the latent space of a continuous variational autoencoder. Some other models use cascaded diffusion such as Noise2Music [20] to progressively increase the sampling rate of the audio. Moïsaï [21] uses a first diffusion model to compress the music and a second one to generate music from this representation and textual descriptions. MusTango [7] uses a latent diffusion model conditioned on textual description, chord, beat, tempo and key. Jen-1 [22] combines a diffusion model and a masked autoencoder trained with multi-tasks objectives. It can perform music generation, continuation and inpainting. A second version [23] uses source separation [24] over their dataset to allow the user to generate and edit music stem by stem. VampNet [25] is a masked modeling approach to music synthesis that uses masking at training and inference time in order to generate discrete audio tokens.

MAGNeT [26] is based on the same masking principle. It can also combine autoregressive and masking to reach the same quality as the autoregressive baseline (MusicGen) but with a 7x faster inference. In MeLoDy [27], a language model is used to model coarse semantic tokens and a dual path diffusion model is then used for acoustic modeling. The authors claim faster than real time generation.

2.2 Jointly trained conditioners for music generative models

Regarding the conditioning, most of the models focused on text-to-music [4, 5, 19–22]. Since pairs of text-music data are rare, most models use a pre-trained contrastive text-music model such as CLAP [16] or MuLan [28], to condition their text-to-music models. Then, massive amount of non-annotated audio data can be used at training time and text is used at inference time. However, these text-to-music models never exploit the fact that audio can be used as conditioning. For other types of conditioning, MusTango [7] is trained with text, beat tempo, key and chords as conditioning, StableAudio [6] takes timing embeddings to control the length and structure of the generated music. Some models generate stems while being conditioned on other stems. For instance, SingSong [29] generates musical accompaniments from singing and Jen-1 Composer [23] handles multi-track music generation on 4 different stems (bass, drums, instrument and melody). MusicGen [5] and Music ControlNet [30] can handle melody as conditioning and the latter can also use dynamics and rhythm. Both papers use chromagrams extraction for melody conditioning.

2.3 Conditioning a pretrained generative model

With finetuning: In Coco-Mulla [8], the authors use parameter-efficient fine-tuning (PEFT) to specialize a text-to-music MusicGen model on chords and rhythm. They finetune on a number of parameter that is 4% the amount of parameters of the original network with only 300 songs. Music ControlNet [30] is a finetuned text-to-music diffusion model that operates in the spectral domain. The finetuning strategy comes from the text-to-image method ControlNet [31] and allows to handle melody, dynamics and rhythm conditioning. The pixel-level control that allows ControlNet on images gives a pixel-level control on the mel-spectrogram.

Without finetuning: In [32], the authors use AudioLDM [18] as a backbone to perform textual inversion [9]. For each textual inversion they use a group of 5 excerpts of 10 seconds. They also try an experiment where they optimize the pseudoword S^* as well as the diffusion neural network which gives them better results. In [33], the authors use a diffusion model trained on musical data with no conditioning and perform various interactive tasks at inference which are infilling, continuation, transition (smooth a transition between two songs) and guidance. The one that is the most similar to our audio conditioning is the guidance where the diffusion model is guided by the PaSST classifier [34] embedding of an audio prompt. However the model only generates 5 seconds excerpts of music. Some

Figure 1. An overview of the Textual Inversion method based on the pretrained text-to-music MusicGen

other papers involve new control with no finetuning such as in [35] or DITTO [36] where the authors use a pre-trained text-to-music diffusion model and control its inference by optimizing the initial noise latent. In SMITIN [37], the authors control a pretrained MusicGen model by steering the attention heads in the direction that maximizes the probability of some features.

3. TEXTUAL INVERSION METHOD

We first present our textual inversion method in the case of autoregressive modeling (see Fig. 1). It is based on previous work in the image domain [9] with diffusion models.

Autoregressive modeling aims to estimate the conditional distribution of the next token y_t given the preceding tokens $y_{<t}$ and a conditioning context c , such as a textual embedding. In the framework of transformer decoder neural networks parameterized by θ , denoted as p_θ , this conditional distribution is typically modeled as a product of individual probabilities:

$$p_\theta(y_{1:T}|c) = \prod_{t=1}^T p_\theta(y_t|y_{<t}, c) \quad (1)$$

Here, $y_{1:T}$ represents the sequence of tokens, and $p_\theta(y_t|y_{<t}, c)$ denotes the probability of observing token y_t given the preceding tokens and the conditioning context. During training, with a given sequence $y_{1:T}$ and its associated textual description c , we compute the cross-entropy loss:

$$\mathcal{L}_{CE}(\theta, y_{1:T}, c) = - \sum_{t=1}^T \log p_\theta(y_t|y_{<t}, c) \quad (2)$$

It is minimized by taking a gradient descent step on $\nabla_\theta \mathcal{L}_{CE}(\theta, y_{1:T}, c)$. This loss quantifies the dissimilarity between the predicted conditional distribution and the true distribution of the next token, serving as the optimization objective for training autoregressive models.

For the textual inversion method, we take a pretrained text-to-music MusicGen for the transformer decoder. We initialize the textual embedding (for instance with the textual embedding of the word "music") c . Given a song Y , we cut it into random chunks $\{y_{1:T}^i\}_i$ and optimize the textual embedding c by taking successive gradient steps on $\nabla_c \mathcal{L}_{CE}(\theta, y_{1:T}^i, c)$. After a few hundreds iterations the learnt c is fed into the text-to-music MusicGen model to generate a song in the style of Y .

4. STYLE CONDITIONING METHOD

4.1 General Architecture

The general architecture, depicted on the left of Fig. 2, is based on the text-to-music model MusicGen [5] with the addition of a style conditioner that is jointly trained with the language model. At train time, a 30 seconds music excerpt paired with a textual description is input to the model. The textual description is fed into a frozen T5 tokenizer and transformer encoder [38]. The style encoder takes a random subsample (between 1.5 and 4.5 seconds) of the input audio and encodes it. The text and style latent representations are both projected with linear layers to have the same dimension as the transformer language model, and provided as prefix to the sequence to model.

The input audio is encoded by a pretrained EnCodec [10] model and the language model is trained in an autoregressive manner with a cross-entropy loss. In addition, the tokens that correspond to the random subsample fed into the style encoder are masked in the loss, as we noticed this reduces the tendency of the model to just copy the style audio input. At inference time, we can use text or/and a short excerpt of music as a conditioning to generate music.

4.2 Architecture of the Style Conditioner

Our style conditioner is designed with bottlenecks (RVQ [14] and downsampling) to prevent transmitting all the information of the conditioning audio excerpt to the model. Without these bottlenecks, the generative models retrieves easily the excerpt and copies it (see the ablation study in Sec. 5.5). The style conditioner depicted on the right of Fig. 2 takes an audio input of length 1.5 to 4.5 seconds, passes it through a frozen feature extractor followed by a trainable transformer encoder and a residual vector quantization (RVQ) module with 6 codebooks. After quantization, we downsample on the temporal axis to obtain a conditioning with a 5Hz frame rate which gives a similar length as a text description (8 to 25 tokens). Finally a linear layer outputs the same dimension as the language model.

The candidates for the audio encoder are an Encodec followed by trainable embeddings for each codebook that are summed, a transformer based music foundation model from [12] (we now name it MusicFM for the rest of the paper) where the authors claim state of the art on several downstream tasks specific to music information retrieval and a MERT model [11], a transformer based music model trained in a self-supervised manner. The first one has a frame rate of 50Hz and 60M parameters, the second one has a frame rate of 25Hz and 620M parameters and the third one has a frame rate of 75Hz and 95M parameters

At training time, we use dropout on the conditioning, keeping both conditions 25% of time, one of the two conditions 25% of time for each (no text or no style) or no condition 25% of time. There is also a dropout on the number of the codebooks used by the RVQ of the style conditioner: at each step of the training, the number of used codebooks is uniformly sampled between 1 and 6. Then, at inference time, we can control the bottleneck of the style conditioner.

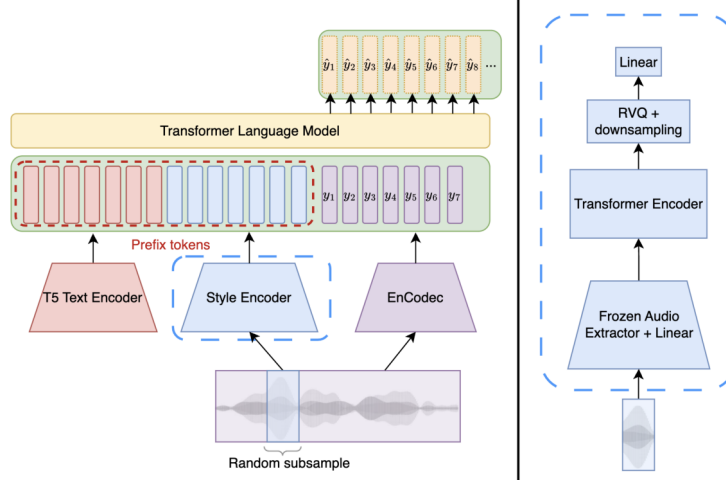

Figure 2. An overview of the general architecture. Text conditioning and style conditioning are provided to the model as a prefix. On the right we present the style conditioner.

Setting the number of codebooks to 1 gives more flexibility to the generative model whereas using 6 levels of quantization constrains it more. In practice, this means that music generated with 6 streams of quantization will sound more similar to the input condition compared to music generated with 1 stream of quantization.

4.3 Double Classifier Free Guidance

When doing next token prediction, let’s denote $l_{\text{style, text}}$ the logits of the model conditioned on style and textual description. Classifier free guidance [15] consists of pushing the logits in the direction predicted with the conditioning, to increase its importance:

$$l_{\text{CFG}} = l_{\emptyset} + \alpha(l_{\text{style, text}} - l_{\emptyset}), \text{ with } \alpha > 1, \quad (3)$$

typically, $\alpha = 3$ is used in previous work [5].

When generating music with a textual description that contradicts the audio of the style conditioning, we observe that the description is ignored by the model. This is explained by the fact that audio is more informative conditioning compared with the text, so that the model weights it more during training. To counteract this effect, we introduce a *double classifier free guidance* in which we iterate the CFG formula: we first push from style only to style and text and we then push these logits a second time from no conditioning.

$$l_{\text{double CFG}} = l_{\emptyset} + \alpha[l_{\text{style}} + \beta(l_{\text{text, style}} - l_{\text{style}}) - l_{\emptyset}] \quad (4)$$

We retrieve the simple CFG with $\beta = 1$. For $\beta > 1$, we boost the importance of the text conditioning (see Sec. 5.6).

4.4 Objective Metrics

The difficulty with generating samples in the same style of a song is that we want to generate something that is similar enough but not too close. This is something that can be subjectively evaluated. For easing the comparison of various approaches and hyper parameters, we also introduce a novel set of objective metrics.

Nearest Neighbours in Common: Let’s note $x_C \in \mathbb{R}^{D \times T}$ ($D = 1$ for mono music) the audio that we input in the style conditioner and $x_G \in \mathbb{R}^{D \times T'}$ the generated sequence. We use an encoder $E : \mathbb{R}^{D \times T} \rightarrow \mathbb{R}^N$ which outputs a single vector whatever the input length T is. In practice, this is done by taking a MusicFM model and averaging on the time dimension. Then, for each song of our valid and test sets, we cut it into chunks of 30 seconds and store the embeddings $\{E_{i,j}\}$, i being the index of the song and j the chunk number. For $E_C = E(x_C)$, we compute the cosine similarities $\cos(E_C, E_{i,j}), \forall i, j$ and the set of its K nearest neighbors: $\{i_1^C, \dots, i_K^C\}$. We do the same for $E_G = E(x_G)$ and obtain a set of K values $\{i_1^G, \dots, i_K^G\}$. We then have found the nearest songs in the dataset. We define our metric $\text{KNN}_{\text{common}}(x_C, x_G)$ for a song x_G that has been generated after being conditioned by x_C :

$$\text{KNN}_{\text{common}}(x_C, x_G) = \frac{|\{i_1^C, \dots, i_K^C\} \cap \{i_1^G, \dots, i_K^G\}|}{K} \in [0, 1]. \quad (5)$$

The intuition behind this metric is that a model performs well at recreating a song in the style of another if the generated song and its conditioning audio have embeddings that are close enough to share neighbors in the dataset. However, if a model copies the conditioning (i.e. $x_G \approx x_C$) the metric will tend to 1, we thus need a second metric to avoid x_G and x_C being too similar.

G is the Nearest Neighbor of C: We want E_G and E_C to be close while being different. One way to be sure that the corresponding audios are not too similar is to check that if we add E_G to the set of embeddings $\{E_{i,j}\}$, E_G is not the nearest neighbor of E_C . Assuring that another song from the dataset is closer to the conditioning means that the model is creative enough and not just copying its input. Formally, denoting $\{E_{\cup}\} = \{E_{i,j}\} \cup \{E_G\}$, we define

$$\text{KNN}_{\text{overfit}}(x_C, x_G) = \begin{cases} 1 & \text{if } \operatorname{argmax}_{E \in \{E_{\cup}\}} [\cos(E_C, E)] = E_G \\ 0 & \text{otherwise.} \end{cases} \quad (6)$$

Model	FAD _{vgg} ↓	KL ↓	CLAP ↑	KNN _{common} ↑	KNN _{overfit} ↓	OVL ↑	SIM ↑	VAR ↓
Textual Inversion	6.07	0.55	0.20	0.20	0.14	78.11 ± 0.93	61.78 ± 1.06	69.53 ± 1.44
MusicGen Continuation	1.22	0.51	0.30	0.26	0.17	83.95 ± 0.83	73.38 ± 0.97	77.24 ± 1.29
MusicGen w. audio CLAP	0.96	0.43	0.31	0.09	0.02	84.76 ± 0.93	62.37 ± 1.04	68.58 ± 1.42
Our Model w. EnCodec, 2 RVQ	0.85	0.49	0.29	0.23	0.12	83.41 ± 1.04	72.16 ± 0.93	72.39 ± 1.33

Table 1. Comparison with baselines. The KNN* metrics, introduced in Sec. 4.4, measure how close the generation is from the style condition, yet different from the matching ground truth. Those are completed with the subjective evaluations from Sec. 4.5. While using MusicGen for continuation matches well to the style audio, it has limited variation. Using a CLAP audio encoder as conditioning does the opposite, while using our style encoder gets the right balance between the two.

For our evaluations, we take 1000 samples of 3 seconds x_C from our test set, generate the corresponding x_G and average the two KNN metrics. Intuitively, the two metrics are positively correlated, but for a similar value for KNN_{common} we will favor the model that minimizes KNN_{overfit}.

Other Objective Metrics To evaluate the quality of the generated music, we also use the official implementation of the Fréchet Audio Distance defined in [39] that uses a VG-Gish model, the KL-divergence based metric introduced in [5] that computes the KL-divergence on the probabilities of the labels of a pretrained audio classifier between the conditioning and the generated music. We noticed that a high FAD (> 2) often indicates a poor quality of the generated samples. The CLAP score [5, 16] computes the cosine similarity between the description and the audio embeddings obtained with the CLAP model. A higher score indicates that the generated audio aligns well with the textual description of the conditioning audio.

4.5 Human studies metrics

We follow a similar protocol as in [5] for the human studies. We ask human raters to evaluate three different aspects of the generated audio: (1) How would you rate the overall quality of this excerpt [OVL]? (2) Without considering audio quality, how similar are these two excerpts in terms of style [SIM]? (3) Without considering audio quality, how likely do you think these two excerpts are from the same song [VAR]?

We believe that the SIM and VAR scores are the subjective versions of KNN_{common} and KNN_{overfit}.

5. EXPERIMENTAL RESULTS

5.1 Hyperparameters for the textual inversion

For the textual inversion method we test different parameters sets and retain these ones: we use a 12 tokens sentence for initialization, a batch size of 8 with 5 seconds segments randomly sampled from a 30 second excerpt with 200 optimization steps, a learning rate of 0.025 with a vanilla Adam optimizer. Finally the main issue that we encounter with this method is its instability. It is hard to find a set of hyperparameters that works well for any song. Some songs seem to be easier to invert for different sets of hyperparameters. For some song, we never achieve to obtain hearable music as the result suffers from glitches, and tempo instabilities. Finally, it seems beneficial to augment the length of the text embedding, as well as performing the inversion

over chunks taken from a 30 seconds excerpt rather than the entire song. The results are shown in Tab. 1.

5.2 Hyperparameters for the style conditioner

All the models that we train are medium size (1.5B parameters) MusicGen models built on top of the 4 stream 32kHz music version of EnCodec [10]. All models are trained for 400K steps on 64 V100 GPUs with the AdamW optimizer using $\beta_1 = 0.9$, $\beta_2 = 0.95$, a batch size of 192, and music sequences of 30 seconds. For the style conditioner, excerpts between 1.5 and 4.5 seconds are subsampled from the original sequence, the transformer encoder has 8 layers, 8 heads, a dimension of 512 and is non-causal, the residual vector quantizer has a codebook size of 1024, 6 streams and a variable number of streams is sampled at each training step, hence allowing the language model to train on all the levels of quantization. The style tokens are downsampled to 5Hz. All our evaluations are done on 1000 samples of the test set. Similarly to the MusicGen Melody model, both the textual description and the style condition are provided as prefix to the language model.

5.3 Datasets

We use 20K hours of licensed music as in [5]. The training dataset is composed of 25K and 365K songs from the Shutterstock and Pond5 music data collections, as well as 10k tracks of an internal dataset. Each song comes with textual description, and is downsampled to 32kHz mono.

5.4 Comparison with baselines and model selection

Apart from the closed-source model udio [40], there is no other audio conditioned music generative model. We use as a baseline a MusicGen model in the continuation setting: given 3 seconds of music, we ask MusicGen to continue the music with no textual prompt. For the second one we train a MusicGen model with a pretrained CLAP audio encoder [16] as conditioning, also taking 3 seconds of audio as input. In Tab. 1, we compare these two baselines with our model with the EnCodec feature extractor for the style conditioner, a quantization level of 2 and with a textual inversion model. We notice that the FAD correlates well with the quality metric (OVL) since the textual inversion model has the worst OVL and FAD scores. Thus excluding this approach, we observe that the KNN_{common} and the SIM metrics ranks the models in the same orders as well as the KNN_{overfit} and VAR metrics.

Feat. Ext.	Quant.	FAD _{vgg} ↓	KL ↓	CLAP ↑	KNN _{common} ↑	KNN _{overfit} ↓	OVL ↑	SIM ↑	VAR ↓
MERT	1	0.78	0.50	0.29	0.19	0.06	84.07 ± 0.93	70.27 ± 1.22	69.69 ± 1.31
MERT	2	0.75	0.47	0.30	0.24	0.13	84.14 ± 0.96	72.53 ± 1.05	72.81 ± 1.21
MERT	4	0.75	0.45	0.31	0.29	0.18	84.32 ± 1.04	74.15 ± 0.96	75.12 ± 1.35
EnCodec	2	0.85	0.49	0.29	0.23	0.12	84.02 ± 0.89	72.69 ± 0.91	72.47 ± 1.28
MusicFM	2	0.70	0.45	0.31	0.28	0.16	84.45 ± 1.09	73.01 ± 0.95	74.01 ± 1.36

Table 2. Comparison between the 3 feature extractors. The human studies correlate well with the KNN metrics. As expected, using coarser quantization of the style features leads to more variations in the generated audio. Self-supervised encoder like MERT and MusicFM outperforms low level acoustic models like EnCodec.

Model	FAD _{vgg} ↓	KL ↓	CLAP ↑	KNN _{common} ↑	KNN _{overfit} ↓
Our Model	0.75	0.45	0.31	0.29	0.18
Smaller Transformer	0.98	0.48	0.29	0.24	0.13
No Transformer	2.92	0.96	0.13	0.01	0.0
No Masking of the loss	1.11	0.53	0.29	0.22	0.30

Table 3. Ablation Study on our model with a MERT feature extractor with 4 quantization streams.

Regarding the baselines, the textual inversion method provides results of poor quality (FAD). The continuation method provides music that has a high similarity to the conditioning (high KNN_{common} and SIM) but that is too similar to it (high KNN_{overfit} and VAR). However, the CLAP conditioning captures a more vague style of the conditioning and generates music that is too far from it (low KNN_{common}, KNN_{overfit}, SIM and VAR). Our model with the EnCodec feature extractor and 2 levels of quantization strikes the right balance between these two baselines.

In order to strengthen our claim that our KNN metrics correlates well with human perception of closeness between musical excerpts, we showcase a second study in Tab. 2. In this study we compare the metrics of the MERT feature extractor with 3 quantization levels 1, 2, 4 (we recall that the models can go up to 6) as well as the EnCodec and MusicFM feature extractors with a quantization level of 2. All models generate music of similar quality (FAD and OVL). We notice that when the bottleneck is larger (i.e. when the quantization level is higher), the KNN_{common} augments. This follows the intuition that if the conditioner transmits more information to the language model, the generated music will be closer to the input condition. The models follows similar orders for KNN_{common} and SIM as well as for KNN_{overfit} and VAR.

5.5 Ablation Study

We perform an ablation study in Tab. 3 on the components of the style conditioner with MERT as a feature extractor, and 4 RVQ streams. When reducing the size of the transformer encoder from 8 layers and 512 dimensions to 4 layers and 256 dimensions, the quality of the generated audio is worse. When removing the transformer encoder, the model generates audio that is far from music (high FAD). When we don't mask the music that is input to the style conditioner in the cross-entropy loss at training time, the audio quality is slightly worse and the model generates music that is too close to the conditioning and tends to loop. The very high KNN_{overfit} indicates it since for a KNN_{common} lower than the best model the KNN_{overfit} is twice its value.

Type	α	β	FAD _{vgg} ↓	CLAP ↑	KNN _{common} ↑
No CFG	X	X	1.54	0.25	0.088
simple	3	X	0.92	0.28	0.162
double	3	3	0.80	0.35	0.123
double	3	4	0.78	0.37	0.104
double	3	5	0.84	0.37	0.095
double	3	6	0.97	0.38	0.081

Table 4. Classifier Free Guidance parameters tuning. Larger β from (4) leads to increasing the importance of the text conditioning (given by the CLAP score), and decreasing the similarity to the style audio, given by KNN_{common}.

5.6 Tuning the Classifier Free Guidance

When style and text conditioning are both used and are not consistent, it is necessary to use double CFG instead of simple CFG so that the text is not ignored. To tune the parameters α, β of the double classifier free guidance given by (4), we rely on the following protocol. For 1000 samples of our test set, we randomly shuffle text descriptions and generate music while conditioning both on text and music. We track the FAD [39], the KNN_{common} and the CLAP score. In Tab 4 we observe the intuitive fact that the KNN_{common} and CLAP score are negatively correlated: if the balancing favors the text condition the CLAP score is higher, if it favors the audio condition the KNN_{common} is higher. The double CFG thus works as expected.

6. CONCLUSION

In this paper we introduced style conditioning for language model based music generative models: given a few seconds of a musical excerpt, one can generate music in the same style using our proposed audio encoder with an information bottleneck. We introduced new metrics to assess the equilibrium between generating music that maintains a similar style to the condition while also being different. We validated those with human studies. Finally, we can also mix this style conditioning with inconsistent textual description and balance them thanks to a new double classifier free guidance method. This method could be applied in other generative models with multiple conditions.

Ethical statement: Improving music generation brings ethical challenges. Through carefully chosen bottlenecks in our style extractor (RVQ, downsampling) we aim for the right balance between increasing the model controllability and possible creative use while ensuring the model does not copy existing works, and provided new metrics to measure this. Finally, we only used music we licensed.

ABSTRACT

Variation in music is defined as repetition of a theme, but with various modifications, playing an important role in many musical genres in developing core music ideas into longer passages. Existing research on variation in music is mostly confined to datasets consisting of classical theme-and-variation pieces, and generative models limited to melody-only representations. In this paper, to address the problem of the lack of datasets, we propose an algorithm to extract theme-and-variation pairs automatically, and use it to annotate two datasets called POP909-TVar (2,871 theme-and-variation pairs) and VGMIDI-TVar (7,830 theme-and-variation pairs). We propose both non-deep learning and deep learning based symbolic music variation generation models, and report the results of a listening study and feature-based evaluation for these models. One of our two newly proposed models, called Variation Transformer, outperforms all other models that listeners evaluated for “variation success”, including non-deep learning and deep learning based approaches. An implication of this work for the wider field of music making is that we now have a model that can generate material with stronger and perceivably more successful relationships to some given prompt or theme.¹

1. INTRODUCTION

The term variation refers to “a form founded on repetition, and as such an outgrowth of a fundamental musical and rhetorical principle, in which a discrete theme is repeated several or many times with various modifications” [1]. In western music, variation is a technique in which the theme is repeated but in an alternate form with various modifications in one or more aspects of melody, rhythm, harmony,

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

texture, instrumentation, etc. An example from game music is provided in Figures 1(a) and (b), where the top and bottom staves in (b) are embellished compared to (a), but the melodic and harmonic structure is largely the same.

In recent years, a number of music generation algorithms and commercialised artificial intelligence (AI) music generation systems have emerged [2–9], but there are only a few studies focusing on symbolic music variation generation [10–14]. Although some infilling systems claim that they have the potential to generate variations [7, 8, 15, 16], an infilling system may sometimes work to continue writing [17] rather than always varying the theme (i.e., generate content with a strong relationship to the given prompt). Accepting a musical input prompt but destroying the original music idea is a “lack of control” issue, and could frustrate composers [18, 19]. It also leaves the presence and perception of rhetorical or narrative content to serendipity (chance), which goes against the rhetorical principle of the definition of musical variation.

Existing music variation research is mostly confined to datasets consisting of classical theme-and-variation pieces [20] or monophonic folk music [21], and most of existing music variation generation models are also limited to varying melody only [11, 12, 14].

To address the issues above, in this paper we develop both new datasets and models for symbolic polyphonic music variation generation. For data annotation, we develop an algorithm for theme-and-variation extraction, and apply it to annotate two datasets: POP909 [22], and VGMIDI [23]. For model design, we propose both deep and non-deep learning-based models, as another shortcoming of recent research is that evaluations ignore models published prior to c. 2015 – assuming, rather than actually testing whether, deep learning approaches are superior for music generation [13, 14, 24]. Three research questions are addressed: **RQ1:** To what extent can AI models generate successful music variations? **RQ2:** Can deep learning approaches outperform non-deep learning approaches on music variation generation? **RQ3:** Would variation generation tools be useful? We conduct a listening study and feature-based evaluation to address these research questions, and finish by discussing the implications of the study’s findings for music generation and the field of MIR.

Figure 1. (a) Theme from “Loneliness” by Kenji Hiramatsu, *Xenoblade Chronicles 2*; (b) Variation from the same piece; (c) Measure-level encodings based on this theme-variation example, discussed in a subsequent section. T_m denotes the encoding of the m th measure of the theme, while V_m denotes the encoding of the m th measure of the variation. The shaded areas are filled with 1s, while the blank areas are filled with 0s, indicating how we condition the model to attend to specific parts of the theme when generating a variation.

2. RELATED WORK

2.1 Symbolic music generation approaches

Before deep learning models became a popular approach for music generation, many models were based on Markov chains [25–28]. Markov models assume that the current state prediction depends on one (first-order Markov model) or more (second-, third-order models) previous states. They have been used to generate music in many styles, and recent work [29] finds evidence that ratings of the stylistic success of their outputs are on a par with deep learning models such as Music Transformer [30].

Among a large number of deep learning approaches to symbolic music generation [30–40], the most popular architectures are the generative adversarial network (GAN) [41], variational autoencoder (VAE) [31, 42, 43], and transformer [44]. More recently, there are also some attempts to adopt the diffusion model [45, 46] to generate music [39, 40]. But to date, we observed these diffusion-based algorithms suffer from the problem of a lack of structure in long-term music generation.

2.2 Symbolic music variation generation

As a sub-task of symbolic music generation, symbolic music *variation* generation takes a prompt/theme as input, and aims to generate variations where the new material is different to the theme but remains musically relatable. Some variation generation approaches are based on genetic algorithms [10, 11], but drawbacks are that they have only been applied to sequential representations of monophonic music and are reliant on manually designed rules [47].

There are also variation generation methods based on probabilistic methods. For example, an algorithm mentioned in [48] starts with the same first beat as the theme, and subsequent beats are generated by a Markov model. To ensure the generated variation begins and ends somewhere “sensible”, the Markov process can be run forwards and backwards from such start and end points, with a join in the middle of a generated phrase that may break the Markov property [26, 48]. Compared to variation generation, these two methods are more like style-composing. In

contrast, an idea in [49] is to decide if each of the states in an existing sequence (such as a theme) should be replaced by another state according to a corresponding probability distribution. However, this approach has only ever been applied to monophonic variation generation.

Compared to non-deep learning approaches, an advantage of deep learning for music generation is that it places less emphasis on the domain knowledge/expertise of the programmer – the trained network weights *should* take on responsibility for generalizing the style/structure of the training data.

There are only a few studies for music variation generation that have adopted deep learning methods. This is because most deep learning approaches are data-driven, and existing theme-and-variation datasets are either relatively small classical music datasets (e.g., the TAVERN dataset [20] with 17 works by Beethoven and 10 by Mozart for a total of 281 variations) or monophonic folk music datasets [21], which restricts the development of deep methods for music variation generation. Although Music Transformer is adopted in [13] for jazz variation generation, the JAZZVAR dataset (502 theme-variation pairs) proposed in this study is still relatively small for deep learning model training. Besides, the lack of listening studies and comparative evaluation makes it difficult to conclude to what extent these models are effective in generating musical variations [13, 14, 24].

3. DATASET

In this section, we introduce our algorithm for automatic extraction of variations from a collection containing annotated themes. We use it to extract theme-and-variations (TVar) pairs from the POP909 [22] and VGMIDI [23] datasets. As a result, two new datasets (POP909-TVar, and VGMIDI-TVar) are constructed.

3.1 Construction of the POP909-TVar dataset

The POP909 dataset [22] contains piano arrangements of 909 Chinese popular songs in MIDI format. We use 809 pieces ($\sim 90\%$) for training, and 100 ($\sim 10\%$) for testing.

As repetitive phrase annotations are provided in the POP909 dataset [50], we use these to estimate the lower and upper bounds of the similarity between human-composed themes and variations by utilizing a symbolic fingerprinting-based similarity calculation [51, 52]. The first occurrence of each repetitive pattern is regarded as the theme, and the following occurrences are regarded as variations. For each theme, we record the minimum and maximum similarity scores between it and its variations. The similarity lower bound is the average of the per-theme minimum scores, and the upper bound is defined correspondingly, with values of 53.03 and 70.95, respectively.

Algorithm 1 TVar extraction on the POP909 dataset

Input: Repetitive pattern labels (\mathbf{P}) and MIDIs (\mathbf{M}) of the dataset, similarity upper bound u and lower bound l

Output: TVar pairs

```

1: for  $p \in \mathbf{P}$  do
2:   Separate the first occurrence of  $p$  as the theme  $t$ , and
   the subsequent occurrences as an array  $\mathbf{V}_{\text{Rep}}$ 
3:    $\mathbf{V}_{\text{Match}} \leftarrow \text{match\_occ}(t, \mathbf{M}, u, l)$ 
4:   Push  $\mathbf{V}_{\text{Match}}$  into  $\mathbf{V}_{\text{Rep}}$ 
5:   for  $v \in \mathbf{V}_{\text{Rep}}$  do
6:     if  $\text{similarity}(t, v) > u$  then
7:       Filter out  $v$ 
8:     else
9:       if Similarity score between  $v$  and the previous
       occurrence  $> u$  then
10:        Filter out  $v$ 
11:       else
12:        Push  $v$  into  $\mathbf{V}_{\text{Out}}$ 
13:       if Occurrence count of  $\mathbf{V}_{\text{Out}} \geq 1$  then
14:         return  $t, \mathbf{V}_{\text{Out}}$ 

```

The pseudocode for TVar extraction is given in Algorithm 1. We take the first occurrence of repetitive patterns as themes when applying our algorithm to POP909 (line 2).² Variations are extracted from both human-annotated patterns (line 2) and the whole dataset (line 3). When extracting variations from human annotations, we exclude variations whose similarity score is larger than the similarity upper-bound (lines 6-7), since we aim to train models to generate variations where there is new but theme-relatable material. When extracting variations of a theme on the whole dataset, we run a symbolic fingerprinting-based pattern-matching approach [51–53] using the same lower and upper bounds mentioned previously to retain variations (line 3). We also filter out variations that are too similar to existing variations (lines 9-12).

The POP909-TVar dataset is constructed by applying our TVar extraction algorithm to POP909, giving 2,609 TVar pairs in the training set, and 262 TVar pairs in the test set.

² First occurrences are not always the *archetypal occurrence*, but it is a reasonable assumption [17].

3.2 Construction of the VGMIDI-TVar dataset

The VGMIDI dataset [23] contains piano arrangements of game music in MIDI format recorded by human performers.³ There are three subsets in VGMIDI: the largest has 2,520 MIDI files for music generation model training, the second one has 136 MIDI files with emotion labels, and the third one (272 MIDI files) is for music discriminator training, which involves both human-composed music and fake data. Here, we merged the largest subset and the subset with emotional labels and adhered to the original train-test split, obtaining 2,301 MIDI files for training and 355 for testing.

Compared to popular music, we infer there could be greater scope for new material in variations in game music, so we reduce the similarity lower bound to 30 but keep the similarity upper bound as 70.95. Also, we restrict the extracted variation and the theme to come from the same song. Then, we follow the steps as in Section 3.1 to obtain variations. In contrast to the POP909 dataset, repetitive patterns are not annotated in the VGMIDI dataset, so we run a slice window with size = 8 measures and step = 4 measures from the beginning to the end of the song to extract theme samples. The similarity between each new theme and previous themes is calculated to filter out theme samples that are too similar (similarity score > upper-bound) to existing themes. The variation extraction function `match_occ()` is applied to each of the theme samples, and then the matched occurrences will be filtered by the same processes as that in Algorithm 1 (lines 5-12). Only theme samples with more than one variation will be retained (lines 13-14 in Algorithm 1).

The VGMIDI-TVar dataset is constructed by applying the above steps to VGMIDI, giving 6,790 TVar pairs in the training set, and 1,040 in the test set.

4. MUSIC VARIATION GENERATION MODELS

In this section, we introduce two new music variation generation models: one is a deep-learning model called Variation Transformer, and the other acts as a non-deep learning baseline called Variation Markov.

4.1 Variation Transformer

Variation Transformer builds on Music Transformer [30], utilizing the REMI representation [54] to encode incoming MIDI files. The design of the relative positional self-attention [55] alleviates the problems of the regular self-attention that attends only locally or at the beginning for a sequence [56] – Music Transformer is used for jazz variation generation in [13]. However, while developing and testing these models, we observed that Music Transformer’s ability to understand the measure-wise relationship between theme and variation was not strong enough. For example, when generating a variation of an 8-measure theme, Music Transformer might generate something new in the first 2 measures, but copy large sections of the theme

³ Sources for this dataset are <https://www.vgmusic.com> and <https://www.ninsheetmusic.org>.

in the following measures [52, 57], showing the failure of the Music Transformer model to learn the theme-and-variation relationship. When a human composer creates a variation, commonly each bar of the variation is related to the corresponding measure of the theme (recall Figures 1(a) and (b)). Thus, in this study, we propose the measure-level encodings (Figure 1 (c)) and **theme-and-variation Attention** (tvAttn) to force the transformer architecture to take into account more information about a specific measure of an existing theme when generating the corresponding measure of a new variation, calling our new model the Variation Transformer.

Figure 1(c) shows the measure-level encoding (which we will notate E_{bar}) to capture the relationship between corresponding measures of theme and variation, with a size of $N \times N$, where N is the length of the encoding of theme concatenated with variation. The formula for tvAttn is then

$$\text{tvAttn} = \text{Softmax} \left((1 + \mathbf{w}E_{\text{bar}}) \frac{QK^\top + S^{\text{rel}}}{\sqrt{D_h}} \right) V, \quad (1)$$

where \mathbf{w} is a learnable parameter, and E_{bar} is the measure-level encodings. Q represents the queries, K is the set of keys, V is the set of values, $1/\sqrt{D_h}$ is a scale factor, and S^{rel} is to encode the relative positional information between each pair of tokens in a sequence.

4.2 Variation Markov

Based on [26, 58] and inspired by [12, 48], we propose a non-deep learning music variation generation strategy based on Markov models. Polyphonic MIDI inputs are represented as states in a state space consisting of beat in the measure and MIDI note numbers relative to estimated tonal center. The transitions between states observed across our training data are stored in a directed graph.

When generating variations, we extract the beginning and end states of each measure of the theme, and run a “scenic pathfinding algorithm” to find replacement states. This algorithm is adapted from Dijkstra’s shortest path algorithm [59]. When finding the shortest path between connected vertices u and v in a graph G , Dijkstra’s method always updates the distance from the starting vertex u to other vertices with shorter distances. In our scenic version, we insert an extra piece of logic to determine whether the distance from the starting vertex u to another vertex will be updated to a shorter distance with probability $p = .5$. In this way, more varied musical content is generated, because the path connecting u to v that results on each occasion is not necessarily the shortest. We replace each measure from the theme with the scenic path alternative with probability $q = .5$, and if u and v are not connected (due to not being observed in a training data sequence), then we retain the original measure from the theme.

5. EVALUATION

5.1 Experimental design

We conduct a listening study and feature-based evaluation on both POP909-TVar and VGMIDI-TVar datasets. The

variation generation ability of three transformer-type models (TTMs) – fast-Transformer (FaTr) [37, 60, 61], Music Transformer (MuTr) [13, 30], and Variation Transformer (VaTr) – and Variation Markov (VaMa) is compared.

For fair comparison, we use the REMI representation [54] to represent MIDI files for all three TTMs, which were trained on A40 GPUs with a batch size of 16 for 10 epochs on each of the two training sets. The learning rate is set as 1×10^{-4} for the first 5 epochs, then decreased to 5×10^{-5} for the last 5 epochs. For model training, we concatenate each theme-and-variation pair, with a [Separate] token inserted between the theme and variation. Ten variations were generated by each algorithm with using each theme in the test set as an initial prompt to provide the pool of stimuli for evaluation.

For hypothesis testing, we utilize a Bayes factor analysis (BFA, [62]), where the ratio of the marginal likelihoods of the alternative hypothesis H_1 to the null hypothesis H_0 is calculated, and notated BF_{10} . A large value of BF_{10} suggests there is strong evidence for H_1 . Conversely, a small BF_{10} suggests strong evidence for H_0 . A table for interpreting BF_{10} values is provided in [63]. BFA is superior to classical (frequentist) hypothesis testing, because of this ability to find evidence in favor of the null, which in (computational) systems testing corresponds to a meaningful non-difference between systems.

5.2 Listening study

Our listening study is approved by the Ethics Committee of the School of Arts and Creative Technologies at the University of York. Our overall design builds on previous listening studies in this domain (e.g., [49]), and our hypotheses are as follows:

1. In terms of variation success, we predict the following ordering of systems: VaTr > MuTr > FaTr > VaMa.
2. TTMs (VaTr, MuTr, and FaTr) achieve better music quality than VaMa.

5.2.1 Participants

We aim to recruit participants with a relatively high level of music knowledge, using student email lists at the University of York, and the C4DM group of the Queen Mary University of London.⁴ Participants are compensated £10 Amazon vouchers for the 30 mins it takes to complete the study. After removing responses that were unfinished or submitted too quickly to fully listen to the music, there are 25 responses under analysis.

Participants’ mean age is 25 years old, and their mean years of formal musical training is 10 years. Over 90% of participants listen to music daily, and 80% of participants play music/sing at least weekly.

5.2.2 Stimuli

For the listening study, 15 groups of stimuli were picked randomly from POP909-TVar generated outputs, and 15

⁴ We follow the consensual assessment technique [49,64] to design our study, which requires participants be experienced in the relevant domain.

from VGMIDI-TVar outputs. In each group, there are one theme and five variations, in which one is composed by a human, and the other four are generated by the models (VaTr, MuTr, FaTr, and VaMa). Each music excerpt is about 30-sec rendered using a piano sound. Each participant listens to 3 groups of music.

5.2.3 Procedure

After informed consent, instructions, and TVar examples, participants listen to a theme and then each variation, rating the musical dimensions of *variation success*, *stylistic consistency*, *similarity*, *creativity*, and *musical quality* on a 1–7 Likert scale, as well as two additional questions – *willingness to use a system that generates this variation (willingness)*, and *the extent to which this variation sounds like it is composed by a human (is human)*.⁵ An optional free text box for any comments follows the rating scales. After completing the evaluation of all 3 groups of materials, the extent to which the participant finds an algorithmic variation generation tool useful for their creative practice is rated (same scale), and a final optional free text box for any comments is provided. Given the participant and stimulus numbers, each TVar stimulus group was heard by approximately 3 participants, and all presentation orders were randomized to mitigate ordering and fatigue effects.

5.2.4 Results

Participants’ ratings for the features mentioned in Section 5.2.2 are shown as violin plots in Figure 2. For the BFA addressing our hypotheses at the top of Section 5.2, results for Hyp. 1 demonstrate that VaTr outperforms all three other algorithms (MuTr, FaTr, and VaMa) on *variation success ratings*, and MuTr outperforms FaTr and VaMa. But there is no difference between FaTr and VaMa. Results for Hyp. 2 indicate that TTMs (VaTr, MuTr, and FaTr) perform better than VaMa on *musical quality ratings*.

In terms of observations of results not tied to particular hypotheses, human-composed variations (Hu) appear to outperform algorithms on all metrics. In addition to *variation success* mentioned above, VaTr achieves higher ratings than other algorithms for *willingness* on both POP909-TVar and VGMIDI-TVar. The TTMs have higher ratings for *stylistic consistency*, *musical quality*, and *is human* than VaMa, but VaMa shows potential for generating creative variations. For POP909-TVar, VaMa and VaTr receive similar *creativity*, which is higher than that of MuTr and FaTr. For VGMIDI-TVar, although VaMa gets lower *creativity* than VaTr, it is still on par with MuTr and FaTr.

Approximately 100 comments are provided explaining the reasons for ratings, from which we find that participants usually consider the success of a variation according to the musical dimensions of pitch, rhythm, structure, dynamics, key signature, and texture, as well as the four more holistic dimensions mentioned in Section 5.2.2 (*stylistic consistency*, *similarity*, *musical quality*, and *is human*). As

⁵ The *variation success* is mainly to address **RQ1** and **RQ2**. Following existing research [37, 40, 65], we also include other music dimension metrics and *is human*. The *willingness* metric is to address **RQ3**.

such, deviations in these musical dimensions (e.g., dissonance, discordant dynamics, confusing structure) during the generation process could lead to unsatisfactory results.

Usually, a lack of stylistic consistency or being too similar/different to the theme will also result in an unsuccessful variation, but sometimes slight alterations (P11) or varying a lot from the theme (P21) can still lead to high ratings.

When considering whether a variation is written by a human composer or generated by AI, participants usually evaluate it in terms of the musical dimensions of rhythmic repetition, and appearance of dissonance, as well as overall musical quality. Lower-quality music seems to be associated with thoughts of being created by machines. But sometimes, even if the variation is recognised as AI-generated, participants are still receptive to it if the creativity and/or quality of the variation is good (P14 and P21).

The distribution of the extent to which participants find an algorithmic variation generation tool useful for their creative practice is: lower quartile = 3, median = 4, upper quartile = 5 on a 1–7 Likert scale. Corresponding comments comprise the following categories: i) benefit of music variation generation AI (MVG-AI) [18, 19, 66], with 8 out of 25 participants mentioning MVG-AI could be beneficial especially for inspiration; ii) concerns about MVG-AI [18, 19, 66], such as the quality and consistency not being sufficient to replace human composers (P7); iii) the clash between “creative ego” and MVG-AI [19], where for example P1 considers composing as creating art that is meaningful to the individual, which should not be done by AI instead. Similarly, P9 and P15 demonstrate wariness of the implications of AI and reluctance to use generative AI [18]; iv) further support/functionality required [18], such as P14 expecting MVG-AI to be able to produce variations that reflect a composers’ own style, and P24 thinking composers may have extra requirements for the MVG-AI in terms of emotional or style targets.

5.3 Feature-based evaluation

We use the whole pool of evaluation materials here, in which ten variations were generated by each algorithm for each theme drawn from the test sets. Three musical features are extracted and evaluated at the measure level:

Similarity score (SS) [67] gives the similarity between each measure of the generated variation and the corresponding measure of the theme in terms of pitch and rhythm.

Translational coefficient consistency (TC) [68] estimates the complexity or music-repetitive structure of an excerpt. A lower TC value means a music excerpt is highly repetitive, and vice versa. Here we calculate the absolute difference between the TC of each measure of the generated variation and the theme.

Key signature consistency (KSC) [69] captures the percentage of measures of the generated variation that have the same estimated key as the theme.

The evaluation results are shown in Table 1. We found that VaMa has the highest *SS* and *KSC* for both datasets. Among the TTMs, VaTr has higher values than MuTr and

Figure 2. Violin plots for rating (1–7) distributions of seven dimensions on two datasets, where the envelope represents the distribution of responses; the lines indicate rating scales; the horizontal line goes from the lower quartile through the median (point) to the upper quartile.

POP909-TVar					
Feat.	Hu	VaTr	MuTr	FaTr	VaMa
SS	26.1 (20.6)	19.0 (18.0)	12.0 (15.2)	6.8 (6.6)	15.8 (9.5)
TC	0.10 (0.09)	0.11 (0.10)	0.12 (0.10)	0.12 (0.09)	0.15 (0.11)
KSC	51.7	41.0	29.0	22.4	52.6
VGMIDI-TVar					
Feat.	Hu	VaTr	MuTr	FaTr	VaMa
SS	25.2 (19.1)	9.7 (16.7)	7.2 (12.9)	4.2 (8.0)	17.4 (14.6)
TC	0.12 (0.13)	0.16 (0.15)	0.17 (0.15)	0.14 (0.13)	0.14 (0.13)
KSC	32.8	22.4	19.7	19.5	52.0

Table 1. The feature evaluation results, with mean and standard deviation (in brackets) for each feature.

FaTr on all three metrics for POP909-TVar, and higher than MuTr and FaTr on SS and KSC for VGMIDI-TVar. But, VaMa is outperformed by TMMs in most of metrics in the listening study (Section 5.2.4), reflecting that feature-based metrics alone cannot evaluate the performance of models from the human-aesthetic perception of music [70].

6. DISCUSSION

In this paper, we propose datasets and models for symbolic variation generation. To address our research questions, we run a listening study and feature-based evaluation for both deep and non-deep learning models, as most recent music generation research only compares deep learning approaches. According to our listening study results, human-composed variations outperform algorithms on all metrics, indicating that there is still a gap between human-composed variations and those generated by our proposed algorithms (RQ1). One of our proposed models (VaTr) is the strongest for variation generation, which demonstrates the superiority of a deep learning over a non-deep learning approach when the task is as specific as “generate a successful variation of this theme”. But our experiment results also show that not all deep learning approaches outperform the non-deep learning approach, especially in creativity (RQ2). And so for the less specific task of “gen-

erate music in a target style”, more research and comparative evaluation is required to establish the superiority of deep learning over alternative music generation methods. We hope that our study encourages researchers to revisit non-deep learning approaches, as well as to test experimentally whether deep learning methods are broadly superior to non-deep learning methods for music-generative tasks. To address RQ3, we further explore the extent to which participants in our listening study find MVG-AI useful for their creative practice, with an average rating of 4 on a 1–7 Likert scale, and some of the comments suggest that MVG-AI could lead to powerful tools for inspiration. One of our proposed models VaTr achieves the higher ratings for *willingness* than other models, and a comparable rating for *willingness* as that for human-composed variations on POP909-TVar (Figure 2).

Although the results are promising, there is still plenty of work to do in order to bridge technology and musical creativity. To increase the willingness of users to adopt MVG-AI, it is necessary to improve the quality of music generation and to consider the expectations of users. For example, to mitigate deviations in musical dimensions like dissonance, which lead to unsatisfactory results, adding a post-processing stage could be useful. Some participants mentioned their expectations about personalized AI in our study as well, as in [18, 19]. Using low-rank adaptation techniques [71, 72] to fine-tune a pre-trained model could be a strategy to explore in future. Another topic for future work entails further investigation of the quality of the provided datasets, to validate the reliability of the extracted theme-variation pairs.

Future applications of this work include: being integrated into AI music making systems to enable these systems to generate music with a stronger relationship to the user’s music prompt; being used in video game music domain, either as a tool to provide inspirations for composers, or for in-game generation to reduce listener fatigue [73, 74]; and structured music generation [12, 24, 75].

7. ETHICS STATEMENT

The listening study in this paper is approved by the Ethics Committee of The School of Arts and Creative Technology, University of York. A Participant Consent Form and a Participant Project Information Sheet is included prior to the start of the questionnaire to inform participants of the project and obtain their consent. Participants have the right to withdraw at any time. Each participant's data is protected by anonymization. The data collected involves ratings and comments as described in Section 5.2.2. The demographic information collected only involves participants' age in years, years of formal music training, regularity of playing music or signing, and regularity of listening to music, which are not sufficiently detailed for participants to be identified. No other identifying data are collected. Researchers shuffle the order of their responses, and then record these responses and use anonymized new IDs, which are person 1, person 2, etc. This way, even the researchers will not be able to identify the person after the survey.

Previous work demonstrates that some deep learning approaches that generate music from scratch tend to copy large sections from the training set with a high risk of copyright infringement [52]. In order to mitigate this issue, our models vary the input prompt. Moreover, future work includes further experiments regarding originality of the generation results. Although the training materials come from open-source datasets (POP909 [22], and VGMIDI [23]), it does not mean all the contents are copyright free. There is a possibility of our models to output copyrighted music. Therefore, our models and data are used for academic research only, not for commercially usages.

8. ACKNOWLEDGEMENT

The Viking cluster was used during this project, which is a high performance compute facility provided by the University of York. We are grateful for computational support from the University of York, IT Services and the Research IT team. Chenyu Gao is a PhD student supported jointly by the China Scholarship Council and the University of York.

ABSTRACT

Moral values play a fundamental role in how we evaluate information, make decisions, and form judgements around important social issues. The possibility to extract morality rapidly from lyrics enables a deeper understanding of our music-listening behaviours. Building on the Moral Foundations Theory (MFT), we tasked a set of transformer-based language models (BERT) fine-tuned on 2,721 synthetic lyrics generated by a large language model (GPT-4) to detect moral values in 200 real music lyrics annotated by two experts. We evaluate their predictive capabilities against a series of baselines including out-of-domain (BERT fine-tuned on MFT-annotated social media texts) and zero-shot (GPT-4) classification. The proposed models yielded the best accuracy across experiments, with an average F1 weighted score of 0.8. This performance is, on average, 5% higher than out-of-domain and zero-shot models. When examining precision in binary classification, the proposed models perform on average 12% higher than the baselines. Our approach contributes to annotation-free and effective lyrics morality learning, and provides useful insights into the knowledge distillation of LLMs regarding moral expression in music, and the potential impact of these technologies on the creative industries and musical culture.

1. INTRODUCTION

Lyrics play a crucial role in how we experience music, affecting our emotions and actions. Positive lyrics can motivate and elevate listeners, whereas negative or aggressive content in songs may negatively impact mood and behaviour [1]. Social, political, and cultural issues, such as racial inequality and gender discrimination, are often reflected in the music lyrics of their time [2, 3]. Songs that feature in successful campaigns typically include uplifting melodies and lyrics that reflect the ideals of a nation, representing values of optimism and progress towards a better future [4]. Moral rhetoric in lyrics has been used to

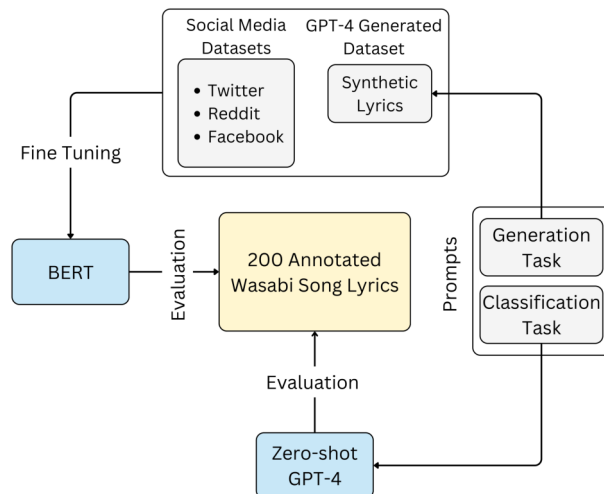

Figure 1. Model Structure for predicting Moral Foundations (MFT) in Lyrics, fine-tuned on out-of-domain social media data, and synthetically generated lyrics with GPT-4.

advocate for what is perceived to be a necessary societal change [5], promote peace and unity [6], and raise awareness for marginalised groups [7]. These narratives are closely related to moral judgements and beliefs, yet their relationship to music listening behaviors has received limited attention by music scientists.

In the field of Music Information Retrieval (MIR), lyrical content analysis has focused primarily on genre classification [8], mood prediction [9], emotion dynamics [10], and lyrics-to-audio alignment [11, 12]. Recent works have elaborated on less attended psychological characteristics of music lyrics, including moral valence. For example, insights into personal values and personality traits derived from lyrics can enhance various MIR tasks, including genre classification, audio tagging, and music recommendations [13]. Preniqi and colleagues [14] showed that moral valence extracted from lyrics can to some extent predict listeners’ moral values, in some cases more accurately than audio features. The possibility to extract morality rapidly from lyrics can enable a deeper understanding of our music listening behaviours.

Inferring moral values from song lyrics is a complex natural language processing (NLP) task from the start due to the subjectivity of our perceptions and interpretations. The progress is further hindered by the lack of an-

notated lyrics for training new or fine-tuning pre-trained models, and for benchmarking. Using models fine-tuned with out-of-domain annotated texts (e.g., from social media [15, 16]) to predict moral values in music lyrics faces significant challenges due to the unique structure of lyrics compared to other textual forms (e.g., greater use of repetition, metaphor, imagery, and other poetic devices).

In light of the above, we investigate the novel task of automatic detection of moral values in music lyrics using an integrated approach that leverages the strengths of two distinct NLP technologies. Specifically, we leverage the generative capabilities of GPT-4 (Generative Pre-trained Transformer) to create morally nuanced synthetic lyrics—a process required only once—and employ BERT (Bidirectional Encoder Representations from Transformers), which demands fewer computational resources, to learn from the synthetic data structure.

Following recent related work [14, 15, 17], we operationalize morality drawing on Haidt and Graham’s Moral Foundations Theory [18], which outlines five core moral traits, or foundations, divided into “virtue” and “vice” based on moral polarity: *Care* and *Harm*, *Fairness* and *Cheating*, *Loyalty* and *Betrayal*, *Authority* and *Subversion*, *Purity* and *Degradation*. We developed a corresponding set of 10 single-label classification models, each customized to predict the presence or absence of one moral value in lyrical text. MFT is a straightforward yet comprehensive model for understanding moral values, uniquely characterized by well-developed term dictionaries [19].

We present a dataset of 200 real song lyrics human-annotated with MFT. To the best of our knowledge, this is the first such dataset. It serves as the basis for evaluating our proposed method. We make the real and synthetic lyrics datasets, and the paper code fully available via a GitHub repository.¹

We report a comprehensive comparison of the proposed models against BERT fine-tuned with out-of-domain human-annotated moral text data and zero-shot classification with GPT-4. Figure 1 summarizes the overall pipeline of this work. The proposed models yielded the best accuracy across experiments, with an average F1 weighted score of 0.8. This performance is, on average, 5% higher than out-of-domain and zero-shot models. When examining precision in binary classification, the proposed models perform on average 12% higher than the baselines. Our approach contributes to annotation-free lyrics morality learning, and provides useful insights into the knowledge distillation of large language models such as GPT-4 regarding moral expression in music.

2. RELATED WORK

The field of music and moral expression has received limited attention. However, recent studies have shown a link between an individual’s moral values and their preferences for lyrics and music, suggesting significant implications for tailoring personalisation in streaming services

[14, 17, 20]. Further research has delved into how moral values and lyrical preferences manifest within specific music communities. For example, Messick and Aranda [21] demonstrated that moral values could explain a unique and significant portion of the variance in lyrical preferences among fans of different metal music sub-genres.

Given the understanding that verbal expressions more effectively convey morality than non-verbal forms [17, 22], initial studies introduced lexicons [23, 24] as an extension of Moral Foundations Dictionary (MFD) [25] for identifying words and lemmas that accurately depict moral foundations. More recent studies focused on examining moral values in texts using human-annotated social media datasets [26–28], and introducing more advanced Natural Language Processing (NLP) approaches to detect moral dimensions in textual content [15, 16]. Trager et al. [27] introduced baseline models for predicting moral values, employing a pre-trained BERT model fine-tuned on the Moral Foundation Reddit Corpus. Guo et al. [16] proposed a multi-label model for predicting moral values with Twitter and news data, incorporating the domain adversarial training framework suggested by Ganin et al. [29] to align multiple datasets and generalise for out-of-domain predictions. A similar approach was taken by Preniqi et al. [15] in predicting moral values in different social media domains.

However, a main challenge that persists is the ability of these models to generalise across various domains. Lisco and colleagues [30] demonstrated that text classifiers perform better when domains are similar. This poses a major obstacle when predicting morality in lyrics because there is no prior study that has presented an annotated lyrics dataset with moral values. Further, manually annotating extensive text demands substantial time, resources, and deep understanding of Moral Foundations Theory (MFT).

To overcome these limitations, we employ GPT-4, an advanced LLM, to generate lyrics infused with various moral undertones, which helps in fine-tuning a moral classifier. This minimises the need for laborious manual annotation of extensive lyric databases, enabling us to utilise a smaller, human-annotated dataset to validate the effectiveness of knowledge distilled from GPT-4. The capacities of LLMs for music tasks are being actively explored for the moment. Doh et al. [31] similarly employed a large language model such as GPT-3 for generating pseudo captions from tags to mitigate the problem of data scarcity in the field of automatic music captioning. While Zhang et al [32] evaluated the quality and correctness of generated music lyrics via GPT-3. Sawicki et al. [33] investigated the possibility of using GPT-3 models to generate high-quality poems in a specific author’s style while suggesting that GPT-3 can be a useful tool in assisting authors.

3. METHOD

3.1 Human-Annotated Lyrics

For this work, we annotated 200 song lyrics, categorising them into 10 different moral foundations. This annotation process was conducted by two skilled annotators: the

¹ <https://github.com/vjosapreniqi/ismir-mft-values>

Figure 2. Distribution of Moral Foundations in 200 song lyrics dataset annotated by human annotators with genre proportions for each moral foundation.

lead author of this study and an external researcher with a background in music and sound design, both of whom agreed to contribute. Before starting, the annotators were informed about their participation rights, including the option to discontinue their involvement at any point. Each annotator was assigned with 125 songs for annotation. To evaluate the agreement between annotators, 50 songs were annotated by both annotators. The inner-annotator agreement was assessed using Cohen’s kappa coefficient for each moral label. This resulted in an almost perfect agreement [34] with an average score of 0.86 across all moral categories identified within the lyrics of the chosen songs. We selected the songs for the moral values annotation from the Wasabi Dataset [35], known for its extensive collection of 2 million songs including lyrics, artist gender, and musical genre among other data. This dataset spans over five decades, enabling the selection of songs from various eras. The process of selecting the songs involved a semi-random approach, with efforts made to retain the distribution of genres, and the timeline of song releases as found in the original dataset. Among the 200 songs annotated for moral values, 18 were from the 60s and 70s, 78 from the 80s and 90s, and 116 from the post-2000 era. The chosen songs represented a balanced mix of genres including Rock, Pop, Hip-Hop, R&B, Soul, and Country. Figure 2 depict the distribution of Moral values in the human-annotated song lyrics with the proportion of genre for each MFT value.

3.2 Predicting Morality in Lyrics with Domain Adaptation

Initially, we tried to predict moral values in lyrics by fine-tuning a BERT model with out-of-domain social media data, following the approach used by Preniqi et al. [15]. We utilised 20,628 tweets from the Moral Foundation Twitter Corpus (MFTC) [26]; 13,995 posts from the Moral Foundations Reddit Corpus (MFRC) [27]; 1,510 posts from Facebook vaccination dataset [28]. Preniqi’s and other work have demonstrated that predicting moral values using a single-label approach—predicting one MFT value at

a time—results in higher accuracy [15, 27]. Informed by these findings, we developed a set of single-label classification models tailored to predict individual moral foundations in lyrics.

As a baseline model, we apply a similar approach to the MoralBERT [15]. We identify the polarities (virtues and vices) of moral foundations, as opposed to just identifying the mere presence or absence of moral values. We incorporate the domain adversarial method aiming to improve the models’ ability to generalise effectively in predicting moral values in lyrics [15, 16]. Adopting this model, we start by deriving a domain invariant representation h from the BERT CLS embedding e :

$$h = W_{inv}e$$

where $W_{inv} \in \mathcal{R}^{768 \times 768}$ is a learnable matrix. Next, we calculate moral values predictions \hat{y}_m using:

$$\hat{y}_m = \text{Softmax}(W_1(\text{ReLU}(W_2h)))$$

with $W_1 \in \mathcal{R}^{768 \times 768}$, $W_2 \in \mathcal{R}^{768 \times c}$ representing 2 learnable matrices, c being the number of classes, ReLU is the rectified linear unit activation function and Softmax is the normalised exponential function. A domain classification head is also included for obtaining domain predictions \hat{y}_d :

$$\hat{y}_d = \text{Softmax}(W_3(\text{ReLU}(W_4h)))$$

with $W_3 \in \mathcal{R}^{768 \times 768}$, and $W_4 \in \mathcal{R}^{768 \times d}$ learnable matrices and with d being the number of domains in the training set. The main rationale of the adversarial network is increasing the loss from the domain head while minimising the loss from the moral values prediction. Hence, the model is “forced” to learn domain-invariant representations. This is achieved by integrating a gradient reversal layer before the domain classification head, while using standard training for minimising moral prediction loss. Cross-entropy (CE) loss is used for both the moral and domain classification heads. The final loss is expressed as:

$$L = CE(\hat{y}_m, Y_m) - CE(\hat{y}_d, Y_d) + L_{norm} + L_{rec}$$

with Y_m and Y_d as the ground truth for moral values and domain, respectively. Two regularisation terms from [16] are added: L2 norm regularisation and reconstruction loss:

$$L_{norm} = \|W_{inv}h - I\|^2, \quad L_{rec} = \|W_{rec}h - e\|^2$$

similar to W_{inv} (defined above), $W_{rec} \in \mathcal{R}^{768 \times 768}$ is also a learnable matrix and I is the identity matrix. These regularization losses are combined with moral and domain classification losses. The regularization terms are not applied when training MoralBERT on a single domain (e.g., when trained on just synthetic lyrics).

The binary setting we use implies the model should learn from highly unbalanced datasets, where the neutral label (negative class) is far more represented than the single moral value to be predicted in each instance (positive

class). To address the class imbalance, we employed two methods. First, weights are assigned to classes [36]:

$$weight_c = \frac{N - N_c}{N}$$

where N is the total training samples and N_c is the count of samples per class c . Second, similar to [37], we employed a separate threshold θ_v for each moral value v , so that we use \hat{y}_m to obtain the final prediction \hat{m} :

$$\hat{m} = \begin{cases} 1 & \text{if } \hat{y}_m > \theta_v \\ 0 & \text{otherwise} \end{cases}$$

with $\hat{m} = 1$ indicating the moral value is present in the lyrics and $\hat{m} = 0$ indicating it is not. The optimal value θ_v for each moral value v was found by optimizing for binary F1 during training, searching in the search space 0.05 to 0.95 with a step of 0.05. The models were trained for 20 epochs using a single Nvidia T4 GPU, a learning rate of $5e-5$, and the Adam optimiser for all MoralBERT experiments.

3.3 Synthetic Lyrics Generation for Moral Assessment

There is a growing interest in knowledge distillation from large pre-trained language models via synthetic text generation [38]. Here we apply a similar knowledge distillation approach by utilising GPT-4 for synthetic lyrics generation. This method eliminates the need to collect real-life data, which is often difficult to gather for a specific NLP task and with a specific input distribution [39]. Initially, we assessed GPT-4’s familiarity with Moral Foundation Theory [25], confirming its fundamental understanding of moral values. We tasked GPT-4 with generating lyrics by formulating a prompt, as follows:

Prompt: *You are an assistant to a songwriter; you need to assist in writing lyrics related to the Moral foundations described in the Moral Foundation Theory. Given the {Moral Foundations Tags}, which represent {Description Tags}, write original lyrics of a song expressing these moral foundations. DO NOT directly mention these moral foundations. DO NOT explicitly talk about morality. Write it in the style of {Artist Tags}.*

We assigned a “role” (songwriter assistant) for the model and provided three types of “input tags”. The {Moral Foundations Tags} comprise any of the 10 moral values. The resulting lyrics can represent 1, 2, or 3 moral values. We determined this based on the moral combinations observed in our human-annotated lyrics dataset. The {Description Tags} represent fundamental concepts of each moral value. The {Artist Tags} represent the names of artists whose styles we employ to diversify the lyrics. Initially, we intended to commence the lyrics generation task solely using moral categories and genres as tags. However, we observed that the lyrics were more uniform and generic compared to when we incorporated the artist’s style. To tailor the lyrical style using various artists, we employed MusicOSet [40], a collection of musical elements (e.g., music, albums, artists, genres and

popularity) suitable for music data mining. To capture the nuances of different genres, we organized the artists according to their popularity and grouped them into prevalent genres like Rock, Pop, Country, Hip Hop, R&B, Soul, Folk, Blues, and Jazz. These genres align very closely with those in the song lyrics we selected for human annotations. We chose to utilise this dataset because it offers detailed data on artist genres and sub-genres, as well as an artist popularity metric that we employ in developing lyric styles. We acquired a dataset comprising 2,721 artificially generated lyrics, each aligned with moral categories similar to our human-annotated lyrics dataset. On average, the generated lyrics had 146 words, with a total of 10,305 unique words across the synthetic lyrics dataset.

3.4 GPT-4 in Moral Classification Task

In addition, we wanted to assess the capability of the 0-shot GPT-4 model in classifying morality in actual song lyrics while comparing it to our proposed model. To do so, we prompted the task as follows:

Prompt: *You will be provided with song lyrics. The song lyrics will be delimited with #### characters. Classify each lyric into 10 Possible Moral Foundations as defined in Moral Foundation Theory The available Moral Foundations are: {Moral Foundations Tags}. The explanation of the moral foundations is as follows: {Description Tags}. This is a multi-label classification problem: where it’s possible to assign one or multiple categories simultaneously. Report the results in JSON format such that the keys of the correct moral values are reported in a list.*

The song lyrics utilised for the GPT-4 model classification are the same as the ones annotated by human annotators. In this way, we can compare the human annotations with those of the model while assessing the general performance of GPT-4 for the classification task.

4. EXPERIMENTS

We started by analysing the MoralBERT technique [20] and fine-tuned models using social media data from Twitter, Reddit, and Facebook. The total number of text records was 35,887. We found that 51% of the texts were neutral and 49% of them were labeled with one or more moral values. This indicated a significant skew towards neutral texts, which we addressed by adding the class weighting technique. After that, we evaluated the BERT models fine-tuned with only GPT-4 generated lyrics. We call these models “BERT SL”. We also fine-tuned the models with a combination of out-of-domain social media data and the generated lyrics data which we call “MoralBERT SL”. We used the Domain Adversarial module only when fine-tuning BERT with multiple domain data, including synthetic lyrics. When fine-tuning solely with synthetic lyrics, this module was not utilized. Lastly, we evaluated GPT-4’s zero-shot classification capabilities against our models on the manually annotated song lyrics.

The results show that the models achieving the highest

	F1 Scores Weighted Average				F1 Scores Binary

Table 1. F1 scores of prediction models with standard deviation estimated via 1,000 bootstraps. Weighted average scores account for both moral and non-moral (neutral) classes, while binary scores only for moral classes. SL = Synthetic Lyrics.

Figure 3. Precision scores for binary classification with standard deviation estimated via 1,000 bootstraps.

performance were BERT SL and MoralBERT SL. These models performed on average 5% better across all moral values in terms of F1 weighted score which accounts for both moral and non-moral prediction classes. While for the binary F1, these models were marginally better than GPT-4. For harm foundation, GPT-4 performed slightly better, possibly due to the synthetic lyrics’ lack of natural variability when expressing this foundation. The fact that MoralBERT SL and BERT SL performances are similar to the one from GPT-4 for binary F1 is expected as the same latent knowledge of GPT-4 has been distilled into BERT by using the generated lyrics. The improvements from MoralBERT SL and BERT SL are significant for what concerns weighted F1, suggesting that given the supervised setting of these models, they were also able to learn the higher prior probability of non-moral (e.g., neutral) instances, which generally outweigh moral instances. The same is evident if we look at Figure 3, which compares the binary Precision scores of the various models. From the figure, it is evident that MoralBERT SL and BERT SL exhibit significantly higher Precision surpassing GPT-4 and

MoralBERT by 12% on average. These models, then, are often correct when labelling lyrics with moral values (even though results vary according to which moral value), while being more cautious in assigning a moral value, given the preponderance of neutral cases. For the evaluation metrics, we report the standard deviation estimated via Bootstrapping which is a statistical resampling technique used to estimate the variability of the metrics. We used 1,000 bootstraps which is typically sufficient to achieve a reasonable approximation of the standard deviation.

Our findings show that BERT-based models are still comprehensible with larger models such as GPT-4, when fine-tuned properly they can excel in specified tasks. GPT-4 demonstrated a very good performance even without any fine-tuning (zero-shot approach) which was anticipated given its state-of-art performance in multiple tasks and its training on an extensive amount of data. These models have been trained on diverse text sources such as Wikipedia, GitHub, chat logs, books, and articles [41], enabling them to comprehend language across various domains [31]. The earlier model, GPT-3, contains 175 bil-

Song Name	Artist	Human Annotations	MoralBERT	GPT-4	BERT SL MoralBERT SL

Table 2. Examples of moral values detected in song lyrics by human annotators and model predictions.

lion parameters, far exceeding BERT base model with 110 million parameters [42]. Such models demand significantly more computational resources than BERT models. In contrast, the BERT model is cost-free, easier to modify, and offers greater control over the models due to its open-source nature. On the other hand, BERT models need fine-tuning, which presents its own challenges due to the necessity for manual labelling and data annotation. Therefore, a hybrid approach like the one we suggest offers an optimised solution that combines the best of both worlds.

Table 2 presents four song examples annotated for moral values by both human annotators and prediction models. These examples show that MoralBERT SL and BERT SL (not shown in the table as it shares the same outcomes as MoralBERT SL for these instances) aligned most closely with human moral assessments. From a general observation of the song lyrics that were annotated by humans and tested with these models, it was noted that MoralBERT and GPT-4 tend to assign more moral attributes per song while increasing their chances of correctly guessing moral labels but also misclassifying neutral ones. In contrast, models trained with synthetic lyrics more accurately identified neutral (non-moral) lyrics, aligning with the quantitative observations of the F1 weighted score. Typically, human annotators did not assign more than three moral values per song. To control the number of assigned moral values per song, we adjusted the thresholds [37] for our prediction models, ensuring optimal accuracy. When lacking ground truth data, a post-processing can be applied for cutting moral labels with lower probabilities. Here we present only F1 and Precision scores. For further details, refer to the project’s results page on GitHub.²

5. CONCLUSION

In this paper, we presented an integrated approach for the automatic detection of moral values in lyrics. We created a synthetic lyrics dataset using GPT-4 which we used to fine-tune the BERT-base model alone (BERT SL) and in combination with out-of-domain social media corpora (MoralBERT SL). We introduced a dataset of 200 song lyrics

sourced from the WASABI dataset annotated for moral values by two experts, serving as the basis for evaluating our moral prediction models. We also assessed the performance of models trained with synthetic lyrics in comparison to those trained solely on social media data (MoralBERT) and a zero-shot GPT-4 classifier. We found that models trained with synthetic lyrics generally achieved significantly better binary Precision and higher weighted F1 scores compared to the GPT-4 classifier and MoralBERT, along with marginally better binary F1.

Our research has some limitations. To begin with, the synthetic lyrics is created via GPT-4, a powerful model but not an open-source, which limits our control of the model. We prompted GPT-4 to create unique lyrics in the style of various artists across different genres. Yet, adding musical composition details, lyrical themes [43], or visual images as descriptors [44], could enhance both the quality and diversity of the generated lyrics. However, we only employ this method for fine-tuning to make BERT models learn the structure and moral expressions in lyrics. The creation of truly creative lyrics for artistic purposes requires greater sophistication and rigorous human review [44]. Further, we analysed the overall moral expressions in the song lyrics without differentiating between structural elements such as verses, bridges, and choruses. Lastly, we focus on inferring moral values in English lyrics, which limits our ability to understand moral expressions in music lyrics from non-Western cultures.

Understanding how lyrics can convey moral values is important for the MIR field, as it can enhance how we experience and interact with music, including improving music tagging and recommendation systems [45]. Addressing challenges in automatic detection of moral values in lyrics can further push the boundaries of current technologies in natural language processing and machine learning applied to music and other creative tasks. Further, as lyrics often reflect societal values and cultural norms, tools for extracting morality rapidly from lyrical text enable researchers to gain insights into the prevailing moral attitudes of different times or cultures. This can be useful in sociological studies, helping scholars understand how music influences and is influenced by societal norms and changes.

6. ETHICS STATEMENT

In this study, we employed large language models (LLMs) to generate synthetic lyrics. Given the vast amount of data on which these models are trained, there is a potential for bias transfer from the training datasets. Additionally, these models may inadvertently contain copyrighted literary works within their training data, necessitating meticulous steps to prevent plagiarism, particularly if the generated lyrics are utilised beyond fine-tuning for artistic and creative outputs [46,47].

We engaged two human annotators to label 200 songs with moral values based on the Moral Foundations Theory (MFT). These annotators signed a consent document that detailed the project’s objectives, their roles, and the nature of their tasks. They were informed of their right to withdraw from the study at any time without consequences. To protect their privacy, all data from the annotators were anonymised.

While powerful language models like BERT and GPT-4 offer significant potential to enhance communication and support social campaigns, they also pose risks if used for manipulative purposes. Our research is committed to advancing the understanding of moral expressions in music and fostering the responsible development and use of AI in creative contexts.

{sebastian.strahl,meinard.mueller}@audiolabs-erlangen.de

ABSTRACT

Automatic piano transcription (APT) transforms piano recordings into symbolic note events. In recent years, APT has relied on supervised deep learning, which demands a large amount of labeled data that is often limited. This paper introduces a semi-supervised approach to APT, leveraging unlabeled data with techniques originally introduced in computer vision (CV): pseudo-labeling, consistency regularization, and distribution matching. The idea of pseudo-labeling is to use the current model for producing artificial labels for unlabeled data, and consistency regularization makes the model’s predictions for unlabeled data robust to augmentations. Finally, distribution matching ensures that the pseudo-labels follow the same marginal distribution as the reference labels, adding an extra layer of robustness. Our method, tested on three piano datasets, shows improvements over purely supervised methods and performs comparably to existing semi-supervised approaches. Conceptually, this work illustrates that semi-supervised learning techniques from CV can be effectively transferred to the music domain, considerably reducing the dependence on large annotated datasets.

1. INTRODUCTION

Automatic music transcription (AMT) converts polyphonic music recordings into symbolic representations that encode which notes are played [1, 2]. The AMT output may be a MIDI-like transcription, containing for every note event information about the instrument, onset time, duration, and velocity. AMT is considered as one of the fundamental problems in music information retrieval (MIR) because its symbolic output can be used for subsequent tasks such as music synchronization, structure analysis, or cover song detection [3]. AMT is challenging since multiple instruments may be active at the same time, due to possible polyphonic activity per instrument, and because sound events may have overlapping harmonics [2].

Early approaches to AMT rely, e.g., on non-negative matrix factorization [4, 5], while most recent approaches

use deep learning-based models [6–13]. The limiting factor in training neural networks for AMT, however, is the scarcity of labeled data. Creating such datasets typically requires manual labeling of each note present in a recording, which can be time-consuming, or relies on music synchronization techniques to align score information with recordings [11, 14]. The latter approach, however, may result in inaccurate labels due to issues such as playing errors or synchronization inaccuracies. Alternatively, one can create datasets with highly precise labels by utilizing instruments that allow automated playback or recording note activity. For instance, several piano datasets were automatically created using a Disklavier, which can synthesize MIDI files or log key activity during performance [15–17]. Since these piano datasets exist, many works [6–9, 12] focus on the special case of automatic piano transcription (APT). Still, it was observed that APT methods cannot generalize well across datasets due to overfitting [18].

In this work, we aim to improve model generalization of APT in scenarios with little labeled data by using semi-supervised learning (SSL), where the idea is to leverage unlabeled data during training. Unlabeled data can be obtained in large amounts as it does not depend on a labeling process. SSL has seen limited application in AMT, with Cheuk et al. [19] among the few to investigate this path. However, we argue that its full potential remains to be realized, especially when considering the significant achievements of SSL in computer vision (CV) [20, 21]. As our main contribution, we adapt techniques originally introduced in CV [22, 23] to APT. More specifically, our method makes use of pseudo-labeling, consistency regularization, and distribution matching as outlined in the following.

In our approach, we use the extended Onsets and Frames model [7, 16], which jointly predicts onsets, offsets, frame activity, and velocities. The raw model outputs for onsets, offsets, and frames are each a piano roll-like representation that can be interpreted as probabilities per time–pitch bin. Initially, we pre-train this model in a supervised fashion using the available labeled data. Thereafter, the model is used to produce binary pseudo-labels for unlabeled data. Only sufficiently confident predictions are converted into pseudo-labels, i.e., those below the lower threshold are set to zero and those above the upper threshold are set to one, while the remaining predictions are considered as unreliable. Next, the model makes predictions for an augmented version of the same recording, where augmentation involves frequency masking [24] and addi-

tion of noise to the data. The predictions made for the augmented data are then used in combination with the pseudo-labels derived from the clean data to compute an additional unsupervised loss. Using an augmented version instead of a clean one encourages the model to produce consistent predictions under these kinds of augmentations and is thus called consistency regularization. As a third technique, we apply distribution matching, which ensures that the pseudo-labels follow the same marginal distribution as the reference labels, preventing the model from collapsing. To achieve this goal, we use an undersampling strategy. For reproducibility, we will provide our code ¹.

The rest of this paper is structured as follows: In Section 2, we give an overview of related work on AMT, SSL, and distribution matching in the context of pseudo-labeling. In Section 3, we describe all steps of the proposed approach. Section 4 describes our experimental setup as well as the experimental results. We conclude the paper in Section 5 with possible future research directions.

2. BACKGROUND AND RELATED WORK

2.1 Automatic Music Transcription

Most research on AMT is based on supervised learning. Sigtia et al. [6] proposed the the first end-to-end approach to APT. Hawthorne et al. [7] emphasized the importance of explicitly predicting onsets alongside frame activity, later extending their model in [16] to include explicit prediction of offsets. In [8], onset and offset estimation is formulated as a regression problem, which yields note predictions with improved temporal resolution. The attention-based Transformer architecture is used for APT [9, 12, 25] and multi-instrument AMT [10]. In [13], the Perceiver architecture is employed for multi-instrument AMT. Recently, AMT has been formulated as a conditional generative task: In [26], a diffusion model is trained to generate realistic piano rolls, being conditioned on the corresponding spectrograms.

Weakly supervised methods are proposed in [11], where unaligned pairs of scores and recordings are used for training, and in [27], where cross-version targets are used to replace pitch labels. Cheuk et al. [19] propose a semi-supervised approach to AMT, utilizing unlabeled data via virtual adversarial training (VAT). VAT [28] perturbs input data to induce substantial changes in the model’s predictions and then encourages the model to produce consistent predictions under these perturbations. In [29], a fully self-supervised method is proposed for frame-level transcription. Their method encourages the concentration of energy around fundamental frequency candidates, invariance to timbral transformations, and equivariance to input translations in both time and frequency.

2.2 Semi-Supervised Learning

In SSL, the idea is to jointly learn from labeled and unlabeled data, and SSL is thus located between supervised and unsupervised learning [30,31]. The objective is to train a model that performs better than a reference model only

trained on the labeled data using supervised learning. SSL has been successfully used in combination with deep learning, e. g., in CV [20, 21], for text classification [32], and also in MIR [33, 34]. For an overview of deep learning-based SSL methods, we refer to [20, 35]. Two important SSL paradigms relevant to this paper are pseudo-labeling and consistency regularization.

Pseudo-labeling, introduced in [36], uses the current classification model to produce artificial labels for unlabeled data. Continuing training with pseudo-labeled data encourages the model to make confident predictions for that data, effectively pushing decision boundaries away from the data points [35]. Maman and Bermano [11] already combined pseudo-labeling and weak supervision for AMT, but the pseudo-labels were updated only at the beginning of every expectation maximization iteration rather than being calculated on-the-fly as in [36].

Consistency regularization methods [37, 38] encourage that the model’s predictions do not change if augmentations (e. g., random translation and addition of noise in the case of image classification [37, 38]) are applied to the unlabeled input data. In [37], this is achieved by adding a consistency loss term which penalizes disagreement in the predictions made for two augmented versions of the data.

The image classification method FixMatch [22] combines both pseudo-labeling and consistency regularization by using the current model to produce artificial labels given a weakly augmented input (e. g., horizontally flipped) to supervise the predictions made for a strongly augmented input (e. g., Cutout [39], where a randomly selected rectangular region is masked). In [40, 41], FixMatch proved to be effective for audio classification as well, where weak and strong augmentations were applied to spectrograms. FixMatch was also adapted to pixel-wise classification problems such as semantic image segmentation [42], which is similar to AMT from a technical point of view.

2.3 Distribution Matching

It is well-known that training classification models on class-imbalanced data is challenging because the models tend to be biased towards the majority classes [43]. Biased model predictions which do not follow a similar distribution as the reference labels are problematic for pseudo-labeling because the model may suffer from confirmation bias [44], where wrong predictions are reinforced. To avoid that problem, several approaches were proposed to match the class distribution of pseudo-labels with that of reference labels. Berthelot et al. [23] rescale the predicted class probabilities for unlabeled data in such a way that their marginal distribution is close to the marginal distribution of reference labels. Kim et al. [45] refine pseudo-labels by solving a convex optimization problem that aims to minimize the distance between pseudo-label distribution and reference label distribution while trying to preserve most information in the pseudo-labels. While Maman and Bermano [11] do not explicitly perform distribution matching for AMT, they set asymmetric thresholds for selecting pseudo-labels, increasing the impact of the minority class.

¹ https://github.com/groupmm/onsets_frames_semisup

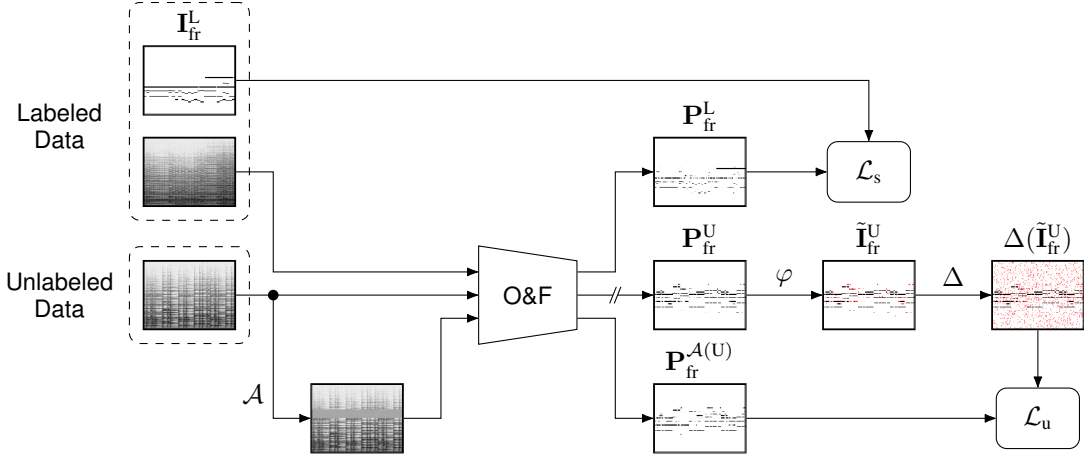

Figure 1: Detailed overview of our semi-supervised approach. The Onsets and Frames transcription model (O&F) [7, 16] is trained using both a supervised (upper branch) and an unsupervised loss (lower branches). Our method uses a clean version of unlabeled data to produce predictions, which, after thresholding (φ), are considered as pseudo-labels. Distribution matching (Δ) ensures that pseudo-labels and reference labels are similarly distributed. The pseudo-labels are used to supervise predictions made for an augmented (\mathcal{A}) version of the same data. The “interrupted” connection to the predictions made for the clean unlabeled input indicates that gradients are not backpropagated in this branch. For a better overview, we only show predictions, labels, and pseudo-labels for frame activity. Red color is used to represent NaN entries.

3. METHOD

In this section, we describe our proposed semi-supervised approach for learning APT. We first describe in Section 3.1 how the transcription model is trained in a supervised fashion. In Section 3.2, we explain how pseudo-labeling and consistency regularization can be used for semi-supervised training, and in Section 3.3, we explain the additional step of matching the pseudo-label distribution with the reference label distribution.

3.1 Supervised APT Baseline

We use the modified Onsets and Frames model [7, 16] and train our supervised APT baseline models similar to the original methodology. This model takes as input a log mel-scaled spectrogram with F frequency bins and T frames, and outputs onset, offset, frame activity, and velocity estimates. In this work, we focus on the involved classification problems and ignore velocity estimation for simplicity. Velocity estimation can be omitted without further consequences, as it is performed by an independent part of the model. We briefly explain how supervised learning is done using labeled data. The model outputs matrices $\mathbf{P}_{\text{on}}^L, \mathbf{P}_{\text{off}}^L, \mathbf{P}_{\text{fr}}^L \in [0, 1]^{P \times T}$ for onset, offset, and frame activity, respectively. In this notation, P denotes the number of MIDI pitches considered, and the entries of the matrices represent probabilities of activities for all time–pitch bins. For instance, $\mathbf{P}_{\text{on}}^L(p, t)$ denotes the predicted probability of an onset with pitch p in frame t . The reference MIDI annotations with continuous-time note events are temporally quantized to match the input frame rate and converted into binary labels $\mathbf{I}_{\text{on}}^L, \mathbf{I}_{\text{off}}^L, \mathbf{I}_{\text{fr}}^L \in \{0, 1\}^{P \times T}$, indicating bin-wise activities as described in [7, 16]. The supervised loss comprises three terms,

$$\mathcal{L}_s = \lambda_{\text{on}}^L \mathcal{L}_{\text{on}}^L + \lambda_{\text{off}}^L \mathcal{L}_{\text{off}}^L + \lambda_{\text{fr}}^L \mathcal{L}_{\text{fr}}^L, \quad (1)$$

with the frame activity loss

$$\mathcal{L}_{\text{fr}}^L = \frac{1}{PT} \sum_{p=1}^P \sum_{t=1}^T \ell_{\text{BCE}}(\mathbf{I}_{\text{fr}}^L(p, t), \mathbf{P}_{\text{fr}}^L(p, t)), \quad (2)$$

where ℓ_{BCE} denotes the binary cross entropy function and $\lambda_{\text{on}}^L, \lambda_{\text{off}}^L, \lambda_{\text{fr}}^L \in [0, 1]$ are suitable loss weights. Onset and offset loss terms are defined analogously. Note that, in contrast to [7], we leave out the weighting of individual frames within the frame activity loss in Equation (2) for simplicity.

3.2 Pseudo-Labeling and Consistency Regularization

We now describe how our approach leverages unlabeled data, which is illustrated in Figure 1. Our method is mainly inspired by FixMatch [22], with the difference that we do not apply weak augmentations to produce pseudo-labels. Instead, we produce pseudo-labels using the unmodified, clean data, which has been found to yield nearly the same results in audio classification [40].

To obtain pseudo-labels for unlabeled data, we first compute the current model’s predictions, $\mathbf{P}_{\text{on}}^U, \mathbf{P}_{\text{off}}^U, \mathbf{P}_{\text{fr}}^U \in [0, 1]^{P \times T}$, given the clean version of the log mel-scaled spectrogram as input. For converting soft probabilities into binary pseudo-labels, we define a thresholding function

$$\varphi(x, \tau_{\text{lo}}, \tau_{\text{up}}) = \begin{cases} 1, & \text{if } x \geq \tau_{\text{up}}, \\ \text{NaN}, & \text{if } \tau_{\text{lo}} < x < \tau_{\text{up}}, \\ 0, & \text{if } x \leq \tau_{\text{lo}}, \end{cases} \quad (3)$$

where τ_{lo} and τ_{up} denote lower and upper threshold, respectively. We obtain the pseudo-labels $\tilde{\mathbf{I}}_{\text{on}}^U, \tilde{\mathbf{I}}_{\text{off}}^U$, and $\tilde{\mathbf{I}}_{\text{fr}}^U$ by elementwise application of the thresholding function to the model predictions, i. e.,

$$\tilde{\mathbf{I}}_{\text{fr}}^U(p, t) = \varphi(\mathbf{P}_{\text{fr}}^U(p, t), \tau_{\text{lo}}, \tau_{\text{up}}) \quad (4)$$

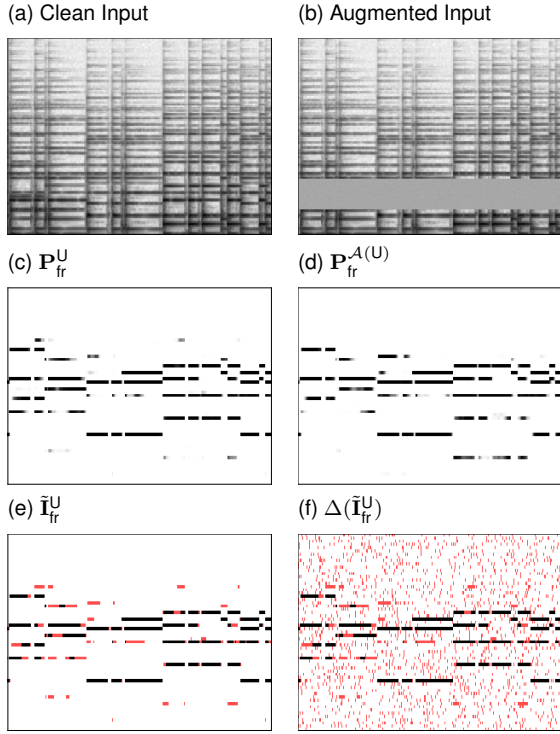

Figure 2: Examples of the representations involved in our semi-supervised method. Red color is used to represent NaN entries.

for $p \in [1 : P]$, $t \in [1 : T]$, and similarly for onsets and offsets. We use thresholds $\tau_{lo} = 0.05$ and $\tau_{up} = 0.95$ based on our observations in preliminary experiments, and we perform an ablation of this choice in Section 4. For illustration purposes, we refer to Figure 2, showing examples of clean model input, corresponding predictions \mathbf{P}_{fr}^U , and pseudo-labels $\tilde{\mathbf{I}}_{fr}^U$ in Figures 2a, 2c, and 2e, respectively, where NaN entries are represented by red color.

To perform consistency regularization, the pseudo-labels are used to supervise predictions made for an augmented version of the input. As in [40], we apply augmentations to the spectrograms. We opt for a simple augmentation pipeline which first applies frequency masking as described in [24], setting a randomly selected contiguous frequency band of up to 30 bins to the mean value of the spectrogram, and afterwards adds Gaussian noise with a standard deviation of 0.01 to the entire spectrogram. This choice of augmentation is inspired by the use of Cutout [39] in FixMatch [22] and the proposal of SpecAugment [24] as similar technique for spectrograms. We decided against temporal masking because this may completely remove information from the spectrogram regarding short events such as onsets. An example of such an augmented spectrogram is shown in Figure 2b. We denote the augmentation pipeline by \mathcal{A} , and the model’s predictions for the augmented input are denoted by $\mathbf{P}_{on}^{A(U)}$, $\mathbf{P}_{off}^{A(U)}$, $\mathbf{P}_{fr}^{A(U)} \in [0, 1]^{P \times T}$, respectively. An example of such predictions is shown in Figure 2d. Finally, the unsupervised loss is given by

$$\mathcal{L}_u = \lambda_{on}^U \mathcal{L}_{on}^U + \lambda_{off}^U \mathcal{L}_{off}^U + \lambda_{fr}^U \mathcal{L}_{fr}^U, \quad (5)$$

with the frame activity loss for unlabeled data,

$$\mathcal{L}_{fr}^U = \frac{1}{PT} \sum_{\substack{(p,t) \in [1:P] \times [1:T] : \\ \tilde{\mathbf{I}}_{fr}^U(p,t) \neq \text{NaN}}} \ell_{\text{BCE}}(\tilde{\mathbf{I}}_{fr}^U(p,t), \mathbf{P}_{fr}^{A(U)}(p,t)). \quad (6)$$

Onset and offset loss for unlabeled data are defined analogously. Only those time–pitch bins contribute to the loss, where the pseudo-labels have a value different from NaN. The loss is normalized by the total number of time–pitch bins for reducing the impact of the unsupervised loss if only a few predictions are confident. As for the supervised loss, we use suitable loss weights $\lambda_{on}^U, \lambda_{off}^U, \lambda_{fr}^U \in [0, 1]$. Note that the gradient of \mathcal{L}_u is not computed with respect to the predictions made for the clean version of the unlabeled input, which the “interrupted” connection in Figure 1 indicates. The overall loss function is obtained as the weighted sum of the supervised and the unsupervised loss,

$$\mathcal{L} = (1 - \lambda_u) \mathcal{L}_s + \lambda_u \mathcal{L}_u, \quad (7)$$

where $\lambda_u \in [0, 1]$ controls the relative weighting of both terms. Following [7], we weight the individual terms in the supervised loss equally, i. e., $\lambda_{on}^L = \lambda_{off}^L = \lambda_{fr}^L = 1$. However, preliminary experiments suggested that better results may be achieved if the unsupervised offset loss is not used. Hence, our default setting is $\lambda_{on}^U = \lambda_{fr}^U = 1$ and $\lambda_{off}^U = 0$. The overall weight of the unsupervised loss is set to $\lambda_u = 0.05$. We explore the impact of these hyperparameter choices through ablation studies in Section 4.

3.3 Distribution Matching

The classification problems involved in training transcription models are heavily imbalanced because the labels typically have only a few non-zero entries. For example, the training set of the MAPS dataset [15] has labels, where only about 0.3% of all entries are ones for both onsets and offsets, and about 3.4% of all entries are ones for frame activity. Hence, the transcription model may be biased towards predicting zeros. To avoid model collapse, we apply distribution matching to the pseudo-labels.

In this paper, we employ a simple method to match the marginal pseudo-label distribution per mini-batch with that of the reference labels. The marginal distribution of the reference labels is estimated by counting zeros and ones across all training examples. These counting operations are denoted by Γ_0 and Γ_1 . The following distribution matching method, explained using frame activity as an example, is similarly applied to onsets and offsets.

During training, we count the numbers of zeros and ones for every mini-batch of pseudo-labels, and will likely obtain a ratio $\Gamma_1(\tilde{\mathbf{I}}_{fr}^U)/\Gamma_0(\tilde{\mathbf{I}}_{fr}^U)$ that differs from the desired ratio $\Gamma_1(\mathbf{I}_{fr}^L)/\Gamma_0(\mathbf{I}_{fr}^L)$. The objective of the distribution matching operator, denoted by Δ , is to ensure that the ratio of zeros and ones is identical for reference labels and pseudo-labels, i. e.,

$$\frac{\Gamma_1(\mathbf{I}_{fr}^L)}{\Gamma_0(\mathbf{I}_{fr}^L)} = \frac{\Gamma_1(\Delta(\tilde{\mathbf{I}}_{fr}^U))}{\Gamma_0(\Delta(\tilde{\mathbf{I}}_{fr}^U))}. \quad (8)$$

Table 1: Performance metrics in percentages evaluated on the test sets of MAPS (ENSTDkAm and ENSTDkCl) and MAESTRO, and on the entire SMD dataset. Performance metrics are calculated per piece and then averaged over all pieces in the respective sets. As for the transcription models, RV is ReconVAT [19], OF is Onsets and Frames [16], OF-SS4 is our proposed semi-supervised method, and MB stands for Maman and Bermano [11]. Decision thresholds of OF and OF-SS4 are tuned using the group S_{ptkBGAm} of the MAPS dataset. F1 scores are highlighted in red for better readability.

To define Δ , we use undersampling as it is frequently used for class-imbalanced learning [46]. The distribution matching works as follows:

1. Determine whether the ratio $\Gamma_1(\tilde{\mathbf{I}}_{\text{fr}}^{\text{U}})/\Gamma_0(\tilde{\mathbf{I}}_{\text{fr}}^{\text{U}})$ is smaller or larger than the ratio $\Gamma_1(\mathbf{I}_{\text{on}}^{\text{L}})/\Gamma_0(\mathbf{I}_{\text{on}}^{\text{L}})$, i. e., whether there is an excess of zeros or ones, respectively, among the pseudo-labels.
2. Randomly select the required number of excess zeros or ones and convert them to NaN entries to obtain the desired ratio.

Distribution matching reduces the number of available pseudo-labels but ensures that the pseudo-labels within a mini-batch follow the same marginal distribution as the reference labels. An example of distribution-matched pseudo-labels is shown in Figure 2f.

4. EXPERIMENTS

4.1 Implementation Details

For our experiments, we use an open-source Pytorch implementation² of Onsets and Frames [7, 16]. Input representation and model architecture are unchanged compared to [7]. However, we do not ensure that input segments do not start in the middle of a note as it is done in [7]. We use a batch size of 8 each for labeled and unlabeled data and average losses across batches. We train our models using the Adam optimizer [47] with an initial learning rate of $6e-5$ and multiply the learning rate by a factor of 0.98 every 5k iterations. Also, we apply gradient clipping with norm 3. All audio recordings were downsampled to 16 kHz.

4.2 Datasets

We train and evaluate our models on three piano datasets: MAPS [15], MAESTRO V3.0.0 [16], and SMD [17].

² <https://github.com/jongwook/onsets-and-frames>

MAPS [15] contains isolated notes, chords, and complete piano pieces, but we only make use of the complete pieces. This dataset contains nine groups with 30 recordings each, where seven of the groups contain synthesized recordings, and the remaining two groups (ENSTDkAm and ENSTDkCl) contain real recordings which were automatically generated from MIDI files using a Disklavier. Following previous work [6, 7, 19], we use the groups with synthetic data as training data, and the real recordings as test data, and we remove the pieces from the training data which are also contained in the test data. This yields training and test sets of 139 and 60 recordings, respectively.

MAESTRO [16] and SMD [17] provide recordings together with the corresponding MIDI annotations automatically captured by a Disklavier. Both MAESTRO and SMD contain actual recordings of live performances, from the International Piano-e-Competition and played by music students, respectively. MAESTRO comprises 1276 performances, with the official data split assigning 962, 137, and 177 performances to the training, validation, and test set, respectively, and SMD comprises 50 performances.

4.3 Evaluation and Threshold Tuning

During inference, a decoding step is performed to obtain estimated note events from the network outputs [7, 16]. Two thresholds, τ_{on} and τ_{fr} , are applied to binarize onset and frame activity predictions. A note event is only recognized if an onset was detected, and the length of the note is determined based on the frame activity prediction. The offset prediction is not explicitly used during decoding.

Following existing literature, we evaluate model performance using note-based and frame-based metrics including precision (P), recall (R), and F1 score. Note-based metrics are computed using the *mir_eval* library [48], where a predicted note is considered as correct if its pitch matches that of a reference note and the onset is within ± 50 ms of that reference note’s onset.

Instead of using fixed thresholds τ_{on} and τ_{fr} , we tune these thresholds using a labeled validation set [27, 49]. We first determine an optimum τ_{on} via grid search so as to maximize the note F1 score, which does not depend on τ_{fr} . Since the frame-based metrics are computed based on the decoded note events, the frame F1 score is affected by both τ_{on} and τ_{fr} . We fix the previously found τ_{on} and determine the τ_{fr} that maximizes the frame F1 score.

4.4 Experimental Scenarios

To compare with [19], we adopt their three experimental scenarios which differ in the choice of the labeled data. The first scenario (*Full*) uses the full MAPS training set, the second scenario (*Small*) uses only the group `AkPnBcht` of the MAPS training set, which contains 23 non-overlapping piano pieces, and the third scenario (*One-Shot*) uses only a single recording (`chp_op31` from `AkPnBcht`) as labeled data. Note that for *One-Shot*, the batch size for labeled data needs to be reduced to 1. In all scenarios, the MAESTRO training set is used as unlabeled data. We use the group `SptkBGAm` of the MAPS training set as validation data—which overlaps with the labeled training data in the *Full* scenario.

In all scenarios, we start training the transcription model from scratch following the training strategy described in Section 3.1 for 50k iterations, using only the labeled data and supervised learning. After that pre-training stage, we train for another 50k iterations using our proposed semi-supervised method as described in Section 3.2. We refer to this model as `OF-SS4`. For a fair supervised baseline in each scenario, we also continue training the pre-trained model for another 50k iterations on only the labeled data, which we will refer to as `OF`.

4.5 Main Results

The main results of our experiments are provided in Table 1, where the models of all scenarios are evaluated on the test sets of MAPS and MAESTRO, and also on the independent SMD dataset. First, we can observe that `OF-SS4` achieves better F1 scores than `OF` almost in all scenarios and across all datasets, with the frame F1 score in the *One-Shot* scenario being the exception. Most notably, `OF-SS4` achieves a note F1 score of 85.0 on the MAESTRO test set in the scenario *Small*, which slightly exceeds the note F1 score 84.2 of `OF` in the scenario *Full*. This shows that our semi-supervised approach is indeed effective, reducing the number of labeled performances by more than 80% for achieving comparable performance in this case. We further note that the optimum decision thresholds of `OF` and `OF-SS4` are extremely low for the scenarios *Small* and *One-Shot*, indicating that threshold tuning is an important step if labeled training data is scarce.

For ReconVAT (RV) [19], we report for every scenario the performance of their semi-supervised method that achieved the highest note F1 score. Still, we observe that `OF-SS4` achieves higher note F1 scores than RV in all scenarios, e. g., 76.7 for `OF-SS4` compared to 68.2 for RV in the scenario *Small*. Regarding the frame F1 score, no clear

	τ_{lo}	τ_{up}	\mathcal{A}	Δ	λ_{off}^U	λ_u	N-F1	F-F1
<code>OF</code>	-	-	-	-	-	-	73.0	51.1
<code>OF-SS1</code>	0.05	0.95	-	-	0.0	0.05	0.1	3.0
<code>OF-SS2</code>	0.05	0.95	-	✓	0.0	0.05	82.4	9.4
<code>OF-SS3</code>	0.05	0.95	✓	-	0.0	0.05	82.7	57.6
<code>OF-SS4</code>	0.05	0.95	✓	✓	0.0	0.05	85.9	58.2
<code>OF-SS5</code>	0.25	0.75	✓	✓	0.0	0.05	74.6	51.6
<code>OF-SS6</code>	0.05	0.95	✓	✓	1.0	0.05	85.6	56.3
<code>OF-SS7</code>	0.05	0.95	✓	✓	0.0	0.01	72.8	51.5

Table 2: Results of an ablation study performed in the scenario *Small*, evaluated on the independent SMD dataset [17]. N-F1 and F-F1 are note F1 score and frame F1 score in percentage, respectively.

trend can be observed, with `OF-SS4` achieving a higher value for *Small*, but lower values for *Full* and *One-Shot*.

As another reference, we include the weakly-supervised method by Maman and Bermano (MB) [11], which also relies on the Onsets and Frames transcription model [7, 16] but benefits from training on much more data and across various instrumentations. Our method does not reach the performance of MB in any scenario, but the performance gap is reasonably small given the difference in amount of training data, e. g., a note F1 score of 85.0 for `OF-SS4` in scenario *Small* compared to 89.7 for MB on MAESTRO.

4.6 Ablation Study

We perform an ablation study to evaluate the efficacy of the individual components of our semi-supervised method. The results of this study are shown in Table 2. The method `OF-SS1` performs pseudo-labeling without consistency regularization and distribution matching, where the performance metrics indicate potential model collapse. Better results are achieved when additionally using either distribution matching (`OF-SS2`) or consistency regularization (`OF-SS3`), achieving already better note F1 scores than the supervised baseline `OF`. The performance is further improved by combining both techniques, which results in our proposed method `OF-SS4`. The remaining ablations change the hyperparameter setting of our method, where less restrictive thresholds for selecting pseudo-labels (`OF-SS5`), calculating the unsupervised loss also for offsets (`OF-SS6`), or a reduced overall weight of the unsupervised loss (`OF-SS7`) yield worse results.

5. CONCLUSION

In this paper, we successfully transferred SSL techniques from CV to the MIR domain. More specifically, we applied pseudo-labeling, consistency regularization, and distribution matching for the task of APT, enabling the option to leverage unlabeled data during training. Thereby, the dependence on large annotated datasets is considerably reduced. For instance, using our semi-supervised approach, we observed reductions in the required amount of labeled data by up to 80% for achieving similar performance as a purely supervised baseline.

In future work, we plan to investigate other augmentation strategies, e. g., musically meaningful augmentations as in [18], to perform consistency regularization, and the extension of the method to the multi-instrument setting.

NOTE-LEVEL TRANSCRIPTION OF CHORAL MUSIC

ABSTRACT

Choral music is a musical activity with one of the largest participant bases, yet it has drawn little attention from automatic music transcription research. The main reasons we argue are due to the lack of data and technical difficulties arise from diverse acoustic conditions and unique properties of choral singing. To address these challenges, in this paper we propose a Transformer-based framework for note-level transcription of choral music. This framework bypasses the frame-level processing and directly produces a sequence of notes with associated timestamps. We also introduce YouChorale, a novel choral music dataset in a cappella setting curated from the Internet. YouChorale contains 452 real-world recordings in diverse acoustic configurations of choral music from over 100 composers as well as their MIDI scores. Trained on YouChorale, our proposed model achieves state-of-the-art performance in choral music transcription, marking a significant advancement in the field.

1. INTRODUCTION

Choral singing stands as one of the most widely engaged forms of musical expression, uniting voices in harmony across cultures and communities. Despite its profound presence in the musical landscape, choral singing has notably been overlooked in the field of Automatic Music Transcription (AMT), a domain predominantly oriented towards instrumental music [1–3], leaving choral singing with scant attention and few dedicated studies [4, 5]. This oversight not only highlights a gap in AMT research but also underscores the potential for significant advancements in the transcription of choral music, an area waiting for exploration and innovation.

The transcription of choral music introduces unique challenges compared with its instrumental counterparts. One of the main characteristics of choral singing is the soft onset of notes and smooth transitions between notes, resulting in indistinct boundaries and complicating the determination of note onsets. Additionally, the complex acoustic environment enriches choral music performances with reverberation, further complicates transcrip-

tion efforts. These factors combined present a formidable challenge in accurately capturing the note occurrences in choral music recordings, necessitating novel approaches to AMT that can handle these specific challenges.

Recent methodologies in AMT fall primarily into two categories: Onsets and Frames [1], which estimates frame-level pitch activation informed by note onset predictions, and then combines such results to note estimates; and the use of models like MT3 [2], which conceptualize transcription as a token prediction task. However, both approaches exhibit limitations in addressing the soft onset characteristic of choral singing. Onset and frame detection methods heavily rely on the successful identification of note onsets, a task made difficult by the blurry beginning of vocal notes. Conversely, models like MT3 predict notes as a series of tokens, which can complicate the aggregation of information pertaining to individual notes, thereby obscuring the cohesive representation of choral music.

Another critical hurdle in advancing choral music transcription is the availability of comprehensive and high-quality datasets. Existing resources include the Dagstuhl ChoirSet [6], which offers less than one hour of high-quality recording of two pieces and a set of systematic exercises. The Erkomaishvili Dataset [7] provides around seven hours of recordings, but the sound quality is poor for model training. The Bach Chorale¹ and Barbershop Quartet² datasets provide tracked recordings, but the music genre is limited in these datasets. Also, they only involve a small group of singers and a fixed recording environment. This dearth of datasets impedes field progress and highlights the need for more robust and accessible resources for choral music transcription.

In response to these challenges, this paper proposes a novel note-level transcription architecture inspired by advancements in object detection and sound event detection. Instead of predicting the frame-level activation or separated MIDI-like events, this model directly decodes the pitch, onset, and duration from a hidden embedding of each note. To take care of the sequential relationships between the notes, we integrate the Transformer model as the backbone of our network, leveraging its proven efficacy in capturing long-term dependencies. Experiment results show that this model has largely improved the frame-level recall of the transcription output, indicating that the proposed model makes better use of the entire process of note articulation. The proposed model has also shown

¹ <https://www.pgmusic.com/bachchorales.htm>

² <http://www.pgmusic.com/barbershopquartet.htm>

robustness against the distortion caused by reverberation in the recordings. To address the critical gap in available resources, we have curated a comprehensive dataset for choral music transcription, comprising 496 real-world recordings across a diverse array of acoustic environments and featuring compositions from over 100 composers, accompanied by their corresponding MIDI scores. This dataset not only facilitates the development of our proposed model but also provides a valuable resource for future research in choral music transcription. Through this work, we aim to bridge the existing gap in AMT research, offering novel insights and methodologies that enhance our understanding and capabilities in transcribing choral music.

The structure of this paper is as follows: Section 2 covers the related works of this study; Section 3 describes the transcription architecture we proposed for the choral singing task; Section 4 introduces the YouChorale dataset, the experimental settings and the results; finally, Section 5 concludes the paper.

2. RELATED WORK

Automatic Music Transcription (AMT) has been a largely investigated task in Music Information Retrieval (MIR), and people have proposed various methods to address this problem. Onsets and Frames [1] represents the start of a group of methods that uses Convolutional Neural Networks (CNN) to extract the onset activation and frame activation in the spectrogram based on which a final note prediction output is aggregated through post-processing. Many other methods have inherited this idea, and several methods have been proposed for piano [8] and multi-instrument transcription [3, 9]. To fully use the activation detection and produce holistic transcription results, Yan et al. [10] proposed a neural semi-CRF-based method that predicts the best interval combinations of the frame-level estimations.

Another choice is to use sequence-to-sequence models that transcribe tokens describing different aspects of the notes, such as note-on and note-off events, velocity, and time stamps [11]. MT3 [2] expanded this method to multi-instrument transcription, and Simon et al. [12] further augmented the training data of such model by mixing monophonic recordings. There also exist methods that use generative diffusion models [13] to perform transcription. However, the performance of this method is still not comparable with other works.

For choral music transcription, Schramm et al. [4] proposed a spectrogram factorization method to transcribe a cappella performances. McLeod et al. [5] proposed using extended probabilistic latent component analysis and music language model to improve the performance further. There is also literature on score transcription of choral music [14], but they focus on producing the music score instead of the precise physical timing of each note in the recordings.

We can view automatic music transcription as a special form of sound event detection, which aims to identify the

note entities in the audio recordings. The strong timing correlations between the notes drive us to detection methods with sequential modeling abilities. Carion et al. [15] proposed an end-to-end object detection architecture with Transformers, which uses the Transformer encoder and decoder to attend to the input image to detect sound events and their corresponding bounding boxes. Such an idea is also adapted in sound event detection, represented by works from Kong et al. [16].

3. METHOD

We demonstrate the architecture of the model in Figure 1. The input mel-spectrogram first goes through a pre-filtering CNN network. After adding the positional encoding, two multi-head attention and feed-forward encoder layers further aggregate information in the spectrogram. The processed spectrogram then goes into the transformer decoder to auto-regressively generate an array of note embeddings. Finally, we employ three Multi-Layer Perceptron (MLP) modules as the feed-forward network to predict the MIDI pitch, onset time, and duration from the embedding of each note.

Inspired by the Transformer-based object detection methods and sound event detection methods, we regard the onset and offset as the “bounding box” of each note. Like pitch, they are the note’s built-in attributes. Since Transformer models are well-known for their capability of learning long-term dependencies, we here let the encoder and decoder layers fully take care of the aggregation of information of each note to achieve end-to-end music transcription.

The model’s input is a batch of segmented spectrograms with the shape of (B, L, M) , where B is the batch size, L is the length of the segment, and M is the number of frequency bins. The model’s output is three parallel arrays of pitch, onset time, and duration, with the shapes of (B, N, K) , $(B, N, 1)$, $(B, N, 1)$, respectively. N is the length of the transcribed note sequence, and K is the number of possible pitch entries. To ensure the one-dimensional note sequence is unique for a polyphonic score, we serialize the notes first in chronological order from earliest to latest and second in pitch order from highest to lowest.

3.1 CNN Preprocessing

We use two layers of the 1D-Convolutional Neural Network (CNN) to preprocess the input mel-spectrogram. The network has a kernel size of 9 and is activated with the ReLU function, creating a receptive field of around 300 ms at each output frame. After the CNN, the shape of the output is (B, L, C) , where C is the size of the hidden dimension. Then, we add the output with positional encoding and feed it into the encoder layers.

3.2 Encoder and Decoder Layers

We inherit the encoder and decoder design in the original Transformer [17], which includes multi-head attention

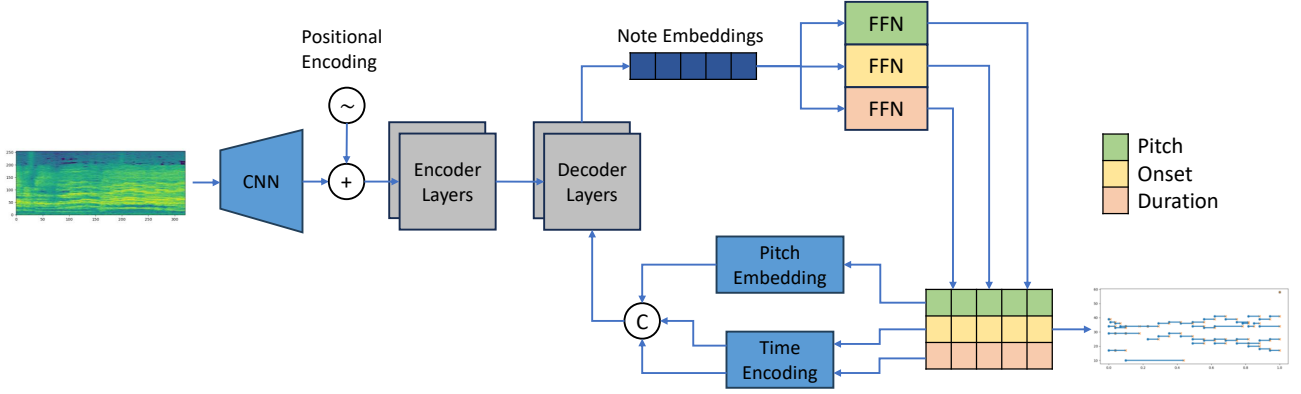

Figure 1. The overall architecture of the transcription model.

blocks and feed-forward layers. The encoder is conducting self-attention with the CNN-processed spectrogram; the decoder also attends to the output of the encoder after a self-attention layer. In our model, we use two layers of encoder layers and decoder layers.

During inference, the decoder performs auto-regressive decoding of the final note sequence. In model implementation, we normalize the time within one segment to $[0, 1]$ and calculate the onset time t_o and duration t_d accordingly to reduce the difficulties in training.

3.3 Positional Encoding

After the mel-spectrogram goes through the CNN filter banks, it will be added to a positional encoding to let the encoder layers learn the sequential relationship between the frames. For the positional encoding before the encoder layers, we adopt the original design in Transformer [17]. Given the frame from the processed spectrogram at pos out of the L possible positions and denote the dimensionality of the Transformer as d_{model} , we define the positional encoding PE at the $2i$ and $2i + 1$ dimension as

$$PE_{(pos,2i)} = \sin(pos/10000^{2i/d_{model}}), \quad (1)$$

$$PE_{(pos,2i+1)} = \cos(pos/10000^{2i/d_{model}}). \quad (2)$$

When we encode the continuous onset time and duration as the input of the decoder layers, we would like to align the decoder time encoding with the encoder’s positional encoding. An onset time at t_o will have the time embedding TE identical to the PE of the corresponding frame position:

$$TE_{(t_o,i)} = PE_{(t_o \times L, i)}. \quad (3)$$

Similarly, the duration of the note t_d is encoded with the same equation, replacing t_o with t_d in Equation (3). In this way, we can align the time in the spectrogram and the onset prediction of the model, which will help the model better find the relationship between the frames in the spectrogram and the time in the final transcription result. After we get the pitch embeddings and time encodings of the previously generated notes, we concatenate them together and send them into the decoder layers.

Figure 2. A demonstration of DIoU calculation.

3.4 Training Objectives

We optimize the loss of pitch estimation and timing estimation. For pitch estimation, we use the cross entropy loss \mathcal{L}_p . For time estimation, we first apply the L1 loss:

$$\mathcal{L}_{time} = \sum_{i=1}^N \|\hat{t}_o^{(i)} - t_o^{(i)}\|_1 + \sum_{i=1}^N \|\hat{t}_d^{(i)} - t_d^{(i)}\|_1, \quad (4)$$

where t_o is the ground-truth onset time, \hat{t}_o is the predicted onset time; t_d is the ground-truth duration, \hat{t}_d is the predicted duration.

We also adapt the DIoU (Distance-IoU, Intersection over Union) loss [18] from object detection to 1D scenario, as in Figure 2:

$$\mathcal{L}_{DIoU} = 1 - IoU + \frac{d^2}{C^2}. \quad (5)$$

Here, IoU is the ratio between the intersection and the union of the predicted time span and the ground-truth time span; d is the distance between the center of the prediction and the ground truth time span to add more penalties to the far away predictions; C is the length of the minimum bounding box that can cover both prediction and ground truth. Note that when there is an overlap between prediction and ground truth, $union = C$; when there is no overlapping between them, $IoU = 0$, we define union as the summation of the length of the two segments.

In the experiments, we trained two models with \mathcal{L}_{time} and \mathcal{L}_{DIoU} respectively and tested their performances.

	Singers in Each Part		Reverberation Time			Number of Parts

4. EXPERIMENT

In this section, we describe experiments that evaluate our models against baselines.

4.1 YouChorale Dataset

In an effort to address the scarcity of resources for choral music transcription, we curated a dataset, YouChorale, from YouTube and a variety of MIDI archive sources^{3 4 5}, focusing exclusively on a cappella choral singing. With a total length of 22 hours 25 minutes, the YouChorale dataset contains 452 recordings of 261 compositions from 118 composers, representing a wide range of historical periods, styles, and complexities inherent to choral music. We have made the dataset publicly available at <https://github.com/ella-granger/YouChorale>, enriching a comprehensive resource of choral music for further exploration and development in the field of Automatic Music Transcription (AMT).

We split the dataset into train, validation and test set by the ratio of 392:30:30. To ensure the intonation of the evaluation recordings, we only selected performances by well-known choirs into the validation and the test sets. The detailed statistics of the dataset are shown in Table 1. The metric “singers in each part” indicates whether the performance is from a small a cappella group (less than or equals to three singers per part) or a larger ensemble (more than three singers per part). “Reverberation time” is an indication of the acoustic environment and how the signal is blurred or distorted. “Number of parts” indicates the complexity of the piece. Most of the pieces contain four to six parts, for example SATB or SSATTB, but there are also extreme cases where over nine parts appear in one composition.

We are also providing an aligned version of MIDI file along with the recordings. The alignment is achieved through the following steps: First, we adjust the key signature of the MIDI files to match the recording. Next, we render the waveform of the MIDI notation and align the Constant-Q Transform [19] feature of the synthesized audio and the performance recording by the soft-DTW algorithm [20]. Finally, we smooth the alignment curve to remove abrupt tempo changes in the aligned MIDI.

⁵ <http://www.maennerchor-sg.ch/midi/>

4.2 BachChorale Dataset

The accurately labeled BachChorale dataset also serves as a benchmark for evaluating the transcription performance of our model and the baselines. This two-volume dataset contains 53 four-part choral compositions by J.S. Bach, with a total length of two hours. Note that during the collection of YouChorale, all the Bach pieces we found are accompanied by organ or orchestra. Therefore, we excluded Bach pieces to keep the dataset in a cappella settings, which also means that using BachChorale as a test dataset does not introduce label leakage.

4.3 Training Settings

For the training data, we downsampled the audio to 16 kHz, and extracted the mel-spectrogram with $N_{FFT} = 2048$, hop length = 256, and number of frequency bins $M = 256$. The length of each segment $L = 320$, which corresponds to 5.12 seconds of audio. The hidden dimension of the model $C = 256$. During training, we set the batch size = 8, and use an Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. The warmup step is set to 12000. We use teacher forcing during the training phase, which provides the ground truth notes as the context and lets the model predict only the next note. We have released our code at <https://github.com/ella-granger/NoteTranscription>.

4.4 Results

We choose Schramm et al. [4], Onsets and Frames [1] and MT3 [2] as our baselines. For Schramm et al. [4], we list their reported frame-level multi-pitch estimation result which was also evaluated on the BachChorale dataset. For Onsets and Frames, we train a new model with the YouChorale training set from scratch; for MT3, we use the provided multi-instrument checkpoint. For the Onsets and Frames, MT3, and the proposed model, we evaluate the transcription result after they produce the final MIDI notes output.

We evaluated the frame-level activation detection and the note onset detection with a tolerance of 50 ms and 100 ms, respectively. The results on the BachChorale dataset are shown in Table 2, and the results on the YouChorale test set are shown in Table 3. We can see that compared with Onsets and Frames or MT3, our proposed model has a more balanced performance on precision and recall at the frame level, and produces the highest f1 score among the

Model	Frame			Onset (50ms)			Onset (100ms)

Proposed- \mathcal{L}_{time}	0.518	0.518	0.518	-0.121 (-18.9%)	0.089	0.180	0.114	-0.069 (-37.7%)

Table 4. Model performance under reverb distortion on BachChorale dataset.

deep learning methods. Although the Onsets and Frames model still reaches a higher precision value on the onset time of the note, the significantly higher recall of our model at the frame level indicates that it places greater emphasis on the entire process of note articulation, not just the onset and offset of the notes, which achieves our goal with holistic note transcription. The deep-learning methods still have some room for improvement towards Schramm et al. [4] on the BachChorale dataset, however, since the dataset only have one singer for each part, Schramm et al. might have some advantage as it was trained on solo singing.

We would also like to compare the performance of the two loss function \mathcal{L}_{time} and \mathcal{L}_{DIOU} . From the results we can see that the \mathcal{L}_{time} trained model tends to have high precision and low recall at frame level and low precision and high recall on note onsets, while the \mathcal{L}_{DIOU} trained model has the opposite behavior. It indicates that the \mathcal{L}_{time} trained model usually extracts shorter fragments of the notes and the \mathcal{L}_{DIOU} trained model longer full notes. This is due to the property of the two loss functions: The L_1 based time loss function focuses more on the absolute distance between the boundary of the predicted notes and the ground-truth notes, while the L_{DIOU} based loss function puts more emphasis on the overall intersection of the prediction and ground truth, and will have the boundaries not as precise as the L_1 loss.

4.5 Performance Under Reverb Distortion

In real-world choral music performances, reverberation is an unignorable part of acoustic effects. For example, concert halls create reverb with a long reberveration time, which introduces distortions into the spectrogram. To evaluate the resilience of our model against common distortions encountered in live settings, we apply an artificial reverb⁶ to our test set to simulate the complex acoustic environmental characteristic of real-world choral performances. The performance of each model is shown in Table 4. The findings indicate that our proposed model still holds a relatively high performance, and the proposed model together with Onset and Frames trained on the YouChorale dataset, retains some ability to predict onset timing while the MT3 model nearly failed to predict any reasonable onset of the notes. This resilience highlights the importance of incorporating diverse, real-world data in training AMT models, ensuring their applicability and effectiveness in practical, everyday transcription scenarios.

Through cautious dataset curation and strategic model design, the experiments have shown our proposed model’s capabilities in the realm of choral music transcription. By directly addressing the nuanced challenges of this genre,

⁶ <https://ccrma.stanford.edu/jos/pasp/Freeverb.html>. The roomsize is set to one.

Figure 3. The precision/recall v.s. threshold curves of frame-level and note-level (onset) transcription from Onsets and Frames.

from soft note onsets to complex acoustic environments, we not only advance the state of AMT but also pave the way for future innovations in the transcription of polyphonic vocal music.

4.6 Limitations of Onsets and Frames Model

If we take a closer look at the result in Table 5, we may find that for Onsets and Frames model, there is a big gap between the frame-level precision and recall. After extracting the frame activation before post-processing and calculating its objectives, we get the result in Table 5. We can see that although post-processing improves prediction precision, it discards a large amount of true-positive frame activations.

Since the Onsets and Frames model will not transcribe any new note until it finds a new onset, the model’s capability of correctly predicting the onset significantly affects the overall performance. Figure 3 shows the precision and recall curve of frame and onset prediction with respect to

Model	Precision	Recall	F1
Onsets and Frames [1]	0.851	0.267	0.400
O&F (frame activation)	0.801	0.632	0.704

Table 5. Comparison between the final transcription result and frame-level activation of Onsets and Frames on Bach-Chorale dataset.

the onset decision threshold. The curves are unbalanced, and the reported result in Table 2 is at the threshold value of 0.05, which means we almost extract all the possible onsets as long as there is a trace amount of activation. All the evidence shows that the limitation of putting too much attention to onsets becomes especially pronounced in the context of choral music, where soft onsets and smooth transitions are prevalent. Instead, we should leverage the information contained in the frame activation and view each note as a whole, and let the model decide where to locate the notes, which is the design principle of our proposed method.

5. CONCLUSIONS

We proposed a novel transcription model architecture for choral music, which conducts holistic note transcription, addressing the soft onset and complex acoustic environment issues. We also introduced a newly curated a cappella dataset for the development of automatic music transcription. Tested on the BachChorale dataset, our model has shown competent performance on the choral music transcription task, particularly in its robustness against reverb. By addressing the noted limitations of existing models and contributing a valuable dataset to the research community, our work paves the way for future innovations in AMT, enhancing the accessibility and understanding of choral music through technology.

The next step of this work would be to distinguish and stream different parts in choral singing, and explore the potential of model architecture to general music transcription tasks.

ABSTRACT

This paper describes a deep learning method for music structure analysis (MSA) that aims to split a music signal into temporal segments and assign a function label (e.g., intro, verse, or chorus) to each segment. The computational base for MSA is a spectro-temporal representation of input audio such as the spectrogram, where the compositional relationships of the spectral components provide valuable clues (e.g., chords) to the identification of structural units. However, such implicit features might be vulnerable to local operations such as convolution and pooling operations. In this paper, we hypothesize that the self-attention over the spectral domain as well as the temporal domain plays a key role in tackling MSA. Based on this hypothesis, we propose a novel MSA model built on the Transformer-in-Transformer architecture that alternately stacks spectral and temporal self-attention layers. Experiments with the Beatles, RWC, and SALAMI datasets showed the superiority of the dual-aspect self-attention. In particular, the differentiation between spectral and temporal self-attentions can provide extra performance gain. By analyzing the attention maps, we also demonstrate that self-attention can unfold tonal relationships and the internal structure of music.

1. INTRODUCTION

Music structure refers to the sequential arrangement of musically coherent units that form a musical work. Music structure analysis (MSA) calls for a comprehensive understanding of various musical elements such as rhythm, melody, and harmony, and has still been an open problem in the field of music information retrieval (MIR), partly due to its multifaceted and ill-defined nature [1].

There are two major ways of representing music structure. The *semiotic* representation [2] uses a set of arbitrary symbols (e.g., A-B-C-B-C) for revealing the relationships between segments within a musical piece. The *functional*

(a) Chromagram representing a chorus section

(b) Multifaceted spectral self-attention maps over time

(c) Multi-scale temporal self-attention maps

Figure 1: Non-local dependencies of music such as chord tones and repeated patterns can be captured with spectral and temporal self-attention mechanisms. (a) The chromagram shows that this musical excerpt is dominated by the C major chord. (b) The spectral attention maps show that pitch classes C, E, and G persistently draw attention while the chroma features vary over time. (c) The temporal attention maps delineate the internal structures of this excerpt.

representation uses a set of semantic labels (e.g., intro-verse-chorus-verse-chorus) for indicating the roles of individual units. The functional representation can be converted into the semiotic one, but not vice versa.

A common deep learning approach to MSA involves using a convolutional neural network (CNN) to extract latent features from a spectro-temporal representation of input audio, such as a mel spectrogram or chromagram [3–5]. The assumption underlying this approach is the time-frequency locality of musical features, which should be treated with caution when characterizing the global structure of music. Actually, musical elements have non-local dependencies. Chords consist of musical sounds that are widely distributed over frequency. Musical patterns such as chord progressions or musical phrases are commonly repeated over time. Such non-local time-frequency dependencies can hardly be captured by a CNN that ag-

gregates local features while reducing the time-frequency dimensions with pooling operations [6, 7].

One promising architecture for learning non-local dependencies in a music recording is the SpecTNT [8], a variant of the Transformer-in-Transformer (TNT) [9] for modeling spectrogram-like representations. The SpecTNT iterates feature transforms of the multi-head self-attention (MHSA) mechanism [10] alternately along the spectral and temporal axes while keeping the time-frequency dimensions of input features. This method, however, suffers from a potential performance limitation because the individual characteristics of spectral and temporal dimensions are indistinguishable to the MHSA.

To overcome this limitation, we propose to integrate specialized MHSA mechanisms into the SpecTNT architecture for the MSA task regarding the functional representation. As outlined in Figure 1, our method involves gathering spectral and temporal information alternately from an input spectro-temporal representation with two types of MHSA mechanisms. The *spectral self-attention* extracts compositional relationships among two types of spectral features at each time step. The *temporal self-attention* aggregates spectral information at multiple time scales. The proposed method is systematically evaluated with three corpora consisting of popular music. In addition, the attention maps are analyzed to advocate paying attention to the non-locality of musical features.

The main contribution of this work is to emphasize the non-local dependencies of music over frequency as well as that over time. While non-local temporal correlations have been extensively studied, spectral non-locality remains underrepresented. In this concern, we adapt MHSA mechanisms to both aspects and analyze the self-attention maps to elaborate on the non-locality of musical features. This work may draw attention to such delicate characteristics that could be crucial for various tasks in MIR.

2. RELATED WORK

Segmentation and labeling are two subtasks of MSA [11]. The former detects the boundaries of structural units, and the latter categorizes musical segments either by the relationships with the semiotic representation or by the structural roles with the functional representation.

For the segmentation task, a spectro-temporal representation or a sequence of higher-level features extracted by a CNN is typically used to compute a novelty curve [12–16], from which musical boundaries are retrieved with a peak-picking algorithm [17, 18]. A key feature of our method is that we employ CNNs without any pooling layers for feature extraction. Since adjacent spectral beams are irrelevant in the sense of music, naive local pooling would hinder the learning of spectral patterns.

For the labeling task, the similarity-based approach is commonly taken in support of the semiotic representation of music structure [19–24], yet deep learning classification frameworks have recently been introduced for the estimation of structural functions [25, 26]. For both scenarios, the segmentation of an input piece will be a byprod-

uct of the labeling task. However, a smoothing method is typically required to refine the fragmented segmentation results caused by unusual label changes. Our method performs joint estimation of functional labels and musical boundaries to alleviate the fragmentation issue.

MHSA-based methods have recently been proposed for MSA owing to the excellent representation capability. The SpecTNT for MSA [27] uses Transformer encoders to capture the dependencies between the two axes of an input spectro-temporal representation. For training the SpecTNT with an increased amount of data, structure annotations from multiple datasets are mapped to the same semantic space with a 7-class taxonomy (‘intro’, ‘verse’, ‘chorus’, ‘bridge’, ‘inst’, ‘outro’, and ‘silence’). While the spectral components are often used for temporal modeling or collapsed before temporal modeling, this is the first attempt in the MSA task to retain the spectral dimension. In contrast, the convolution-augmented MHSA (CAMHSA) mechanism [28] captures temporal self-similarities on the self-attention maps derived from multiple types of acoustic features for capturing the repetitive nature of music. These network designs impose inductive biases that can enhance the representation learning.

Given the complementary aspects of these techniques, we integrate specialized MHSA mechanisms into the SpecTNT architecture for better modeling non-local features in spectral and temporal dimensions. Compared with the original CAMHSA [28], we retain the spectral dimension of the input data and aim to estimate the functional structure instead of the semiotic one, because the functional description conveys generic attributes of structural units that are comprehensible to the public. Compared with the original SpecTNT [27], we deal with spectro-temporal characteristics of music and processes input data at the track level rather than at the chunk (or segment) level, because the functional role of a structural unit might depend on the global organization of a musical piece.

3. PROPOSED METHOD

We tackle the functional MSA task with the 7-class taxonomy [27]. The estimation of the functional structure is formulated as a sequence labeling problem. Given a spectro-temporal representation, $\mathbf{X} \in \mathbb{R}^{T \times S}$, with S spectral components and T time steps, the goal of the estimation task is to output a sequence of categorical labels, $\mathbf{C} \in \mathbb{R}^T$, indicating the structural function of each time step $t \in T$. In practice, an extra binary sequence, $\mathbf{B} \in \{0, 1\}^T$, which specifies whether t is a boundary, is generated for smoothing the estimated labels within a segment surrounded by two boundaries. As depicted in Figure 2a, our model consists of three parts: a CNN-based frontend, L stacks of spectral and temporal encoders, and output layers in charge of the predictions of \mathbf{B} and \mathbf{C} respectively (in this paper, we use $L=2$ stacks for experiments).¹

¹The source code is available at <https://github.com/Tsung-Ping/music-structure-analysis>.

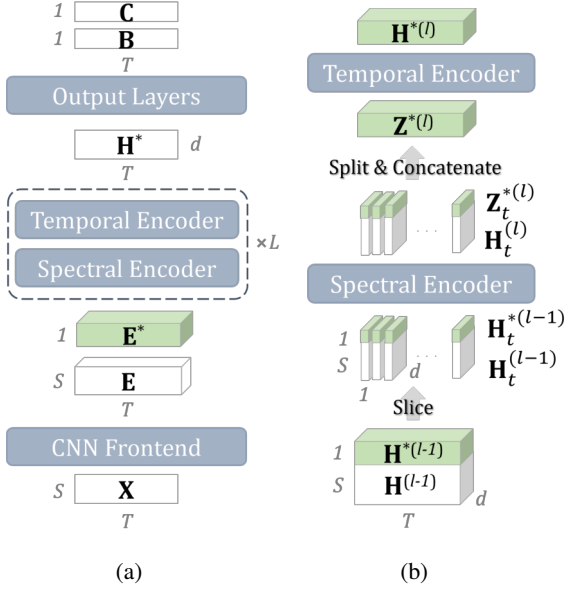

Figure 2: (a) Model architecture. Extra spectral components \mathbf{E}^* are stacked on the frontend output \mathbf{E} before the encoder blocks. (b) Schematic diagram of the spectral and temporal encodings, where the initial input $\mathbf{H}^{(0)} = \mathbf{E}$, $\mathbf{H}^{*(0)} = \mathbf{E}^*$, and the final output $\mathbf{H}^{*(L)} = \mathbf{H}^*$. The spectral encoder represents the time slices ($[\mathbf{H}_t^*; \mathbf{H}_t]$) separately, and then the temporal encoder aggregates the extra components (\mathbf{Z}_t^*) and outputs a representation.

3.1 CNN Frontend

The frontend is composed of an initial stem with two 2-D convolutional layers followed by a residual block [29]. Let f_c denote a convolutional layer with d filters parameterized by θ . The outputs of the stem and the residual block, denoted by $\{\mathbf{X}', \mathbf{E}\} \in \mathbb{R}^{T \times S \times d}$, are computed as follows:

$$\mathbf{E} = f_c(f_c(\mathbf{X}', \theta_3), \theta_4) + \mathbf{X}', \quad (1)$$

$$\mathbf{X}' = f_c(f_c(\mathbf{X}, \theta_1), \theta_2). \quad (2)$$

In effect, two frontends are employed to leverage different types of acoustic features. The two networks take as input the mel spectrogram ($\mathbf{X}_1 \in \mathbb{R}^{T \times S_1}$) and the chromagram ($\mathbf{X}_2 \in \mathbb{R}^{T \times S_2}$) respectively, and output $\mathbf{E}_1 \in \mathbb{R}^{T \times S_1 \times d}$ and $\mathbf{E}_2 \in \mathbb{R}^{T \times S_2 \times d}$. A unified representation is then obtained by concatenating the two outputs along the spectral dimension, i.e., $\mathbf{E} \in \mathbb{R}^{T \times (S_1+S_2) \times d}$. We set $S_1 = 80$, $S_2 = 12$, and $d = 80$ for this work.

Note that adjacent pitch classes are irrelevant in the traditional sense of musical harmony, and we thus design the frontend for the chromagram carefully. Specifically, we concatenate \mathbf{X}_2 and the first 11 columns of \mathbf{X}_2 along the pitch-class axis, i.e., $\hat{\mathbf{X}}_2 = \text{concat}(\mathbf{X}_2, \mathbf{X}_2[:, 1:11])$, and use convolutional layers with kernels that enclose the 12 pitch classes at once. This manipulation enables the CNN to capture key (or tonic)-independent patterns.

3.2 Spectral and Temporal Encoders

The spectral and temporal encoders are both built upon the Transformer encoder [10] that comprises stacks of MHSA

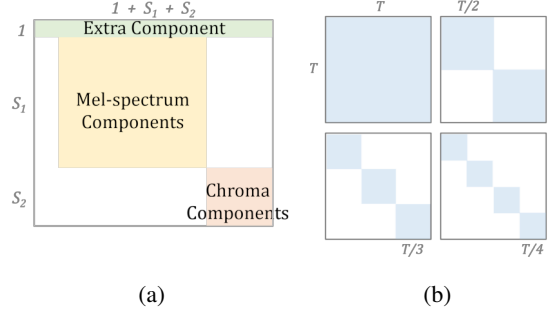

Figure 3: Attention masks for (a) the spectral MHSA and (b) the temporal MHSA. The rows (resp. columns) indicate queries (resp. keys) of the MHSA mechanism. Attention scores outside the colored regions will be filtered out.

blocks and feed-forward networks. Motivated by [28], we replace the standard MHSA of the temporal encoder with the CAMHSA mechanism. Moreover, we leverage relative position encodings [30] for enabling the model to process audio tracks of variable length.

As illustrated in Figure 2b, the two encoders in a stack are sequentially applied to the output of the previous stack. Let $\mathbf{E}_t \in \mathbb{R}^{S \times d}$ denote a time slice of \mathbf{E} at t , and $\mathbf{E}_t^* \in \mathbb{R}^{1 \times d}$ a learnable vector that behaves as an extra spectral component. The spectral encoder (SE) jointly extracts latent features $\mathbf{Z}_t^* \in \mathbb{R}^{1 \times d}$ and $\mathbf{H}_t \in \mathbb{R}^{S \times d}$ from \mathbf{E}_t^* and \mathbf{E}_t . Then, the temporal encoder (TE) exchanges information of \mathbf{Z}_t^* across time as follows:

$$\mathbf{H}^* = [\mathbf{H}_1^{*(L)}; \dots; \mathbf{H}_T^{*(L)}], \quad (3)$$

$$[\mathbf{H}_1^{*(l)}; \dots; \mathbf{H}_T^{*(l)}] = \text{TE}([\mathbf{Z}_1^{*(l)}; \dots; \mathbf{Z}_T^{*(l)}]), \quad (4)$$

$$[\mathbf{Z}_t^{*(l)}; \mathbf{H}_t^{(l)}] = \text{SE}([\mathbf{H}_t^{*(l-1)}; \mathbf{H}_t^{(l-1)}]), \quad (5)$$

where $\mathbf{H}^* \in \mathbb{R}^{T \times d}$ is the final output of the temporal encoder, $[\cdot; \cdot]$ denotes concatenation along the first dimension, l is the index of the stack, $\mathbf{H}_t^{*(0)} = \mathbf{E}_t^*$, and $\mathbf{H}_t^{(0)} = \mathbf{E}_t$. The extra spectral component \mathbf{H}_t^* in each stack mimics the initial CLS token introduced in the BERT model [31] and is used to encapsulate spectral information at each time step. For a detailed description of the intertwined architecture, we refer the readers to [8].

To use the SE and TE for modeling spectral and temporal dependencies, we impose constraints on the attention maps of the MHSA block, as shown in Figure 3. For the SE, the attention between the two types of spectra (i.e., mel spectrum and the chroma features) and the attention on the extra component are masked out because such attentions would likely result in *diluted* representations [32]. While the between-type attentions are prohibited, their relations can be extracted via the extra component. For the TE, contextual information is aggregated simultaneously at four time scales (i.e., T , $T/2$, $T/3$, and $T/4$) in a *structure-aware* manner. Take the scale $T/2$ as an example, a time step $t < T/2$ can only attend the first half of the time axis. Considering that binary and ternary forms are common structures in Western music, such location-related information is expected to enhance the learning of music structure.

We leverage the multi-head nature of the MHSA block for simultaneous multi-scale attention.

3.3 Output Layers and Inference

The output layers consist of a three-layer fully connected neural network and take \mathbf{H}^* as input to estimate the boundary likelihoods, $\mathbf{P}^B \in [0, 1]^T$, and the probability distributions over the 7 classes, $\mathbf{P}^C \in [0, 1]^{T \times 7}$, for all time steps:

$$\mathbf{P}^B = \text{sigmoid}(((\mathbf{H}^* \mathbf{W}_1^B) \mathbf{W}_2^B) \mathbf{W}_3^B), \quad (6)$$

$$\mathbf{P}^C = \text{sigmoid}(((\mathbf{H}^* \mathbf{W}_1^C) \mathbf{W}_2^C) \mathbf{W}_3^C), \quad (7)$$

where $\{\mathbf{W}_1^B, \mathbf{W}_2^B, \mathbf{W}_3^B, \mathbf{W}_1^C, \mathbf{W}_2^C, \mathbf{W}_3^C\} \in \mathbb{R}^{d \times d}$, $\mathbf{W}_3^B \in \mathbb{R}^{d \times 1}$, and $\mathbf{W}_3^C \in \mathbb{R}^{d \times 7}$ are learnable weight matrices. Note that we use the sigmoid function instead of the softmax activation in Eqn (7) for the function labeling is modeled as seven individual binary sequences.

To detect the boundaries \mathbf{B} from \mathbf{P}^B , we use a common peak-picking method [17] implemented in the librosa library [33]. To estimate the function labels \mathbf{C} , we give the segment between two adjacent boundaries (say t_1 and t_2) a label taking the largest average probability, i.e., $\mathbf{C}_t = \arg \max \sum \mathbf{P}_n^C \forall t_1 \leq t, n < t_2$.

3.4 Loss Function

Given the ground-truth boundaries and labels (represented by a sequence of one-hot vectors), $\mathbf{Y}^B \in \{0, 1\}^T$ and $\mathbf{Y}^C \in \{0, 1\}^{T \times 7}$ respectively, we compute the binary cross-entropy (BCE) losses for the model output to compute the overall loss (\mathcal{L}) as follows:

$$\mathcal{L} = \mathcal{L}^B + \mathcal{L}^C, \quad (8)$$

$$\mathcal{L}^B = \text{BCE}(\mathbf{Y}^B, \mathbf{P}^B), \quad (9)$$

$$\mathcal{L}^C = \text{BCE}(\mathbf{Y}^C, \mathbf{P}^C). \quad (10)$$

4. EXPERIMENTS

We conducted comparative experiments using the Beatles [34], RWC [35], and SALAMI [36] datasets. For the Beatles dataset, we used the refined Beatles-TUT annotations for 174 Beatles songs.² For the RWC dataset, we used the 100 songs from the Popular Music Database (denoted by RWC-POP). For the SALAMI dataset, we created a subset consisting of only popular music (SALAMI-POP), which amounted to 245 tracks. The maximum track length for each corpus was around 468 sec, 368 sec, and 438 sec. Following [27], we carried out cross-dataset evaluations for all the experiments. Each of the three corpora served as the test data in turn while the remainder was used for training. We augmented the training set via pitch shifting (within ± 2 semitones) and pre-emphasis (with a coefficient of $\{0.7, 0.97\}$).

4.1 Statistics of the Function Labels

Structural annotations of the three corpora were converted to the 7-class label space with the mapping algorithm proposed in [27]. As illustrated in Figure 4, all the corpora

Figure 4: Statistics of the 7 function labels in each of the Beatles, RWC-POP, and SALAMI-POP corpora.

were with concentrated distribution, where Verse and Chorus are the most common labels, since that verse-chorus form is widely used in popular music. It is also worth noting that Inst (i.e., 'instrumental') is extremely rare in the Beatles and RWC-POP datasets as a result of their annotation criteria and the mapping algorithm.

4.2 Input Representation

For each audio track, we computed the mel spectrogram with 80 mel bands and the chromagram with 12 chroma bins. The initial time resolution for both representations was 25 ms. We downsampled the two types of features by a factor of 20 (hence 1 frame = 0.5 sec) with the median filter so that the model could take as input a full-length track under memory constraints.

4.3 Evaluation Metrics

The performance on the MSA task was evaluated with the *mir_eval* library [37] in terms of segmentation and labeling. For segmentation, we computed the F1 score of the Hit Rate [38] with a time tolerance of ± 0.5 sec and ± 3 sec (denoted by HR.5F and HR3F respectively). For labeling, we computed the F1 score of the pairwise agreement [39] at the frame size of 0.1 sec (denoted by PWF).

In addition, the frame-wise labeling accuracy was measured in two ways. First, we converted the sequence of probabilities (\mathbf{P}^C) into the labeling sequence (\mathbf{C}) either by taking the *argmax* function at each time step or by using the proposed *smoothing* strategy (Section 3.3). The derived labeling sequences were denoted by \mathbf{C}_a and \mathbf{C}_s , respectively. Two types of labeling accuracy (ACC_a and ACC_s) were then computed by comparing \mathbf{C}_a and \mathbf{C}_s with the

ground-truth labeling sequence, $\bar{\mathbf{C}} \in \{0, 1, \dots, 6\}^T$:

$$\text{ACC}_a = \frac{1}{T} \sum_{t=1}^T \delta_{\bar{\mathbf{C}}_t, \mathbf{C}_{a,t}}, \quad (11)$$

$$\text{ACC}_s = \frac{1}{T} \sum_{t=1}^T \delta_{\bar{\mathbf{C}}_t, \mathbf{C}_{s,t}}, \quad (12)$$

where $\delta_{a,b}$ denotes the Kronecker delta function.

4.4 Baseline Methods

To validate the effectiveness of the spectral and temporal self-attentions, we conducted an ablation study with the following baseline models:

- **ST-MHSA:** Both the spectral and temporal encoders used the standard MHSA as in the SpectTNT [27].
- **TE-Only:** The spectral encoder was removed in a way similar to the CAMHSA work [28].
- **SE-Only:** The temporal encoder was removed from the proposed model. This was a localized prediction model taking only short-term context into account.

The ST-MHSA and TE-only are considered substitutes to the two previous works [27, 28], and we did not make a direct comparison to their results for a couple of reasons. First, the data used are different due to the difficulty of obtaining the exact audio signals: we used only the Beatles dataset while [27] used the Isophonics [34]; the subsets created from the SALAMI dataset are also different (245 tracks in our experiments and 274 tracks in [27]). Second, our model aims to predict semantic labels whereas the model of [28] outputs semiotic representations, and accordingly the data used are different.

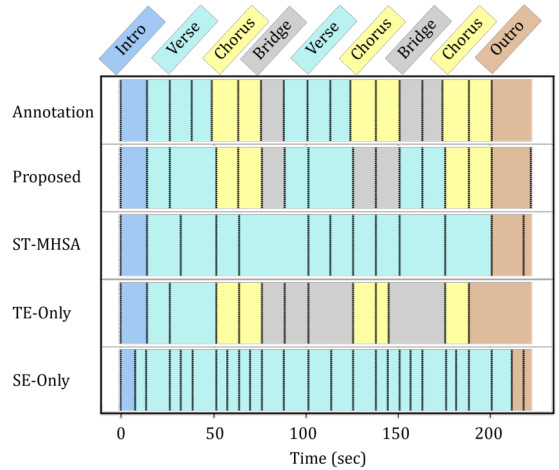

Figure 5: Structure analysis results of a song (“RM-P045”) from the RWC-POP. The first row is the ground-truth annotation, and the other rows are the estimations by the proposed method and baseline models. The estimated boundaries are denoted by dashed lines.

To scrutinize our model design in relation to the performance, we also built variants of our model as follows:

- **w/ Pool:** The pooling operation was inserted into the CNN frontend for the mel spectrogram (Section 3.1). Precisely, we used a pooling layer for \mathbf{X}'_1 before the computation of Eqn (1). Following [12], we reduced the spectral dimension of the mel spectrogram using a max-pooling layer with a kernel size of 6 (while the temporal dimension was kept unchanged).
- **w/o S-Mask:** The spectral attention mask was not used (Section 3.2 and Figure 3a). This is equivalent to using a standard MHSA block for the SE.
- **w/o T-Mask:** The temporal attention mask was not used (Section 3.2 and Figure 3b). This is equivalent to using the CAMHSA mechanism for the TE.

5. RESULTS

We here report and discuss the results of the comparative and ablation experiments.

5.1 Comparison with Baseline Models

The results of the cross-dataset evaluations are summarized in Table 1. The proposed method outperformed the baseline methods on the three corpora in most metrics (with a comparable PWF score to the ST-MHSA and the TE-Only on the Beatles). In comparison with the ST-MHSA, the performance gain of the proposed method was mainly attributed to the tailored MHSA blocks for spectral and temporal modelings, validating the importance of the MHSA adaptation to the task. Given that the TE-Only obtained better ACC scores than the SE-Only, the temporal self-attention was considered to have a greater impact on identifying structural functions than its spectral counterpart.

Table 2: Evaluations of the model design choices.

Nonetheless, the differences between the SE-Only and TE-Only were not clear in terms of the HR and the PWF scores, implying that spectral and temporal self-attentions both can contribute to the tasks. In addition, we found that our inference strategy smoothed the structural labeling results while having a minor effect on the ACC score.

Figure 5 portrays the structural labeling results for one song from the RWC-POP corpus. Regarding the segmentation results, all the models were able to detect the transitions between different sections, but the finer structure (i.e., repetitions or variants within a coarse section) was sometimes overlooked. In particular, the SE-Only over-segmented the musical track due to the limited contextual information. Regarding the labeling results, the proposed method and the TE-Only were capable of correctly estimating the five function labels in the track, whereas the ST-MHSA and SE-Only failed to identify all the chorus and bridge sections, possibly owing to the insufficient capability of temporal modeling.

5.2 Evaluation of Design Choices

Experiments results regarding the model design are listed in Table 2. As we expected, the severe performance degradation was caused by the pooling operation (w/ Pool) on the three corpora. Spectral components are not pixels that are highly correlated in local regions, and therefore naive local pooling could be detrimental to spectral features. As for the attention masking (w/o {S, T}-MASK), the results suggested that the imposed constraints can have a positive impact on the performance. On the SALAMI-POP, which is the most challenging one among the three corpora, the MHSA mechanism without any constraints resulted in a clear performance drop. In particular, we found that unconstrained spectral components tended to give great attention to the extra component (\mathbf{H}_i^*) rather than themselves.

A similar effect was also reported by previous research in the field of natural language processing [40, 41]. This kind of concentrated attention to a special (or artificial) component that has distinct semantic meanings could downplay the representation capability of the MHSA.

5.3 Evaluation of Spectro-Temporal Self-Attentions

The attention maps implicitly computed with the MHSA mechanism often disclose illuminating relationships between input elements [42–45]. The spectral and temporal self-attentions of our model also exhibited such an effect. As depicted in Figure 1c, the leftmost temporal self-attention map highlighted a potential musical event at around 66 sec, which could be associated with the variant repeat of the first 10 sec of this chorus section (as can be seen in Figure 1a, two triangular patterns span from 56 to 66 sec and from 66 to 76 sec, respectively). This result echoes the observation that self-attention maps can represent music structure [28]. In contrast, the spectral self-attention, as illustrated in Figure 1b, uncovered the tonal relationships between the 12 pitch classes with an emphasis on the notes comprising the tonic chord (assume in the key of C major). Particularly, pitch class E gained persistent attention over this section even though it had a low energy level for most of the time. Through alternate self-attention across the spectral and temporal dimensions, the contextual information of individual aspects can be mingled effectively and provide insights into music structure.

6. CONCLUSION

We have presented a deep learning model for music structure analysis, especially from the perspective of the functional structure representation. The core idea of this study is to learn non-local spectral and temporal dependencies inherent in music with clear distinction. For this purpose, we adapted the multi-head self-attention mechanism for each aspect and leveraged two types of the Transformer encoder to unravel the spectro-temporal relationships. Compared with the ablated variants of the Transformer encoder, the proposed model with the specialized self-attention mechanisms worked better on three datasets in music segmentation and structure labeling. The learned self-attention maps unveiled that the correlations between separated spectral or temporal components can be effective clues for modeling music structure.

In spite of these encouraging results, we acknowledge the computational limitation of our approach. Apart from an M -head temporal self-attention having the memory footprint of $M \times T \times T$, an N -head spectral self-attention involves intermediate attention maps with $T \times N \times S \times S$ space complexity. Given that our method aims to process full-length audio data (hence larger T) and leverage multiple types of acoustic features (hence greater S), memory-efficient self-attention mechanisms are critical to this kind of dual-axis modeling. Time and frequency are intricately interwoven to form the musical fabric, and each individual aspect is worth considerable attention.

ABSTRACT

In this paper, we propose a novel Self-Supervised-Learning scheme to train rhythm analysis systems and instantiate it for few-shot beat tracking. Taking inspiration from the Contrastive Predictive Coding paradigm, we propose to train a Log-Mel-Spectrogram-Transformer-encoder to contrast observations at times separated by **hypothesized** beat intervals from those that are not. We do this without the knowledge of ground-truth tempo or beat positions, as we rely on the local maxima of a Predominant Local Pulse function, considered as a proxy for Tatum positions, to define candidate anchors, candidate positives (located at a distance of a power of two from the anchor) and negatives (remaining time positions). We show that a model pre-trained using this approach on the unlabeled FMA, MTT and MTG-Jamendo datasets can successfully be fine-tuned in the few-shot regime, *i.e.* with just a few annotated examples to get a competitive beat-tracking performance.

1 Introduction

Beat-tracking, *i.e.* locating the times in a musical audio signal where beats are perceived or notated in the corresponding score, is still one of the most challenging subjects in the Music Information Retrieval (MIR) research field. This is owing to the large use of the beat information in many applications and to the complexity of the task: beats belong to a hierarchy/tree of rhythmic accentuations (hence entailing ambiguities), arise both from perceptual and cognitive cues. It, therefore, requires knowledge of the cultural specificities of the studied music.

To alleviate these issues, data-driven systems purely rely on training data composed of music tracks that have been annotated (supposedly) by experts. However, this labeling process remains costly and as a consequence, the amount of data annotated into beats (at most a few thousands tracks) remains extremely low in MIR, as compared to other research fields (speech or computer vision). For this reason, developing approaches that allow training

beat-tracking systems without annotated data, a.k.a. Self-Supervised Learning (SSL), is important. This is the goal of this paper.

By alleviating the need of large annotated datasets, SSL, has recently gained significant attention in the field of machine learning. The goal is to learn meaningful representations of the input data without the need for human annotations. To do so, the target outputs are directly inferred from the dataset itself, and often referred to as "pretext-task labels". Such supervision can be obtained by masking some part of the input and asking the model to predict it [1–4] or to generate two views of the same input and force a model to learn similar representations for the two views [5–8]. Another popular SSL approach is contrastive learning [9, 10] where one trains a network to predict whether two inputs are from the same class (or not) by forcing their trained embeddings to be more or less close from each other. Usually, upon pre-training completion, the model is fine-tuned in a supervised fashion for one or more downstream tasks, where the data is smaller in size.

Our contributions are the following:

- We propose a novel contrastive SSL scheme producing representations which are useful for automatic rhythm analysis tasks, in particular the beat-tracking task. Its key component is the pretext-task design exploiting Predominant Local Pulse (PLP) local maxima to effectively sample anchor, positive, and negative time-steps for our contrastive loss function.
- We show that the pre-trained model can be fine-tuned in a few-shot learning setting to get competitive beat-tracking results. Moreover, we show that our approach yields, in most cases, at least better performance than Zero-Note Samba (ZeroNS) [11], which is, to the best of our knowledge, the only alternative SSL approach to this problem to date.
- Furthermore we show that our model outperforms ZeroNS in a cross-dataset generalization setting.
- Finally we compare our model to the state of the art in a 8-fold cross-validation setting and show that it is competitive.

Paper organization. The paper is organized as follows. In section 2 we present works related to our proposal. In section 3 we present our proposed contrastive SSL training strategy. Finally in section 4 we present the results of the different experiments we performed. To facilitate reproducibility, we make our code available.¹

2 Related Work

In the following, we provide a quick overview of related contrastive SSL techniques and review the attempts made along this line in the field of MIR, especially for beat and downbeat tracking. We also discuss the recent advances made towards solving these important MIR tasks.

2.1 Self-Supervised Representation Learning

Our approach takes inspiration from contrastive methods. In CPC (Contrastive Predicting Coding) [9], representations are learned from sequential data by predicting the future latent representations from the (aggregated) past ones. For this, an encoder is trained to produce latent representations with the task of making it easy to distinguish in the obtained latent space (positive) future latent representations from a set of negative samples. This encourages the model to capture meaningful information. Instead of predicting the future, in Wav2Vec2 [10] the task is to predict masked observations. In Wav2Vec2, features are extracted from an audio signal with a Convolutional Network and fed to a transformer encoder where some frames are masked. Additionally, the audio features are quantized and the model is trained to contrast the masked output with the quantized output and a set of distractors.

2.2 Self-Supervised Learning in MIR

Following the trend in speech processing research, SSL approaches have started to become popular in MIR. On the one hand, these approaches can be used to train general-purpose models, the so-called “foundation models” (such as MULE [12] or MERT [13]), which are supposed to be useful to solve a whole set of downstream tasks (see the MARBLE benchmark [14]). On the other hand, models can be developed to learn representations that are well aligned with a specific MIR task. Among those, learning representations that are equivariant to a semantic distortion of the audio signal has become a popular approach (e.g., for pitch or tempo estimation using siamese networks [15–18]).

Few works have proposed to apply SSL for rhythm analysis tasks. Zero-Note Samba (ZeroNS) [11] leverages the synchronization of the various instrument stems in a music track. For this, they separate music tracks into their percussive and non-percussive parts and train an encoder to force the synchronization between the corresponding latent representations, which are then used for beat tracking. In [19] they used binary metric regularity to derive supervision for their CRF loss, enabling the network to model a hierarchical metrical structure.

2.3 Beat and Downbeat tracking

Before the rise of deep-learning approaches, beat and downbeat tracking systems were based on two-step systems: first audio features were extracted from the audio signal (including an onset detection function, Predominant Local Pulse (PLP), spectral features or a novelty function);

then those were used as “observations” to a probabilistic model (such as Hidden Markov Models or Dynamic Bayesian Network) [20–22].

The shift toward data-driven approaches started with [23] where the authors proposed to process spectral features with bi-directional Long Short-Term Memory (LSTM) networks. [24] then proposed to replace the LSTM with a Temporal Convolutional Network (TCN) to process the spectral features. Later on, the model was improved by solving jointly multiple tasks (beat and downbeat positions, as well as tempo) [25, 26]. Currently, models based on the Transformer architecture, used in a multi-task setting (joint beat-downbeat tracking) are the most successful. In [27] the authors apply the Spectral-Temporal Transformer (SpecTNT) architecture [28] to tackle this task. This architecture combines a spectral transformer that processes harmonic features and a temporal transformer that aggregates the processed features over time. To further improve the performance, the authors combined SpecTNT with a Temporal Convolutional Network (TCN). Beat Transformer [29] incorporates dilated self-attention to capture long-range dependencies. Furthermore, in the middle layers, they alternate time-wise dilated self-attention with instrument-wise self-attention².

3 Proposed Contrastive Learning SSL scheme

In this paper, we propose a novel SSL approach to learn representations useful for rhythm analysis tasks, and instantiate it for the beat tracking downstream task. We aim to learn a projection (an encoder) such that the resulting projections of observations at PLP peaks whose distance from each other is a power of 2 are close to each other, and different otherwise. The two key insights behind this is that: i) a significant fraction of the PLP peaks (supposedly aligned to the tatum grid) is expected to represent beat positions, with high probability, and ii) most of the musical recordings tend to have a binary metric structure (i.e. beats can be musically divided by two and grouped by two). We conjecture that despite being over-simplistic, these ingredients are “good-enough” to define a pretext-task that will be effective for training representations useful for various rhythm analysis tasks, especially beat tracking, provided that a downstream fine-tuning phase is anyway envisaged. In the following we will refer to the distance between two PLP peaks as *tatum-unit* and denote it by *tu*.

We solve this pretext-task using contrastive learning. We learn to distinguish observations at times separated by an interval of a power of 2 in *tu* units, from those that are not. Once computed, the PLP function is used to select an anchor, its associated positive, and a set of negative samples. We further explain the procedure in section 3.1. We then train our encoder to attract the anchor and the positive while repelling the set of negatives in the latent space using a contrastive loss. We describe the architecture of

² The instrument-wise attention is conducted along the stems of a demixed audio signal, contributing to a comprehensive analysis of the audio data.

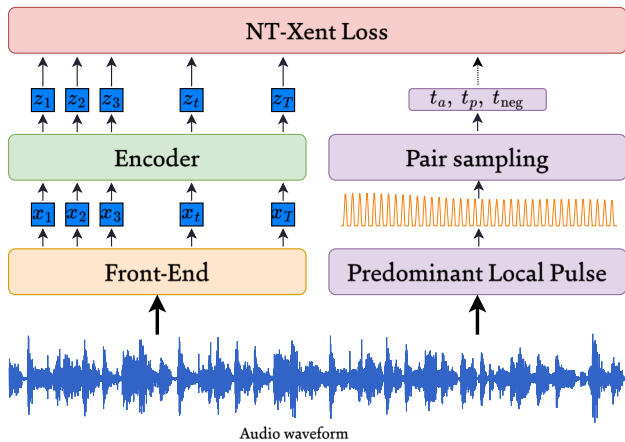

Figure 1: Our proposed contrastive SSL scheme for beat tracking. The left part displays our processed audio waveform to obtain the representations z_t . The right part displays our mining of positive and negatives.

our encoder in section 3.2. Our approach is summarized in Figure 1.

3.1 Mining positive and negatives

The key part of our work is to learn representations in a contrastive way. Therefore we need to define an anchor, a positive and multiple negative samples within each given audio excerpt. We rely on the Predominant Local Pulse (PLP) [30] function to extract local pulse information (see 3.1.1). Given such information, we sample positive and negative times for a selected anchor (see 3.1.2).

3.1.1 Predominant Local Pulse

The PLP method analyzes the Onset Strength Function (OSF) of an audio signal in the frequency domain to find a locally stable tempo for each frame. For this, a “tempogram” (a Short-Time Fourier-Transform, STFT) of the OSF is computed. At each time position, the maximum of the “tempogram” indicates the dominant pulse frequency. Using the corresponding amplitude and phase of this maximum, one can re-synthesize the corresponding temporal signal (a sinusoidal component). Using the usual overlap-and-add (OLA) inverse STFT method, a smooth temporal signal is formed by overlapping-and-adding the sinusoidal components with various dominant pulse frequencies over time. This temporal function is termed PLP and represents a localized enhancement of the original novelty function’s periodicity.

Computation. Given an audio signal, we compute the PLP function with the same frame rate as our audio front-end (*i.e.* 20ms). We used the *beat.plp* function from Librosa [31]. The function is fed with an OSF computed from a spectrogram³ with 2048 points and the default minimum and maximum tempo parameters. We then estimate the local maxima peak y_k of the PLP using the *find_peaks* function from scipy.

³ In a preliminary experiment, we found that using the spectrogram to get the OSF was working better than using the Mel-spectrogram

3.1.2 Sampling from PLP

In the following we will refer to the distance between two PLP peaks as *tatum-unit* and denote it by tu . For simplification, we do the following assumptions. We assume that the tatums correspond to the 8-th note and that most tracks are in a 4/4 meter.⁴ Following this, we consider that the positives have a time distance Δ from the anchor which is a power of two of the tatum unit: $\Delta = i \times \alpha \times tu$ with $\alpha = 2^n$ and $i \in \mathbb{Z} \setminus \{0\}$. In this work we consider $n = 2$ (which corresponds to an inter-distance of two beats).

We define by $Y = \{y_1, \dots, y_K\}$ the set of PLP peaks within a given audio segment. We first sample an anchor a uniformly in $[1, K]$. We denote by y_a the time associated to a (blue arrow in Fig.2). Given this anchor, we sample its associated positive time step p . This positive must be situated $i \times \alpha$ peaks away from the query. For a given anchor a , we therefore sample p uniformly from $Y_a = \{y_{a \pm i \times \alpha}, 0 \leq a \pm i \times \alpha \leq K\}$.

We denote by y_p the time associated to p (green arrow in Fig.2, green empty arrows are all the elements of Y_a).

We then sample N negative time steps at which we define hard negative and easy negative examples. An *easy negative* corresponds to a time step that is not a PLP peak. They are sampled uniformly in $[0, T] \setminus Y$. We also apply a “safety window” (whose duration was empirically determined to one frame) around peak time steps to avoid sampling negatives that are too close to a peak. A *hard negative* corresponds to a time step that is a peak but that is not in Y_a . They are sampled uniformly in $Y \setminus (Y_a \cup \{y_a\})$. We sample $N = 10$ negatives, half of them are hard negatives, and the other half are easy negatives.

To prevent any errors coming from the PLP function we discard audio segments where the inter-peak distance is not almost constant. We empirically set the allowed variation to 20 percent of this inter-peak distance within a segment (more details about this are given on the companion website).

3.2 Architectures

Front-end. We compute Mel spectrogram features from audio sampled at 16kHz using 128 bands, a window size of 2048 samples, and a hop size of 320 samples (20ms frame rate). We apply log compression and normalization⁵. Subsequently, a linear layer projects the frames to the embedding dimension. The resulting sequence x_t serves as the input to the encoder. We use audio segments of 20s long to ensure the model sees a sufficiently large context. However, we did not explore varying the length of audio segments fed into the encoder.

Encoder. For the encoder, we use a Transformer architecture similar to the one used in Wav2Vec2 or Hubert [10, 32]. It is composed of a stack of Transformer

⁴ In a preliminary experiment, we delve deeper into determining the metrical level that the peaks of the PLP correspond to. Our findings suggest that these peaks align with either the beat, the 8-th note or the 16-th note level.

⁵ For normalization, we use the mean and standard deviation computed over the training set.

Figure 2: Proposed mining strategy of Positives and Negatives (easy and hard) given an Anchor time in the PLP function. Positive are sampled among peaks of the PLP whose time index is distant from the Anchor by a power of two tatum units tu (here $\alpha = 4 \times tu$); Negatives are the remaining times and are considered Easy if not peaks of the PLP and Hard if peaks of the PLP. Here we sample two hard and two easy negatives.

encoder layers. Each layer is composed of a multi-head self-attention mechanism followed by a feed-forward network. We use 8 layers each of which has 8 attention heads and apply a 0.1 dropout in the attention layer. The encoder outputs the embedding sequence z_t . The embedding dimension is set to 512 and the hidden dimension of the feed-forward network is set to 1024. In total, the model has 19.1M learnable parameters. We did not explore other architectures as the focus of our work was to study the proposed SSL scheme.

3.3 Contrastive Loss

Among the various formulations of the contrastive losses, we have chosen to use the NT-Xent loss [5] one. We define the similarity measure between two vectors u and v as $\text{sim}(u, v) = \frac{u^\top v}{\|u\| \|v\|}$. Given an anchor y_a , a positive y_p and a set of N negatives time-steps $t_{\text{neg}} = \{t_{n_1}, \dots, t_{n_N}\}$, we compute the contrastive loss as follows:

$$\mathcal{L}_{\text{NT-Xent}}(y_a, y_p, t_{\text{neg}}) = -\log \frac{\exp(\text{sim}(z_{y_a}, z_{y_p})/\tau)}{\sum_{i=1}^N \exp(\text{sim}(z_{y_a}, z_{t_{n_i}})/\tau)} \quad (1)$$

We set the temperature to $\tau = 0.1$. For each audio in a batch, we use 80% of the available peaks as anchors. For each of them, we sample their corresponding positive and negatives. We compute the above contrastive loss over each pair and each audio. We then average the losses to obtain the global loss for the batch, that is if we have a total of M pairs in the batch:

$$\mathcal{L} = \frac{1}{M} \sum_{y_a, y_p, t_{\text{neg}}} \mathcal{L}_{\text{NT-Xent}}(y_a, y_p, t_{\text{neg}}). \quad (2)$$

4 Evaluation

To evaluate our model, we performed three experiments. In all three experiments, the model is pre-trained in a SSL way using unlabeled data.

In Experiment 1, we test the Few-Shot Learning (FSL) abilities of our model using only a few data for fine-tuning.

Experiment 2 tests the generalization of our model on unseen conditions and serves as comparison to ZeroNS. Finally, Experiment 3 compares our performance to the ones obtained using fully-supervised beat-tracking models.

4.1 Datasets

For SSL pre-training, we use a combination of unlabeled datasets (in terms of beat positions): the Free Music Archive (FMA) [33], MTG-Jamendo [34], and MagnaTagaTune (MTT) [35]. FMA contains 106,574 full tracks spanning 161 genres. MTG-Jamendo contains around 55,000 full audio tracks. Finally, MTT contains approximately 26,000 excerpts of 30-s duration from 5223 unique tracks. Overall the combined datasets offer around 165k full audio tracks and a total of 8,000 hours.

For fine-tuning and testing, we used the following labeled (into beats) datasets, commonly used in previous works: SMC [36], Ballroom [37] and Hainsworth [38], GTZAN [39,40], RWC [41] and Harmonix [42]. The Harmonix dataset is mainly composed of pop music tracks, whereas the Ballroom, GTZAN, RWC, and Hainsworth datasets offer a wider variety of musical genres.

4.2 Evaluation Metrics

We report the commonly used metrics in the literature including the F-measure with a tolerance window of $\pm 70\text{ms}$, continuity-based measures at the correct metrical level (CMLt & CMLc), and at alternate metrical levels such as double/half and offbeat (AMLt & AMLc) [43].

4.3 Implementation details

4.3.1 Pre-training

For SSL pre-training we kept 0.05% of the data for validation (9,000 tracks). Our model is pre-trained during 200 epochs (equivalent to around 270,000 steps). Training was conducted on 4 A100 GPUs utilizing float 16 precision and a global batch size of 96. We employed the Adam optimizer [44] with an initial learning rate set at $1e-4$ and

applied a polynomial decay learning rate scheduler. The learning rate gradually increased to $5e-4$ within the first 32,000 steps, then reverted to its initial value over the subsequent 250k steps. Additionally, gradient clipping was employed. We keep the model that gives the best validation loss.

4.3.2 Fine-tuning

After SSL pre-training, we need to adapt the model to the downstream task of beat tracking. This is done by adding a linear classification probe $g(\cdot)$ and fine-tuning both the encoder and the linear probe. $g(\cdot)$ projects the embedding into the scalar beat activation function. Instead of feeding $g(\cdot)$ with the output of the encoder, we feed it with a weighted sum of the outputs of each layer of the Transformer [45]. That is $z = \sum_{l=1}^8 \alpha_l z^{(l)}$, where $z^{(l)}$ is the output of layer l . The weights α_l are jointly learned with the linear probe $g(\cdot)$.

The system is trained to minimize the binary cross-entropy loss between the beat activations and the target. Following the literature we widened the beat targets by a window [0.25, 0.5, 1, 0.5, 0.25] [26]. We used the Adam optimizer [44] with an initial learning rate of $1e-5$ and a polynomial decay learning rate scheduler.

During fine-tuning, we utilized audio chunks of sizes similar to those used during pre-training (20s). However, during inference, to avoid potential out-of-memory errors, we split audio excerpts exceeding 45 seconds into 20-second chunks with 5-second overlap. Subsequently, we overlap-add the activations to derive the beat activations for the whole track.

These beat activations are then fed into a Dynamic Bayesian Network (DBN) [46] to predict the beat positions. The DBN is configured to model a tempo range of 40-270 beats per minute with transition lambda set to 45, observation lambda to 9, and a threshold of 0.15.

4.3.3 Data Augmentation

We found that both pre-training and fine-tuning could benefit from data augmentation, in particular time-stretching. We apply time-stretching in two manners: constant factor and time-varying factor. In both cases, we constrain the time-stretching factor to lie in the interval [0.8, 1.2]. For the constant factor case, we used sox effects in TorchAudio [47], and for time-varying factor we used LibTSM [48]. When using a time-varying factor we randomly sample time instants at which the stretching factor is modified (also randomly, see the repository for details). This was found to be particularly beneficial for the pre-training stage. Indeed because we have filtered out tracks where the inter-peak distance is not almost constant, the SSL training data does not contain examples of time-varying tempo. Using time-varying time-stretching allows us to simulate this in a controlled fashion.

We found that it was better to compute the Predominant Local Pulse (PLP) curve before time-stretching and shift the peaks accordingly, rather than on the time-stretched audio.

4.4 Experiment 1: Few-shot learning

Protocol. The goal here is to test the ability of our model to learn with only few examples, Few-Shot Learning (FSL). To be able to compare our results with previously published ones, we replicate the evaluation protocol proposed in ZeroNS [11]. We consider *individually* each dataset (both for fine-tuning and testing): $T \in \{\text{SMC, Ballroom, Hainsworth, GTZAN}\}$. For each dataset T , we split it into 8 folds, we use one for testing T_{test} , one for validation T_{valid} and perform FSL with the remaining ones T_{train} . The FSL ability is evaluated by selecting randomly $k \in \{1, 2, 3, 4, 6, 8, 12, 16, 24, 48, 64, 96\}$ items from T_{train} . For each k we sample 10 variations: $T_{train,i}^k$.

For each choice of k , we fine-tune our pre-trained model on each variation $T_{train,i}^k$ and keep the one that performs the best on T_{valid} .

Results. We give the results in Figure 3 for the T_{test} of each dataset (SMC Mirex, Ballroom, Hainsworth, and GTZAN) and each value of k (x-axis). We report the mean and standard deviation of the metrics over the training set variations $T_{train,i}^k$. Our model performs at least as well as ZeroNS on almost all metrics and datasets. The exceptions are with AMLt on SMC and AMLc and AMLt on GTZAN and SMC. We observe that our model performs significantly better on Hainsworth, with up to 10% absolute improvement in F1 score and almost 20% absolute improvement in CMLt and CMLc. Also, the performance gap is significant on Ballroom when using very few data (less than 10 tracks) where we can observe almost 10% absolute improvement in F1 score and up to 15% improvement in AMLc.

4.5 Experiment 2: Generalization

Protocol. The goal here is to test the generalization ability of our model, *i.e.* training our model on one dataset and testing on another. For this, we replicate the protocol proposed in ZeroNS [11]. For each choice of dataset $T \in \{\text{SMC, Hainsworth, Ballroom}\}$, we split it into 8 folds, we use one for validation T_{valid} , and the remaining seven for training T_{train} . We then use the best-performing model on T_{valid} . Instead of using the linear probe described above, we obtained better results using a MLP (two linear layers interleaved with a ReLU), also fed by the weighted sum of layer sequences (sec 4.3.2). Whatever the choice of T , the test is performed on the GTZAN dataset.

Trained on	Method	F1 (%)	AMLt (%)	CMLt (%)
SMC	Ours	79.5 ± 0.5	88.0 ± 0.6	64.4 ± 0.9
	ZeroNS	74.8 ± 2.1	86.3 ± 2.3	51.0 ± 2.1
Hainsworth	Ours	85.1 ± 0.8	89.9 ± 0.9	73.2 ± 1.8
	ZeroNS	80.6 ± 0.9	89.4 ± 0.7	62.8 ± 2.3
Ballroom	Ours	83.9 ± 0.3	88.4 ± 0.5	72.3 ± 0.9
	ZeroNS	82.6 ± 0.5	89.0 ± 0.8	67.6 ± 1.1

Table 1: Results of Experiment 2: Generalization

Results. We indicate the results in Table. 1. We report the mean and standard deviation of F1, AMLt, and CMLt

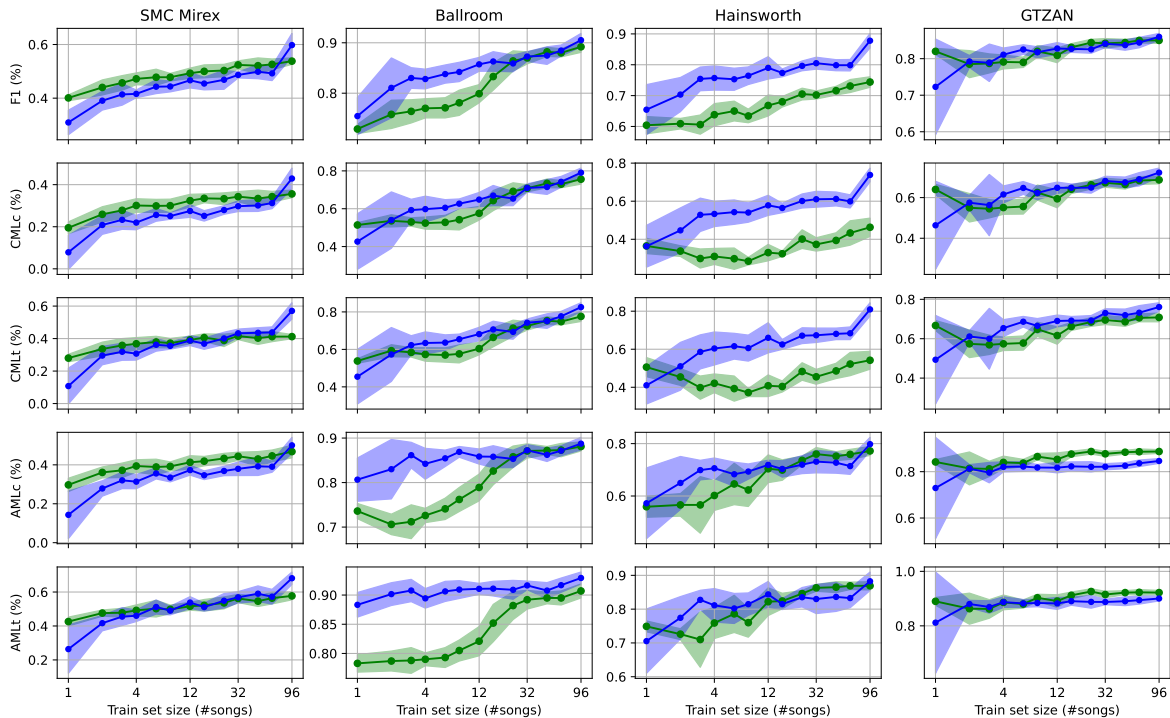

Figure 3: Results of Experiment 1: Few-Shot Learning. Shaded areas representation the standard deviation. (ZeroNS in green and our method in blue)

Method	F1	CMLt	AMLt
Böck [26]	0.885	0.813	0.931
Hung [27]	0.887	0.812	0.920
Zhao [29]	0.885	0.800	0.922
Ours	0.876	0.802	0.918

Table 2: Results of Experiment 3: Comparison with supervised baseline

scores across the different folds. Overall our model performs better than ZeroNS on all datasets except when for the AMLt metric when trained with Ballroom, but the difference is not statistically significant. This means that our model can generalize well to unseen data. Precisely we observe a 5% improvement in F1 score and more than 10% improvement in CMLt when training on SMC or Hainsworth. We nearly reach the F1 score of fully supervised models (presented next) when training solely on 7/8 of Hainsworth (*i.e* 194 tracks).

4.6 Experiment 3: Comparison with supervised baseline

Protocol. The goal here is to compare the performance of our model to the ones provided by fully-supervised models. For this we replicate the commonly used 8-fold cross validation set-up after [26,27,29]. GTZAN is kept as a test set and is never seen in training. We average the metrics over the 8 training folds to obtain the final results.

Results. We give the results in Table 2. It is clear that the proposed beat tracking approach using our self-supervised

pre-training can be competitive with state-of-the-art methods on GTZAN, a dataset covering a wide diversity of genres. While our method does not outperform the best-performing method, it achieves comparable results across all metrics, proving the quality of the learned representations.

5 Conclusion

In this paper, we proposed a novel Self-Supervised Learning approach to learn representations useful for the task of beat tracking using contrastive learning where the selection of anchor, positive and negative peaks derives from a Predominant Local Pulse function.

We assess our proposal positively based on a series of experiments. In a first experiment, we showed that our proposed approach was superior on some datasets to the previous SSL approach, ZeroNS, in a few-shot learning setting. In a second experiment, we show that our model has better generalization capabilities to unseen data. In the last experiment, we show that our model also yields comparable performances to the fully supervised baseline, indicating that our pre-training scheme effectively learns meaningful beat-related representations.

To further improve our method, future work will focus on developing a more sophisticated sampling mechanism that can handle other metrical structures than the binary one used-here (such as 6/8, 3/4). One potential approach is to incorporate additional audio features, such as self-similarity matrices, to gain a deeper understanding of the rhythmic structure within an audio segment and adaptively select positive positions for a given anchor.

ABSTRACT

The task of music structure analysis has been mostly addressed as a sequential problem, by relying on the internal homogeneity of musical sections or their repetitions. In this work, we instead regard it as a pairwise link prediction task. If for any pair of time instants in a track, one can successfully predict whether they belong to the same structural entity or not, then the underlying structure can be easily recovered. Building upon this assumption, we propose a method that first learns to classify pairwise links between time frames as belonging to the same section (or segment) or not. The resulting link features, along with node-specific information, are combined through a graph attention network. The latter is regularized with a graph partitioning training objective and outputs boundary locations between musical segments and section labels. The overall system is lightweight and performs competitively with previous methods. The evaluation is done on two standard datasets for music structure analysis and an ablation study is conducted in order to gain insight on the role played by its different components.

1. INTRODUCTION

Music structure analysis consists of locating segments that compose a track and grouping them into semantic categories, referred to as musical sections [1]. Approaches to solve this task have significantly been advanced in the past few years, notably due to the creation of large audio datasets along with their structural annotations [2–4]. These annotated corpora have allowed researchers to leverage recent progress in deep learning and design systems that learn signal representations to predict song structures.

1.1 Related work

One crucial aspect when analyzing musical structures is the strong temporal dependency among different events

within a track. A musical observation at a given time can impact other observations at any other point in time, and this, at different scales. This multi-level dependency still poses a significant challenge when training music segmentation systems [1]. Recent methods successfully relied on modelling these temporal connections through the use of self-attention mechanism [5–8]. In these cases, the model is equipped with multiple self-attention layers so as to automatically learn to identify such dependencies. While these proved to be effective, they do not rely on any prior knowledge about musical structure and therefore tend to require large training sets or multiple input audio representations (*e.g.* multiple audio features [8], separated instrument stems [7]) so as to better characterize mutual relationships between time instants in the input track. The method introduced in this work proposes to explicitly model such temporal dependencies by leveraging the natural geometry of a track’s self-similarity matrix.

Self-similarity representations have been a useful tool to predict the structure of a track [9–12]. A line of work has for example focused on improving this representation through the use of contrastive learning [13–15]. By extracting better audio features, the resulting self-similarity matrices carry more meaningful patterns that can ease structure prediction performed by downstream segmentation methods [10, 16]. In the proposed approach, the self-similarity representation is not used as direct input to a segmentation system but rather to extract structural link features between time frames within the input track. This step is jointly performed with the audio feature extraction stage, the prediction of segment boundaries and section labels, allowing each task to benefit from the others.

1.2 Contributions

In this work, a supervised approach to segmentation of western popular music is proposed that effectively combines the three music structure principles which have been identified in previous studies [1]: *homogeneity*, *repetition* and *regularity*. To this end, the segmentation task is formulated as a graph partitioning problem where links (*i.e.* edges) between musical audio observations taken at any two time instants (*i.e.* nodes) are first characterized as whether connecting elements from the same segment, section or distinct structural entities (different segment or sec-

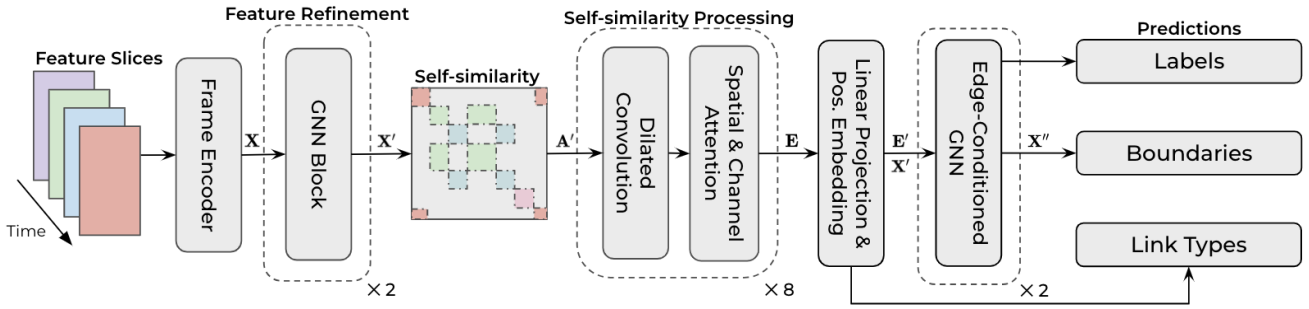

Figure 1. Model overview. Input feature patches are first processed through a frame-level encoder and a first GNN block. A self-similarity of the output features is passed through a 2-dimensional dilated convolutional network to extract link features. Node and link features are finally combined with graph attention network layers to predict boundary locations and section label assignments.

tion). These extracted link features condition a subsequent analysis block based on attention graph neural networks to further refine node features. The system outputs final predictions composed of boundary locations and frame-wise section label likelihoods. Overall, the main contributions of this work are the following: (1) we demonstrate that music segmentation can be modelled as a pairwise link prediction task, which offers a flexible framework that is inspired by well-identified structure principles ; (2) we use graph attention networks to allow frames in the track to dynamically exchange information between each other and we successfully inform this process by the learned link features ; (3) we demonstrate in an ablation study that link features provide some useful structural information about the input track, which significantly improves segmentation performance.

2. METHOD

2.1 Overall approach

The segmentation method proposed in this work proceeds in three main steps, depicted in Figure 1. First, the input track is passed through a frame encoder to obtain a sequence of frame-wise feature vectors. These are further smoothed by a graph neural network (GNN) block, allowing each individual frame to aggregate and combine information from all other time instants in the track. A self-similarity matrix is calculated from these features and fed as input to a 2-dimensional convolutional neural network. A spatial learnable bias is added to the output feature map to inform about each component’s source and destination frames’ relative positions. The link features, along with the smoothed frame features, are effectively combined through an edge-conditioned graph attention module. The updated frame features finally serve to predict segment boundaries and section labels.

2.2 Audio representation

2.2.1 Input features

For a given track, we start by estimating probable beat positions using an off-the-shelf beat tracking algorithm so as

to reduce the length of the feature sequence to be analyzed. Following previous work [14, 15, 17], the input signal is then converted into a log-scaled Mel-spectrogram representation, from which slices centered around each detected beat position are extracted.

2.2.2 Frame encoder

The sequence of mel-spectrogram slices is passed through an encoder to obtain a sequence of feature vectors $\mathbf{X} \in \mathbb{R}^{N \times d}$ where N is the number of detected beats (*i.e.* slices) and d is the embedding dimension. The objective of this step is to extract relevant spectro-temporal information from each slice. The architecture of the encoder is inspired from the work by Won *et al.* [18] for music tagging. It consists of three convolutional blocks to extract low-level features, followed by two transformer encoder layers which temporally summarize the content of each slice. To obtain more robust audio representations, the pre-training strategy proposed by Buisson *et al.* [15] is followed. It uses a contrastive loss to learn an embedding space in which frames from repeating sequences over the whole track are close. In this work, the self-supervised pre-training stage is performed on 20,000 unlabelled tracks, covering various music genres such as rock, popular, rap, jazz, electronic or classical.

2.3 Feature refinement

The sequence of feature vectors \mathbf{X} is processed by a first GNN block. The objective is to further refine local discontinuities by allowing each frame to exchange information with all other frames in the track. To this end, a self-similarity matrix $\mathbf{A} \in \mathbb{R}^{N \times N}$ is calculated from \mathbf{X} such that its elements $A(i, j)$ are defined as:

$$A(i, j) = \exp \left(-\gamma \left\| \frac{x_i}{\|x_i\|_2} - \frac{x_j}{\|x_j\|_2} \right\|_2^2 \right), \quad (1)$$

where the bandwidth parameter γ is simply set as $\gamma = \frac{1}{2s}$, with $s = \text{std} \left(\left\| \frac{x_i}{\|x_i\|_2} - \frac{x_j}{\|x_j\|_2} \right\|_2^2 \right)$ and $\|\cdot\|_2$ denotes the ℓ_2 -norm. The matrix \mathbf{A} can be regarded as the weighted adjacency matrix of a complete graph $G = (V, E)$, where

the set of nodes V corresponds to each frame contained in the track, and its edges E represent the strength of their mutual connections (*i.e.* similarity). However, each feature slice was transformed independently by the frame encoder (see Section 2.2.2). To improve both segment homogeneity and discriminability, two graph convolution layers [19] are applied to smooth the node features \mathbf{X} , of which the update rule for an arbitrary layer l is expressed as:

$$x_i^{(l+1)} = \sigma \left(\sum_{1 \leq j \leq N} \frac{A(j, i)}{N} x_j^{(l)} \mathbf{W}^{(l)} + b^{(l)} \right), \quad (2)$$

where $\mathbf{W}^{(l)}$ and $b^{(l)}$ are learnable weight parameters and σ is an activation function: Exponential Linear Unit (ELU) in this work. Equation (2.3) shows that each frame in the sequence \mathbf{X} receives a weighted combination of all other frames in the track and is then linearly transformed before applying a non-linear activation. A common issue encountered with graph neural networks is the over-smoothing phenomenon [20], where all points end up having the same representation after passing through several layers. To limit this effect, the output features are further processed by a multi-layer perceptron (MLP) [21], yielding the refined node features $\mathbf{X}' \in \mathbb{R}^{N \times d}$.

2.4 Link feature extraction

2.4.1 Motivations

Recognizing the structure of a song can be achieved by learning to fully characterize the mutual relationships between time frames from its beginning to its end. In other words, if for any pair of time points (*i.e.* audio frames), one can successfully predict if they belong to the same musical segment or section, then the overall structure of the song can be easily recovered (*e.g.* through a simple graph traversal). Figure 2 shows a visual representation of this link prediction task.

Figure 2. Schematic representation of the link characterization task. For each time instant, the goal is to classify its mutual relationship with all other instants in the input track as either, from the same segment, section or a different section.

It is interesting to notice that each of the structure principles somehow translates into specific characteristics of the self-similarity matrix. The *homogeneity* of musical segments can be observed through the appearance of block-like structures on the main diagonal. Similarly, *repetitions* of sequences can be spotted by diagonal stripes whereas repeating homogeneous segments will appear as off-diagonal blocks. The notion of *regularity* is visible as

the relative size of these patterns, which tends to be consistent within a track and in specific genres such as western popular music. Therefore, the self-similarity representation of a track yields crucial information on its structural organization and can be exploited to extract link-related information. Additionally, it provides an efficient information bottleneck which can improve generalization across different songs.

2.4.2 Self-similarity processing

The refined features $\mathbf{X}' \in \mathbb{R}^{N \times d}$ returned by the first GNN block are used to build a self-similarity matrix $\mathbf{A}' \in \mathbb{R}^{N \times N}$, in the same fashion as in Section 2.3. The goal of the link feature extraction step is to classify each component of the input matrix \mathbf{A}' into three categories: “same-segment”, “same-section” or “different section” links (see Figure 2). To this end, a 2-dimensional convolutional neural network is used, which is composed of blocs as shown in Figure 3. The kernels’ dilation rate is increased expo-

Figure 3. CNN block containing dilated convolution, channel & spatial attention and a residual connection. Each layer contains $C = 16$ channels and has an exponentially increasing dilation rate ranging from 2^0 to 2^7 to efficiently combine structural features at different scales.

nentially at each layer to enlarge the receptive field of the network and capture structural patterns at different scales. Because the goal is to classify each pixel (*i.e.* link), no pooling is applied in-between layers. To further enhance the intermediate feature maps, each convolution is followed by a multi-scale attention module [22] that leverages both spatial and channel interactions. A residual connection is added to the output of each attention block before applying ELU activation. We denote the output feature map as $\mathbf{E} \in \mathbb{R}^{C \times N \times N}$, with C being the number of convolution channels.

2.4.3 Positional embedding

If two frames are similar, then determining whether the pair is “same-segment” or “same-section” may be difficult without information about their position in the piece. To address this ambiguity, a learnable relative positional embedding $\mathbf{B} \in \mathbb{R}^{C \times N}$ is added to \mathbf{E} . Formulated as a function of $|i - j|$, it aims to provide each element in \mathbf{E} information on its relative distance to the main diagonal. We opt for a simple strategy which consists, for a given link between nodes i and j , in adding the $(|i - j|)$ th vector from a learnable embedding matrix \mathbf{B} to $e_{i,j}$. After doing so for every possible links, the result of this addition denoted as \mathbf{E}' , is fed to a linear layer with softmax activation. The link feature extraction network is optimized

using a cross-entropy loss function $\mathcal{L}_{\text{Link}}$ between the link-wise predictions \hat{y}_{link} and the ground-truth y_{link} obtained from structural annotations.

2.5 Edge-conditioned graph attention sub-network

The refined node features \mathbf{X}' and the edge features \mathbf{E}' provide a detailed representation of the input track. The former contains relevant acoustic information, which has been exchanged between frames for better discriminability across musical segments, while the latter provides information about their pairwise links. To efficiently combine these complementary views of the graph, we propose the use of edge-conditioned graph attention networks [23]. Node features are further improved by aggregating information from all other nodes in the graph, weighted by some learnable attention coefficients. These attention coefficients depend on each node’s features and the edge features that link them. For a given node x'_i , the update rule is defined as:

$$x''_i = \mathbf{W}_s \cdot x'_i + \sum_{j \in \mathcal{N}(x'_i)} \alpha_{j,i} (\mathbf{W}_n \cdot x'_j + \mathbf{W}_e \cdot e'_{j,i}), \quad (3)$$

where \mathbf{W} is used to denote learnable weight matrices for the transformation the node features to update (s=“self”), neighboring nodes (n=“neighbor”) and edge features (e=“edge”). The attention coefficients $\alpha_{j,i}$ are obtained as follows:

$$\alpha_{j,i} = \text{softmax}_i \left(\sigma \left(a^T [\mathbf{W}_n \cdot x'_i \parallel \mathbf{W}_n \cdot x'_j \parallel \mathbf{W}_e \cdot e'_{j,i}] \right) \right), \quad (4)$$

with a corresponding to a learnable vector, σ to a LeakyRelu activation, \parallel denotes the concatenation operation and $e'_{j,i}$ is the refined link features going from node j to node i . The softmax_i operation normalizes all incoming edges of node i . The forward-pass formulation from Equation (3) closely resembles that of the transformer, but additionally introduces edge features to calculate attention maps and output node features. We use a series of two graph attention layers with residual connections and ELU activation in-between. Both layers use 8 attention heads, the outputs of all heads are concatenated after the first layer and averaged after the second. The output node features are denoted as $\mathbf{X}'' \in \mathbb{R}^{N \times d}$.

2.6 Boundary and label predictions

The output of the overall system consists in boundary locations, expressed in beat indices, along with frame-wise section-label likelihoods. For boundary prediction, consecutive node features x''_i and x''_{i+1} are first concatenated, along with the corresponding link features $e'_{i,i+1}$ between them. The result of this concatenation is transformed through a linear layer with sigmoid activation to output the probability \hat{y}_{bound} of a segment boundary between these frames. For section-label predictions, we simply feed each frame to a linear layer with softmax activation, resulting in a predicted class assignment matrix $\mathbf{S} \in [0, 1]^{N \times K}$, where K corresponds to the number of section labels. We derive a boundary curve by concatenating the boundary predictions

\hat{y}_{bound} over time. To obtain the final boundary locations, we use the peak picking method after Ullrich *et al.* [24] without any thresholding on the RWC-Pop dataset, and the one from Kim *et al.* [7] for Harmonix. For the section label assignment, a simple majority vote is applied within each detected segment to determine its structural label. Due to the imbalance between boundary and non-boundary points, we use a dice loss $\mathcal{L}_{\text{Bound}}$ to optimize the boundary predictions, as it has proven useful in many segmentation tasks before [25]. We use a cross-entropy loss $\mathcal{L}_{\text{Label}}$ for section label predictions.

2.7 MinCut regularization

The objective of the proposed segmentation system is to assign each frame of the input track to one of K possible section labels. Ideally, we want this assignment to be equal for nodes in the graph that are either in the same segment or section, and orthogonal in the remaining cases. From the perspective of graph theory, given the input graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, this problem comes down to partitioning the set of nodes \mathcal{V} into K disjoint subsets by removing a minimum volume of edges, which is equivalent to maximizing:

$$\frac{1}{K} \sum_{k=1}^K \frac{\text{links}(\mathcal{V}_k)}{\text{degree}(\mathcal{V}_k)} = \frac{1}{K} \sum_{k=1}^K \frac{\sum_{i,j \in \mathcal{V}_k} \mathcal{E}_{i,j}}{\sum_{i \in \mathcal{V}_k, j \in \mathcal{V} \setminus \mathcal{V}_k} \mathcal{E}_{i,j}}, \quad (5)$$

where the numerator corresponds to the volume of edges within each cluster, and the numerator counts the edges between the nodes in a cluster and the rest of the graph. This task is referred to as the K -way *normalized MinCut* problem. Spectral clustering provides an optimal solution of this problem by projecting the nodes into the Laplacian eigenspace [10, 26]. However, calculating the spectrum of the Laplacian matrix is a costly operation and the final class assignment relies on non-differentiable operations, thus preventing it from being optimized along with the rest of the network.

In order to learn a model that finds an approximate spectral clustering solution in a differentiable manner, we base ourselves on the work by Bianchi *et al.* [27]. They propose a continuous relaxation of the normalized MinCut problem, where a GNN is trained to compute a cluster assignment matrix $\mathbf{S} \in [0, 1]^{N \times K}$ by optimizing the objective defined as:

$$\mathcal{L}_{\text{MinCut}} = -\frac{\text{Tr}(\mathbf{S}^T \mathbf{A} \mathbf{S})}{\text{Tr}(\mathbf{S}^T \mathbf{D} \mathbf{S})} + \left\| \frac{\mathbf{S}^T \mathbf{S}}{\|\mathbf{S}^T \mathbf{S}\|_F} - \frac{\mathbf{I}_K}{\sqrt{K}} \right\|_F, \quad (6)$$

where $\mathbf{A} \in \mathbb{R}^{N \times N}$ is the graph adjacency matrix, \mathbf{D} is the degree matrix of \mathbf{A} , K is the number of classes and $\|\cdot\|_F$ corresponds to the Frobenius norm. The left-hand-side term encourages connected nodes to be clustered together. It reaches its minimum when $\text{Tr}(\mathbf{S}^T \mathbf{A} \mathbf{S}) = \text{Tr}(\mathbf{S}^T \mathbf{D} \mathbf{S})$, meaning that the cluster assignments are equal for all the nodes in the same class and orthogonal to the cluster assignments of nodes from different classes. To avoid degenerate minima (uniform cluster assignments or all nodes being assigned to the same cluster), the right-hand-side term encourages the cluster assignments to be orthogonal

and the clusters to be of similar size. While in practice, it is not always desirable to have a perfectly balanced cluster assignment for music segmentation (due to the variable sizes of musical sections), the loss term $\mathcal{L}_{\text{MinCut}}$ acts as an effective regularizer that helps making the cluster assignment sharper. During training, we use the label agreement matrix \mathbf{Y} of each track as adjacency matrix and the predicted label assignment matrix \mathbf{S} defined in Section 2.6 as \mathcal{A} and \mathcal{S} in Equation (2.7) respectively. The whole system is trained end-to-end in a multi-task fashion, so as to minimize the overall loss function $\mathcal{L}_{\text{total}}$ defined as:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{Bound}} + \mathcal{L}_{\text{Label}} + \mathcal{L}_{\text{Link}} + \mathcal{L}_{\text{MinCut}}. \quad (7)$$

3. EXPERIMENTAL SETTING

3.1 Datasets

The proposed method is assessed on two standard datasets for music structure analysis. To reduce the number of possible section labels, we apply the annotation pre-processing step proposed in the work by Wang *et al.* [5]. We end up with a total of 7 unique section labels for both of the following datasets:

RWC-Pop: the Popular subset of the RWC dataset [28] contains 100 songs with section annotations. The original ones provided by the authors (AIST) are used.

Harmonix: the Harmonix dataset [3] is composed of 912 annotated tracks covering various genres of western popular music such as pop, electronic, hip-hop, rock, country and metal. The audio files were retrieved from YOUTUBE and structural annotations were manually adjusted.

3.2 Evaluation metrics

Common evaluation metrics for automatic structure analysis are employed throughout our experiments. For boundary detection, we report the F-measure¹ of the trimmed² boundary detection hit-rate with a 0.5 and 3-second tolerance windows (HR.5F, HR3F respectively). For structural grouping, we report the F-measure of pairwise-frame clustering [30] (PFC) and the F-measure of the normalized conditional entropy (NCE). We additionally measure the weighted label prediction accuracy (Acc), which indicates how well the model predicts frame-wise section labels.

3.3 Implementation details

All tracks are resampled at 22.05 kHz. As input to the frame encoder, we use log-scaled Mel-spectrograms with a window and hop size of 1024 and 256 samples respectively. We compute 64 Mel-bands per frame. The *TorchAudio* library is used for feature extraction [31]. As in previous work [15, 32], beats are estimated for all tracks using the algorithm from Korzeniowski *et al.* [33] implemented in the *madmom* package [34]. Slices of 64 frames

(≈ 0.75 s) centered at each detected beat location are fed as input to the frame encoder. The frame embedding dimension is set to $d = 32$ and kept fixed throughout the whole system. The number of channels in the link-feature extractor is set to $C = 16$, convolutions use kernels of size $k = 5$. All GNN layers are implemented using the *Deep Graph Library* [35] package. The whole model, including the pre-trained frame encoder, contains less than 330K parameters and is implemented³ with Pytorch 2.0 [36].

3.4 Experiments

In order to study the impact of each part of our method, we perform an 8-fold cross-validation ablation study on the Harmonix dataset. At each episode, one element from the system is removed: the pre-training stage (Section 2.2.2), the feature smoothing step (Section 2.3), the link features extraction (Section 2.4.2), the positional embedding (Section 2.4.3) and the MinCut regularization (Section 2.7). We use 6 splits for training, one for validation and the remaining one for testing. Then, we perform a cross-dataset evaluation, where one dataset is used for training (split beforehand into training and validation sets) and the other one for testing.

4. RESULTS

4.1 Ablation study

Results from the ablation study given in Figure 4 show the performance of the system when some of its components are discarded during training and inference. The different metrics are averaged over the 8 splits. In the first scenario, the frame encoder is randomly initialized like the rest of the model. We observe a significant decrease on all metrics, showing that the pre-training stage provides robust initial frame representations which are further tuned by the network during training. It is interesting to notice however that without pre-training the frame encoder, the model still predicts a good label assignment matrix, both in terms of pairwise frame clustering and label accuracy. We assume that the impact of this step is rather limited due to the relatively large size of the Harmonix dataset, which provides enough training examples to still learn useful frame features. In the second case, the MinCut regularization is discarded, which negatively impacts all metrics. This tends to confirm that the MinCut regularization enforces sharper cluster assignments, especially around segment boundaries where these can be more evenly distributed.

The most significant variation in segmentation performance is observed when the link feature extraction step is omitted. In this case, pairwise links between nodes are only characterized by their positional embedding and do not contain any structural information. This observation strongly suggests that the model benefits from both perspectives (node and link features) of the input track. When positional embeddings are removed, the link loss $\mathcal{L}_{\text{Link}}$ stops decreasing after several training iterations. Notably

¹ All evaluations are done using the *mir_eval* package [29].

² The first and last boundaries are discarded during evaluation, as they correspond to the beginning and the end of the track and therefore, do not provide any information regarding the system's performance.

³ Code: github.com/morgan76/LinkSeg

Figure 4. Ablation results on the Harmonix dataset in the cross-validation setting. Metrics are averaged across splits and standard deviation denoted with dark grey vertical bars.

because the network fails to differentiate “same-segment” from “same-section” links, which provides useful structural information near segment boundaries. In the case when the features smoothing step is removed, performance on all metrics, except the label prediction accuracy, is negatively impacted.

4.2 Comparison with previous work

This section compares the performance of our system against recent work for music structure analysis. The first one from Wang *et al.* [14], which we denote as DSF, uses supervised metric learning and spectral clustering [10] for boundary and section label predictions. SpecTNT [5] is based on a spectrogram transformer architecture and directly outputs both a boundary probability curve along with a frame-wise section label assignment. All in One [7] uses demixed spectrograms and several layers of neighborhood attention, operating simultaneously at the instrument and the temporal levels. These three baselines were trained and evaluated on the Harmonix dataset in a cross-validation setting. CBM, for Convolutional Block Matching [37] relies on dynamic programming to find the segmentation that minimizes a cost function. Its parameters were set by cross-validation on the RWC-Pop dataset.

Results on Harmonix and RWC-Pop are given in Table 1. In the cross-validation setting, the proposed method performs worse for boundary detection than the reported baselines. On RWC-Pop, despite being trained on a very small number of tracks (75 at each episode), the model still manages to pick up transitions between structural elements, even so at a high temporal resolution (± 0.5 second). This is to be compared with the first two baselines, namely DSF [14] and SpecTNT [5] which used the whole Harmonix dataset for training, along with additional datasets for the latter. The CBM algorithm [37] shows the strongest performance in this setting, as it explicitly favors musical segments of pre-defined length (which is around 8 bars in most cases for RWC-Pop), whereas our method does not make any assumption on the distribution of section lengths. It is also important to note that our system operates on a rather coarse time resolution (beat level) and only requires

a gross discretization of the input track’s timeline to function. We argue that better performance could be achieved by providing a more fine-grained time division (tatum level for example) but at a higher computational cost.

	HR.5F	HR3F	PFC	NCE	Acc
Harmonix					
DSF [14]	.497	.738	.689	.743	—
SpecTNT _{24s} [5]	.570	—	.700	.714	.701
SpecTNT _{36s} [5]	.558	—	.712	.724	.723
All in One [7]	.660	—	.738	.769	—
<i>Cross-val.</i>	.568	.717	.771	.772	.742
<i>Cross-dataset</i>	.462	.664	.660	.671	.530
RWC-Pop					
DSF [14]	.438	.653	.704	.739	—
SpecTNT _{24s} [5]	.623	—	.749	.728	.675
CBM [37]	.644	.806	—	—	—
<i>Cross-val.</i>	.585	.750	.785	.802	.813
<i>Cross-dataset</i>	.648	.786	.812	.812	.747

Table 1. Boundary detection and structural grouping results on Harmonix dataset. *Cross-val* indicates results that were obtained through cross-validation, averaged across splits. *Cross-dataset* refers to the results obtained when the model is trained on one and tested on the other.

In terms of structural grouping, the method proposed in this work outperforms all baselines on both datasets in most settings. Even though the label prediction method employed is rather simple and directly dependent on the boundary detection results, the model successfully learns to group frames across repetitions of identical musical sections. Finally, the high section label prediction accuracies obtained show that the network not only manages to successfully group frames together, but also predicts the right section label in a vast majority of cases.

Finally, cross-dataset results from RWC-Pop to Harmonix (*Cross-dataset* row) show that the model still generalizes to some extent, despite the very small quantity data used for training. On the other hand, training the model on Harmonix and testing it on RWC-Pop leads to strong performance both in terms of boundary detection and structural grouping, indicating that the network’s generalization capacity increases as more annotated data is available for training.

5. CONCLUSION

This work proposes a new approach to music segmentation by learning to characterize pairwise relationships between time instants in a musical recording. The structural view of the input track obtained from this auxiliary task can be combined with local frame information to effectively predict boundary locations between musical segments and section labels. Future research includes the extension of the link prediction task to various levels of segmentation and arbitrary labels semantic.

ABSTRACT

We introduce a project that revives a piece of 15th-century Korean court music, *Chihwapyeong* and *Chwipunghyeong*, composed upon the poem *Songs of the Dragon Flying to Heaven*. One of the earliest examples of *Jeongganbo*, a Korean musical notation system, the remaining version only consists of a rudimentary melody. Our research team, commissioned by the National Gugak (Korean Traditional Music) Center, aimed to transform this old melody into a performable arrangement for a six-part ensemble. Using *Jeongganbo* data acquired through bespoke optical music recognition, we trained a BERT-like masked language model and an encoder-decoder transformer model. We also propose an encoding scheme that strictly follows the structure of *Jeongganbo* and denotes note durations as positions. The resulting machine-transformed version of *Chihwapyeong* and *Chwipunghyeong* were evaluated by experts and performed by the Court Music Orchestra of National Gugak Center. Our work demonstrates that generative models can successfully be applied to traditional music with limited training data if combined with careful design.

1. INTRODUCTION

Six dragons fly on the east land; every endeavour is a heavenly blessing. This is the first line of lyrics in *Yongbieocheonga*, the first text written in the Korean alphabet (Hangul, 한글). Sejong the Great, one of the most respected figures in Korean history, invented and introduced Hangul in 1446. In addition to this remarkable achievement, he ordered scholar-officials to write *Yongbieocheonga*, and composed music to accompany the lyrics. Three other pieces composed at the time are *Yeo-Min-Lak*, *Chi-Hwa-Pyeong* and *Chwi-Pung-Hyeong*.

* Work mainly done during her master’s at Sogang University

Figure 1: Overview of the proposed research framework

These compositions are still preserved in the *Veritable Records of Sejong*, which is the oldest surviving musical score in Korea [1]. More detailed information is available here [2].

Among these three pieces, only *Yeominlak* is handed down to the present day, while the other two are no longer performed. The National Gugak Center¹, which is the primary organization dedicated to the preservation and development of traditional music, commissioned the task of reconstructing these two pieces in a performable format using artificial intelligence systems. Given a simple melody of 512 *gaks* (measures) of *Chihwapyeong* or 132 *gaks* of *Chwipunghyeong*, the system must generate scores for six different instruments.

Our solution encompasses a wide range of tasks in the field of music information retrieval—constructing a specialized dataset, optical music recognition, designing a

¹ *Gugak* (국악) is the Korean term for traditional music

domain-specific encoding scheme, training models with limited data, and generating music of concert-level quality. In this paper, we present in detail the different frameworks used in the project: two types of transformer-based models; a symbolic dataset of Korean court music acquired through optical music recognition; and a novel “Jeonggan-like” encoding method that notates monophonic melody by combining notes’ position and pitch, along with a beat counter that informs the transformer the temporal position. The effectiveness of the proposed techniques was validated through quantitative metrics and subjective evaluation by experts from the National Gugak Center. Finally, we introduce a web demo that allows users to examine and generate traditional Korean court music interactively.

This project has significance not only for cultural preservation but also for wider considerations in machine learning and music generation. One of the many benefits to be had from the inter-cultural study of music is the different perspectives expressed in ‘the music itself’ as well as any notational and/or theoretical traditions that go alongside it. As presented in previous research [3], the encoding of music makes significant differences in machine learning tasks. In thinking through different ways of digitally encoding music, we stand to learn a great deal from the various syntaxes that have been used in diverse traditional contexts.

2. RELATED WORKS

Recent advances in neural network-based music generation have resulted in much artistic output. Since 2020, the *AI Music Generation Challenge* [4] has been held annually, focusing on generating songs in the style of Irish and Swedish folk music. This event has allowed for exploration of new methods for generation and evaluation of traditional music through the means of deep learning models.

The *Beethoven X project* [5] utilized neural networks to learn Beethoven’s compositional style and complete his unfinished 10th Symphony. The resulting work has been performed by an orchestra—a project outline similar to that of ours.

Attempts at automatic generation have been made for traditional music from beyond the West, including Persia [6] and China [7]. The limited progress in such areas is often due to the distinctive traditional musical systems that demand deep understanding and unique methodologies. Such idiosyncrasies put much interest and meaning in the computational research of traditional music, since it can present new methods and perspectives to the field as a whole, while also helping preserve diverse musical heritages.

3. JEONGGANBO DATASET

3.1 Jeongganbo Notation

As depicted in Figure 1, Korean court music is performed on a variety of instruments, including plucked string instruments (*Gayageum* and *Geomungo*), bowed string instruments (*Haegum* and *Ajaeng*), and wind instruments

Figure 2: An example of Jeongganbo in the original notion (below) and a broadly equivalent conversion to Western classical notion (above). Dashed lines are part of neither notation and added simply to clarify the temporal alignment between the two systems.

Figure 3: Jeonggan-like encoding position labels

(*Daegum* and *Piri*), among others. These instruments are played together in a heterophonic texture, with each instrument employing its distinctive playing techniques and ornamentations.

Much of Korean court music is written in *Jeongganbo*, a traditional musical notation system. *Jeongganbo* is recognized as the first system in East Asia capable of simultaneously representing both pitch and duration of notes [8,9]. This versatility has been instrumental in passing down court music throughout history [10].

Jeongganbo uses grid-divided boxes (*Jeonggans*) as the basic unit of time. The *number* of characters (notes) and their *position* within each *jeonggan* varies to denote rhythm. Figure 2 provides an example passage, and figure 3 provides a schematic overview of possible positions.

Here, we provide a broad introduction to this rhythmic notation system in quasi-Western musical theoretic language. Each *jeonggan* is broadly equivalent to a beat. If a *jeonggan* features only one character, this note event starts at the beginning of the beat and lasts the beat’s full duration. The first box (‘0’) in figure 3 is in this form as is the second *jeonggan* of figure 2 where the ‘compound beats’ correspond to the duration ♩. (in this case for the note B♭4). At the next metrical level we have the ‘column’ division of the ‘rows’. This number of ‘rows’ relates broadly to the top level division of the beat. The use of three vertically stacked characters refers to 3 equal divisions of this beat (here, 3 x ♩s). For example, in figure 3, the numbers 4–9 feature a 3-part division of the ♩ beat into 3 x ♩s (positions 4, 6, 8), and a 2x division of those ♩s (e.g., 4–5). If the following *jeonggan* is empty, the previously played note is sustained.

Playing techniques and ornamentations called *sigimsae* are sometimes notated for each instrument. When *sigimsae* are placed to the right of notes, they serve as ornamentations or embellishments for the corresponding note; when written on their own, they indicate timed instructions to play a specific note or musical phrase. For convenience,

Figure 4: Comparison between encoding schemes

the example score is notated horizontally, but in practice, the score page is read from top to bottom and right to left. A line in *Jeongganbo* can consist of anything from four to twenty beats, with each line representing a phrase unit.

3.2 Machine Readable Dataset

We have constructed a dataset of 85 pieces by applying optical musical recognition (OMR) to all compositions available within the manuscripts published by the National Gugak Center. The manuscripts cover the entire repertoire of remaining Korean court music². OMR was necessary since the scores are only provided as PDF images and the semantic data is unavailable. We implemented and trained an encoder-decoder transformer with CNN by synthesizing various *Jeonggan* images in a rule-based approach [11]. In total, the dataset comprises 28 010 jeonggans across 85 pieces. When counting each instrument part independently, the combined total amounts to 141 820 jeonggans. Out of 90 pieces notated in jeongganbo for ensembles of at least two different instruments in the published manuscripts, we excluded 5 pieces that have discrepancies in the total number of jeonggans across instruments.

4. JEONGGAN-LIKE ENCODING

In the field of symbolic music generation for Western monophonic and polyphonic music, encoding schemes such as ABC notation, which denotes pitch and duration separately, are effective and prevalent [12, 13]. However, when it comes to Korean court music, whose heterophonic structure is a defining characteristic, it is crucial that the intricate alignment of different melodies be well-represented in encoding. The genre also exhibits prolonged notes and considerable variations in note lengths, which proves to be a challenge for learning algorithms, especially when data is limited.

These distinct musical qualities call for a specialized encoding scheme; for this, we propose *Jeonggan (JG)-like encoding*, which closely follows the positional notation of *Jeongganbo*. This symbolic music encoding method is modeled to inherently reflect the composition and notation style of traditional Korean court music.

The detailed rules of encoding are as follows. The boundary of a *Jeonggan* is designated as a bar (|) to-

² The term “court music” used in this paper originally refers to *Jeong-ak*. Jeong-ak includes not only court music but also salon music and military music. However, for readability, we use “court music” here.

ken. Change of measure (called *Gak*) is indicated by a line break ($\backslash n$). As illustrated in Figure 3, the position of each note is denoted by a number between 0 and 15, after which the pitch symbol follows.

Ornamentations (*sigimsae*) can either have a duration or not. *Sigimsae* with duration, such as the ‘ \neg ’ symbol in Figure 4, are handled in the same way as pitch symbols. *Sigimsae* without duration such as ‘ \wedge ’, which appear at the side of the pitch character, are placed after the corresponding pitch symbol.

There are several advantages that we can expect to gain from using *JG-like* encoding. First, with position-based encoding, the duration-related vocabulary is limited to just 16 entries. In contrast, duration-based encoding schemes require learning each duration token as a separate entry, resulting in a significantly larger vocabulary. Additionally, rather than determining the length of a note with a single calculation, JG-like encoding allows for the flexible adjustment of note lengths during inference via combination of *jeonggan* boundary and position tokens. This enables generation of music that is more adaptable to the time step and takes into account the sequence of the input source, which can be expected to result in more dynamic and context-aware music generation.

4.1 Other Possible Encodings

REMI (revamped MIDI-derived events) [14] first proposed the usage of beat-position feature rather than time-shifting to encode temporal position. We also experiment with REMI-like encoding which adopts three token types: beat position, new beat (instead of new measure), and pitch tokens. We intentionally design REMI-like and JG-like encoding to share the same structure and result in the same number of tokens for a given melody. They differ in that JG encoding provides intra-JG position, while REMI encoding provides the beat position of the note. According to the position labels shown in Figure 3, any of [0, 1, 4, 10, 12] can correspond to beat position 0. However, in JG-like encoding, each occurrence of position tokens limits the possibilities of subsequent ones. For instance, a position token of 0 implies that no more notes will occur in the same *jeonggan*, and if the first note is 1, one or more additional notes should follow with values of 2-3 or 6-9. In contrast, in REMI-like encoding, any offset value can follow a beat position of 0. To examine the impact of this position-based logic on the generation process, we use REMI-like encoding as our first baseline for comparison.

As a second baseline, we implement an ABC-like encoding scheme that does not have a separate bar token and encodes each note as a combination of pitch and duration values. Note that we do not omit duration tokens that are equal to unit length as ABC encoding typically does.

5. ORCHESTRAL PART GENERATION

5.1 Transformer Sequence-to-sequence Model

We implement an encoder-decoder transformer [15] model to generate melodies for different instruments based on a

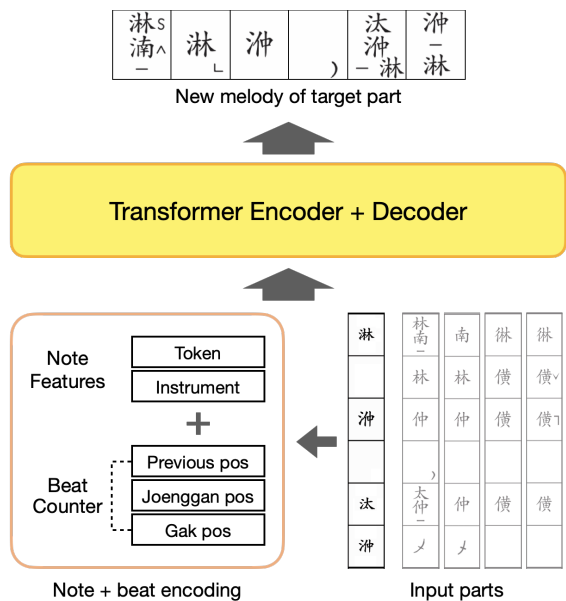

Figure 5: Orchestral part generation

given instrument’s melody, leveraging its ability to learn long-term dependencies. Unlike RNN-based models, the transformer calculates relationships between all elements in a sequence via the self-attention mechanism, enhancing its capability in symbolic music generation [16, 17, 18]. The model consists of an encoder that processes the input sequence and a decoder for generating the output sequence. Our objective is to generate melodies that synchronize with the input melody across musically equivalent phrases; self- and cross-attention within the model enable understanding of musical context at measure and bar levels, capturing the repeating structure of melodies and accents prominent in traditional Korean court music.

5.2 Beat Counter

Instead of sinusoidal [15] or learned [19] positional embedding commonly utilized in transformer-based models, we implemented a ‘beat counter’ embedding that provides information about temporal position.

For a model to learn to ‘parse’ semantic position only from the tokens’ sequential position is challenging, if not impossible, with limited training data and a small number of transformer layers. Therefore, we explicitly encode the musical position of each symbol as a combination of measure index, beat index, and sub-beat index (in-*jeonggan* position) as shown in Figure 5. This information is summed into note embedding, just like positional encoding of transformer [15].

As previous research of PopMAG [20] demonstrated, metrical position embeddings can replace the positional encoding of transformers in symbolic music. A minor difference between PopMAG and our approach is that the model predicts only the appearance of new measures or new beats without the index of them, and that the new beat can be used for elongating the duration of previous note.

The same idea of embedding the beat counting has been

previously applied to RNN-based Irish melody generation in ABC format [21], while its advantage was not properly evaluated. A similar idea, using metrical position instead of or along with absolute token position, has also been applied to transformer architecture [20, 22, 23]. However, our results presented in Section 6.3 demonstrate that this beat counter embedding is essential for making the model properly understand the musical contents.

6. EXPERIMENT AND RESULTS

6.1 Training

We split the *Jeongganbo* dataset into three subsets: 75 pieces for training, 5 for validation, and 5 for testing. Each piece contains melodies for up to 6 instruments. The sequence-to-sequence model takes 4 measures of melody, each from a randomly selected number of instruments, as input to the encoder; and given a target instrument condition, it generates the corresponding 4 measures of melody for the target instrument. Note that the number of beats in a single measure is at least 4 or to a maximum of 20 in our dataset.

The transformer encoder and decoder both consist of 6 layers, 4 attention heads, and a hidden dimension size of 128 with dropout of 0.2. We train for 35 000 updates across 300 epochs using negative log-likelihood loss. We also employ mixed precision training [24] to enhance performance and efficiency. We utilize the Adam optimizer with an initial learning rate of 0.001 and apply a cosine learning rate scheduler with 1000 warmup steps. Using a batch size of 16, training can be conducted on a single Nvidia RTX A6000 GPU.

6.2 Evaluation Metrics

6.2.1 Length Match Rate

As an evaluation metric, we check whether the input and output melodies share the same number of measures, a consistency necessitated by our task. Since the length of a measure can change in the middle of a piece, this metric serves as an indicator of the model’s ability to capture the musical context of the input melody and accordingly generate a musically complete melody. We measure *length match rate* as the percentage of generated melodies whose number of *jeonggans*, after decoding the output tokens, matches that of the input melody.

6.2.2 F₁-Score

Regarding the generation task as one with a fixed answer, we can measure the accuracy of the generated melody by directly comparing it with the ground-truth target melody. Thus, as a general accuracy metric, we calculate the F₁-score of predicted notes, where only the notes with the exact same onset position and pitch are counted as correct. To make a fair comparison between encoding methods, note onset positions in JG-like encoding were converted to those in the REMI-like format. Ornamentations without duration were not counted.

	<i>Piri to Geom.</i>		<i>Every to Daeg.</i>	
	len-mat	F1	len-mat	F1
JG-like	0.942	0.679	1.0	0.614
REMI-like	0.923	0.567	1.0	0.532
ABC-like	1.0	0.704	0.903	0.542
JG w/o Counter	0.135	0.043	0.269	0.052
REMI w/o Counter	0.269	0.081	0.192	0.039
ABC w/o Counter	0.403	0.090	0.115	0.016

Table 1: Quantitative evaluation results

6.3 Results and Discussion

In our sequential generation process, melody for the instrument geomungo, characterized by its low pitch range and simple melodies, is the first to be generated from the initial piri melody. The daegeum, typically featuring the most complex and nuanced melodies among the six instruments, is the last in line. Table 1 displays the results of objective evaluation, specifically focusing on geomungo and daegeum.

For generation of geomungo melodies, ABC-like encoding yields the best results. This appears to be due to the simple and regular melodic structure of the geomungo which fits in well with ABC-like encoding. On the other hand, in the task of generating daegeum melodies, JG-like encoding achieves higher F₁-scores. This indicates that JG-like encoding outperforms other methods in generating complex and varied melodies. We also discover that as rhythmic complexity increases, the measure length match rate of ABC-like encoding decreases.

To examine the effectiveness of the beat counter technique, we compare our model that incorporates beat counter with a baseline model that instead employs absolute position embedding [19], a technique commonly used in symbolic music generation.

The results in the lower part of Table 1 show that the models without beat counter fail to generate melodies with appropriate lengths. The problem is less severe in ABC-like encoding, as processing accumulating duration tokens can be easier than counting *jeonggan* boundaries. This demonstrates the efficacy of the beat counter technique in JG-like encoding, and its ability to replace traditional positional encoding.

7. 15TH CENTURY MELODY TRANSFORMATION

To generate an entire ensemble score using our method, we require an initial input melody with a specified instrument. However, the remaining 15th-century score of *Chihwapyeong* and *Chwipunghyeong* only provide a single melody without any mention of instruments. It also features rhythmic groupings of eight beats, which is rare in court music that is played today. We therefore need to transform the old melody for a specific instrument used in court music; to maintain the outline of the original melody while achieving plausible transformation, we train a masked language model on our *Jeongganbo* dataset be-

fore infilling the 15th-century melody.

7.1 BERT-like Masked Language Model

Bidirectional Encoder Representations from Transformers (BERT) [25] is a self-supervised language representation learning model that uses a bidirectional transformer instead of a causal transformer decoder. It is trained with a masked language model (MLM) objective, where tokens in the input sentence are randomly masked and the model predicts the original vocabulary ID of said masked tokens. Because of its advantage in exploiting bidirectional context, BERT-like models have also been adapted for music audio generation [26] and symbolic music generation [27, 28] along with representation-learning purpose adaptation on symbolic music [22, 29].

7.1.1 Piano-roll-like Encoding

One of the main limitations of using a BERT-like model for generative tasks is that the sequence of given (unmasked) tokens and masked tokens has to be pre-defined. This means that one has to decide the number and position of new tokens to be inserted for a given original sequence. To avoid this, we use piano-roll-like encoding for the MLM, a technique widely employed in works on music generation with limited rhythmic patterns such as in Bach Chorales [30, 31, 32, 33]. Here, each *jeonggan* is represented as six frames, with each frame including features for symbol (pitch or *sigimsae* with duration) and for ornamentation. We also apply the aforementioned beat counter in piano-roll encoding.

7.1.2 Training with Masking

Following examples in MusicBERT [29], we train the model with masked language model objective with various masking methods: i) masking 5% of frames, ii) replacing 5% of frames, iii) masking 20% of note onsets, iv) replacing 10% of note onsets, v) erasing 10% of note onsets, vi) masking the entire 6 frames of 15% of *jeonggans*, and vii) masking 50% of ornamentations.

Though the model can be trained to handle an arbitrary number of input instruments, we only train the model with a single instrument as with our orchestration transformer, since the main intended usage of the model is to create variations of a single melody. We train a 12-layer model with the same dataset and hyperparameter settings as with the orchestration model.

7.2 Inference Procedure

For converting and performing monophonic melodies, we opt for a 30x ♩ span which equals to 10 *jeonggans*. This also corresponds to the rhythmic pattern of the 4–7th movement of *Yeominlak*. The original *Chihwapyeong* and *Chwipunghyeong* melody, which can be interpreted in an 8/8 time signature, were modified by strategically inserting empty *jeonggans* to the 5th and 7th positions, to imitate *Yeominlak*'s rhythmic pattern. Utilizing the masked language model, the modified melodies were seamlessly

transformed into a piri melody. Piri, a double-reed instrument known for its loud volume, was chosen as the main instrument for conveying the original melody due to its prominent role in contemporary court music.

As the models were all trained on 4-measure chunks, we generate the full sequence of 512 or 132 measures using a moving window, providing two measures of previously generated output as teacher-forcing inputs and generating one more measure for each four-measure input. These were applied in a similar manner to both melody transformation and orchestral part generation. Once the melody is transformed into a piri melody, we feed it to the orchestral transformer to generate parts for five other instruments. We sequentially generate for each instrument with the previously generated part as input. The final generation order is as follows: piri, geomungo, gayageum, ajaeng, haegeum, and daegeum.

Following the initial generation of melodies for all six instruments, we perform a refinement step. Here, each instrument’s melody is regenerated with the melodies of the other five as input. This additional process helps to reinforce the melodies that initially had to be generated without the context of the other instruments.

7.3 Expert Reviews

The Court Music Orchestra of the National Gugak Center performed the generated *Chihwapyeong* and *Chwipunghyeong* on the birth anniversary of King Sejong at Gyeongbokgung Palace on May 14th, 2024. They performed it again at the National Gugak Center on June 2nd, 2024 with an introduction to technical background by the authors. Due to time constraints, only partial excerpts from the entire score were performed.

The musicians gave positive opinions such as “*genre-specific rhythm and melodic flow were well-represented*” and “*the generated pieces presented ornamentation techniques and melodic progressions specialized for each instrument.*” Still, there were a few instances where notes that did not fit the scale appeared, and when notes outside the appropriate range were present, the performers had to alter or omit them or change their octave to perform the piece. However, the generated results were acknowledged to closely resemble the target style of Yeominlak. Thus, the Court Music Orchestra decided to play the pieces in a similar ensemble size to Yeominlak without further modification.

We additionally evaluate the generated scores, focusing on the effects of the refinement step. The evaluation criteria were carefully selected to assess aspects that require a deep understanding of the genre. These criteria include 1) the appropriateness of the scale and range for each instrument (*scale*), 2) the proper use of unique characteristics and ornamentations specific to each instrument (*sigimsae*), 3) the suitability of the rhythmic structure of strong and weak beats (*rhythm*), and 4) the harmony and coherence among the instruments when performed together as an ensemble (*harmony*).

Seven employees from the National Gugak Center who

	<i>No Refinement</i>	<i>With Refinement</i>
Scale	4.0 (± 0.53)	4.0 (± 0.53)
Sigimsae	3.4 (± 0.73)	4.0 (± 0.53)
Rhythm	2.9 (± 0.35)	3.3 (± 0.45)
Harmony	2.9 (± 0.83)	3.3 (± 0.70)

Table 2: the average and std of opinion scores from 7 judges for systems with and without refinement.

majored in Korean traditional music instruments or theory participated in a subjective survey. We name the pre-refinement generation results piece A, and the final output after the refinement step piece B. The evaluators were not informed of this distinction. The participants assessed the pieces for the four criteria on a 5-point scale (1-5) and provided qualitative feedback on the two compositions. The results are summarized in Table 2. These results demonstrate that the proposed refinement process effectively enhances the overall quality of the generated music, especially for *sigimsae* of each instrument.

8. CONCLUSION

Throughout this work, we explored how music generation models can resurrect ancient melodies into new compositions that meet style of current-day Korean court music.

Venturing into relatively uncharted territory, we approached each step meticulously—from data curation and parsing to model architecture design—while carefully considering the unique nuances of the musical tradition. To enhance the quality of the generated outputs, we proposed a novel encoding framework and validated its effectiveness through objective and subjective measures. This endeavour to tackle an underrepresented non-Western music genre through diverse MIR lenses hopefully expands the horizons of the field.

The *Jeongganbo* dataset and its conversion to Western staff notation in MusicXML is available online, along with other code of this project, and video recording of the performance.³ To the best of our knowledge, this will be the first dataset of machine-readable *Jeongganbo*. We believe that this dataset can significantly contribute to computational ethnomusicology beyond its usage as a training dataset for music generation demonstrated in this paper.

We also provide an interactive web demo⁴ that showcases our proposed generative model. While this project focused on reviving melodies from the 15th-century, the web demo allows users to input their own melodies and create orchestrations of Korean court music. The interactive platform enables users to directly engage with the generative model in the web browser.

We hope that this project contributes to moving closer to leveraging machine learning to make traditional music more accessible and enjoyable for modern audiences.

ABSTRACT

This paper discusses the transcription of a collection of musical works using Optical Music Recognition (OMR) technologies during the implementation of the Spanish PolifonIA project. The project employs a research-oriented OMR application that leverages modern Artificial Intelligence (AI) technology to encode musical works from images into structured formats. The paper outlines the transcription workflow in several phases: selection, preparation, action, and resolution, emphasizing the efficiency of using AI to reduce manual transcription efforts. The tool facilitated various tasks such as document analysis, management of parts, and automatic content recognition, although manual corrections were still indispensable for ensuring accuracy, especially for complex musical notations and layouts. Our study also highlights the iterative process of model training and corrections that gradually improved transcription speed and accuracy. Furthermore, the paper delves into challenges like managing non-musical elements and the limitations of current OMR technologies with early musical notations. Our findings suggest that while automated tools significantly accelerate the transcription process, they require continuous refinement and human oversight to handle diverse and complex musical documents effectively.

1. INTRODUCTION

In recent years, many institutions have digitized their collections to preserve them and make them available online for broader public access. Digital images, however, merely contain a grid of pixels and lack inherent musical meaning; thus, they do not lend themselves to the myriad possibilities offered by music information retrieval and digital musicology approaches, ranging from plain-text content searches to more sophisticated analytical purposes. To leverage these technologies, the music depicted in the

images must be encoded in a structured format, such as MEI [1] or MusicXML [2], among others.

Over the past few years, Optical Music Recognition (OMR) technologies have been employed to facilitate the encoding of music scores into structured digital formats [3]. Alfaro-Contreras et al. [4] demonstrated that the most effective method for obtaining digitally encoded scores is through the use of OMR technology. Their research indicates that the accuracy of OMR in recognizing musical notations varies depending on the type of document, the quality of the source material, and the complexity of the notation.

Despite its advances, OMR technology seldom produces flawless results, and the extent of necessary post-editing is determined by the intended use of the digitized content. For instance, some initiatives, such as F-Tempo¹, utilize OMR outputs—even when they contain errors—for conducting search operations. However, when a polished transcription is required, manual corrections become indispensable. This was the case considered in the digitization of a vast array of files for the KernScores database.²

The limitations of OMR technology are not solely determined by its recognition accuracy. To date, no OMR system is capable of comprehensively processing the entire spectrum of symbols found in all kinds of musical notations. The complexity of analyzing orchestral scores, with their varied layouts and the inclusion of *ossias*, or managing compositions where different parts are noted on separate sheets, further complicates the scenario. Consequently, in many practical applications, the encoding is ultimately carried out by human transcribers using computerized notation software like MuseScore³ or Sibelius.⁴ In specific projects such as Didone [5], about 4 000 18th-century Italian Opera arias are manually transcribed in Finale⁵ before being converted into MusicXML. This methodology was similarly employed to achieve the encoding of modern versions of Renaissance compositions from the “Josquin Research Project”.⁶

Furthermore, several OMR solutions exist for tran-

scribing Common Western Modern Notation (CWMN), with Audiveris⁷ standing out as the sole open-source option alongside several proprietary alternatives, including SmartScore,⁸ PhotoScore,⁹ and PlayScore 2.¹⁰ The performance of these varies significantly based on the sheet music’s complexity and clarity. An evaluation of their efficiency in recognizing content from music theory books is detailed in the work of Moss et al. [6], highlighting the challenges they face in complex situations.

For early notations, the choices are much more limited. The SIMSSA project [7] considered two software tools—Gamut and Aruspix [8]—for automatic information extraction from images, although these tools are no longer actively supported. Additionally, the project developed an OMR meta-workflow named Rodan, enabling users to assemble custom processing systems from a library of image processing and machine learning modules [9]. While Rodan is not tailored to any particular musical notation, its components are predominantly focused on plainchant. Recently, a web-based OMR application named MuRET has been introduced as a research-oriented tool designed to facilitate the scientific study of the complete OMR workflow across various scenarios and notations [10]. This includes analyzing the real impact of improvements in automatic recognition models and their integration for practical purposes in the work of transcribers.

In this paper, we outline the entire process undertaken in the context of the Spanish PolifonIA project, for which MuRET has been utilized and refined to transcribe the entire collection of white Mensural notation held by the National Library of Spain (BNE) from scratch. We will detail all stages of the process, aiming to provide useful takeaways for other similar projects and transcription tools based on OMR. This includes discussing both manual and automated stages, the steps that may benefit from advancements in OMR techniques, those that still require human intervention, and which processes need to be streamlined due to their significant impact on workflow performance.

To illustrate the aforementioned aspects, figures will detail how, by the end of the project, more than 60 books containing around 12,000 images—some consisting of several pages—were encoded in just 18 person-months. Additionally, the figures will showcase how an iterative approach of transcription, correction, and AI-model training gradually accelerated the whole process.

The remainder of the paper is organized as follows. First, the data that has been transcribed is briefly introduced in Section 2. The following Section 3 describes the whole workflow used for obtaining a final digital score from a set of images in the source collection. This workflow will be analyzed from a quantitative point of view in Section 4, and then discussed from a qualitative perspective in Section 5. Finally, Section 6 concludes the work and discusses possible ideas for future research.

2. DATA

Although the workflow and evaluation described in subsequent sections are somewhat generic, this section provides details of the digitized collection to contextualize its significance.

The collection considered for the project totals 63 works, almost entirely in print editions dating from 1533 to 1811, and mostly written in white Mensural notation. The genres of these works are varied, comprising mainly vocal polyphonic pieces, although there is a presence of instrumental, dramatic, and even treatises. Their functions are predominantly religious, with some presence of profane songs. Their formal structure is linked to this, highlighting the complexity of formats in religious works ranging from Passion Cycle and Missae to the simpler forms of chansons or motets, among others. In polyphonic works, the parts are usually written in separate books.

Regarding printers, the collection features works from the Italian School such as: Scoto, Gardano or Vicenti from the Venetian; Dorico and Robbetti from the Roman; and Carlino and Beltrano from the Neapolitan. Le Roy and Ballard are prominent in the Paris School, along with the Flemish School’s Phalesius, Bellere, and Susato. Spanish publishers include Ibarra, Doblado, and Martinez Dávila in Madrid editions.

3. TRANSCRIPTION WORKFLOW

The transcription workflow can be broken down into several sequential phases.

The first stage involves the selection and compilation of works to be transcribed, either in PDF format or as a set of individual images. These are properly ordered through their file names following a lexicographic criterion for avoiding the need for time-consuming manual reordering within the tool.

For the sake of time and organizational management, the works are classified into different collections according to similarities in notation and/or publisher. This allows works sharing similar visual aspects to utilize the same machine learning models without adjustments between them. Considered features include notation type (plain chant, mensural, transitional scores, modern notation), engraving method (handwritten or typeset—where the copyist or printer is noted for sharing typography and layout styles), contents (treatises, instrumental and vocal music including lyrics), and the presence of elements such as basso continuo.

The next step involves uploading the works to MuRET. This tool employs OMR models that drastically reduce the image sizes to heights of 256 pixels. Although it utilizes IIIF servers that manage image resizing, for transcription purposes, it is not necessary to import high-quality images, but rather those with sufficient resolution to be readable on the user’s device. To avoid wasting server processing time and space, a prior down-sampling of images is advisable.

In the next stage, we refine the content imported into the tool. Most of the imported image sets contain covers, empty pages, and indexes that, while not containing strictly

Figure 1. Example of document analysis and part assignment. Box colors represent different region types.

music information, are useful for extracting metadata and should be discarded but not removed, as they can guide the transcription process. Although some processes exist to automate this detection of pages with actual music content [11], MuRET does not include this desirable feature. Once the images are loaded and filtered, longer works to be transcribed must be divided into sections, such as the different parts of a mass (Kyrie, Agnus, etc.) or the movements of a concerto.

The final block aims to perform the actual transcription of the works. It consists of four main operations that will be detailed below: analyzing the document layout and dividing it into regions of interest, associating each staff with a part or instrument, recognizing the music contained in each staff and its encoding, and, finally, using all that information, scoring up all the parts to form a final digital score.

The document analysis and staff-level recognition of music symbols are performed using deep learning technologies [10]. Generally, we follow the same scheme for handling new works to be transcribed. First, models trained with previous collections are applied, mistakes are corrected, and then iteratively, new models are built, either specific for the collection if it is very different from previous documents, or following the proposal in [12], general for all transcribed collections. When faced with a new manuscript, the strategy is to first evaluate with the latest general model. If this does not perform well—which is evaluated subjectively by the user—we proceed to label, with or without the help of the OMR output, about twenty pages of the new work, then build specific OMR models and, in addition, enrich the general model for future works.

3.1 Document analysis

Upon arranging the images, the initial action in transcribing a manuscript, termed *document analysis*, involves dividing each image into distinct elements. This process detects various region types within the images, such as staves, lyrics, part names, among others, as illustrated in Figure 1. Typically, an image encompasses only a single page. However, scans of entire books are also common, resulting in images that depict multiple pages simultaneously, akin to the example shown in the figure.

3.2 Part management

The majority of materials requiring processing are polyphonic, composed of multiple voices or instruments. These

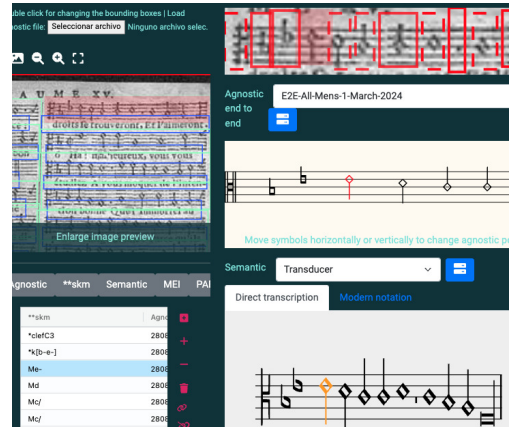

Figure 2. Agnostic representation and its semantic conversion in MuRET.

materials come in various formats, such as compositions with parts spread over several pages, or choir-books that display two voices on a single page (see Figure 1), among others. Occasionally, the document intended for transcription is dedicated to music theory, as seen in music treatises [6], predominantly featuring textual content with occasional musical illustrations. Currently, the assignment of parts is performed manually.

3.3 Region-wise content recognition

After distinguishing and assigning the various staves to their respective parts, it becomes essential to extract the musical elements located within each staff.

The approach applied divides the recognition of the musical content in a staff in two steps (see Figure 2). First, it extracts what is referred to as *agnostic representation* [13], i.e., tokens that have not yet been assigned a specific musical meaning, as well as their absolute vertical positions on the staff, regardless of the clef used. Then, these are automatically transduced into a meaningful ***mens* encoding [14], that can be manually post-edited.

After the automatic recognition, the eventual mistakes must be corrected. We found four different kinds of errors, with different impacts on the time required to be corrected. The easiest mistake is that of the vertical position of a recognized symbol (1), that is amended just with a mouse or keyboard action. A symbol whose type is wrongly detected (2) requires a slight higher effort, as it takes some seconds to find the expected symbol among all the possibilities. The removal of a symbol (3) is a very quick operation, while adding an undetected symbol (4) requires drawing a box over the manuscript image.

Note that for those difficult manuscripts for which all automatic models generate too many errors, as that shown in Figure 2, it might be preferable to manually add all agnostic symbols as described above.

3.4 Scoring up and exporting

As above mentioned, most of the works transcribed in the project are organized into separate parts or choral books, where different voices or instruments are scattered across

Figure 3. Example of alignment in MuRET. Some textual data is included below the staves to indicate reference points of the corresponding source image. Dashed bar lines are used to help detecting alignment errors.

different pages. Having already identified to which instrument each staff belongs (Sect. 3.2), this operation is simply accomplished by concatenating all the staves of the same part.

However, in Mensural notation, a preliminary step is required to correctly align the voices. In this notation, some notes may have different durations depending on the context, despite their appearance. The contextual resolution of durations, resulting in changes called *perfection* and *alteration*, can be carried out in MuRET either automatically, by applying the rules established in [15], or manually, by editing the `**mens` code.

In any case, mistakes such as missing symbols, incorrect duration elements, or invalid perfection assignments can only be detected by visually inspecting the aligned score (see Figure 3).

The final step of the process is exporting the transcription into an interchange or storage format. In the particular case of MuRET, the MEI standard is considered, offering two possible export formats: a parts-based MEI format that includes graphical information in the facsimile element or the arranged score MEI file.

4. QUANTITATIVE EVALUATION

MuRET records all operations performed by the user, saving the timestamp of each action and the element on which it is performed.

In this evaluation we address three questions. The suitability of using a transcription tool such as MuRET in a real-world scenario, the relative importance in OMR operations compared to the other tasks, and the ability of machine learning approaches to improve their accuracy as training datasets are iteratively expanded.

The first question is evaluated by comparing the performance of the tool with the theoretical hypothesis proposed in [4]. The first two rows of Table 1 show the times reported in [4] for processing 126 typeset pages of a *Magnificat*, either totally manually, or using an OMR.¹¹ Note that in that work, only the agnostic representation is obtained, and the time required for performing all the other tasks, such as the document analysis, or document preparation is

discarded. Automatic processing times are in all cases less than 1 second after loading the models into memory.

The next two rows show the process performed in the current project with the same *Magnificat*. First, the time to perform OMR processes (document analysis and recognition of agnostic symbols in each staff), then the entire transcription process, including all phases of the workflow. The final review of the scoring up has been excluded from these figures because in many cases the time is spent on musicological discussions of the manuscript rather than mechanical issues.

Finally, we have added to the table the worst case of those encountered in the project because it is a very difficult one due to the very low resolution of the images, which would have been extremely tedious to transcribe without the help of OMR (see Fig. 2), and the best case found for which the existing general OMR models have been able to correctly detect almost all symbols, and no part management was required.

The times reported demonstrate the suitability of using an OMR approach, but also the major impact on the whole process of the other, non-directly OMR processes, which cannot be overlooked.

Table 1. Summary of annotation times per page.

Scenario	Avg. Time/Page
<i>Magnificat work</i>	
Manual agnostic annotation [4]	49'19" ± 11'27"
OMR of agnostic representation [4]	15'23" ± 2'44"
OMR: doc. analysis and agnostic	22'07" ± 20'42"
Whole transcription process	29'09" ± 23'37"
<i>Whole project collection</i>	
Worst case (whole transcription)	52'31" ± 23'31"
Best case (whole transcription)	4'30" ± 1'51"

Regarding the second question, compare the relative importance of classic OMR operations with other operations such as document preparation or parts management for an entire collection, we show in Table 2 the times of all actions performed in MuRET grouped by all the workflow phases described in Sect. 3. The figures show that as it could be expected, the recognition of the musical symbols in each staff is the most time consuming task, followed by the semantic conversion and the document analysis, and what a priori could seem a slow operation, the manual assignment of parts to the staves, is a very small portion of the total, even lower than the preparation of images and organization into sections prior to the transcription itself.

Finally, to evaluate how incremental training of OMR models leads to better OMR behavior, we report in Fig.4 the number of operations performed on each image throughout the life of the project. Using the date axis is interesting because as the project has progressed, we have had more accurate OMR models because we have been trained on more data.

In the figure, we have used the number of operations instead of times because the time depends on the laptop on

¹¹ This value is computed from the values of Figure 2 in [4]

Table 2. Summary of time per phases.

Phase	Processing times
Document preparation	830'08''
Document analysis	4.913'36''
Part management	429'37''
Agnostic representation	1.9536'59''
Semantic encoding	10.923'55''

Figure 4. Evolution of transcription operations over time for all images in the project. Each point represents the number of operations required to transcribe a page.

which the operation was performed, since all classification models in MuRET are executed in the browser. Also, depending on the work, the number of staves of each image varies. To solve this, the graph shows the relationship between the number of operations and the number of staves of each image.

The figure shows how the average number of operations over time tends to be lower as the date progresses. We observe that an initial specialization of the OMR engine does help, and after that the user effort is stabilized.

5. QUALITATIVE EVALUATION OF THE WORKFLOW: OPPORTUNITIES

In this section we analyze the suitability of the involving stages of the transcription workflow to draw good practices for the development of OMR tools. We will discuss which operations we believe could be fully or partially automated to speed up the process and avoid tedious and repetitive work as much as possible.

The preparation of the works to be transcribed and its correct organization have been decisive for the success of the project. Since there is not yet a universal OMR model capable of dealing with any possible entry, the grouping of the pieces according to time period and typographic or calligraphic style, and the arrangement of the transcription following these groups, has been a key factor. In cases where, for some reason, we interleaved a piece out of that order, the performance decreased. While this clustering process was performed manually by computer scientists and musicologists, automating it could help to know in advance which existing OMR model could be applied to a new manuscript. Also, it is interesting to automatically de-

tect whether no model is able to process the manuscript and manual labeling of a number of pages is required to build a specific one.

A factor that we have already mentioned is that of the image resolution and, implicitly, the weight of the files. Although IIF servers are able to deal with the resizing of images, we have experienced a noticeable speed-up when the uploaded images are of smaller sizes.

Initially in the project, each work was processed following the different steps sequentially image by image. After processing some, instead, another approach was proved to be more convenient: perform all the operations of each phase for all the images of the work in batches. This allowed us to follow up on the work and detect possible errors made or not detected. It is important to note that in cases where we did all the tasks on each page and only reviewed them once, we made more errors. This approach was enhanced by a new feature added to MuRET in the middle of the project: the possibility of automatically tagging all work for later correction, which drastically improved transcription times by saving us OMR processing times for each page and staff (done “offline”).

A key aspect with a huge impact on the throughput of the workflow has been the (sometimes questionable) decisions of the MuRET developers in terms of UI/UX. The simplicity on the correction of the agnostic staff level automatic transcription and its automatic conversion into a meaningful semantic encoding in `**mens` format helped to minimize the impact of inaccurate OMR model predictions. A paradigmatic example has been the change in MuRET for the way of processing ligatures. The first OMR models in MuRET were not able to detect different mensural ligatures, but all different ligatures as a common symbol. The conversion of all ligatures to their final `**mens` encoding took longer than automatically encoding and correcting an entire page. During the transcription project, this tool was able to detect all the individual components of the ligature (plicas and note heads). Being quite accurate, when failing, the correction of the individual components took the same time as deleting the whole detection and adding them again. In a later version, this approach was changed by another one where the ligature was converted in a lower number of elements (different notes with or without plicas) with a bit worse OMR performance. However, for the purpose of final correction times, this change was appropriate because from then on, the correction time for errors was equivalent to the correction time for any other element.

Following this line, an aspect that could improve the efficiency of use of the system would be an easiest correction procedure of wrongly detected agnostic symbols. Currently, the user has to locate the symbol into a grouped list of possibilities. Even though this a specific criticism to MuRET, any simple mechanism in any transcription tool for locating the desired element to use, as some keyboard filtering approach, would significantly reduce the correction times.

The separation between agnostic representation and its final semantic encoding has proven to be an efficient way of processing early music. The ease of checking that the

graphic symbols are the same as those in the manuscript, regardless of musicological considerations, has greatly accelerated the process, allowing each member of the team to focus on one of the phases, leaving the expert musicologist to deal only with the final transcription. It's worth to mention, that in this process, a specialized language model to detect syntactic mistakes would have improved the efficiency of the process, as we have devoted most of the time to visually inspect the output of the OMR classifiers, even more than correcting wrong symbols.

Although the conversion of the agnostic representation of each staff into a final encoding is performed automatically, we've found cases where it has been necessary to make some adjustments, such as the encoding of implied accidentals. MuRET does not use any WYSIWYG approach but asks the user correct directly writing `**mens` format. Having a steep learning curve, the code has proven to be efficient for performing this kind of operations.

In that regard, another important feature, without which the correction operations would have been more tedious, has been the proper synchronization of the views of the different representations of the selected transcribed musical symbol: when selecting the agnostic symbol, it was automatically highlighted in the original manuscript preview, and in the final encoding. The absence of this feature in the final MuRET scoring-up process has made the final review and correction time consuming and error-prone.

For dealing with many different works with a large number of images each, it is very important to keep track of the status of the work. MuRET asks the user to record the status of each phase (document analysis, part linking, music transcription) for each image. Although a priori this seems reasonable, we usually forgot to perform this operation, and the simple task of going back individually to mark each image and step as completed has been a time consuming operation. For any transcription tool, it is extremely important to include a project management tool to easily annotate and visualize, either individually for each image or in batch, the progress status of the transcription, including the addition of user comments.

An interesting result of our transcription experience is that some operations do not require any algorithm, but are simply performed with a correct graphical user interface. This has been the case for document analysis labeling of new manuscripts for which no model was good enough to correctly identify the regions of interest. At the beginning of the project, when this situation arose, we had to manually label a number of pages of the manuscript to build a new model that was subsequently improved with new samples. For collections in which the layout of the regions of interest and the parts to which they belong is repeated over several pages, this process does not need any complex machine learning process, but a process of reusing the existing tagging is enough. During the project, MuRET included a tool to copy the document analysis and link parts to other images. This simple tool turned this tedious and repetitive operation of tagging the pages first into only a minor issue.

A notable case occurs in the event that the tool, or a component of a tool, does not support a required feature. For instance, bar-lines crossing a note in late Mensural no-

tations or the rendering of *signum congruentiae* is not supported in Mensural notation by the engraving tool used in MuRET, Verovio [16]. In those cases, our principle has been to store a specific element, such a text, and print them to be visualized, and once they are supported by the tools, replace them.

Finally, when focusing on the transcription of musical content, most tools discard many non-musical elements such as titles, part, instrument or voice names, capital letters miniatures. All this information, if automatically detected, could help to the users to have a better overview of large works to organize the transcription process.

6. CONCLUSIONS AND FUTURE WORK

Most of the OMR community's efforts are focused on achieving high accuracy rates in automated music reading. We have shown in Section 4 that the use of an OMR tool has proven to be an adequate means to transcribe a whole collection of works saving an enormous amount of time and effort for the user. While this approach is valid, it is important not to overlook aspects that are not intrinsically OMR and that can impact even more than the performance of the transcription tool on the effort required to transcribe collections.

In this work, we have shared our experience in transcribing a complete collection of works written in Mensural notation, describing all the steps taken and discussing issues we believe are important to achieve a streamline process, both from the perspective of the OMR tool used and in the preparation of the collections to be transcribed.

This paper has not addressed aspects that would be interesting to explore in the future. Some are related to the functioning of the computer system itself, such as the impact of classification times of automatic systems on the overall process and program response delays, as well as the measurement of the impact of execution errors or a comprehensive study from the perspective of human-computer interaction (HCI) in operations such as editing the staff transcription made or the final scoring up.

Other factors to consider are purely musical, such as the use of musical language models, both melodic and harmonic, for error detection, the impact of using one musical encoding over another, assistance in aligning lyrics with music, the treatment of abbreviations in the lyrics, or the detection of specific properties of the notation type such as the semitonia subintelecta in Mensural notation, the processing of multiple voices in piano-form music, the detection of hidden graphical elements such as the digit '3' in triplets in common western music notation, or finally the specific cases described by Byrd and Simonsen [17].

Regarding the OMR system, it is interesting to compare different strategies at work within a complete transcription system, not just in isolation. For instance, replace the MuRET stages (document analysis, agnostic representation, semantic encoding), for those based on graphical primitives and later semantic encoding reconstruction [18], or the direct obtaining of the final encoding from a complete page [19].

7. ACKNOWLEDGMENTS

This paper is part of the I+D+i TED2021-130776A-I00 (PolifonIA) project, funded by MCIN/AEI /10.13039/501100011033 and European Union NextGenerationEU/PRTR. ABSTRACT

Recent advancements in audio processing provide a new opportunity to study musical trends using quantitative methods. While past work has investigated trends in music over time, there has been no large-scale study on the evolution of vocal lines. In this work, we conduct an exploratory study of 145,912 vocal tracks of popular songs spanning 55 years, from 1955 to 2010. We use source separation to extract the vocal stem and fundamental frequency (f_0) estimation to analyze pitch tracks. Additionally, we extract pitch characteristics including mean pitch, total variation, and pitch class entropy of each song. We conduct statistical analysis of vocal pitch across years and genres, and report significant trends in our metrics over time, as well as significant differences in trends between genres. Our study demonstrates the utility of this method for studying vocals, contributes to the understanding of vocal trends, and showcases the potential of quantitative approaches in musicology.

1. INTRODUCTION

Current technologies for audio processing provide new opportunities to study musical trends using quantitative methods. While researchers have analyzed music for generations, studying the evolution of music at a large scale has only been possible recently, due to the availability of large datasets [1–3]. Additionally, recent improvements in source separation technology have allowed researchers to study individual instruments [4, 5]. However, the vocal lines of songs have been understudied, even though they are often the most salient part of a song [6, 7], and many popular songs are built around the vocal line.

In this study, we examine trends in the vocal lines of 145,912 songs over 55 years (from 1955 to 2010). We use modern source separation methods to isolate vocal lines of

songs (30–60 second-long excerpts) from their respective accompaniments. Altogether, our dataset makes up over 59 days of continuous listening. This work is exploratory: we examine what trends and patterns can be observed from such a large corpus of vocal data. We have made our list of track IDs publicly available, along with our implementations.¹

2. RELATED WORK

The transformation of music over time has received a lot of focus in recent years. This is partially thanks to the release of open-source resources such as The Million Song Dataset (MSD) [1]. The MSD is a free collection of audio features and metadata for one million contemporary music tracks. Datasets such as MSD allow researchers to quantitatively analyze patterns in music at a large scale.

Serrà *et al.* used musical ‘codewords’ based on MSD clips to identify changes in pitch, timbre, and loudness over time [2]. They found that newer songs have less variety in pitch transitions, more homogenized timbres, and increased loudness. Parmer *et al.* did similar work using the MSD to study musical complexity from 1960–2010. They found that pitch complexity has been generally stable over that time period, while loudness and rhythm complexity has decreased and timbral complexity has increased [8]. Parmer also studied the complexity of popular songs from the Billboard chart,² and found that the complexity of popular songs is concentrated around the mean complexity level of all songs. This supports the inverted U-shaped model for music complexity and likeability: that listeners prefer intermediate levels of complexity [9, 10].

Another team of researchers used the MSD songs along with quantitative modeling to study musical influence: the impact that a particular artist has on the music by other musicians [3]. They identified clusters of songs that were indicative of a genre, and studied how those clusters evolved over time. A different study used a corpus of 17,000 songs from Billboard to study the “Evolution of Popular Music” between 1960 and 2010 in the United States [11]. They used timbral and harmonic features derived from Billboard songs, and identified three musical stylistic revolutions in

Figure 1: Top: Chronological distribution of the dataset organized in 5-year demi-decades. Bottom: Relative distribution of genres in the dataset by demi-decade.

Musical Genre & Number of Tracks					
Rock	64,203	Country	6,166	Punk	3,444
Pop	19,560	Metal	5,841	Latin	3,352
Rap	8,755	Reggae	4,689	Blues*	2,359
Electronic	8,754	Jazz	3,953	World*	2,044
RnB	8,647	Folk	3,630	New Age*	515

Figure 2: Number of tracks per musical genre. Blues, World, and New Age music (labeled “*”), were excluded from the by-genre analyses due to lower track count.

1964, 1983, and 1991. Other researchers have studied a more niche topic in detail over decades, including the evolution of a single band’s performances [12], changes in dynamics/compression in mainstream music [13], or spectral characteristics of recordings over time [14].

In an early vocal corpus study, in 1959, Alan Lomax’s Cantometrics project analyzed over 4,000 traditional vocal music songs from 400 cultures [15]. Researchers listened to songs and labeled them with 37 “style-factors,” for example group cohesion in singing, and tense or relaxed vocal quality. The Cantometrics project suggested a correlation between song style and social norms of cultures.

In a more recent study, researchers developed a set of features to capture pitch and melodic embellishments of world vocal performances [16]. Using these features, they trained a classifier to distinguish vocal from non-vocal segments and learn a dictionary of singing style elements. Results showed that clusters were distinguished by characteristic uses of singing techniques such as vibrato and melisma. A different study categorized a collection of 360 Dutch folk songs, and found that the aspects of melody that are important for establishing similarity are contour, rhythm, and motifs [17]. Despite these previous works on vocal datasets, there has been no large-scale study on the evolution of the vocal lines of popular music over the years.

3. DATASET

We used a subset of the MSD [1] that has genre labels (the Tagtraum MSD annotations [18]). 278,619 tracks had genre labels available. Next, a group of songs was dropped due to a low presence of vocals in the excerpt, indicated by a low ratio of RMS (root mean square) energy of the separated vocal stem to RMS energy of the full audio file (see 4.1). Songs that did not have the release year available were also dropped. In a final filtering step, we chose to conduct analyses only starting in the year 1955, as data was sparse before 1955. The final dataset had 145,912 songs.

Figure 1 shows a chronological distribution of songs in demi-decade bins (i.e., 1990-1994). We observe a strong bias towards more recent songs. A relative distribution of genres across years shows fewer genres in earlier years, with a greater variety in more recent years. Figure 2 lists the number of tracks in each musical genre in the dataset. Blues, World, and New Age music (labeled with a '*'), were excluded from the by-genre analyses due to having a lower number of tracks.

Our dataset inherits biases from the MSD. The tracks in the MSD were selected based partly on their association with ‘familiar’ artists, as determined by The Echo Nest, followed by inclusion of tracks from similar artists.³ The creators of the MSD also included artists that fit the 200 most frequently-occurring Echo Nest descriptive terms, as well as songs that were extreme in acoustic attributes. In general, songs in the dataset are generally widely listened-to, and the majority come from North America or Europe. There are much more data in recent years (1990s onward) than in earlier years. There is very little non-western and classical music in the dataset. The Latin music genre does contain non-western music, primarily performed in Spanish or Portuguese. Our findings apply to this dataset, not necessarily to music as a whole, and our work will have biases if applied to other datasets. Importantly, these dataset biases do not affect our methods.

4. METHOD

4.1 Source Separation

First, we used source separation to separate the vocal line of each song from the mix. For this, we use Hybrid Transformer Demucs (HT Demucs), a hybrid temporal/spectral bi-U-Net [5]. After computing the ratio of the vocal stem’s RMS energy to the overall mix’s RMS energy, we excluded any songs with a ratio below 0.08 (Figure 4). This ratio was set using a preliminary sub-sample of the data. These excerpts are either purely instrumental songs (non-vocal), or the clip happens to capture a part of the audio file with very few or no vocals (i.e., a guitar solo).

4.2 Pitch Characteristics

To study pitch characteristics, we did fundamental frequency (f_0) estimation on the estimated vocal stems using PYIN [19] as implemented in Librosa v0.8.1 [20].

³ <http://millionsongdataset.com/faq/>

Figure 3: f_0 extraction evaluation scores for 29 clean and source-separated vocal stems from MedleyDB, when compared with the MedleyDB f_0 annotations.

We set the lower frequency limit at 70Hz and the upper limit at 900Hz, aligning with the human vocal range described in other works, while also extending one musical whole step in each extreme [21]. We chose PYIN over CREPE, another f_0 -estimator, as it allows us to set a lower and higher pitch bound for f_0 -estimation [22]. Other than changing the sampling rate to 44.1 kHz, we used the Librosa defaults: frame length 2048, hop length 512, number of thresholds for peak estimation 100, switch probability 0.01, and no-trough probability 0.01. We collect an f_0 estimate approximately every 12 milliseconds.

We evaluated the pitch tracking accuracy of the PYIN algorithm on source-separated audio by running PYIN on 29 monophonic vocal stems from MedleyDB. We used `mir_eval` to compute the standard evaluation metrics used in MIREX: Voicing Recall (VR), Voicing False Alarm (VFA), Raw Pitch Accuracy (RPA), Raw Chroma Accuracy (RCA) and Overall Accuracy (OA) [23]. First, we compared several different PYIN settings: the number of thresholds, switch probability, and no-trough probability parameters, and found the Librosa defaults performed among the best. Next, we compared the accuracy of PYIN on clean stems and source-separated stems, each respectively compared to the annotations included in MedleyDB, and observed only a small decrease in accuracy. The median evaluation metrics of our method on the 29 clean vocal stems were: for clean stems, OA 0.781, RPA 0.924, RCA 0.928, VR 0.984, VFA 0.375, and for source separated stems, OA 0.771, RPA 0.865, RCA 0.888, VR 0.964, VFA 0.340 (see Figure 3). The source separation process only slightly reduces the accuracy of our f_0 -estimation.

Some tracks in the dataset have vocal harmonies. PYIN tends to track the pitch of the most prominent voice. We ran a query on last.fm,⁴ and found that tags for vocal harmonies are present in less than 1% of songs in the dataset. We assume that the presence of vocal harmonies is uncorrelated with the variables we study: time and genre. Through informal listening, we found that Demucs and PYIN were comparably effective for older and newer audio recordings from the time period we study, 1955-2010.

PYIN also provides a voicing detection estimate, which we used to identify contiguous regions of pitched sound in the vocal stem. We converted f_0 values in hertz to cents

Figure 4: Distribution of the ratios of the vocal stem RMS energy to the full mix RMS energy in the data. A threshold of 0.08 was used to discard non-vocal clips.

Figure 5: Example f_0 tracks. The top track, selected from the Metal genre, has a low TV and high PCE. The bottom track, from the Rap genre, has a high TV and low PCE.

using Eqn (1), where 16.35Hz is the frequency of C0:

$$f_0[c] = 1200 \cdot \log_2 \frac{f_0[\text{Hz}]}{16.35}. \quad (1)$$

For example, "middle C" on a piano is 4800 cents, and $C\#/Db$ is 4900 cents. Using this information we extracted pitch features, dropping unvoiced frames. We calculated mean pitch (in cents) of each song, defined as the mean of each f_0 array.

We also calculated total variation (TV) [16]. TV summarizes the rate of pitch change and is defined in Eqn (2):

$$\text{TV}(x) = \frac{1}{N} \sum_{i=1}^{N-1} |x_{i+1} - x_i| \quad (2)$$

for a given f_0 contour $x = (x_1, \dots, x_N)$. TV is calculated independently for each voiced region within a song and then aggregated to a single total. Our TV calculations do not change the time interval between f_0 values.

4.3 Pitch Class Entropy

We calculated pitch class entropy (PCE) to measure the degree of unpredictability for the set of vocal pitches. Entropy was calculated over the probability of occurrence of each pitch class (independent of octave) in the vocal line [24]. Higher values of PCE indicate a greater spread in the pitch distribution, while lower values indicate a smaller and more predictable set of pitches. There is a theoretical maximum PCE of $\log_2(12) \approx 3.59$, achieved by a uniform distribution of the 12 pitch classes.

Figure 5 illustrates two example f_0 tracks with somewhat extreme TV and PCE values.

4.4 Statistical Analyses

We used R (4.2.2) and RStudio (2022.12.0+353) to implement linear regression with the `lm` function. Post-hoc tests

⁴ <https://www.last.fm/>

were implemented using the *emmeans* package with Tukey correction for multiple comparisons.

5. EXPERIMENT AND RESULTS

For each of our variables of interest (mean pitch, TV, PCE), we followed the same procedure. We first ran a linear regression to examine the relationship between the variable of interest (e.g., TV) and the year of track release (e.g., TV \times year). We then calculated a linear regression between the variable of interest and musical genre (e.g., TV \times genre). Finally, we calculated independent linear regressions between the variable of interest and year of track release for the twelve most frequently-occurring genres. We calculated independent regressions because each of the genres becomes prevalent in the dataset during different years (i.e., Rap music starting in 1984).

When looking at musical genres, we chose to study the twelve genres with the most song entries in the dataset. We began analyzing each genre at the first year of a five-year period where at least ten songs were released in that genre annually. The twelve genres with corresponding start years were as follows: Country (1956), Electronic (1979), Folk (1963), Jazz (1955), Latin (1986), Metal (1980), Pop (1961), Punk (1977) Rap (1984), Reggae (1972), RnB (1957), and Rock (1956).

5.1 Mean Pitch

We found a significant positive relationship between mean pitch for a track and the year it was released ($\beta = 0.957$, $t = 7.23$, $p < .001$). For every one-year increase in the release year, the mean pitch of the track increased by a little less than one cent, on average (see Figure 6).

Next, we assessed mean pitch and musical genres. We found a significant main effect of genre ($F(1, 140982) = 1378.6$, $p < 0.001$). All genres were significantly distinct (all p values < 0.001) except for: electronic and pop music ($t=1.891$, $p=0.765$), jazz and Latin ($t = 0.276$, $p=1.000$), jazz and rock ($t=-2.854$, $p = 0.158$), and Latin and rock ($t = -3.005$, $p = 0.107$). Data for the mean pitch per song in each of these genres is illustrated in Figure 7.

We found a significant main effect of year for nine of the twelve musical genres, though the direction of the trends varied (see Figure 8). Specifically, country music ($\beta = 3.991$, $t = 7.970$, $p < 0.001$), folk music ($\beta = 1.374$, $t = 2.395$, $p < 0.001$), jazz ($\beta = 2.901$, $t = 4.482$, $p = 0.017$), metal ($\beta = 7.269$, $t = 4.612$, $p < 0.001$), punk ($\beta = 3.301$, $t = 3.815$, $p < 0.001$), reggae ($\beta = 2.053$, $t = 3.301$, $p < 0.001$) and rock ($\beta = 1.097$, $t = 5.529$, $p < 0.001$) showed a significant positive relationship between year and mean pitch. Conversely, rap ($\beta=-6.653$, $t=-7.757$, $p<0.001$) and RnB ($\beta=-3.800$, $t=-11.75$, $p<0.001$) showed a significant negative relationship between year and mean pitch. No significant effect was found for electronic, Latin, or pop music.

5.2 Total Variation

The results for the TV and year regression between TV and year showed a significant negative relationship ($\beta = -$

Figure 6: Mean pitch in cents as a function of year globally. Each dot represents a song. The red line represents the predicted slope with 95% confidence intervals. The green diamond and ribbon represent the mean per year and the standard error. This relationship was significant, with mean pitch increasing by approximately one cent per year.

Figure 7: Mean pitch per song in each of the twelve genres across the dataset. Means are shown with boxes representing the interquartile range, error bars indicating the 95% confidence interval, and outliers as circles. There were significant differences between all genres except electronic and pop, jazz and Latin, jazz and rock, and Latin and rock

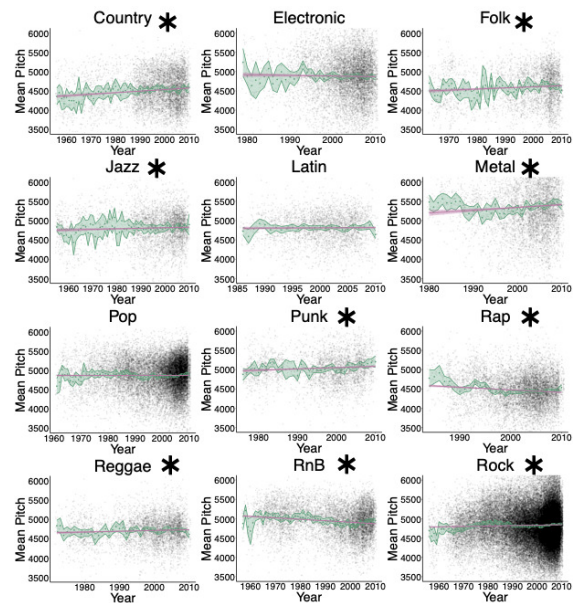

Figure 8: Relationship between mean pitch (in cents) and year for each genre. “*” denotes a significant effect of year. The red line represents the predicted slope with 95% confidence intervals. The green diamond and ribbon represent the mean per year and the standard error.

Figure 9: Total Variation as a function of year. Each dot represents a song. The red line represents the predicted slope with 95% confidence intervals. The green diamond and ribbon represent the mean TV per year and the standard error. There was a significant negative correlation between TV and year.

0.027, $t = -10.47$, $p < .001$; see Figure 9). When assessing the relationship between TV and musical genre, we found a significant main effect of genre ($F(11, 140,980) = 1247.9$, $p < 0.001$). Post-hoc tests showed that all genres were significantly different from one another (all p values < 0.05) except for country and Latin ($t=0.661$, $p = 1.000$), country and punk ($t = -3.214$, $p = 0.059$), electronic and punk ($t = 0.877$, $p = 0.999$), electronic and reggae ($t=0.269$, $p=1.000$), folk and pop ($t = -2.407$, $p = 0.4013$), folk and rock ($t = 0.185$, $p = 1.000$), Latin and pop ($t = 3.006$, $p = -.107$), and punk and reggae ($t = -0.569$, $p = 1.000$; see Figure 10). Importantly, TV was significantly higher for rap music than for all other genres.

We found a significant main effect of year on TV for eleven of the twelve musical genres, though the direction of the trends varied (see Figure 11). Specifically, metal music ($\beta = 0.066$, $t = 3.338$, $p < 0.001$), reggae music ($\beta = 0.058$, $t = 6.512$, $p < 0.001$), and RnB ($\beta = 0.013$, $t = 3.44$, $p < 0.001$) showed a significant positive relationship between year and TV. Conversely, electronic music ($\beta=-0.126$, $t=-4.803$, $p<0.001$), folk ($\beta=-0.065$, $t=-7.852$, $p<0.001$), jazz ($\beta=-0.079$, $t=-6.418$, $p<0.001$), Latin music ($\beta=-0.041$, $t=-2.349$, $p=0.019$), pop ($\beta=-0.033$, $t=-8.698$, $p<0.001$), punk ($\beta=-0.045$, $t=-3.259$, $p=0.001$), rap ($\beta=-0.158$, $t=-11.06$, $p<0.001$) and rock ($\beta=-0.062$, $t=-13.79$, $p<0.001$) showed a significant negative relationship between year and TV. No significant effect was found for country music.

5.3 Pitch Class Entropy

A linear regression showed a statistically significant negative relationship between PCE and year ($\beta = -0.004$, $t = -50.02$, p -value < 0.001 ; see Figure 12). There was a ceiling effect for PCE, with some of the tracks hitting close to the theoretical maximum of 3.59.

We ran a linear model with genre as the only main effect and found a significant main effect of genre on PCE ($F(11, 140,982) = 759.64$, $p < 0.001$). Post-hoc tests showed that all genres were significantly different than one another (all p -values < 0.05) except for folk and Latin ($t=-0.936$, $p=0.999$), folk and pop ($t=2.484$, $p=0.350$), folk and reggae ($t=1.255$, $p=0.984$), jazz and RnB ($t=3.123$, $p=0.077$; approaching significance), Latin and rap ($t=-2.952$, $p=0.123$), Latin and reggae ($t=2.218$, $p=0.536$), and pop and reggae ($t=-1.054$, $p=0.996$; see Figure 13).

Figure 10: Total variation in each of the twelve genres across the whole dataset. Means are shown with interquartile range, 95% confidence interval error bars, and outliers. There were significant differences in TV between all genres except between country and Latin, country and punk, electronic and punk, electronic and reggae, folk and pop, folk and rock, Latin and pop, and punk and reggae.

Figure 11: Relationship between TV and year for each genre. “*” denotes a significant effect of year. The red line represents the predicted slope with 95% confidence intervals. The green diamond and ribbon represent the mean per year and the standard error.

Figure 12: Pitch Class Entropy as a function of year. Each dot represents a song. The red line represents the predicted slope with 95% confidence intervals. The green diamond and ribbon represent the mean PCE per year and the standard error. There was a significant negative correlation between PCE and year

Figure 13: Pitch class entropy in each of the genres. Means are shown with interquartile ranges, 95% confidence interval error bars, and outliers. There were significant differences in PCE between all genres except between folk and Latin, folk and pop, folk and reggae, jazz and RnB, Latin and rap, Latin and reggae, and pop and reggae.

Figure 14: Pitch class entropy in each of the genres. “*” denotes a significant main effect of year. The red line represents the predicted slope with 95% confidence intervals. The green diamond and ribbon represent the mean per year and the standard error.

Finally, we found a significant negative relationship between PCE and year for eleven musical genres (country: $\beta=-0.002$, $t=-7.847$, $p<0.001$; electronic: $\beta=-0.005$, $t=-5.126$, $p<0.001$; folk: $\beta=-0.001$, $t=-3.650$, $p<0.001$; jazz: $\beta=-0.001$, $t=-4.382$, $p<0.001$; Latin: $\beta=-0.004$, $t=-5.047$, $p<0.001$; pop: $\beta=-0.003$, $t=-18.61$, $p<0.001$; punk: $\beta=-0.003$, $t=-4.938$, $p<0.001$; rap: $\beta=-0.007$, $t=-11.61$, $p<0.001$; reggae $\beta=-0.001$, $t=-2.849$, $p=0.004$; RnB: $\beta=-0.002$, $t=-12.64$, $p<0.001$; rock: $\beta=-0.003$, $t=-28.75$, $p<0.001$; see Figure 14). The effect of year for metal music ($\beta=-0.002$, $t=-1.717$, $p=0.086$) approached significance.

6. DISCUSSION

In this study, we analyzed vocal pitch characteristics across years and genres. We found musical genres are often significantly different from one another in mean pitch, total variation, and pitch class entropy. The data generally ex-

hibited a significant negative relationship between year and total variation and year and pitch class entropy, respectively. This was the case both overall and for 8 and 11 musical genres, respectively (see Figure 10 and Figure 13).

If TV and PCE are taken to be measures of musical complexity, these findings could mean vocals, in this dataset at least, are getting less complex over time. This is somewhat in line with previous studies using the MSD. Serrà *et al.* found that newer songs have less variety in pitch transitions and more homogenized timbres, and Parmer *et al.* found that pitch complexity has been generally stable, but loudness and rhythm complexity have decreased [2] [8]. Our findings also parallel those of recent publications looking generally at Western popular music. In a recent study, authors found over five decades, lyrics have become simpler in their vocabulary richness, readability, complexity, and repetitiveness [25]. In another study analyzing popular melodies from 1950 to 2023, Hamilton and Pearce identified melodic revolutions that correspond to decreases in melodic complexity [26].

In our study, we observed that the rap genre had a higher TV than the other genres (see Figure 10), showing that rap songs feature more pitch variation than other musical genres, on average. This could be because rap vocals tend to have less sustained pitch than other genres. Previous work showed that pitch variance in rap music is a complex and significant feature of the genre [27, 28]. Rap music, only coming into prevalence in this dataset in 1984, may have influenced the genres that exhibit a significant positive relationship between year and total variation, counter to the all-genre-pooled negative trend: metal, reggae, and RnB.

We found mean pitch increased over time (see Figure 6). Gender and vocal range are key factors when considering pitch, and genre-specific gender prevalence may exist. However, we did not find a sufficiently reliable gender or vocal range classifier to support further analysis.

Interestingly, mean pitch was the highest for the metal genre, which has a low presence of female vocalists compared to other genres [29]. Therefore, the higher mean pitch of the metal genre cannot be fully explained by a higher prevalence of high-voiced singers. The average mean pitch of metal vocals sits quite high in a typical tenor range [21]. We hypothesize this is because screaming in metal music tends to have a higher f_0 than singing, but more investigation into metal vocals is needed [30].

7. CONCLUSION

In this exploratory research, we examined trends in the vocal lines of 143,152 songs spanning 55 years. Our work has identified relationships between vocal pitch and popular musical genres over time, providing valuable insights into the changing sound of music. We have demonstrated the utility of the methods presented here for studying vocals, and believe they have the potential to be applied to the study of other musical instruments as well as general musical phenomena including historical and cultural trends, changes in musical forms and structures, and stylistic differences across genres and periods.

ABSTRACT

Autoregressive generative transformers are key in music generation, producing coherent compositions but facing challenges in human-machine collaboration. We propose RefinPaint, an iterative technique that improves the sampling process. It does this by identifying the weaker music elements using a feedback model, which then informs the choices for resampling by an inpainting model. This dual-focus methodology not only facilitates the machine’s ability to improve its automatic inpainting generation through repeated cycles but also offers a valuable tool for humans seeking to refine their compositions with automatic proofreading. Experimental results suggest RefinPaint’s effectiveness in inpainting and proofreading tasks, demonstrating its value for refining music created by both machines and humans. This approach not only facilitates creativity but also aids amateur composers in improving their work.

1. INTRODUCTION

Advanced autoregressive models [1, 2] have enabled the automatic generation of complex musical performances [3–7]. However, while autoregressive models generate music in a strictly forward-moving manner, human composers often follow a more iterative approach, frequently revisiting and refining earlier sections of a piece before proceeding [8–10]. Although there are some iterative methods for music generation [11–13], there are still areas for improvement in terms of controllability and human-in-the-loop aspects, such as inferring where to modify composition and inpainting capability to enable partial modification.

Iterative refinement proved effective for image generation; in particular, Lezama’s Token-Critic [14] shows how feedback mechanisms can enhance image synthesis. Similarly, such feedback could benefit music composition for iteratively refining generated music. Within the spectrum of music composition tools, the Piano Inpainting Application (PIA) [15] stands out for its capabilities for automatic

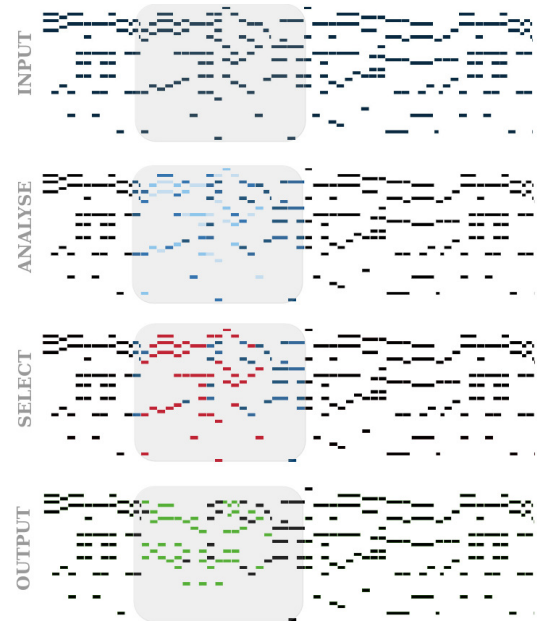

Figure 1: A user selects a MIDI section for enhancement (gray rectangle). Our methodology uses token-level feedback (blue) to highlight critical notes or sequences (red) for regeneration (green). This cycle repeats iteratively.

music generation that addresses the missing parts of musical performances, a technique referred to as inpainting. We highlight their handling of the musical context both before and after the selected gaps, enabling precise note-level inpainting. On account of that, inspired by image generation’s success with iterative feedback and how PIA handles music context, our research explores applying these concepts to enhance controllability, human-in-the-loop functionality, and iterative refinement capability in automatic music generation.

In this work, drawing from Token-Critic and PIA, we propose RefinPaint, which aims to boost automatic inpainting and proofreading in music generation. Our approach includes an iterative process of identifying areas in a composition needing modification and applying inpainting techniques to these areas. In this context, proofreading refers to automatically identifying and correcting errors or inconsistencies in a music composition. This dual-focus methodology facilitates the machine’s ability to improve its automatic inpainting generation through repeated cycles, and offers a valuable tool for humans seeking to refine

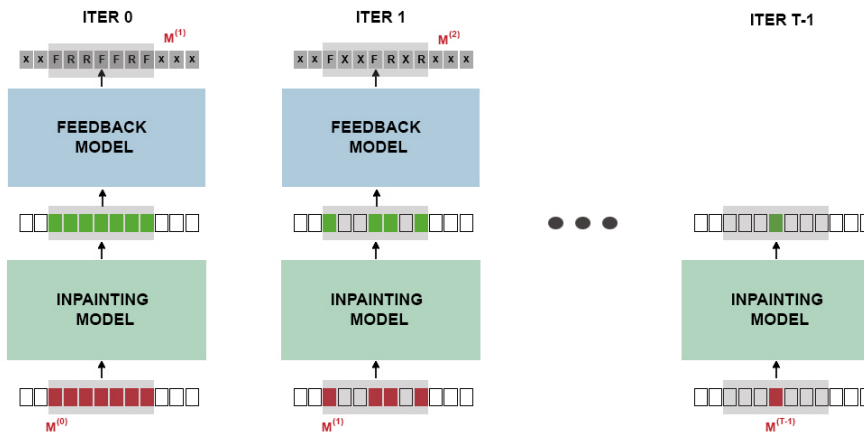

Figure 4: RefinPaint uses inpainting and feedback models to iteratively suggest changes, based on specific note feedback. It reduces the selected tokens in each iteration.

their compositions with automatic proofreading.

Our RefinPaint method is grounded in an autoregressive inpainting model to generate synthetic music tokens and a feedback model trained to distinguish between original and synthetic tokens. This differentiation is key during the sampling stage when deciding on token retention or revision. RefinPaint takes an iterative approach, integrating feedback into the inpainting model for selectively regenerating parts in each iteration, as Figure 1 shows. In contrast to Token-Critic, RefinPaint focuses on modifying a specific part of a composition using a contextual model and exposes the intermediate outputs of the autoregressive inpainting model to human inspection in each iteration.

The human-in-the-loop approach we propose allows for selecting the number of tokens to modify and revise the analysis heatmap at each iteration, as described in the following section. Through experimentation, we confirm RefinPaint’s effectiveness in inpainting and proofreading tasks, demonstrating its utility for enhancing music created by both machines and humans. Finally, we provide a companion page featuring examples¹ and the code along with the trained models of RefinPaint for reproducibility².

2. METHODOLOGY

Our proposed methodology employs two models: an inpainting model \mathcal{I} , and a feedback model \mathcal{F} , alongside our iterative algorithm RefinPaint. Initially, \mathcal{F} identifies areas within a MIDI file that need improvement based on the specific criteria described in Section 2.2. It uses a heatmap for detailed MIDI token-level feedback, allowing one to assess the context and relevance of each note in the selected region. Then, model \mathcal{I} can regenerate the selected tokens considering the feedback, as described in Section 2.1. The methodology involves using both models iteratively with RefinPaint and encompasses three main stages: training the inpainting model (Section 2.1.1), training the feedback model (Section 2.2.1), and finally executing the iterative process for MIDI sequence generation (Section 2.3).

2.1 Inpainting model (\mathcal{I})

The inpainting model aims to predict, or fill in, missing parts of a MIDI sequence based on a given mask. We adopt an encoder-decoder architecture for sequence-to-sequence tasks, as shown in Figure 2, inspired by the PIA study for music generation [15]. This model involves an encoder converting input data into a latent representation and a decoder predicting the final output.

With an anti-causal mask, self-attention within the encoder prevents future data access, while with a causal mask, self-attention within the decoder limits access only to previous data. With an identity mask, cross-attention enforces positional alignment between the encoder and decoder outputs, which is helpful for aligned sequence tasks.

The attention mechanisms are defined as follows, where M_{type} is the mask type (anti-causal, causal, or identity):

$$\text{Attention}(Q, K, V) = \text{softmax} \left(\frac{QK^\top}{\sqrt{d_k}} \odot M_{\text{type}} \right) V. \quad (1)$$

This structure enhances the capability of the model to handle bidirectional input-output relationships, essential for inpainting, where future context influences the generation process. Furthermore, we add an extra binary embedding to the encoder input with information about the mask M_s —the tokens to regenerate—for the inpainting model.

2.1.1 Training the Inpainting Model (\mathcal{I})

The training process is outlined in Algorithm 1. A batch x is sampled from the MIDI dataset \mathcal{D} , and a random fragment M_u is chosen for each sample in x with a length determined by t_1 . It is important to note that t_1 refers to the length in terms of the token sequence, rather than the MIDI duration. Consequently, a random mask M_s , with the masking ratio controlled by $\gamma(t_2)$, is then applied to M_u . The forward pass of the model calculates the loss using the batch x , the mask M_s , and the Cross Entropy (CE) loss function to evaluate the difference between the predicted outputs and the actual labels. The model is subsequently updated via gradient descent. The function γ , a cosine scheduler, dynamically adjusts the masking ratio. It operates on a domain defined by a random variable t_2 within the interval $[0, 1]$. Specifically, for any chosen value t_2 drawn uniformly from the interval $[0, 1]$, the value undergoes a cosine transformation γ to determine the masking ratio, where $\gamma(t_2) = \cos\left(\frac{\pi t_2}{2}\right)$.

Algorithm 1 Training the Inpainting model (\mathcal{I})

Require: MIDI dataset \mathcal{D} , Inpainting model \mathcal{I}

- 1: **while** convergence **do**
- 2: $x \sim \mathcal{D}$ ▷ Sample batch
- 3: $t_1 \sim U(0.1, 0.6), t_2 \sim U(0, 1)$
- 4: $M_u \leftarrow \text{Fragment}(x, t_1)$
- 5: $M_s \leftarrow \text{Random Masking}(M_u, \gamma(t_2))$
- 6: $L \leftarrow \text{ForwardInpaintingModel}(\mathcal{I}, x, M_s)$
▷ model forward and compute loss
- 7: GradientDescent(L)
- 8: **end while**

2.2 Feedback model (\mathcal{F})

We employ an encoder-only transformer architecture for the feedback phase that classifies music tokens as fake or real. We use this output distribution to select the k most realistic tokens to retain while the others are regenerated. Unlike the encoder-decoder inpainting model, \mathcal{I} ,

this model processes the input through a parallel and bidirectional attention mechanism without employing any attention masks, thus facilitating an unrestricted analysis of the musical context. Additionally, we add an extra binary embedding to the encoder input with information about the mask M_u —the selected fragment—for the feedback model.

2.2.1 Training the Feedback model (\mathcal{F})

Algorithm 2 Training the Feedback model (\mathcal{F})

Require: MIDI dataset \mathcal{D} , Inpainting model \mathcal{I} , Feedback model \mathcal{F}

- 1: **while** convergence **do**
- 2: $x \sim \mathcal{D}$ ▷ Sample batch
- 3: $t_1 \sim U(0.1, 0.6), t_2 \sim U(0, 1)$
- 4: $M_u \leftarrow \text{Fragment}(x, t_1)$
- 5: $M_s \leftarrow \text{Random Masking}(M_s, \gamma(t_2))$
- 6: $\hat{x} \leftarrow \mathcal{I}(x, M_u)$
- 7: $L \leftarrow \text{ForwardFeedbackModel}(\mathcal{F}, \hat{x}, M_u)$
▷ model forward and compute loss
- 8: GradientDescent(L)
- 9: **end while**

After training the inpainting model \mathcal{I} , we train an encoder-only feedback model \mathcal{F} . This model aims to evaluate the output from \mathcal{I} , offering feedback on the composition quality of each music fragment denoted by M_u .

One ideal way of training \mathcal{F} would involve a vast dataset of computer- or human-generated music compositions and human experts’ revisions for inpainting and proofreading applications. Instead, we propose a more feasible synthetic training strategy, described in Algorithm 2. The inpainting model \mathcal{I} generates tokens within the selected fragment of a music piece, M_u , which we label as ‘Fake’, while we label as ‘Real’ the original unchanged tokens. We utilize these labels to instruct \mathcal{F} , following the process illustrated in Figure 3.

The training of \mathcal{F} is based on the output of \mathcal{I} . We begin by sampling a batch x from the dataset \mathcal{D} , then apply masking M_s and M_u . Model \mathcal{I} regenerates specific tokens within x , yielding a modified output \hat{x} . Model \mathcal{F} then assesses each token of \hat{x} against M_s , categorizing them as ‘Real’ or ‘Fake’. The loss L for \mathcal{F} is computed using the Binary Cross Entropy (BCE) loss function, and is minimized through gradient descent. The outcome is a heatmap for M_u , which indicates the probability of each token being ‘Real’ or ‘Fake’, determined by the sigmoid activation of the model output.

2.3 Generation of MIDI sequences (RefinPaint)

We capitalize on the strengths of the inpainting and feedback models for the iterative MIDI sequence generation. The process shown in Figure 4 begins with a MIDI sequence x introduced by the user, setting the stage for a loop that spans a predetermined number of iterations T .

Initially, the user selects the fragment to be modified $x_m^{(0)}$ and sets the initial selection rate $k = 0$ for complete inpainting. Alternatively, different values for k allow the

user to control how much of the content to keep in the selected fragment when proofreading.

In the proposed Algorithm 3, at each iteration t , the inpainting model \mathcal{I} generates a new version of the sequence \hat{x} , based on the current masked input $x_m^{(t)}$. In the human-in-the-loop scenario, the user can then adjust this generated sequence. The feedback model \mathcal{F} evaluates \hat{x} and provides a new mask $M^{(t+1)}$, which the user may also modify. This mask highlights the tokens that are deemed most realistic. The number of selected realistic tokens k follows a decreasing function γ of the iteration t , which models the increasing confidence in the tokens produced over time. Moreover, we add an extra binary embedding to the encoder input with information about the mask M —the given context—where M changes over iterations.

Refining the music sequence through each iteration aims to achieve a compositional process that closely aligns with that of a human composer so that the user intervention becomes interpretable and natural. It fosters a collaborative environment between the user and the machine and tailors the generation process to the user’s specific directives and preferences.

Algorithm 3 Generation Algorithm (RefinPaint)

Require: Inpainting model \mathcal{I} , Feedback model \mathcal{F} , masked MIDI $x_m^{(0)}$, No. masked tokens N , No. iterations T

- 1: **for** $i = 0$ to $T - 1$ **do**
 - 2: $k = \lceil \gamma \left(\frac{i}{T} \right) \cdot N \rceil$
 - 3: $\hat{x} \leftarrow \mathcal{I}(x_m^{(i)})$
 - 4: **if** $i \neq T - 1$ **then**
 - 5: $M^{(i+1)} \leftarrow \mathcal{F}(\hat{x})$
 - 6: $x_m^{(i+1)} \leftarrow k\text{-realistic tokens}(\hat{x}, M^{(i+1)}, k)$
 - 7: **end if**
 - 8: **end for**
-

3. RELATED WORK

Automatic music generation has rapidly advanced recently. Significant progress has been made [4–6], especially in solo piano compositions [3, 7, 15], through the capabilities of autoregressive models in producing coherent musical outputs. However, several challenges remain for creating successful interactions with humans [3, 11, 15–22].

Previous work has explored various approaches to generate music iteratively and allowed for partial modification—often referred to as inpainting—which enhances controllability. Among them, sequential handling of musical elements has been a common strategy, as in models like DeepBach [11] and Coconet [12]. Although these models allow for inpainting and iterative generation, they often rely on random iterations without a mechanism for discriminative feedback to guide improvements. This lack of directed refinement contrasts with the human compositional process, which typically involves iterative improvements based on evaluative feedback. Our proposed approach addresses this limitation by incorporating a feedback model that identifies areas for improvement for both

humans and machines to refine the composition.

Although it is not designed as an inpainting model, ES-Net’s approach to music generation integrates generative and discriminative capabilities in one model [13], with a feature for correcting past errors for iterative refinement. Our model differs significantly: it takes into account the context of the selected fragment, could improve any existing inpainting model, and can handle general MIDI formats. In [23], the authors propose a GAN model for piano music composition with a discriminator model that discerns real and fake compositions in the training process. However, it does not give feedback on which generated parts are good or bad and does not create compositions iteratively. Yet, the application of discriminative feedback in music generation, particularly in a manner that mimics human iterative refinement, remains largely unexplored.

Finally, inpainting models in music have seen various approaches but remain less studied compared to their counterparts in image generation [24]. They typically focus on quantized scores, with significant contributions like Gibbs sampling for Bach chorales [11] and RNN-based melodies inpainting [25]. Studies on transformers for multitrack inpainting have advanced the field, such as MMM [26], which utilizes a decoder architecture akin to GPT2 [2], and PIA [15], which uses a specialized transformer design. We chose PIA over MMM as a ground element in this work, given it is capable of working in the token level or larger contexts and inpainting multiple little fragments at the same time, similar to Token-Critic’s generator [14].

4. EXPERIMENTAL SETUP

4.1 Data preparation

Our study utilizes the Lakh MIDI dataset (LMD), an extensive collection of approximately 170k unique multi-track MIDI files, compiled by Colin Raffel for music research [27]. The dataset offers a wide variety of music, albeit with varying quality due to its internet-sourced nature. Despite this, the volume and diversity of the LMD dataset make it a valuable asset for our proofreading task. We extracted only the piano parts, totaling 120,000 tracks.

We tokenize the piano tracks using REMI (REvamped MIDI-derived events) [16], a music representation method that converts MIDI events into a structured format optimized for Transformer-based models that significantly enhances their ability to comprehend and produce music. REMI categorizes music elements into distinct event types, including timing for rhythm and note events for melody, but we exclude velocity events for simplicity. Specifically, we use a modified version of REMI tailored for handling single-track piano performances, as implemented in [28]. The dataset was split into training (hashes 0–d), validation (hash e), and testing (hash f) segments, based on each file’s MD5 hash’s leading digit, akin to previous methods [5, 6]

4.2 Model development

We train the inpainting and feedback models with the AdamW optimizer, using eighty per cent of the dataset for training and the remainder for validation. Each epoch consists of a randomly selected fragment from the training set,

512 tokens in length. We also employ an augmentation procedure that transposes the pitch tokens of a sequence by adding or subtracting up to 6 semitones. For the inpainting model, we apply a cross-entropy loss and use the maximum batch size that our system can handle; a single V100 GPU with 16GB allows for 48 samples. The encoder-decoder inpainting model comprises 12 layers: 4 encoder layers and 8 decoder layers, similar to the original PIA, with 8 heads and an embedding dimension of 512. We employ a cosine scheduler for training, with 16,000 warmup steps, reaching up to a 0.0006 learning rate. The feedback model consists of 6 layers, with an embedding dimension of 512, a dropout rate of 0.1, 8 heads, and the same cosine scheduler. Finally, we acknowledge that optimizing these models was not the main focus of this paper, so there might be better hyperparameter values.

In the particular case of proofreading without human intervention, i.e. for evaluation purposes, the final output is the iteration that maximizes the feedback model probability distribution. Using a sigmoid function, the model determines whether each token in a sequence is fake or real. By averaging the output probabilities, we calculate a global feedback score (GFS) for the sequence’s overall realism and select the best regeneration output based on it.

5. INPAINTING RESULTS

5.1 Divide and conquer with the inpainting model

We conducted an experiment to explore how the model’s inpainting performance is affected by the percentage of tokens to inpaint in a selected fragment. We hypothesize that the more tokens to inpaint, the harder the problem is, so the model performance is lower. The experiment uses the inpainting model trained as detailed in section 2.1.1, and we report its Negative Log-Likelihood (NLL) loss and perplexity of the next predicted token. The evaluation covered the entire test set, with masking ratios ranging from 1 (fully masked) to 0 (no tokens to inpaint) and a fixed 30% fragment size rate of the 512 tokens sequence. Results shown in Table 1 indicate better performance with reduced masking, confirming our hypothesis. Notably, the average Perplexity value is less than half at 0.05 compared to the 1.0 masking ratio. This finding is crucial for RefinPaint’s effectiveness as it reduces the number of tokens to be inpainted in subsequent iterations, considering the iterative process as a top-to-bottom strategy.

5.2 Objective evaluation of proofreading inpainting

This section conducts a comparative analysis between the reference inpainting output, as described in [15] (PIA), and our enhanced method. Our method applies the RefinPaint proofreading process to the initial PIA’s inpainting output over ten iterations and is referred to as ‘Ours’. For fragment sizes of 50%, 30%, and 10% of the 512-token test sequences, we computed 1,000 instances each. It is important to note that the PIA method discussed is our reimplementation, since the original code was not available.

Table 2 shows the average global feedback score (GFS), computed as explained in Section 4.2, and the number of

masking ratio	NLL	AVG PPL
0.05	0.56	0.31
0.10	0.58	0.33
0.15	0.58	0.34
0.20	0.58	0.33
0.40	0.64	0.41
0.60	0.70	0.49
0.80	0.77	0.59
1.00	0.86	0.73

Table 1: Summary of the inpainting experiment with different masking ratios. A masking ratio of 1.0 corresponds to being fully masked, and 0 indicates no masking. The standard deviation is less than 0.01 in all the experiments.

evaluations in which each algorithm outperforms the other (Wins) and in which their scores are the same (Ties). Table 3, on the other hand, focuses on the comparison between PIA and Ours, employing the NLL loss, a metric of the next token prediction in generated music. This metric, derived from an autoregressive model we trained explicitly from scratch to assess the inpainting results, is a benchmark metric in our evaluation. Similar evaluations have been employed in previous studies in natural language processing [29] and music generation [30]. Consequently, our study employs a 12-layer Transformer-based autoregressive model with REMI representation. Our goal is to assess the similarity between the distribution of musical elements in inpainted sections and those in the original dataset, including aspects such as rhythms, harmony, or melodies. A lower NLL loss indicates a more accurate prediction of the next token, reflecting a closer approximation to the dataset’s inherent musicality. Note we assess this metric over the entire output sequence.

	GFS (↑)		Wins		Ties
	PIA	Ours	PIA	Ours	
50%	0.458	0.696	0	870	130
30%	0.515	0.730	0	886	114
10%	0.650	0.803	0	891	209

Table 2: Comparison of global feedback scores (GFS) between PIA and the proposed RefinPaint methodology, Ours. Higher values indicate better performance.

	NLL (↓)		Wins		Ties
	PIA	Ours	PIA	Ours	
50%	2.01	1.97	330	541	129
30%	1.68	1.66	347	533	120
10%	1.63	1.62	321	457	222

Table 3: Comparison of Negative Log Likelihood (NLL) between PIA and the proposed RefinPaint methodology, Ours. Lower values indicate better performance.

Results in Table 2 indicate that our model’s GFS score is generally better than the baseline, suggesting that the optimization goal of the RefinPaint iterative process is met.

The PIA model never wins because this experiment selects the best GFS of all the iterations, as mentioned in Section 4.2. Although dynamic programming or genetic algorithms could enhance the process, this study uses a simpler method, focusing on the iteration with the highest GFS.

In Table 3, RefinPaint consistently achieves a slightly lower average NLL loss than PIA, suggesting that the inpainted content by RefinPaint is more consistent with the original dataset used for training. Furthermore, RefinPaint wins more evaluations than PIA across all the percentages of fragment size evaluated. This further underscores the enhanced performance of RefinPaint in producing sequences more akin to human compositions. However, comparing both tables, we acknowledge that higher GFS does not always imply a better NLL loss, calling for other types of evaluation, as addressed in the next section.

5.3 Listening test of proofreading inpainting

While computational metrics provide valuable insights into the quality of our inpainted music sections, human perception adds another perspective for evaluating musical quality and appeal. A user-based evaluation was conducted to capture a holistic view of the inpainted outputs' musicality.

For each experiment, which involved 50%, 30%, and 10% fragments of inpainted content, 15 different annotators evaluated both the first iteration of inpainted content (PIA) and the complete iterative process of RefinPaint (Ours) for ten iterations. Participants were exposed to two scenarios, Experiment 1 and Experiment 2: one from the PIA model and one from our RefinPaint model. The order in which these pairs were presented was randomized to avoid any bias. Additionally, we provided the original music fragment without the inpainted content for reference. Participants listened to both the PIA and RefinPaint versions before making their evaluations. They were asked to assess the inpainted content's quality by comparing it to the original fragment, focusing specifically on coherence and creativity. To make their choice, participants were given four options to prevent bias: 'Experiment 1,' 'Maybe Experiment 1,' 'Maybe Experiment 2,' and 'Experiment 2'.

Figure 5 shows the listening test results. Firstly, PIA got lower preference scores than RefinPaint for the different fragment size conditions. In addition, RefinPaint's performance for different fragment sizes shows that the coherence scores increase as the fragment size gets larger, even if the creativity varies. This means that as there is more to inpaint, RefinPaint gets better at being coherent. In contrast, PIA does not show such a strong trend.

The quantitative and qualitative evaluations point towards a clear trend: RefinPaint tends to yield superior inpainting results when proofreading machine inpainted sections compared to the baseline. Our methodology produces music sequences that are more consistent, perceptually closer to the original, and preferred by listeners.

6. CASE OF STUDY ON PROOFREADING AMATEUR COMPOSITIONS

We conducted an additional study to explore the proposed system's capabilities for proofreading music compositions

Figure 5: Results of the participants' votes for the listening test comparing PIA and RefinPaint (Ours) along different fragment sizes (50%, 30%, and 10%).

by humans. Given the intrinsic difficulties of such a study and due to practical restrictions, we limited our experiment to four amateur composers—two with classical music training and two with modern popular music training.

Participants used a straightforward proofreading interface that enables bar selection for regeneration, allowing them to choose how much of the content to keep in certain sections of their work, as described in 2.3. Additionally, we allowed the users to change the RefinPaint feedback in the selected area and experiment with the tools by conducting as many trials as they wanted.

After testing our inpainting tool on a 30-second music piece, participants responded to questions about their experience. They evaluated whether the tool (i) enhanced their original draft, (ii) sparked new ideas, (iii) could save time over manual proofreading, and (iv) was something they would use in the future. All chose "yes" for (i), (iii) and (iv) with three "yes" and one "maybe" for (ii), suggesting time efficiency as a key advantage and providing an overall positive view of the tool.

The positive feedback prompted us to showcase the proofread compositions on our companion website. Participants suggested the tool could be particularly effective in overcoming creative blocks, noting that inspiring ideas stemmed from all iterations, not just the last one. Additionally, two participants especially valued the option to alter tokens within the RefinPaint selection.

7. CONCLUSION

In conclusion, our novel approach, RefinPaint, significantly enhances music generation by identifying and improving weaker musical elements through iterative feedback. Its effectiveness in both inpainting and proofreading tasks promises a new direction for creative assistance and quality enhancement in compositions by humans and machines alike. Future work could fruitfully extend the research to multitrack compositions and explore control mechanisms for this model, such as conditioning by harmony, rhythm, genre, or other musical factors.

8. ETHICS STATEMENT

While RefinPaint can represent a significant leap forward in music composition technology, ensuring ethical deployment and use is crucial. We advocate for a future where such technologies support and enrich the creative process, complementing rather than displacing human creativity. While RefinPaint aims to democratize music creation, making it accessible and achievable for amateurs, there is a risk that professional musicians and composers could feel their roles and contributions are being undermined or replaced by machines. It is essential to strike a balance where this technology serves as a tool for enhancement and learning rather than a substitute for human creativity. Furthermore, it will be vital to establish guidelines that protect the intellectual property rights of original compositions, whether entirely human-made or AI-assisted.

ABSTRACT

Deep learning has significantly advanced music source separation (MSS), aiming to decompose music recordings into individual tracks corresponding to singing or specific instruments. Typically, results are evaluated using quantitative measures like signal-to-distortion ratio (SDR) computed for entire excerpts or songs. As the main contribution of this article, we introduce a novel evaluation approach that decomposes an audio track into musically meaningful sound events and applies the evaluation metric based on these units. In a case study, we apply this strategy to the challenging task of separating piano concerto recordings into piano and orchestra tracks. To assess piano separation quality, we use a score-informed nonnegative matrix factorization approach to decompose the reference and separate piano tracks into notewise sound events. In our experiments assessing various MSS systems, we demonstrate that our notewise evaluation, which takes into account factors such as pitch range and musical complexity, enhances the comprehension of both the results of source separation and the intricacies within the underlying music.

1. INTRODUCTION

Music source separation (MSS) is a key task in Music Information Retrieval (MIR), involving the separation of a musical mixture into individual components like vocals, instruments, and other sound elements [1]. Deep learning techniques have significantly advanced MSS, especially in scenarios with sufficient training data. In particular, this progress is evident in popular music separation, making use of the existence of multitrack recordings inherent in the production process [2–5]. In scenarios with limited training data, systems are often trained using artificially generated mixes through synthesis techniques [6,7] or data augmentation approaches [8,9]. An example of such a sce-

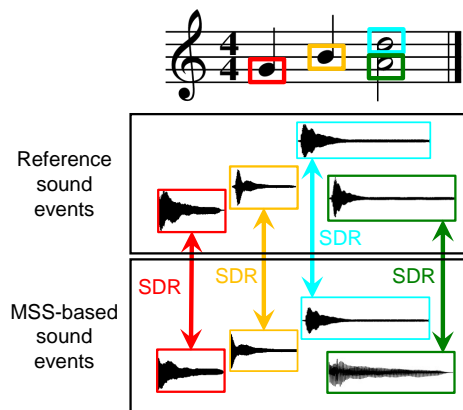

Figure 1: Illustration of the proposed evaluation method for music source separation (MSS), considering signal-to-distortion ratio (SDR) values based on notewise sound events rather than entire recordings.

nario, also addressed in this paper, is presented in [10], where the goal is to separate piano concertos into piano and orchestra tracks.

Extensive efforts have been devoted to evaluating and understanding existing MSS systems. Specifically, in the realm of popular music, evaluation campaigns like the Signal Separation Evaluation Campaign (SiSEC) [11] and the Music Demixing Challenge (MDX) [12] have significantly contributed to the comparison of current systems. In these campaigns, along with evaluations in most approaches described in the literature, one typically relies on quantitative evaluation measures such as the signal-to-distortion ratio (SDR) [13]. These measures are computed and aggregated over audio excerpts or even entire recordings, offering ease of computation and convenience for comparison. However, it is well recognized that such measures provide limited insights into the effectiveness of source separation methods [14, 15]. On the other hand, designing perceptually or musically more relevant measures is challenging, and performing listening tests is often cumbersome and infeasible.

In this paper, we introduce a novel evaluation methodology aimed at attaining a more nuanced understanding of separation quality. This involves comparing a reference signal with a separated signal, utilizing an evaluation

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

metric based on musically meaningful sound units instead of the entire excerpt. To achieve this, we employ score-informed nonnegative matrix factorization (NMF) [16] to decompose signals into notewise sound events. Then, we calculate SDR values for individual units before aggregating this information in various ways (see Figure 1). This methodology draws conceptual parallels to the evaluation of tasks where automatic speech recognition (ASR) is used as a downstream task. For example, Chen et al. [17] computed word-level and utterance-level metrics to evaluate the quality of the speech separation system.

In a case study, we apply this methodology to the intricate task of separating piano concerto recordings into piano and orchestra tracks. Besides utilizing the Piano Concerto Dataset (PCD) [18], which comprises piano concerto excerpts performed by five pianists in four distinct acoustic settings, we generated piano scores for all the excerpts. We then employed music synchronization techniques [19, 20] to align these scores with all recorded excerpts. As an additional contribution to this paper, we release these annotations, thereby adding a score-based layer to the PCD collection.

In systematic experiments, we apply our evaluation methodology to effectively compare several academic and commercial source separation systems. Our approach uncovers general trends and yields insights into how separation quality is affected by factors like pitch range and musical complexity. In particular, it allows users to explore evaluations in-depth by pinpointing complex passages and challenging sound units where source separation systems tend to fail. Along these lines, we provide qualitative discussions that deepen insights into the behavior of source separation systems and the complexity of the underlying music.

The remainder of the paper is organized as follows. In Section 2, we review relevant literature on source separation and introduce the MSS models used for separating piano concertos. Subsequently, in Section 3, we elaborate on the score-based extension of PCD and outline our evaluation approach, covering NMF-based audio decomposition and notewise SDR-based metrics. In Section 4, we provide details on the experimental settings and report our empirical findings. Finally, in Section 5, we conclude and discuss potential directions for future work.

2. MUSIC SOURCE SEPARATION

As mentioned earlier, the decomposition of music recordings into individual sound components has garnered significant attention in academia and industry in recent years [1–5, 21–23]. While there is a multitude of approaches and architectures proposed in the literature, one can broadly distinguish between spectral-based, waveform-based, and hybrid models. Spectral-based models, such as Open-Unmix (UMX) [2] or Spleeter (SPL) [3], estimate the magnitude spectrograms of target musical sources given the magnitude spectrogram of an input mixture. Techniques like binary masking, soft masking, or multichannel Wiener filtering are then employed to reconstruct the separated audio

Model ID	Domain	Size (MB)	TS (Hours)
UMX	Spectrogram	34	52
SPL	Spectrogram	75	52
DMC	Waveform	510	52
HDMC	Hybrid	319	52
AudioShake	Hybrid	N/A	500+

Table 1: MSS models considered in our experiments. TS denotes the size (in hours) of the training set used.

signals [24, 25]. Waveform-based models, such as Demucs (DMC) [21], process the raw waveform of an input mixture and predict the waveforms of the individual separated sources. Hybrid models integrate complementary information from waveform- and spectrogram-based models, encompassing both spectral and temporal branches. In these architectures, latent representations are combined through the addition of shared layers to leverage the advantages offered by both domains [4, 26, 27]. Examples include the hybrid Demucs model (HDMC) introduced in [4] and a system (AudioShake) provided by the company AudioShake.

In this paper, we consider the challenging source separation scenario of decomposing piano concerto recordings into distinct piano and orchestral tracks. Piano concertos involve an intricate interplay between the piano and the entire orchestra, resulting in high spectro-temporal correlations among the constituent instruments. Additionally, the absence of multitrack data for training poses an extra challenge for data-driven source separation approaches. To overcome the lack of training data, the approach in [28] proposes generating artificial training data by superimposing randomly chosen audio patches from the solo piano repertoire (e.g., piano sonatas and etudes) and orchestral pieces without piano (e.g., symphonies). The training procedure and comparison of four different models mentioned above are described in [28], including the use of further data augmentation techniques. In our experiments, we employ four pre-trained models from the study [28], shown in Table 1. Additionally, we utilize the commercial system AudioShake, trained with over 500 hours of multitrack music recordings spanning various genres, with a focus on popular music. It is important to note that the AudioShake system has not been specifically adapted to the piano concerto scenario but is trained on mixtures where the vocal stem is usually dominant.

Finally, we want to emphasize that the implementation details and the reproducibility of the various MSS systems are not the main focus of this paper. Instead, these MSS systems and the piano concerto scenario serve as a framework for illustrating our evaluation methodology, as we will further discuss in Section 4.

3. EVALUATION APPROACH

We now introduce our novel evaluation approach, which we will apply to compare reference piano recordings and separated piano tracks. In Section 3.1, we briefly describe the PCD collection, which will serve as a test dataset, and present our score-based extensions. Then, in Section 3.2,

Room ID	Room Description	Piano	Dur	#Notes
R1	Lecture hall	Yamaha C3	180	1780
R2	Private studio	Yamaha C3X	180	2216
R3	Small concert hall	Seiler	252	2305
R4	Big concert hall	Steinway D	360	3741
Σ			972	10042

Table 2: Overview of the PCD test set, indicating the four rooms and the piano models employed, and including the duration (in seconds) and the number of notes (piano only).

we revisit the score-informed NMF approach for audio decomposition. Finally, in Section 3.3, we define the SDR-based evaluation metrics, which we use to gain a deeper understanding of the source separation results.

3.1 Piano Concerto Dataset and its Extension

The PCD collection, introduced in [18], is based on piano concerto recordings featuring five different amateur and professional pianists playing along with orchestral recordings provided by the publisher *Music Minus One*¹. Multitrack recordings with clean piano and orchestra reference tracks were produced from these sessions. The PCD consists of 81 multitrack excerpts, each lasting 12 seconds, selected from 15 piano concertos spanning the Baroque to Post-Romantic period. As summarized in Table 2, the PCD comprises excerpts recorded in four distinct acoustic settings with different grand piano models.

Our novel evaluation approach relies on synchronized score information used for notewise audio decomposition. To this end, we manually generated symbolically encoded sheet music representations using the *Sibelius* software² for the piano tracks (and piano-reduced versions of the orchestra tracks, which are not utilized in this study). We employed the *Sync Toolbox* [20]³ to automatically align the score information with the PCD audio excerpts. To ensure high synchronization accuracy, we computed these alignments in two independent ways: once based on the piano-only tracks and another time based on the piano–orchestra mixes. We then applied fusion techniques to establish the final score annotations. Additionally, expert listeners verified the final results using visual cues provided by the *Sonic Visualizer* [29] and acoustic cues using sonified score annotations overlaid with the audio excerpts. With regard to note onsets, the accuracy of the score annotations for the piano tracks can be expected to lie in the range of 20–40 ms. Additionally, we manually annotated the left-hand (LH) and right-hand (RH) notes, resulting in further musically meaningful note groupings beyond the notewise ones.

We release the symbolically encoded sheet music along with the score-based annotations of the audio excerpts, thereby adding an additional score-based layer to the PCD collection as part of the contributions of this paper.⁴

Figure 2: Illustration of the decomposition of the piano track into left-hand (LH), right-hand (RH), and individual note events as indicated by the rectangular windows.

3.2 NMF-Based Audio Decomposition

Nonnegative matrix factorization (NMF) is an algorithm for approximating a nonnegative matrix as the product of two low-ranked nonnegative matrices [30]. In the context of music processing, NMF has been widely applied to decompose a magnitude spectrogram into the product of two nonnegative matrices [31], where the columns of the first matrix encode spectral prototype patterns (called *templates*), and the rows of the second matrix encode their occurrences in time (called *activations*). Thanks to nonnegativity and multiplicative update rules, NMF facilitates the straightforward integration of prior musical knowledge, such as information from an acoustic model or a musical score. For instance, one may constrain the spectral template matrix to enforce a harmonic structure [32] or use aligned score information to constrain the activation matrix [16]. In addition to stabilizing the convergence of the NMF algorithm, such constraints also guide the factorization process to yield decompositions of musical relevance [33].

Following the approach in [34], we adopt a score-informed NMF approach to decompose a given audio signal x into its constituent notewise audio events x^m for $m \in [1:M]$ and a residual signal r such that

$$x = \sum_{m=1}^M x^m + r. \quad (1)$$

Here, we assume that we have a score representation with M denoting the number of note events, which are aligned to the audio signal. Note that this alignment does not need to be completely accurate, as it only serves to constrain the NMF algorithm, which can then improve the accuracy in the iteratively learned decomposition process. Besides applying this procedure to obtain a notewise decomposition of the audio signal, one can use the same approach to obtain a decomposition corresponding to note groups, resulting, for example, in the decomposition of the LH and RH notes, as illustrated in Figure 2.

We conclude our description of the NMF-based decomposition approach with some final remarks regarding implementation issues encountered in our experiments based on the PCD test set. Note that, in general, NMF training based on iterative update rules yields more reliable decom-

⁴ www.audiolabs-erlangen.de/resources/MIR/PCD

position results when applied to longer input spectrograms exhibiting a coherent template structure. Therefore, rather than applying the NMF-based decomposition to individual 12-second excerpts, we concatenated all 12-second excerpts recorded in the same room (see Table 2). This strategy is grounded on the assumption that the learned spectral templates, encoding characteristics of the piano and room acoustics, exhibit coherence within each room. Subsequently, we executed the NMF algorithm for 100 iterations on the concatenated data for four subsets with distinct room acoustics, using the same configurations and initialization approach introduced in [16]. This procedure was applied to both the reference piano recordings and the separated piano tracks generated by each MSS model. The resulting notewise decomposition results serve as the basis for our experiments, as reported in Section 4.

3.3 SDR-Based Metrics

The signal-to-distortion ratio (SDR) is a widely used metric in the evaluation of source separation performance, measuring the quality of a separated source by comparing it to the reference source in terms of signal distortion [13]. In our evaluation, when given a reference signal x and a separated signal \hat{x} , we use instead the more computationally efficient SDR metric proposed at the recent SDX challenge [35], also denoted as SDR:

$$\text{SDR}(x, \hat{x}) := 10 \log_{10} \frac{\|x\|^2}{\|\hat{x} - x\|^2}. \quad (2)$$

Rather than comparing entire excerpts, we use a localized variant referred to as $\text{SDR}_{\text{local}}$ that better accounts for significant level differences within the signal. To this end, we split the reference and separated signals into 1-second segments x_k and \hat{x}_k , respectively, defining:

$$\text{SDR}_{\text{local}} := \frac{1}{K} \sum_{k=1}^K \text{SDR}(x_k, \hat{x}_k) \quad (3)$$

In our evaluation, we have $K = 12$, as each excerpt in the PCD test set has a duration of 12 seconds.

To obtain a musically more informed evaluation metric, we exploit the decomposition as defined in Equation (1) and consider notewise SDR values:

$$\text{SDR}_{\text{note}} := \text{SDR}(x^m, \hat{x}^m), \quad (4)$$

where x^m and \hat{x}^m denote the notewise sound events of the reference signal and the separated signal, respectively. Note that, using the same score-based activation constraints in the NMF decomposition for x and \hat{x} , respectively, the lengths of x^m and \hat{x}^m are identical for a given $m \in [1:M]$.

4. EXPERIMENTS

In this section, we report on our systematically conducted experiments to highlight the potential of our notewise evaluation methodology. In this context, the piano concerto separation task, along with the five MSS systems described

Model	Piano	Orchestra
UMX	8.38 ± 4.24	3.61 ± 2.19
SPL	8.16 ± 3.99	3.46 ± 2.25
DMC	7.59 ± 4.38	2.82 ± 2.13
HDMC	9.61 ± 4.42	4.75 ± 2.31
AudioShake	12.82 ± 4.24	8.01 ± 2.97

Table 3: $\text{SDR}_{\text{local}}$ values (mean and standard deviation) averaged over all PCD excerpts for different MSS systems (see Table 1).

Figure 3: Comparison of different evaluation methodologies for the piano case using boxplots. The three outliers for AudioShake, indicated by the black oval, are shown in Figure 8.

in Section 2, should be considered an illustrative case study of practical relevance. When describing the various experiments, we progress from a coarse to a fine perspective. We start with a more global view of the source separation quality of the MSS systems (Section 4.1). Subsequently, we adopt a more fine-grained perspective, delving into the separation quality depending on the musical pitch (Section 4.2). Finally, we assume an excerptwise view and discuss specific examples to illustrate how separation errors may occur in musically complex situations (Section 4.3). This hierarchical discussion underscores how the notewise evaluation methodology serves as a tool, enabling users to delve into and comprehend not only the separation results but also the intricacies within the underlying music.

4.1 Global Perspective

To gain an initial understanding of the overall performance of the five MSS systems, Table 3 presents the $\text{SDR}_{\text{local}}$ values averaged across the 81 PCD excerpts for both separated piano tracks and orchestra tracks. For instance, in the piano case, DMC achieves the lowest $\text{SDR}_{\text{local}}$ value at 7.59, while HDMC shows a higher value of 9.61, and AudioShake outperforms all other models with a value of 12.82. Similar trends are evident in the separated orchestra case, although all values are notably lower compared to the piano case. Similar tendencies have been reported in [28].

In the subsequent finer-grained evaluation, we employ notewise evaluation metrics. Since we have the required

Figure 4: SDR_{note} values aggregated by pitch (specified by MIDI note number) shown for five MSS systems.

symbolic score information for the score-based NMF decomposition exclusively for the piano tracks, we confine our analysis to the piano case.⁵ Extending the evaluation methodology for the five MSS systems, Figure 3 shows boxplots that indicate the median, first quartile, third quartile, and outliers of differently computed SDR values. The first group of boxplots (Excerpt) provides the SDR_{local} values computed as in Table 3. The second (LH) and third (RH) groups show the SDR_{note} values for the left-hand and right-hand notes, respectively, and the last group (All Notes) shows the SDR_{note} values for all individual notes.

While the general trends for the five MSS systems are similar to those shown in Table 3, the different evaluation methodologies provide additional information. Firstly, being based on notewise aggregation, outliers in the SDR_{note} -based boxplots offer explicit cues worth further investigation. For instance, outliers such as the three indicated by the black oval in Figure 3 yield interesting examples for musically complex passages as further explored in Section 4.3. The boxplots in Figure 3 also facilitate a comparison of SDR_{note} values between the LH and RH notes. Notably, for all MSS systems, a better separation quality can be observed for the right hand compared to the left hand, with a difference of approximately 5 dB. Drawing from these observations, one can formulate various hypotheses regarding the relationship between source separation quality and pitch or musical complexity, as we detail in the subsequent sections. Please visit our demo webpage to find audio examples separated by five MSS models.⁶

4.2 Pitchwise Evaluation

Considering that RH typically contains higher notes than LH, one may conjecture that source separation quality depends on the pitch of the played notes. To test this hypothesis, Figure 4 provides an overview of the SDR_{note} values aggregated by pitch (specified by MIDI note number). While the overall trend regarding the MSS systems’

performances remains the same (AudioShake performing best, DMC worst, and HDMC being in between), the pitch-dependent SDR_{note} values indicate that, overall, source separation quality tends to increase for higher pitch numbers, with the highest values in the pitch range 74–80.

However, such trends, and drawing conclusions from them, need to be taken with care. For example, the curves in Figure 4 may indicate that source separation becomes more difficult for very high pitches in the range 96–104. However, these numbers lack statistical significance due to the limited occurrence (indicated by the dotted line). Also, one may assume that such pitches may rarely occur in the training material used for training the MSS systems, thus leading to poor generalizations on the test set.

4.3 Excerptwise Evaluation

Rather than source separation quality solely being a matter of pitch height, there may be other confounding factors underlying the trend. An alternative hypothesis could be that the LH (or lower-pitched) piano notes are more interwoven with the orchestral track, while the RH (or higher-pitched) piano notes stand out and can be better isolated by MSS systems. To explore aspects of musical complexity, we present in Figure 5 SDR_{note} values aggregated by excerpt (specified by PCD ID), this time focusing on the results for the two best-performing MSS systems, HDMC and AudioShake. Sorting the excerpts, e. g., based on decreasing mean values concerning AudioShake, facilitates the identification of challenging excerpts, which are depicted toward the right side of the plot.

Guided by the plot in Figure 5, let us consider some concrete examples. Examining the top three excerpts (PCD IDs 045, 042, and 024), a manual inspection reveals that these excerpts share a common characteristic of relatively low musical complexity, consisting of slower passages drawn from the second movements of piano concertos by Beethoven and Mozart. For such passages, both MSS systems achieve a good separation quality.

Next, let us examine the excerpt with the lowest SDR_{note} value. This excerpt has PCD ID 076 and corresponds to measures 18–24 of the first movement of Tchaikovsky’s Piano Concerto Op. 23, as shown in Figure 6. Evidently, this passage exhibits a high musical complexity, with both piano and orchestra playing numerous

⁵ For the orchestra, we generated only piano-reduced scores due to the considerable effort required for full scores. Additionally, automated synchronization and decomposition approaches present greater challenges for orchestral music compared to piano, extending beyond the scope of the case study presented in this paper.

⁶ www.audiolabs-erlangen.de/resources/MIR/2024-ISMIR-PianoSepEval

Figure 5: SDR_{note} values aggregated by excerpt (specified by PCD ID) shown for the two best-performing MSS systems, HDMC and AudioShake. The mean (solid line) and standard deviations (filled regions) are indicated. The excerpts are sorted based on decreasing mean values with regard to AudioShake.

Figure 6: Excerpt with PCD ID 079: Tchaikovsky’s Piano Concerto Op. 23, measures 18–24 of the first movement (only four measures are shown here).

Figure 7: Excerpt with PCD ID 000: Bach’s Piano Concerto BWV 1056, measures 1–8 of the first movement (only four measures are shown here).

Figure 8: Musical context within the piano scores for the three notewise outliers marked in Figure 3 (here indicated by the red circles). (a) PCD ID: 052. (b) PCD ID: 061. (c) PCD ID: 077.

notes within a wide pitch range. Particularly notable are the fortissimo and broken chords in the piano part, which strongly interfere with the full orchestral sound, not to mention the effects resulting from the application of the sustain pedal. As a second concrete example, let us have a

closer look at the excerpt with PCD ID 000, also yielding a low SDR_{note} value. This excerpt corresponds to the first measures of Bach’s Piano Concerto BWV 1056, where the piano and orchestra play many notes in unison (see Figure 7). This scenario represents one of the most challenging situations for source separation models to deal with [36, 37].

Finally, we revisit the boxplots shown in Figure 3, where we marked three outliers indicating problematic notewise sound events with low SDR values, poorly separated by AudioShake. Figure 8 provides the musical context within the piano scores where these notes occur. A common feature in these examples, which is also typical in piano music in general, is the simultaneous playing of two notes that belong to the same pitch class, contributing to a rich and complex sound texture. Obviously, such instances are difficult for any MSS system, as well as the NMF algorithm to handle.

Overall, these examples show that while MSS systems like AudioShake and HDMC are capable of achieving impressive separation quality, their efficacy is highly influenced by the intrinsic characteristics of the musical pieces.

5. CONCLUSION

In this paper, we have considered a novel evaluation methodology that compares separated sounds with reference sounds on a notewise basis rather than at the excerpt level. For the challenging piano concerto scenario and employing five MSS systems, we applied this methodology in a case study focusing on the separated piano tracks. This allowed us to gain insights into the separation quality and the complexity of the underlying music. While our focus has been on the piano case, future work may involve evaluating other orchestral instruments and guitars. This could pose additional challenges not only for source separation itself but also for automated synchronization and decomposition approaches. On a meta-level, we hope that our hierarchical discussion, assuming different perspectives, also showcased the potential of musically informed evaluation methodologies, providing a basis for interdisciplinary dialogue between engineering and music experts.

ABSTRACT

Musical dynamics form a core part of expressive singing voice performances. However, automatic analysis of musical dynamics for singing voice has received limited attention partly due to the scarcity of suitable datasets and a lack of clear evaluation frameworks. To address this challenge, we propose a methodology for dataset curation. Employing the proposed methodology, we compile a dataset comprising 509 musical dynamics annotated singing voice performances, aligned with 163 score files, leveraging state-of-the-art source separation and alignment techniques. The scores are sourced from the OpenScore Lieder corpus of romantic-era compositions, widely known for its wealth of expressive annotations. Utilizing the curated dataset, we train a multi-head attention based CNN model with varying window sizes to evaluate the effectiveness of estimating musical dynamics. We explored two distinct perceptually motivated input representations for the model training: log-Mel spectrum and bark-scale based features. For testing, we manually curate another dataset of 25 musical dynamics annotated performances in collaboration with a professional vocalist. We conclude through our experiments that bark-scale based features outperform log-Mel-features for the task of singing voice dynamics prediction. The dataset along with the code is shared publicly for further research on the topic.

1. INTRODUCTION

Musical dynamics, such as *piano* and *forte* [1], are key elements in adding expressiveness to the singing voice [2]. They enhance overall performance and facilitate the conveyance of the desired emotional impact [3]. Despite extensive research on the singing voice, the analysis of dynamics in this context has received limited attention for several reasons. Firstly, annotating dynamics is an expensive process that requires repeated listening to audio tracks

to accurately identify the dynamics category. Secondly, unlike other musical features such as pitch or tempo, the categorization of dynamics is not clearly defined, and even the same annotator may interpret a piece differently on multiple listens. Finally, a significant challenge for modern deep learning applications is the lack of reliable, existing dynamics based annotated datasets that can be used for the development of automatic analysis systems [4].

Despite the challenges of dynamics-based annotations for the singing voice, investigating dynamics in singing performances is worthwhile. On one hand, dynamics are a key component of expressivity in a music performance [5, 6]. On the other hand, dynamics are also an integral part of the music writing tradition [1, 7]. The use of dynamics in Western classical music evolved significantly from the Baroque period to the Romantic era. Particularly during the Romantic era, when expressivity became prominent, the annotation of dynamics alongside the score became widespread and accepted as part of the composition process. Composers frequently utilized symbols such as *forte*, *piano*, *crescendo*, and *diminuendo* to convey their desired variations in musical dynamics, and adhering to the dynamics instructions given by the composers became an important part of a Classical music performance.

While dynamics is a musical concept, its automatic estimation for music performance analysis relies on properties derived from audio signals. The audio characteristic most similar to musical dynamics is loudness or perceptual intensity. However, the mapping of musical dynamics to audio-based features from Music Information Retrieval (MIR) technologies is still not clearly understood. Extensive research exists on dynamics and tempo as expressive dimensions for Western classical piano performances [8]. However, unlike piano, there are almost no publicly available dynamics-based annotated datasets for the singing voice, which hinders the development of such technologies for the vocal performance analysis.

In this work, we propose to take advantage of the existing OpenScore Lieder corpus to curate a dataset of vocal performances with dynamics annotations, using state-of-the-art source separation and alignment as intermediate steps¹. Furthermore, we curate a dataset of 25 other performances of different genres annotated manually by a professional Classical vocalist to test the model. At the end,

Figure 1: Data Preparation Pipeline: Corresponding to the Lieder scores from OpenScore Lieder Corpus, we apply Vocal Separation followed by Automatic Alignment. Finally, we validate the aligned score-performance data using Visualizations

we study the relationship between score based musical dynamics to perceptually motivated audio features [9] like log-Mel and bark-scale based features, testing the model with different analysis window-size, and genres of the test dataset.

Figure 1 illustrates the overall pipeline of the task. Using the meta-data information of the repository accompanying Lieder corpus, we start with searching for corresponding performances on YouTube. Further, we apply vocal separation on the performance to get vocals. Thereafter, using state-of-art alignment techniques, we align the corresponding score with the performance. At this stage, to test the accuracy of the alignment process, we develop visualization to filter out performances with mismatched aligned scores. Using the aligned score and performance data, we train a model for estimating dynamics based markings for an unknown performance.

The rest of this paper is structured as follows. In section 2, we cover the related works. Section 3 describes the dataset and the curation process. In section 4, we describe the experiments conducted with the curated data, followed by discussion and future work.

2. RELATED WORK

Although musical dynamics has been a topic of investigation in several studies [6, 7, 10, 11], especially for the case of piano [8, 12–14] there remains a notable gap in research concerning standalone musical dynamics analysis for the case of singing voice, particularly from an MIR perspective. Despite this gap, dynamics form a fundamental aspect of analysis within the interconnected fields of singing voice synthesis [15] and voice pedagogy [5].

In Singing Voice Synthesis (SVS) systems, dynamics play a crucial role in conveying expressive nuances [16]. Typically, dynamics are modelled as measures of energy in the signal [15–17] at the frame level. However, while there exists a close correlation between energy of the signal and musical dynamics, the influence of other parameters, such as pitch and timbre [10], remains largely unexplored. Understanding the relationship between pitch, timbre and dynamics could lead to more realistic representations of musical expression in SVS systems.

Bous and Roebel [4] explore the relationship between musical dynamics and timbral characteristics of the singing

voice, employing mel-spectrogram features. Their experiment involves modifying the singing voice dynamics using a neural auto-encoder to transform voice levels. Effectiveness is assessed through evaluating perceived changes in voice level in the transformed recordings. However, a significant challenge arises as there is currently no reliable labels to determine the perceived changes in musical dynamics corresponding to "voice-level" changes as proposed in the system.

Narang et al. [18] utilize perceptually-motivated *some* scale, comparing loudness curves of different professional renditions and student renditions for "musical dynamics" comparison following the methodology outlined by Kosta et al. [12] for comparing musical dynamics in piano. However, the study encountered limitations due to the lack of dynamics annotated datasets for evaluation.

While there are some aspects of the research on Vocal Pedagogy [5] that has been utilized for the case of singing voice research from an MIR perspective, for example, Phonation mode [19] dataset or VocalSet [20] (which also contains some singing voice dynamics annotations but confined to vowel renditions), research outcomes of the vocal pedagogy remain largely unexplored by the MIR community. One direction is the role of voice source in singing voice, or how the positioning of the diaphragm affects vocal characteristics [21]. A study on vocal dynamics can help infer the voice source characteristics that can directly aid in vocal pedagogy.

3. DATASET

Dynamics are considered to be the most commonly manipulated parameter of an expressive performance and research investigations show that professionals or experts have much better control in expressive parameters in comparison to novice performers [6]. Further, songs from the 19th century Romantic era of Western classical music are widely known to be rich in expressive parameters. Drawing inspiration from this notion, we curate a dataset comprising professional renditions of 19th-century songs sourced from the OpenScore Lieder corpus [22]. Notably, composers often embed numerous dynamic markings within their scores, laying a foundational framework conducive to the analysis of dynamics.

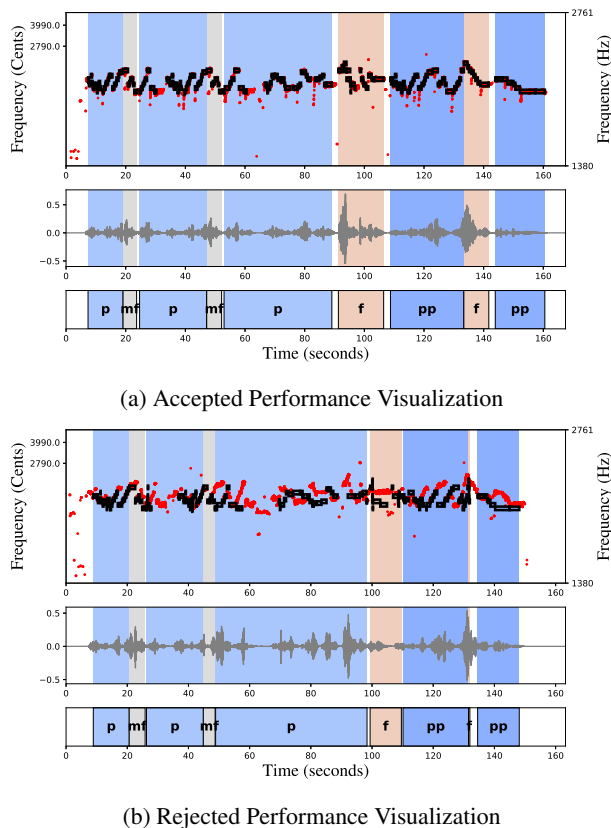

Figure 2: Example visualization after automatic alignment on "The Shepherds Song" by Edward Elgar; For each sub-figure: red dots represent f_0 using crepe, black dots represent note-information from the score (top), audio waveform (middle), dynamics information from the aligned score after automatic alignment (bottom)

3.1 Training Dataset Curation Process

3.1.1 Score Sources

Lieder Scores is a comprehensive collection of over 1200 19th century songs encoded over several years [22]. Within the Lieder dataset, we capitalize on two specific resources to facilitate our data curation process:

- The GitHub repository of Lieder provides MSCX files along with batch-conversion script to convert to MusicXML, enabling further processing with tools such as music21 [23]
- In the metadata section of the Lieder scores, a comprehensive compilation of composers, score names, and their respective MuseScore IDs is provided. This rich metadata serves as a valuable resource during the performance collection stage, enabling efficient querying and selection of performances.

3.1.2 Filtering Criteria for Scores

From all the batch-converted MusicXML files, we filter all scores, focusing on those with more than 3 dynamics annotations, and containing only 3 streams of score data: vocal, piano left hand and piano right hand.

3.1.3 Performance Sources

For the identified scores with greater than 3 dynamics markings, we search for multiple corresponding performances on YouTube using the query term obtained from the meta-data information of the scores. We curate multiple performances of similar pieces with the intention of extracting general dynamics based expressive patterns from professional singers. Our aim is to glean insights into varied interpretations, as there is no singular correct rendition of a performance that strictly adheres to the score. Subsequently, we carefully listen to each performance, specifically selecting those featuring vocals accompanied solely by piano. It is to be noted that not all composers have available performance data; thus, our selection process initially prioritizes renowned figures such as Schubert, Schumann, Brahms or Debussy, and ones with greater than 10 dynamics annotations. Once having exhaustively searched for performances of these well known composers, we proceed to search for lesser known composers following similar criteria. We automate the download process by utilizing YouTubeDL batch download to acquire the identified performances. The method yields a final list of 970 performances comprising identified composers, performances, and their respective MusicXML score files with dynamics based annotations.

3.1.4 Filtering Criteria for Performances

Following the filtration of scores and the manual curation of performance links, we advance to filtering performances suitable for the dynamics learning process. This process includes the following steps:

Source Separation Singing voices typically aren't presented in isolation. Even for solo performances, piano accompaniment is part of the performance. However, for our analysis, we require solo vocal renditions to accurately discern variations in performance dynamics. The initial step involves isolating the vocal component from the vocal-piano mix. This process, known as source separation, entails breaking a mixture into its constituent components, and significant research has been dedicated to separation of vocals from the mix. We use Demucs v2 [24] to extract the vocals for the chosen songs. The robustness of using vocals resulting from source separation as an intermediate step was examined with the MusDB dataset [25].

Automatic Alignment To ensure that our curated performances can effectively serve as the basis for dynamics analysis, it's essential to achieve a basic alignment with the scores. Our approach to label creation draws inspiration from the methodology outlined by Tamer et al. [26, 27], who leverage Dynamic Time Warping (DTW) based music synchronization techniques [28] for creating pseudo labels in the realm of Violin transcription. Additionally, the concept of utilizing audio-to-score alignment as a pre-processing step for curating datasets in a semi-automatic manner for musicological endeavours was introduced in works by Weiss et al. [29], with a focus on the curation of Schubert's Winterreise dataset. While the works by Weiss et al. utilize MIDI-to-score alignment, we have chosen to

conduct the alignment using musicXML scores. This decision stems from the fact that dynamics information such as *piano*, *forte*, *crescendo*, and *diminuendo* can be less reliable in the process of MIDI conversion.

Manual Filtering using Visualizations The alignment stage yields a score with time information mapped to the corresponding performance files. Subsequently, we develop a visualization process utilizing fundamental frequency (f0) data extracted from performance files using CREPE [30] to validate the alignment between time-aligned performance and score files. Figure 2 showcases a sample visualization from the dataset. Figure 2a illustrates a performance that was accepted, and Figure 2b depicts a performance that we manually excluded during the selection process. The performance in Figure 2b was rejected because f0 curve from crepe (red dots) do not align with note-information from score (black rectangles) after automatic alignment, and hence the final labels lose reliability. The end result of this step is a comprehensive dataset of 509 performances for 163 aligned score files, which can be used to extract precise note-level expressive information from the score using tools like music21 [23].

3.1.5 Dynamics based Labels Extraction from Aligned Score Files

The aligned score files consist of all score-based information crucial for dynamics prediction. In this stage, we process the musical dynamics labels extracted using music21. Our approach adheres to the following principle: consecutive notes in the aligned audio are assumed to maintain similar dynamics unless there is a change in dynamics annotation in the score. When encountering labels like *sfz* or *sf* for a note, the value of the label of the consecutive note is assigned to be the dynamic value of the note preceding *sf* or related categories. This process results in a note-level mapping of 13 musical dynamics categories: *pppp*, *ppp*, *pp*, *p*, *mp*, *mf*, *f*, *ff*, *fff*, *ffff*, *sf*, *crescendo*, *diminuendo* directly extracted from the score. It is to be noted that we consolidate accent related categories, such as *sf*, *sfz* into a single category. Additionally, while we focus on musical dynamics for our task, the aligned score-performance data holds potential for various other Music Information Retrieval (MIR) tasks related to singing voice, including transcription, synthesis, or pedagogy.

3.2 Test Dataset Curation Process

For testing, we curated performances from a diverse selection of genres, ranging from operatic pop to theatre, R&B, or jazz, which lie outside the typical classical music domain. We collaborated with a Classical Vocalist, possessing over a decade of experience, to identify artists renowned for their wide vocal range. Once identified, we created reference scores for selected performances by these professional artists. The distribution of the genres in the selected pieces is as follows: pop(13), rock(12), jazz(3), soul(5), R&B(5), theatre(2) and other miscellaneous genres(5) including categories such as "post-disco", "acoustic" or "progressive rock", amongst others.

Figure 3: Dynamics Distribution across Train and Test Performances

3.2.1 Annotation Methodology

This section details the annotation methodology for dynamics-related markings of selected pieces as outlined by the musician: In the first listening, the piece's starting dynamic value is determined according to the dynamic markings such as: *pp*, *p*, *mp*, *mf*, *f*, *ff*, creating a reference point for each piece. This phase captures the most prominent features, recognizing that notation conveys more than mere amplitude. Subsequent listenings entail adding details, both in terms of dynamics and articulation of the text and musical phrases. Increased attention reveals additional layers of variation, often unnoticed during the first listening. In the third listening, decisions are made based on unification criteria. If different notations were used for the same musical effect in similar portions of the piece (e.g., different verses), the notation that best represents the musical intent is selected and unified with the rest. Rarely, genuine differences may exist between similar sections, in which case they are left distinct. In the final listening, no further notations are added. Instead, a mental musical reading of the entire work, from beginning to end, is undertaken. This involves elaborating on the interpretation following the written notations while simultaneously comparing it with the rendition produced by the artist.

3.2.2 Processing Methodology for Test Dataset

The processing methodology followed for the test dataset is similar to that of the training dataset, i.e., we apply source separation followed by automatic alignment to fetch the annotated labels using curated reference scores and performances.

Table 1: Results with Mel and Bark Features. Temporal resolution refers to the final feature rate after downsampling.

Seq Length	Temporal Resolution	Perceptual Feature	Acc	Acc(± 1)	Acc(± 2)
4096	17.4 ms	log-Mel	6.95	38.46	63.02
10000	29 ms	log-Mel	11.35	42.55	68.38
4096	16 ms	Bark	20.44	59.17	82.24
10000	30 ms	Bark	20.96	60.71	84.78

3.3 Dataset Statistics

Audio Statistics: The total duration of all the performances for the training dataset is 25.91 hours. The total duration of test files is 1.614 hours. The distribution of the labels as identified in dataset section 3 is illustrated in Figure 3. We observe that Lieder scores follow a relatively uniform distribution of dynamics with large number of dynamics annotations centered on a ‘*piano*’. And for the test dataset, the distribution curve is largely gaussian with majority of the distribution centered around *mp* and *mf*, which is not surprising considering the nature of pop music and mixing and mastering effects added to the final renditions.

Performance Count Per Piece: Although a single performer can deviate from the annotated score dynamics, having multiple performers per piece can help the model learn the general patterns closer to composer’s intention. To leverage this effect, we collect performances with an average count of 3.12 performances per piece (std: 2.13), with a maximum of 12 performances for a piece by Robert Schumann. The average performance duration was observed to be 9.54 minutes (std: 9.36 minutes), with a maximum of 74.27 minutes for a piece by Franz Schubert and a minimum of 1.01 minutes for a piece by Peter Warlock.

4. EXPERIMENTS AND RESULTS

For the experiments outlined in this section, we utilize the curated dataset of Classical vocal performances for training and the dataset created in collaboration with the Classical vocalist for testing. We convert the note-level dynamics labels spanning from *pianissississimo* (*pppp*) to *fortissississimo* (*ffff*) into framewise labels encompassing 10 dynamics classes, and train and test our models for estimating the frame-wise dynamics. Thus, we consider dynamics estimation as a 10-class classification problem operating at the granularity of individual frames.

Input Representations: For model inputs, we consider two perceptually-motivated loudness features that are extracted after isolating the vocal tracks using DemucsV2 [24]. As our first input representation, we consider log-Mel features, which are commonly used in many audio and music processing tasks. These features are extracted using the librosa [31] library from audio sampled at 44.1 kHz using a hop size of 5.8 ms. As our second representation, we consider the specific loudness in Bark critical bands, which was previously studied in the context of piano dynamics [12] and singing voice loudness analysis [18]. The 240 dimensional Bark features are extracted using the MoSQUITo library [32, 33], following the Zwicker

loudness calculation method for time-varying signals [34] as specified in the ISO.532-1:2017 standard. The extraction process adheres to the default settings of a 48 kHz audio sampling rate and a 2 ms hop size.

Alongside these different input representations, we also study the effect of input sequence length and rate. To that end, we experiment with sequence lengths of 4096 and 10000. Since the original input representations have different temporal resolutions, we employ various downsampling rates to ensure that the models receive comparable feature rates during analysis. In our study with short context (4096 frames) dynamics modeling, we downsample the Bark features by 8 to operate at 16 ms, and downsample the log-Mel features by 3 to operate at 17.4 ms. For modeling dynamics detection using longer contexts (10000 frames), we downsample the log-Mel features by 5 to achieve a temporal resolution of 29 ms, and downsample the Bark features by 15 to achieve a comparable resolution of 30 ms.

Model Architecture and Training: For the frame-level estimation of dynamics, we employ a multi-scale Convolutional Neural Network (CNN) with self-attention² [35], originally introduced for the closely related task of frame-wise playing technique detection. In our implementation, the network receives input features with a fixed sequence length and outputs probabilities for 10 dynamics classes, with the class having the highest probability taken as the estimate. During training, we utilize the Adam optimizer with a learning rate of 0.002, aiming to reduce the Cross Entropy loss between the predicted dynamics classes and the aligned dynamics labels. We report our results on training the same network for different input representations, sequence lengths, and feature rates.

Metrics: One big challenge in the experimentation with musical dynamics is the subjectivity and relativity in its evaluation. For instance, one piece may span dynamics ranging from *pp* to *f*, and another piece may span dynamics ranging from *p* to *ff*. However, the measured loudness values of performances derived from both music pieces might be similar, as both sets of labels indicate a transition from relatively "soft" to "loud" dynamics. Therefore, the mapping between perceived performed dynamics and labeled musical dynamics may not be absolute. To address this challenge, we present the results in terms of exact match (Acc), relaxed accuracy 1 (Acc ± 1), and relaxed accuracy 2 (Acc ± 2). Relaxed accuracy denotes that estimates are not penalized for a mismatch of 1 or 2 classes, respectively.

²Based on the modified version of <https://github.com/LiDCC/GuzhengTech99/blob/main/function/model.py>

Figure 4: Model input and outputs for the log-Mel spectrum features. log-Mel-spectrogram (top), annotated labels by musician(middle), model estimates (bottom)

4.1 Results

The results are summarised in Table 1. Despite the subjectivity of the task, we observe that the most confusion lie within the ± 1 or ± 2 range with significantly higher relaxed accuracies. Furthermore, we see that bark-based features outperform log-Mel features for the task. The highest relaxed accuracy ± 2 is achieved with bark-based features, indicating the models ability to differentiate between upper and lower bounds of dynamics. For example, a fortissimo is not classified to be a piano in almost 85% of the cases. An example prediction using log-Mel features and bark-based features for a theatre song "sound of music" is presented in Figures 4 and 5 respectively.

The effect of larger and smaller temporal contexts can also be seen in Table 1. Providing larger temporal contexts results in better performance for dynamics estimation. This effect is more prominent for log-Mel features compared to the Bark features. We found that the best performing model is the one with the entire song frames included in the context window i.e., the sequence length is long enough to encapsulate the whole song.

5. DISCUSSION

One of the primary challenges in predicting musical dynamics lies in the fact that performance information is available through recordings, which is a result of mixing and mastering. Consequently, the loudness information captured in recordings may diverge from performers original intentions. However, we contend that despite the influence of mixing and mastering, it is possible for musicians as well as non-musicians to infer whether a performer is singing softly, loudly or even shouting independent of raw loudness levels. Our approach leverages perceptually motivated features that encapsulate timbral characteristics, which have the potential to enhance musical dynamics estimation while remaining agnostic to variations in loudness levels.

Figure 5: Model input and outputs for the bark based features: bark-critical-bands (top), annotated labels by musician (middle), model estimates (bottom)

While the labels are created semi-automatically, there are potential discrepancies due to performers not adhering strictly to the score or editors creating alternative versions of the score different from the one curated in the dataset.

Additionally, we have framed the dynamics estimation at an absolute level, with the expectation that the model will learn the variations in relative markings given a large amount of data. However, musical dynamics at any given time in a performance depend on the context rather than the absolute value of measured loudness [36]. Additionally, addressing class imbalance remains a significant challenge.

On software front, while MuseScore offers extensive annotation capabilities, some categories cannot be accurately modeled. To mitigate this, musicians often use note-level "TextExpressions" in MuseScore to add additional information. During our experimentation, we encountered terms like "sempre piano," "poco dolce," and "calando" that musicians add to the score. While we were able to mitigate challenges with some labels, achieving comprehensive coverage requires further collaboration with vocalists to refine the target labels.

6. CONCLUSION AND FUTURE WORK

We've developed a methodology for large-scale dataset curation focused on singing voice. The semi-automatically curated dataset serves as a valuable resource for tasks such as transcription, expression analysis, synthesis, and vocal pedagogy. It currently includes 509 performances aligned with 163 score files from 25 composers. Using this dataset, we trained a CNN with multi-head attention for dynamics prediction and found that bark-scale-based features outperform log-Mel features. To test the model, we curated score-performance dataset manually in collaboration with a Classical vocalist. Future work involves integrating pitch features with loudness features to enhance prediction accuracy, improving the model to address class imbalance, and expanding the dataset to include more composers.

ABSTRACT

We present JASCO, a temporally controlled text-to-music generation model utilizing both symbolic and audio-based conditions. JASCO can generate high-quality music samples conditioned on global text descriptions along with fine-grained local controls. JASCO is based on the Flow Matching modeling paradigm together with a novel conditioning method that allows for both locally (e.g., chords) and globally (text description) controlled music generation. Specifically, we apply information bottleneck layers in conjunction with temporal blurring to extract relevant information with respect to specific controls. This allows the incorporation of both symbolic and audio-based conditions in the same text-to-music model. We experiment with various symbolic control signals (e.g., chords, melody), as well as with audio representations (e.g., separated drum tracks, full-mix). We evaluate JASCO considering both generation quality and condition adherence using objective metrics and human studies. Results suggest that JASCO is comparable to the evaluated baselines considering generation quality while allowing significantly better and more versatile controls over the generated music. Samples are available on our demo page <https://pages.cs.huji.ac.il/adiyoss-lab/JASCO>

1. INTRODUCTION

Conditional music generation has shown a great improvement in recent years, specifically in the task of *text-to-music* generation [1–6]. Such advancements in music generation hold great potential to empower content creators, advertisers, and video game designers. Though presenting highly realistic music samples, most of the prior work is focused on global conditioning only. Such methods mainly consider textual descriptions or melody in the form

*Equal contribution

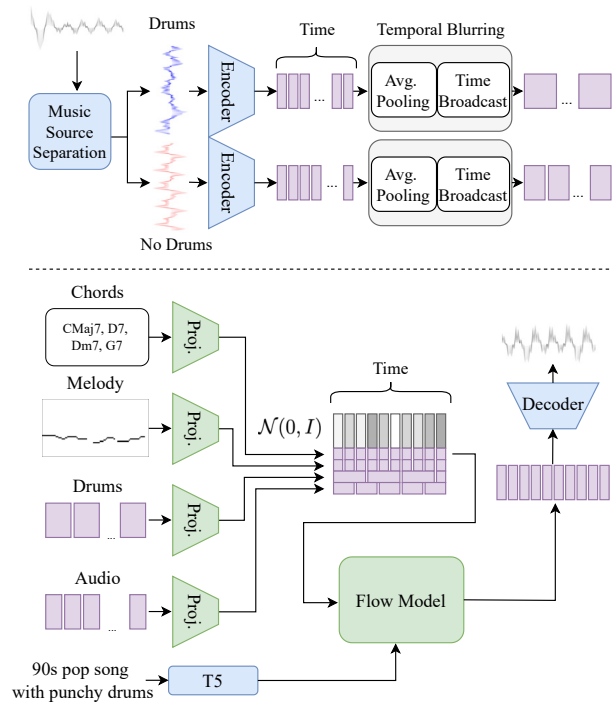

Figure 1. Top figure presents the temporal blurring process, showcasing source separation, pooling and broadcasting. Bottom figure presents a high level presentation of JASCO. Conditions are first being projected to low dimensional representation and are concatenated over the channel dimensions. Green blocks have learnable parameters while blue block are frozen.

of spectral features [3]. However, when considering music production, global controls may not be enough. During the creative process, professional musicians often use chords, melodies, or audio prompts, at the local level, rather than global descriptions. As a result, current models may be limited in their relevancy for music creators.

More recently, several works study text-to-music generation using temporally aligned controls. The authors in [7] suggest adding symbolic beat and dynamics conditions on top of the previously explored melody conditioning. The authors in [8] further explore musical structure conditioning, such as A-part and B-part. Unlike these works, the proposed method provides local controls considering both

symbolic representation and raw audio together with a global textual description. When considering music editing, the authors in [9] propose leveraging chord progression to guide the generation process towards the harmony of the inputs signal. For that, the authors extract an internal representation from stemmed data using a pre-trained chord classification model. The proposed method is different as we focus on generating full musical pieces rather than editing a given one. Specifically, we allow symbolic chord progression conditioning during inference time.

In this work, we present JASCO, a locally controlled Joint Audio and Symbolic COnditioning text-to-music model. JASCO uses time-aligned controls, namely audio prompts, melodies and chord progressions, comprised of either symbolic signals or raw waveforms. We relieve the need for either studio quality stemmed data or supervised datasets by using off-the-shelf pre-trained models to automatically extract the relevant information. JASCO is based on the Flow-Matching [10] modeling paradigm. Figure 1 provides a high level description of the proposed method. Results suggest that JASCO achieves comparable performance in terms of generation quality w.r.t the evaluated baselines while allowing significantly richer set of controls. The main contributions of this work are as follows: (i) We introduce a simple yet effective approach for audio conditioning with high temporal-adherence. (ii) We offer specific evaluation metrics to measure the alignment and accuracy of our suggested controls. (iii) We provide a thorough analysis on the components composing JASCO and compare to several baselines.

2. BACKGROUND

Audio Representation. Modern audio generative models mostly operate on a latent representation of the audio, commonly obtained from a compression model [11–13]. Compression models such as [14] employ Residual Vector Quantization (RVQ) which results in several parallel streams. Each stream is comprised of discrete tokens originating from different learned codebooks.

Specifically, the authors in [14] introduced EnCodec, a convolutional auto-encoder with a latent space quantized using RVQ [15], and an adversarial reconstruction loss. Given a reference audio signal $x \in \mathbb{R}^{D \cdot f_s}$ with D the audio duration and f_s the sample rate, EnCodec first encodes it into a continuous latent tensor $z \in \mathbb{R}^{D \cdot f_r \times N_{\text{enc}}}$ with a frame rate $f_r \ll f_s$ and $N_{\text{enc}} = 128$. Then, z is quantized into $q \in \{1, \dots, N\}^{D \cdot f_r \times K}$, with K being the number of codebooks used in RVQ and N being the codebook size. After quantization, we are left with K discrete token sequences, each of length $T = D \cdot f_r$, representing the audio signal. In RVQ, each quantizer encodes the quantization error left by the previous quantizer, thus quantized values for different codebooks are in general dependent, where the first codebook holds most of the information. Finally, the quantized representation is decoded back to a time domain signal using the decoder network applied to the sum of the representations learned by the different codebooks.

In JASCO, we use the continuous tensor z as the latent representation, while leveraging the discrete representation q for audio conditioning.

Flow Matching. The Flow Matching modeling paradigm [10] was recently found to provide impressive results on image [10], speech [16] and environmental sound generation [17]. More specifically, Conditional Flow Matching (CFM) is a novel training technique for Continuous Normalizing Flow models [18], that captures the continuous transformation paths of samples from a basic prior distribution, usually standard normal $\mathcal{N}(0, 1)$, to their counterparts in a target data distribution, \mathcal{S} . The position on this path is denoted by a time parameter t , starting from the prior state at $t = 0$ and ending at the data state at $t = 1$.

In this work, we focus on Optimal Transport (OT) paths as defined in [10]. The model is trained to predict the vector field of the continuous latent audio variable z , given t and a set of conditions \mathbf{Y} . Formally, the model minimizes the regression loss

$$\mathcal{L}_{\text{CFM}}(\theta; z_0, z_1, t | \mathbf{Y}) = \|v_\theta(z, t | \mathbf{Y}) - (z_1 - (1 - \sigma_{\min}) \cdot z_0)\|^2, \quad (1)$$

where $z_0 \sim \mathcal{N}(0, I)$ is a sampled noise, $z_1 \sim \mathcal{S}$ is the latent representation of a data sample, and

$$z = (1 - (1 - \sigma_{\min}) \cdot t) \cdot z_0 + t \cdot z_1, \quad (2)$$

is an interpolation between the noise and the data sample. For numerical stability, we use a small value $\sigma_{\min} = 10^{-5}$ in both terms. During inference we follow an iterative process, starting with the prior noise $z \leftarrow z_0 \sim \mathcal{N}(0, 1)$ and with $t = 0$. In each step, we translate the estimated vector field $v_\theta(z, t | \mathbf{Y})$ into an updated latent sequence z , and gradually converge toward the data distribution.

3. METHOD

Given a textual description, and a set of temporal conditions - such as melody, chord progression or drum recording, our goal is to produce high-quality samples that are musically aligned with the given controls, while complying to the arrangement description provided in the text.

JASCO tackles the aforementioned problem by a CFM model, operating on the continuous latent space of EnCodec. JASCO is conditioned on low-dimensional embeddings of melody, chords and audio signals, together with a T5 embedding of the textual description. All local controls are concatenated to the model’s input across the feature dimension, while text is being passed via cross attention. To diminish timbre-related information, JASCO further applies temporal blurring to the audio-based controls, as well as band-pass filtering. See Figure 1 for a visual description, and Section 3.1 for detailed information.

3.1 Temporal Controls

Symbolic. We use Chordino¹ chord progression model to extract an integer categorical chord label sequence, and a

¹ <https://github.com/ohollo/chord-extractor>

pretrained multi-F0 classifier [19] to obtain melody scores per time step. We resample all features to match EnCodec’s frame rate using nearest-interpolation for chords and linear-interpolation for melody. For Chords, we use a learned embedding table to map the raw integer sequence, denoted as \mathbf{c}_{crd} , to its corresponding condition matrix in shape $T \times d_{\text{crd}}$. For Melody, we zero out values with a score lower than a pre-defined threshold (0.5). Then, we select the maximal non-zero score per time step from the remaining values, and set it to 1 while setting the rest to 0. This yields a binary matrix $\mathbf{c}_{\text{mld}} \in \{0, 1\}^{D \cdot f_r^{\text{mld}} \times N_{\text{mld}}}$. Finally, we linearly project the binary matrix and obtain the melody condition representation in shape $T \times d_{\text{mld}}$. We use $N_{\text{mld}} = 53$ (corresponding to G2-B7 notes), and $d_{\text{crd}} = d_{\text{mld}} = 16$.

Audio. We consider general audio and separated drum stems. We use a pretrained source separation model [20], to extract the drum stem from a source audio. We pass the waveform through EnCodec to obtain the corresponding quantized discrete representation \mathbf{q} . We then convert the first token stream back to its continuous latent representation, using EnCodec’s first codebook while discarding all other streams, yielding $\mathbf{c}_{\text{aud}}, \mathbf{c}_{\text{drm}} \in \mathbb{R}^{T \times N_{\text{enc}}}$. We chose to use only the first codebook stream to further discard timbre information, stressing the forced information-bottleneck further. Following that, we apply temporal blurring to the reconstructed latent. First, we apply average pooling using non-overlapping windows along the temporal axis. Then, we broadcast the signal to its original temporal dimension. Finally, we linearly project the blurred condition to a low dimensional feature space and obtain the condition matrix. For general audio, we use a window size of 5 and output dimension of 1, while for drums we use a window size of 3 and output dimension of 2.

Inpainting and Outpainting. In/Out-painting is the task of filling in a masked region, where in/out refers to the masked segment position in the sequence, be it at the middle (in) or at the end (out). Following prior work [5], we add in/out-painting as an additional condition to the model. We randomly choose between inpainting/outpainting, and mask a random segment of 40-90% from the reference waveform. Then, we use the raw EnCodec latent representation of the masked waveform $\mathbf{c}_{\text{iop}} \in \mathbb{R}^{T \times N_{\text{enc}}}$ as the condition, with no learned projection.

3.2 Model and Optimization

Similarly to prior work [17], our CFM model consists of a Transformer, with U-Net-like residual connections. We replace the standard residual addition with channel-wise concatenation followed by a linear projection. We use learned convolutional positional encoding [21] as well as symmetric bi-directional ALiBi self-attention biases [22]. We use a model scale of 330M parameters, with 24 Transformer layers, 16 attention heads, embedding dimensionality of 1024 and a feed-forward dimension of 4096.

We train our model using the \mathcal{L}_{CFM} objective as defined in Section 2. We further experiment with non-uniform loss

weighting as function of t , and find the following formulation to produce the best overall sample quality:

$$\mathcal{L}_{\text{WeightedCFM}} = \sum_{\substack{t \sim \mathcal{U}(0,1) \\ \mathbf{z}_0 \sim \mathcal{N}(0,1) \\ \mathbf{z}_1 \sim \mathcal{S}}} (1+t) \cdot \mathcal{L}_{\text{CFM}}(\theta; \mathbf{z}_0, \mathbf{z}_1, t | \mathbf{Y}), \quad (3)$$

where $\mathbf{Y} = \{\mathbf{c}_{\text{crd}}, \mathbf{c}_{\text{mld}}, \mathbf{c}_{\text{aud}}, \mathbf{c}_{\text{drm}}, \mathbf{c}_{\text{iop}}\}$. We provide an ablation study for this scheme in Section 5.

3.3 Inference

During inference, as in [10], we use *dopri5* [23], an off-the-shelf numerical ODE solver, to iteratively solve for \mathbf{z} given the estimated vector field v_θ . Specifically, at each iteration the solver determines the increment to the time parameter t , resulting in a dynamic scheduling for the inference process. The process halts when an acceptance criterion is met, defined by an error approximation of the solver and a tolerance parameter provided by the user.

Multi-Source Classifier Free Guidance. We employ classifier-free guidance (CFG) [24] for the conditional vector field estimation $v_\theta(\mathbf{z}, t | \mathcal{Y})$. Since our set of conditioning signals combines both global and local concepts, we further experiment with multi source CFG. While prior work [25] suggest a separate evaluation for each condition, we evaluate the model considering all and partial conditions. During each inference step, we obtain an estimated vector field for each set of conditions $\mathcal{Y} \in \{\{\text{local}\}, \{\text{text}\}, \{\text{local}, \text{text}\}\}$. The resulting CFG formulation then follows:

$$\text{CFG}(v_\theta, \mathbf{z}, t) = (1 - \sum_{c \in \mathcal{Y}} \alpha_c) v_\theta(\mathbf{z}, t) + \sum_{c \in \mathcal{Y}} \alpha_c v_\theta(\mathbf{z}, t | c). \quad (4)$$

When following the standard CFG setup ($\alpha_{\text{text}} = \alpha_{\text{local}} = 0$), we observe that the model adheres to the temporal condition while ignoring instrumentation information provided in the text prompt. To increase text influence on guidance, we set a positive weight to the text-only term $\alpha_{\text{text}} > 0$. We found that $\alpha_{\text{text}} = 0.5, \alpha_{\text{local}} = 0, \alpha_{\text{local}, \text{text}} = 1.5$ offer a good trade-off between audio quality, text alignment and temporal controls adherence.

4. EXPERIMENTAL SETUP

Implementation Details. We follow the same experimental setup as in [3, 6], and use a training dataset consisting of 20K hours of licensed music from the Shutterstock² and Pond5³ data collections with 25K and 365K instrument-only music tracks, respectively. We additionally include a set of proprietary data consisting of 10K high-quality tracks. All datasets are sampled at 32kHz, paired with textual descriptions. We present results on the MusicCaps benchmark [1], comprising 5.5K 10-second samples together with an in-domain test set of 528 tracks.

² shutterstock.com/music

³ pond5.com

We use the official EnCodec model provided by [3, 12], with a frame rate of 50 Hz, and 4 codebooks, each with a size of 2048. For text representation we use a pretrained T5 model [26]. For melody extraction we use the pretrained deep salience multi-F0 detector⁴, for chords extraction we use Chordino, while for drum track extraction we use the Hybrid Demucs model [27].

All single condition models were trained with 40% condition dropout, and in the multi-condition experiments we train the models with 20% condition dropout for all conditions. In the remaining 80% we set 50% dropout for each of the conditions independently excluding the in/out-painting, for which we set 70% dropout.

We experiment with multi-source CFG coefficients in $(\alpha_{\text{text}}, \alpha_{\text{local}}, \alpha_{\text{text,local}}) \in \{0.0, 0.5\} \times \{0.0, -0.5\} \times \{1.5, 2.0\}$ and report the best overall configuration. All models were trained for 500k steps over audio segments of 10 seconds, with a batch size of 336. We use Adam [28] optimizer with linear learning rate warm-up up to a peak of 10^{-4} during the first 5k steps, followed by a linear decay, and a gradient clipping with a norm threshold of 0.2.

4.1 Evaluation Metrics

We perform a thorough empirical evaluation, using both objective metrics and human studies. We evaluate JASCO on several temporal alignment aspects, namely harmonic matching, rhythmic alignment and melody preservation. Additionally, we measure audio quality and text adherence.

Objective Evaluations. We evaluate our method with widely used metrics, namely Fréchet Audio Distance (FAD), Kullback-Leiber Divergence (KL) and CLAP score (CLAP), as well as more specific metrics designed to quantify the adherence of our suggested controls. We report FAD [29] using the official tensorflow implementation where a low FAD score indicates that the generated audio is associated with higher quality. Following [3, 12], we use an audio classifier [30] to compute the KL-divergence over the probabilities of the labels between the original and the generated music. The generated music is expected to share similar concepts with the reference music when the KL is low. Last, CLAP score [31, 32] is computed between the track description and the generated audio, measuring audio-text alignment. We use the official pretrained CLAP model⁵. To evaluate melody compatibility, similar to [3] we use a cosine similarity metric on either a simple quantized chroma representation, or multi-octave melody representation obtained from a pretrained multi-F0 classifier [19]. For beat adherence, as in [7] we evaluate the onset F1 score using *mir eval*⁶ considering a 50ms tolerance margin around classified onsets in the reference signal. Lastly, to evaluate chord progression, we use the Chordino model to extract the chord progression from both the reference and the generated signals and compute the intersection over union (IOU) score between the two.

Model	FAD↓	CLAP↑	Mel Sim.↑	Mel Acc.↑
MusicGen	5.90	0.29	0.61	44.0
MusicControlNet	10.81	0.22	-	47.1
JASCO	6.05	0.26	0.67	49.1

Table 1. Melody conditioning evaluation over MusicCaps. We evaluated MusicGen with 300M parameters.

Human Study. We request raters to evaluate three aspects of given audio samples: (i) overall quality; (ii) similarity to text description; and (iii) adherence to either melody or rhythmic pattern from a reference recording. Raters were instructed to rate the recordings on a scale between 0-100 where higher is better. Raters were recruited using the Amazon Mechanical Turk platform. We evaluate randomly sampled files, where each sample was evaluated by at least 5 raters. We use the CrowdMOS package [33] to filter noisy annotations and outliers. We remove annotators who did not listen to the full recordings, annotators who rate the reference recordings less than 90, and the rest of the recommended recipes from [33]. Similarly to [3], for a fair comparison, all samples are normalized at -14dB LUFS [34]. Overall, we 179 raters evaluated the generation quality, 121 raters evaluated the text relevancy, 159 raters evaluated the adherence to rhythm patterns using drum conditioning, and 142 raters evaluated melody conditioning.

5. RESULTS

Melody Conditioning. We start by evaluating the proposed method considering melody conditioning. We compare JASCO to MusicGen [3] and MusicControlNet [7]. For a fair comparison, we train MusicGen (300M) on 10 second music segments using Audioscraft⁷ repository, considering text and melody conditions. For comparison compatibility with [7] we compute melody accuracy score on both JASCO and MusicGen. We experiment with melody conditioning using the commonly used 12-bins chroma representation which is octave invariant. Results are presented in Table 1.

Results suggest that JASCO surpasses the evaluated baselines w.r.t melody adherence. When considering melody accuracy, JASCO provides better alignment to the conditioning melody. Notice, we hypothesize this is due to the conditioning method: both MusicGen and MusicControlNet inject conditions as an additive bias (i.e., cross-attention and zero-convolutions), this is in contrary to JASCO which follows the concatenation approach for melody conditioning (see Section 6 for more experiments).

Local Controls. We train a single-condition variant for each observed condition-type as well as two multi-condition models. Under the multi-condition setup, we train models with Drums tracks passed through a Band-Pass-Filter (BPF) over 200-800 Hz frequency range, and

Table 3. Human evaluation results. Observing general quality (Q), text match (T) melody match (M) and drums match (D). Evaluated on a 0-100 scale (higher is better).

Audio condition excluding drums. This was found to better disentangle Drums and Audio conditions in preliminary experiments, and allows users to provide different drum beats than the one presented in the Audio. When applying Audio/Drums conditions, we evaluate Melody, Onset F1, and Chord IoU using the reference audio as a condition, while for the computation FAD, KL, and CLAP scores we use a randomly selected audio from the test set.

As there are no open-source relevant baselines available, we compare the proposed method against a text-only condition model. We perform experiments using both the open source MusicCaps dataset, and an internal proprietary dataset, highlighting our model performance on diverse, high quality recordings. Table 2 summarizes the results.

Results depict a systematic improvement considering local control adherence. For instance, chords conditioning shows apparent improvement in Chords IOU metric, improving from 0.09/0.07 to 0.59/0.61. In addition, in spite of being evaluated with randomly selected audio conditions, FAD, KL, CLAP scores mostly remain comparable w.r.t to the baseline. This highlights JASCO’s disentangling property as local controls metrics improve while text adherence and audio quality metrics stay roughly the same.

The lower section of the table presents multi-control setup results. This section draws a similar trend to the single control setups, allowing for multiple controls while preserving FAD, KL, CLAP. This highlights JASCO’s ability to incorporate multiple controls simultaneously with no significant penalty to quality and text alignment.

Human Study. Lastly, we perform a human study in or-

der to validate both quality and text alignment as well as local control adherence. We evaluate JASCO vs MusicGen considering: (i) text only; and (ii) both text and melody. We additionally, provide results of the proposed method with text and drums conditions. Results seen on Table 3, indicate that JASCO achieve similar generation quality as MusicGen across all setups. As of text relevancy, MusicGen reaches superior performance to the proposed method, however, when considering melody conditioning, JASCO reaches significantly better scores. Lastly, when conditioned on drums, JASCO provides the best rhythmic pattern similarity scores. This highlights JASCO’s ability to provide better controls over the generated music without sacrificing quality and text alignment. Interestingly, after including melody or drums conditions, as expected, the relevant metrics are improving (i.e., melodic and rhythmic similarity) while the quality and text adherence remain comparable to the unconditioned model.

6. ANALYSIS

Condition Injection Method. We compare the proposed method to two widely used condition injection methods proposed in prior work. Specifically, we perform a controlled experiment in which we evaluate cross-attention as used in MusicGen, and zero-convolution as used in MusicControlNet, considering the same training configuration.

Results shown in Table 4 suggest that the temporal adherence using the concatenation method performs the best overall. This can be seen in both higher Chord IoU, as well as better FAD and KL, where CLAP was 0.36 for all methods. Additionally, the concatenation method allows training from scratch as opposed to zero-convolutions, in which we start from a pretrained model) without a significant increase in the number of trainable parameters.

Flow vs. Diffusion. Most of prior work on music generation is mainly based on Diffusion models [2, 4, 5, 35]. In this experiment we evaluate, under controlled settings, both Diffusion (v-Diffusion) and Flow Matching modeling approaches for music generation. We report FAD, KL, and CLAP scores. Results are depicted in Figure 2. As can be seen, the Flow Matching approach is superior across all metrics, with the biggest gap observed in FAD.

Conditioning	Chord IOU \uparrow	FAD \downarrow	KL \downarrow
Concat	0.6	1.19	0.71
Cross Attn.	0.59	1.61	0.73
Zero Conv	0.26	1.64	0.74

Table 4. Ablation for conditioning method. evaluated on internal dataset. All models started from a text-to-music pretrained checkpoint and trained for 500K steps.

Figure 2. Comparison of v-Diffusion vs Flow Matching. We report FAD, KL, and CLAP on the internal dataset.

The Effect of Weighted Loss. Finally, we evaluate the effect of the proposed modification to the loss function as presented in Equation (3). We compare the proposed objective function against the loss as describe in Equation (1), considering FAD, KL, and CLAP scores in Table 5. Results suggest the new objective function modification improves the generation quality. It provides significantly better FAD while having comparable KL and CLAP scores.

7. RELATED WORK

Flow Matching for Audio Generation. Flow Matching [10] was recently studied for speech generation. A notable work in this context presented VoiceBox [16], a Flow Matching model, operating on spectrograms, for text-guided multilingual speech generation. More recently, AudioBox [17] was presented, in which self-supervised infilling objectives were leveraged to improve the generalization capabilities of VoiceBox. Similar to our model, AudioBox operates on the continuous latent representations of EnCodec [14]. Though the scope of audio modalities was extended in AudioBox to both speech and environmental sounds, applying a Flow Matching approach for music generation remained less explored.

Temporally Controlled Music Generation. Recent work offered several forms of temporally restrictive controls for music generation. Melody conditioned text-to-music was studied in MusicLM [1], in which a melody embedding was trained using a dedicated dataset consists of multiple cover versions of musical tracks paired with aligned singing and humming performances. In MusicGen [3] and Music ControlNet [7], the need for supervised data was relieved, and instead an unsupervised melody extraction was performed using the argmax note of the audio chromagram. Audio-to-audio setups were studied for drum gener-

Weighted loss schedule	FAD \downarrow	KL \downarrow	CLAP \uparrow
$w(t) = 1$	1.73	0.71	0.38
$w(t) = 1 + t$	0.99	0.73	0.37

Table 5. Ablation for loss weighting method. Evaluated on internal dataset. All models were trained for 500K steps.

ation conditioned on drumless track [36], accompaniment generation given singing voice [37], and single instrument generation given partial mix [25] [9]. Recently, generation conditioned on multiple symbolic controls was studied in Music ControlNet [7], a spectrogram diffusion text-to-music model, fine-tuned using the ControlNet scheme [38], to generation with melody, beat and dynamics controls. In DITTO [8], inference time optimization was explored, for tiding a text-to-music diffusion model to perform several tasks including inpainting, outpainting, loop generation, melody and dynamics conditioned generation, as well as conditioning on musical structures. In [39], classifier guidance was used to perform music inpainting, outpainting and style transfer given a pretrained unconditional latent diffusion model. Inpainting was further explored in [5], [40], and [41]. Style transfer was explored also in [42] and [9].

8. DISCUSSION

In this work we present JASCO, a temporally controlled text-to-music generation model, supporting both audio and symbolic conditioning. JASCO is based on the Flow Matching modeling paradigm operating over a dense music latent representation. Through extensive experimentation we empirically show JASCO generates high-fidelity samples that can be conditioned on global textual description together with harmony, melody, rhythmic patterns, and overall musical style. Results suggest JASCO provides comparable generation quality to the evaluated baselines while allowing significantly better control over generation.

Limitations. The main limitations of the proposed approach are: (i) Similarly to previous diffusion-based text-to-music models, the length of the generated samples is relatively short (~ 10 seconds) compared to the auto-regressive alternative. Although this can be extrapolated with overlaps, it may limit the capability of the model in capturing global structure in the generated music; (ii) although generating the whole sequence at once, generation time is slower than auto-regressive alternatives, while not supporting streaming capabilities.

Future work. For future work we intend to support additional controls, such as music dynamics, musical structure, etc. together with editing options, e.g., add or replace specific instrument in a given recording. We believe such a research direction, and specifically the proposed approach, holds great potential in empowering musicians, creators, and producers which require richer set of controls during their creative process.

9. ETHICAL STATEMENT

The use of large-scale generative models raises several ethical concerns. To mitigate at some of them, we first made sure all the data used for training our models was obtained legally through an agreement with Shutterstock. Another issue is the potential lack of diversity in the dataset, which predominantly consists of western-style music. However, we believe that the proposed method is not tied to any specific genera and can help expand the scope of applications to new datasets.

Moreover, generative models could potentially create an unbalanced competitive environment for artists, a problem that is yet to be solved. We are firm believers in the power of open research to provide all participants with equal opportunities to access these models. By introducing more sophisticated controls, like chords and rhythmic patterns as suggested in this work, we aspire to make these models beneficial for both amateurs and professional musicians.

ABSTRACT

Recent advancements in deep generative models present new opportunities for music production but also pose challenges, such as high computational demands and limited audio quality. Moreover, current systems frequently rely solely on text input and typically focus on producing complete musical pieces, which is incompatible with existing workflows in music production. To address these issues, we introduce Diff-A-Riff, a Latent Diffusion Model designed to generate high-quality instrumental accompaniments adaptable to any musical context. This model offers control through either audio references, text prompts, or both, and produces 48kHz pseudo-stereo audio while significantly reducing inference time and memory usage. We demonstrate the model’s capabilities through objective metrics and subjective listening tests, with extensive examples available on the accompanying website.¹

1. INTRODUCTION

Deep generative modeling has recently made significant strides, greatly expanding the toolbox for synthesizing visual and auditory art [1–6] and signaling a new era of enhanced creative expression. These technologies promise more intuitive, high-level control over digital creations, yet their deployment in music production comes with inherent challenges. Generative music systems frequently rely solely on text inputs for control and typically focus on generating complete musical pieces rather than individual sounds or instruments. This approach can limit their integration into existing musical workflows and may compromise the artist’s control over the final product. Furthermore, the computational demands of these advanced models often necessitate access to specialized hardware or online services. Additionally, they often fail to meet professional audio standards, such as true stereo output at 48 kHz.

Aouameur, M. Grachten, and S. Lattner, “Diff-A-Riff: Musical Accompaniment Co-creation via Latent Diffusion Models”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

In this paper, we introduce Diff-A-Riff, a novel Latent Diffusion Model designed for generating single-instrument accompaniments. A distinct feature of our approach is the ability to condition on musical audio contexts. This specific form of control crucially allows the music to dynamically adapt to the artist’s style, enabling a more personalized creation process. Additionally, the model supports conditioning using joint text-and-audio embeddings from CLAP [7], which can be derived from either textual descriptions or audio references, providing versatile input options for directing the music generation.

At the core of Diff-A-Riff are two pivotal technological elements. First, the efficiency of a Consistency Autoencoder with a high compression rate enhances the system’s performance in terms of inference time and memory usage [8]. Second, the model employs the expressiveness of Elucidated Diffusion Models (EDMs), known for their robust handling of complex data distributions and improved efficiency in model parameterization and inference [9].

We validate Diff-A-Riff through comprehensive evaluations, assessing its performance in ablation studies using objective metrics, and we compare it to other models and estimate context adherence using subjective listening tests. The results, detailed in Sections 5 and 6, demonstrate that our model not only achieves state-of-the-art audio quality (statistically not distinguishable from real audio) but also effectively adapts to various conditional settings confirming its potential for practical applications in music production.

The paper is organized as follows: after a review of related work in Section 2 and background in Section 3, we describe our methodology in Section 4. We then present our results in Section 5 and conclude with a discussion and potential future research directions in Section 6.

2. RELATED WORK

End-to-end models. The landscape of generative models for music has undergone transformative advancements in recent years. End-to-end Autoregressive Models (AMs) have traditionally been at the forefront of sound fidelity, diversity, and long-term coherence [10, 11]. Nonetheless, their high computational demands render AMs unsuitable for music production settings (i.e., sample rate ≥ 44.1 kHz, stereo). In contrast, Generative Adversarial Networks [12]

and Variational Autoencoders [13] exhibit exceptional generation speed at high sampling rates [14–16], positioning them as valuable assets for commercial music production technologies [14, 17]. However, these strategies typically require simple datasets with reduced diversity [14, 15], and often restrict generation to fixed lengths [16, 17]. Recently, diffusion models showed a balanced equilibrium between generation quality, diversity, and efficiency [18–21]. Nevertheless, these rely on an iterative denoising process that, while faster than AMs, still demands long and heavy computations.

Latent models. To address the challenges inherent in end-to-end modeling, generative models have recently pivoted towards operating on compressed representation spaces learned via autoencoders [3–6, 22]. By doing so, generative systems can allocate representational capacity separately for learning immediate auditory characteristics of sound and longer-term music structure. Additionally, they facilitate the interpretation and integration of multi-modal control data, such as text [3, 5, 6], audio [23, 24], or melody [4]. Within this evolved framework, AMs leverage discrete representation spaces crafted through vector-quantized variational autoencoders [25, 26], resulting in faster models with better long-term structure [3, 4]. Recent developments have equipped AMs with parallel decoding using masked token modeling techniques [23, 27, 28], enabling sample rates as high as 44.1 kHz with acceptable inference speed.

Latent Diffusion Models (LDMs) also operate on compressed representation spaces, which are typically continuous [5, 6, 29]. This evolution has catalyzed the development of various LDMs capable of generating high-resolution musical audio with long-term structure [5, 6, 29, 30]. Notably, some works can generate audio at sampling rates as high as 48 kHz [6] and stereo [29, 30]. Other works like Stable Audio [5] improve inference efficiency, enabling the generation of 44.1 kHz sampling rate and stereo audio at an unprecedented speed.² Following this spirit, our system leverages a pre-trained Consistency Autoencoder [8] which enables Diff-A-Riff to function within a highly compressed representation space, allowing faster generation than previous systems. Further, our LDM employs the framework of Elucidated Diffusion Models (EDMs) [9, 20], a departure from the Denoising Diffusion Implicit Models (DDIMs) [31] used in previous approaches [5, 6, 29].

Control mechanisms. As evidenced by the state-of-the-art, text prompts currently serve as the most common interface for users to guide audio generative models [3–6]. To facilitate finer control, Jukedrummer [32] and Music ControlNet [33] utilize time-varying controls such as rhythmic and dynamic envelopes and melodic lines. By exploiting the semantic properties of multi-modal text-and-audio spaces, recent works propose zero-shot solutions to music editing via latent space manipulations [34] and inversion methods [35]. Alternative approaches to control pretrained models include inference-time optimization [36] or guidance [37]. Another method for influencing audio output involves conditioning on audio signals, a technique pri-

marily used in style transfer and accompaniment tasks. In style transfer, the objective is to emulate specific aspects of the source audio, e.g., melody [4], timbre [24]. For accompaniment, the focus is on generating musical content that complements or enhances the conditioning audio [23, 24, 38–40]. Recent works attempting joint music generation and source separation also exhibit compositional capabilities such as accompaniment generation without requiring paired data [41, 42]. Inspired by these control mechanisms, our system introduces conditioning on audio and textual features derived from CLAP [7] alongside audio signals that serve as music context, widening the scope of generative capabilities, e.g., accompaniment generation, text-driven generation, and style transfer.

3. BACKGROUND

In this section, we provide a brief overview of Consistency Models and Denoising Diffusion Models. For an in-depth explanation, we encourage the reader to review the corresponding references.

Consistency Models (CMs) [43, 44] are a novel class of generative models that can produce high-quality samples in a single forward pass without adversarial training. CMs learn a mapping between noisy and clean data samples via a probability flow Ordinary Differential Equation (ODE) [31]. Given a noise level t , the consistency function f transforms a noisy sample $x_t \sim p_t(x)$ to a clean sample $x \sim p_{data}(x)$ by mapping $f(x_t, t) \mapsto x$. This consistency function is approximated by a neural network $f_\theta(x_t, t)$ with parameters θ . It must satisfy the boundary condition $f_\theta(x, t_{\min}) = x$ and is trained by minimizing the discrepancy between its output and a teacher CM at adjacent noise levels t_i and t_{i+1} .

Denoising Diffusion Models (DDMs) [45] are generative models originally inspired by the concept of thermodynamic diffusion [46]. DDMs first add noise to data in a *forward* diffusion process and then use a neural network to *reverse* this process by removing the noise iteratively. The forward diffusion process is detailed by a Stochastic Differential Equation (SDE), introducing noise to the original data x_0 over T steps, resulting in a noisy version x_T . This process is defined by $dx_t = f(x_t, t)dt + g(t)dB_t$. Here, dB_t is the increment of a Wiener process (the random noise), $f(x_t, t)$ is the drift term, $g(t)$ is the diffusion term, and t represents the diffusion time step. The reverse process aims to reconstruct the original data from its noisy version by removing the noise. This is achieved by modeling the score of the data distribution, i.e., the gradient of the log probability density function of the noisy data with respect to the data itself, $\nabla_x \log p(x|t)$. The reverse process is described by another SDE, which guides the denoising $dx_t = [f(x_t, t) - g(t)^2 \nabla_x \log p(x_t|t)]dt + g(t)dB_t$, where a neural network g_θ , with parameters θ , is trained to estimate this score function, i.e., $g_\theta(x_t, t) \approx \nabla_x \log p(x_t|t)$. During inference, by performing this process iteratively, we can progressively transform pure noise inputs into data points following the training data distribution.

² 95 seconds of audio in 8 seconds on an A100 GPU

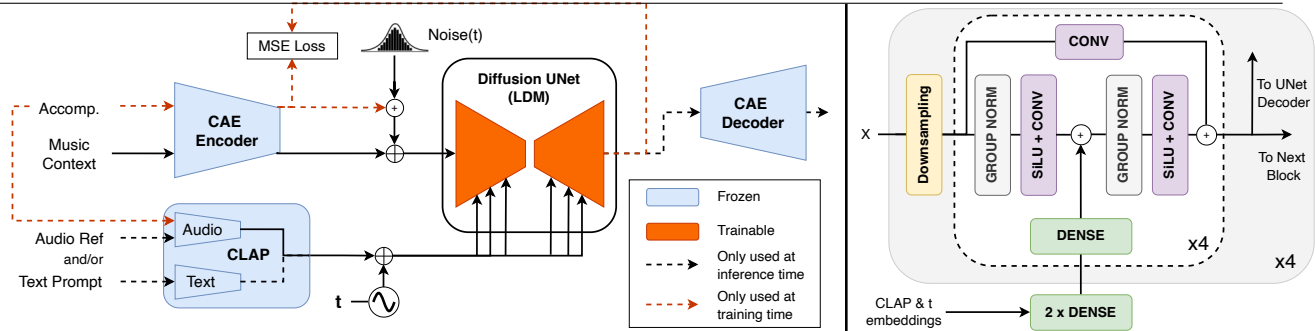

Figure 1. Overview of Diff-A-Riff. **Left:** The CAE Encoder transforms the music context into a compressed representation, concatenated with a noisy sample, and further processed through a multi-scale U-Net. At each scale, conditional CLAP and time-step embeddings are integrated through a feature-wise linear transformation. The generated latent sequence is decoded via the CAE Decoder. We highlight frozen components in blue and trainable elements in orange. Text prompting is only used at inference. **Right:** The encoder architecture comprises four down-sampling blocks with four convolutional and group norm layers with skip connections. The decoder mirrors this architecture.

4. METHODOLOGY

4.1 Dataset

We train our model on a proprietary dataset comprising 12,000 multi-track recordings of diverse music genres (e.g., pop/rock, R&B, rap, country). Each multi-track has various instrument tracks, including bass, guitars, pianos, vocals, and more. We resample each track to 48 kHz, convert it to mono and segment it into overlapping windows of approximately 10 seconds with a 3-second hop size. In training, we randomly select a target *accompaniment* track (excluding vocals) and construct the music *context* by mixing a random subset of the remaining tracks for each segment. We apply this data segmentation and sampling strategy offline to obtain 1M training pairs of audio segments. Following the same methodology, we derive a validation set from 1,200 multi-tracks.

4.2 Diff-A-Riff

4.2.1 Consistency Autoencoder

In this work, we employ a consistency model-based Autoencoder (CAE). We use it pre-trained and freeze its parameters to train a generative model on its latent embeddings (see Fig. 1). The CAE encodes audio samples into a continuous representation space with a $64\times$ compression ratio. It operates on complex Short-Time Fourier Transform (STFT) spectrograms, with real and imaginary components as separate channels. The architecture uses convolutional residual blocks interleaved with down/up-sampling layers. The *CAE Encoder* produces 64-dimensional encodings in the range $(-1, 1)$ with a sample rate of 12 Hz for 48 kHz input audio. The model has ~ 58 million parameters and is trained following the consistency training framework [44]. For a detailed description of the architecture and training procedure, we refer the reader to the original reference [8].

4.2.2 Latent Diffusion Model

We train a Latent Diffusion Model (LDM) on the latent space learned by the CAE. The proposed LDM follows

the framework of Elucidated Diffusion Models (EDMs) [9], a departure from DDIMs [31] for improved model parametrization and inference. The architecture follows DDPM++ [47], an upgraded version of the originally proposed Diffusion Probabilistic Model [45]. We only adapt the network’s input dimensionality to that of the CAE’s latent space (64 channels, see Sec. 4.2.1). Also, we increase the dimensionality of the conditional embedding input with that of CLAP [7] (i.e., 512 dimensions). Our UNet is composed of four down/up-sampling blocks with convolutional layers and skip connections, both for the encoder and the decoder (see Fig. 1 Right). Self-attention is employed in the penultimate resolution layer. We use 512 base channels and double their number at each resolution block. Additionally, the model relies on two dense layers to project the concatenation of CLAP embeddings and the sinusoidal denoising step embeddings into a joint representation. The resulting embedding is used in all down/up-sampling blocks to condition the denoising process as illustrated in Fig. 1.

4.2.3 Training

Fig. 1 provides a high-level overview of Diff-A-Riff’s setup. Given a pair of input *context* and target *accompaniment* audio segments, the model is trained to reconstruct the *accompaniment* given the *context* and a CLAP embedding derived from a randomly selected sub-segment of the target itself. This prevents the model from relying on CLAP for temporal alignment. In order to use Classifier-Free Guidance (see Sec. 4.3.1) and allow the model to optionally operate unconditionally, we drop the audio context and clap embeddings both with a 50% probability. We train Diff-A-Riff over 1M iterations using a batch size of 256 (2 weeks on a single RTX 3090 GPU). We use AdamW [48] as the optimizer and a base learning rate of 10^{-4} . We use a learning rate schedule with an initial warm-up phase and a reduce-in-plateau process that decreases the learning rate to a minimum value of 10^{-6} . We keep an Exponential Moving Average (EMA) on the weights with a momentum of 0.9999. The resulting model has 500M parameters (including the CAE and not CLAP) and occupies 3 GB of memory.

4.3 Evaluation

Objective comparison of Diff-A-Riff with existing state-of-the-art models [4–6] is challenging as these are generally trained to perform a substantially different task (generation of fully mixed music with no accompaniment conditioning). Even though StemGen [23] and SingSong [39] are trained to generate accompaniments, their implementation and pretrained weights are not publicly available. Therefore, we focus on subjective listening tests to compare with available music generation models. Additionally, we perform objective evaluations to analyze different inference parameters (e.g., number of diffusion steps, conditioning information; see Section 4.3.1) to understand which configurations of our proposed model perform the best on our set of metrics. We then apply the gained insights in order to generate the samples that are proposed in the user studies. In the following sections, we describe how we generate the samples used for evaluation, the objective metrics, the listening test methodology, and the baselines we compare against.

4.3.1 Inference Configurations

In this section, we describe the inference configurations that we use for the objective and subjective evaluations.

Conditioning Signals: Different conditioning signals are evaluated. $CLAP_A$ refers to the audio-derived CLAP embeddings, which are obtained by using CLAP to encode real audio from a track of the evaluation set. We can also condition the model on text-derived CLAP embeddings, despite them never being fed during training to the model, since CLAP offers a joint embedding space for both modalities. Because our dataset does not contain audio/text pairs, we create $CLAP_T$ embeddings by asking ChatGPT to write text descriptions of single-stem tracks. Finally, *Context* refers to the conditioning signal obtained by solely encoding the music context into the CAE Encoder.

Classifier-Free Guidance (CFG) [49] allows to improve generation quality by increasing the influence of conditioning signals in the sampling process. Given the guidance strength CFG, we implement guidance as $x_{t-1} = f_{\theta}(x_t) + \text{CFG} \cdot (f_{\theta}(x_t, c) - f_{\theta}(x_t))$. At inference time, we can use different guidance strengths for *Context* and $CLAP$ embeddings, denoted as $\text{CFG}_{\text{Context}}$ and CFG_{CLAP} , respectively.

Number of Diffusion Steps: At inference time, the number of denoising steps T allows to trade between audio quality and generation speed.

Pseudo-Stereo Generation: We generate pseudo-stereo audio by denoising until a given diffusion time step, and then by independently concluding a stochastic denoising process twice, one for each audio channel. We define the *stereo width* as the proportion of denoising steps used for stereo generation over the total number of steps. In the user study, we set this parameter to 0.4.

4.3.2 Objective Metrics

We evaluate Diff-A-Riff through objective metrics to assess various aspects of the generated audio. These include the standard *Squared Maximum Mean Discrepancy* (MMD2) [50] and *Fréchet Audio Distance* (FAD) [51] for audio quality as well as *Density* and *Coverage* [52] for evaluating fidelity and diversity. To study the system’s responsiveness to text prompts, we employ the *Clap Score* (CS) [53], which calculates the cosine similarity between text and audio embeddings. In order to evaluate the alignment of the generated accompaniment with the context, we employ the *Audio Prompt Adherence* (APA) [54], a metric based on FAD tailored to evaluate accompaniment systems. All metrics are calculated by averaging five batches of 500 candidate samples. We use CLAP [7] as the embedding space for metrics that compare distributions (like MMD2 and FAD) using a reference set of 5,000 real audio examples.

4.3.3 Listening Tests

Subjective Audio Quality (SAQ): We perform a Mean Opinion Score (MOS) test to assess audio quality. Participants were presented with 5-second audio segments from real data as well as generations from the baselines and the proposed system. Their task is to rate the audio quality of these segments on a 5-level Likert scale ranging from poor (1) to excellent quality (5). For all items (real data, Diff-A-Riff, and baselines), we compare both complete music pieces as well as solo instruments.

We generate solo instruments with Diff-A-Riff by conditioning the model on text or audio-derived CLAP embeddings ($CLAP_A$ or T) and without an input context (for a fair comparison with the baselines, which do not rely on contextual audio inputs). Despite the model not being trained for this task, we can also generate *complete* music pieces using $CLAP$ and *Context* embeddings, following an iterative approach: First, we create sets of $CLAP_A$ or T embeddings as described in 4.3.1. Then, from an initially empty context, we generate new tracks from those $CLAP$ embeddings, iteratively summing the resulting generation into the input context from which we derive the next *Context* embeddings.

We compare Diff-A-Riff against three state-of-the-art text-to-music baselines: AudioLDM2 [6], MusicGen [4], and Stable Audio [5].³ For each baseline, we generate 20 5-second excerpts of complete music and solo instruments using text prompts generated by ChatGPT.

Subjective Audio Prompt Adherence (SAPA): We also conduct a subjective assessment of audio-prompt adherence. Participants are provided with a reference 10-second music segment and are asked to rate the compatibility of five distinct accompaniments on a scale from 0 (indicating no adherence) to 100 (perfect adherence), according to harmonic, rhythmic, and overall music style compatibility.

³ We use the open-source AudioLDM2 model ‘AudioLDM2-48kHz’ operating at 48 kHz. For MusicGen, we use the open-source model ‘MusicGen-large’ operating at 32 kHz, and for Stable Audio, we use their public API.

^a × 10⁻⁴, ^b obtained from white noise, ^c obtained by using a random accompaniment from the dataset

Table 1. Objective metrics using two configurations, *Diff-A-Riff*_{T=30}^{CFG=1.25} and *Diff-A-Riff*_{T=10}^{CFG=1}, and different conditional settings (see Sec. 4.3.1). We compare against higher bounds obtained from the *real* validation set, and lower bounds obtained from random *noise* or random pairs (*Real*, *Random acc.*). Some cells are empty for APA and CS in the case of context and text-free generation respectively.

The reference segments are derived from music pieces within the evaluation set by summing all tracks in a multitrack, excluding one track, which is reserved to serve as the original accompaniment. Each accompaniment is presented mixed with the reference segment, with slight panning applied to the right to aid in distinguishing between them. The five accompaniments include the original accompaniment, a randomly selected one from the evaluation set, and three generated by our model under different conditional setups: (*CLAP*_A + *Context*), (*CLAP*_T + *Context*) and (*Context* only). To remove a potential bias toward better-quality audio, the original and random segments are encoded and decoded through the CAE.

For both studies, we used the GoListen platform [55]. All audio segments are normalized to a loudness of -20 dB LUFS and not cherry-picked. Sample questions are available on the accompanying website.

5. RESULTS & DISCUSSION

5.1 Objective Evaluation

Fig. 2 shows the MMD2 score of our model as a function of the number of denoising steps, with each line corresponding to a different conditional setting (see Sec. 4.3.1), all without classifier-free guidance (CFG). Note that MMD2 compares the distributions of embeddings of generated and real audio in CLAP’s latent space. This means it indicates not only audio quality but also how well the distributions of generated instrument types and timbres match the test data distribution. For this reason, when using audio CLAP conditioning (*CLAP*_A), the results are considerably better, as we force the timbre distribution to be equal to the test data distribution (by using embeddings of that distribution as conditioning). However, the improvement of the results when increasing the number of denoising steps can be con-

Figure 2. MMD2 as a function of the number of denoising steps *T* for various conditional settings (see Sec. 5.1).

sidered independent of the timbre distribution.

Based on the results described above we perform a grid search over diffusion steps (*T*) and multi-source classifier-free guidance strength ($CFG_{<source>}$). $T = 30$ steps and $CFG_{Context} = CFG_{CLAP} = 1.25$ yields the best results. We denote this configuration as *Diff-A-Riff*_{T=30}^{CFG=1.25} in Tab. 1. In addition, we compare to a specific configuration that achieves real-time performance⁴ on a CPU with acceptable quality using $T = 10$ steps and $CFG = 1$, denoted as *Diff-A-Riff*_{T=10}^{CFG=1}. For reference, we also include metrics computed on *real* data and a *lower bound*, calculated from white noise in the case of quality metrics or random real pairs for input adherence metrics (APA and CS). The overall trend suggests that dense conditioning information helps the model in all metrics: audio quality, *coverage* and *density*, as well as APA. Also, the results could suggest a slight dependency of the model on *CLAP*_A embeddings, with metrics close to real data, even in the absence of music context. Only *density* exhibits a minor drop without con-

⁴ 95 seconds of audio in 73 seconds on an AMD EPYC 7502P

text conditioning, suggesting that generating from a silent context leads to samples that sometimes fall in low-density regions of the CLAP space.

The impact of Classifier-free Guidance (CFG) on MMD2 can be estimated by comparing Fig. 2, that displays results without CFG, with Tab. 1, where CFG was used. In Fig. 2, the metrics for both ($CLAP_A + Context$) and ($CLAP_A$ only) converge towards an MMD2 of 0.5, while the corresponding values in Tab. 1 show a reduction to about half this figure. For ($CLAP_T + Context$) and ($CLAP_T$ only), the MMD2 drops from approximately 5 to about 4 with CFG, and for *Context only*, it decreases from around 6 to approximately 5.

Finally, we calculate the Clap Score (CS) for text-conditioned generation ($CLAP_T + Context$, $CLAP_T$ only). We compare $Diff\text{-}A\text{-}Riff_{T=30}^{CFG=1.25}$ against random pairs of text and real audio (CS=-0.07), suggesting that the model is only somewhat responsive to text prompts (CS=0.25).

5.2 Subjective Evaluation

Table 2 presents the outcomes of the Subjective Audio Quality (SAQ) test based on 74 users who each rated 32 audio segments, resulting in 2368 ratings. In this test, we compare results against leading baselines (see Sec. 4.3.3) and *real* audio data. Our analysis includes a comparison between these benchmarks and the audio generated by Diff-A-Riff in both mono (ch=1) and pseudo-stereo (ch=2) formats (see Sec. 4.3.1). Results show that the pseudo-stereo samples generated by Diff-A-Riff received ratings that are statistically indifferent from *real* audio ratings (p-value=0.79), indicating that participants found the audio quality of the generations indistinguishable from real data. This outcome is particularly remarkable given that Diff-A-Riff was not explicitly trained on complete musical pieces nor stereo music generation, but is still competitive to other models. Further, it highlights the influence of stereo imaging on the perceived audio quality.

Tab. 3 shows the results for the Subjective Audio Prompt Adherence (SAPA) listening test based on 35 users, each rating 25 accompaniments. The results include ratings scored by *real* accompaniments, *random* accompaniments, and the various conditional settings described in Sec. 4.3.1. Following the trend of previous results, the default setting ($CLAP_A + Context$) scores the closest to *real* accompaniments, suggesting that the model can effectively adapt to the context under this setting. When conditioned on (*Context only*), Diff-A-Riff is rated worse but still significantly better than *random* accompaniments. Further, for ($CLAP_T + Context$), the accompaniments are rated the lowest. A reason could be that the overall quality is worse because CLAP embeddings of text prompts have not been shown during training. Another problem could be that the randomly chosen text prompt is incompatible with the provided music context (e.g., "A drum machine with electronic textures" with an acoustic blues context), which reduces perceived adherence due to conflicting styles.

Overall, SAPA results are interesting given that APA (see Tab. 1) suggested rather pessimistic results for

	SR/Ch	Params	RTF ^a	Solo	Songs

($CLAP_T + Context$) and (*Context only*). This could potentially be attributed to APA's sensitivity to audio quality and timbre differences between reference and candidate sets.

5.3 Control Mechanisms

In the accompanying website, we show examples of *Diff-A-Riff* generations for different inference settings (see Sec. 4.3.1). We also showcase other controls that naturally emerge from the denoising process, such as *in/out-painting* or the generation of *variations* and *loops*, as well as controls derived from the manipulation of CLAP embeddings, e.g., text-audio *Interpolations*.

6. CONCLUSION

This work introduced Diff-A-Riff, a Latent Diffusion Model capable of generating instrumental accompaniments adapted to a user-provided musical audio context. It can be controlled based on style audio references, text prompts, or both. We also proposed a simple method for producing pseudo-stereo audio. By exploiting the efficiency of a Consistency Autoencoder, Diff-A-Riff can generate 48 kHz sample rate pseudo-stereo audio with unprecedented speed and quality. Through extensive objective and subjective evaluation, we showed that our model achieves state-of-the-art audio quality, adapts to various conditional settings, and generates content that adheres to pre-existing musical audio contexts. We believe this work represents a significant step towards AI-assisted music production tools that prioritize artist-centric interactions, enriching the landscape of human-machine music co-creation.

7. ETHICS STATEMENT

Sony Computer Science Laboratories is committed to exploring the positive applications of AI in music creation. We collaborate with artists to develop innovative technologies that enhance creativity. We uphold strong ethical standards and actively engage with the music community and industry to align our practices with societal values. Our team is mindful of the extensive work that songwriters and recording artists dedicate to their craft. Our technology must respect, protect, and honour this commitment.

Diff-A-Riff supports and enhances human creativity and emphasises the artist’s agency by providing various controls for generating and manipulating musical material. By generating a stem at a time, the artist remains responsible for the entire musical arrangement.

Diff-A-Riff has been trained on a dataset that was legally acquired for internal research and development; therefore, neither the data nor the model can be made publicly available. We are doing our best to ensure full legal compliance and address all ethical concerns.

ABSTRACT

This study presents the *Music Informatics for Radio Across the GlobE* (MIRAGE) online dashboard, which allows users to access, interact with, and export metadata (e.g., artist name, track title) and musicological features (e.g., instrument list, voice type, key/mode) for 1 million events streaming on 10,000 internet radio stations across the globe. Users can search for stations or events according to several criteria, display, analyze, and listen to the selected station/event lists using interactive visualizations that include embedded links to streaming services, and finally export relevant metadata and visualizations for further study.

1. INTRODUCTION

Despite its scholarly neglect relative to television, film, and print [1], radio's convergence with the internet has extended its reach via web browsers and smartphone apps, enabling the medium to persist as a central site of culture and daily life for communities around the world [2,3]. The recent resurgence of pirate and community radio stations on the internet alongside national and multinational networks also reflects internet radio's lower production costs relative to short-wave terrestrial (e.g., FM or AM) radio [4], resulting in a diverse range of both standardized and specialized programming [5–7].

And yet, the volume and scope of much of the research in fields like radio studies has been freighted heavily towards the Global North [1]. In doing so, the research program just described attempts to situate listeners within a particular musical tradition (e.g., western classical or popular music), rather than within a particular geographic environment (e.g., El Paso, Texas) where myriad musical traditions might co-exist. As a result, music's vast global marketplace has yet to receive sustained scholarly attention in the MIR community.

To address this issue, this study presents the development release (v0.2) of the *Music Informatics for Radio Across the GlobE* (MIRAGE) online dashboard, which

allows users with potentially little training in computational methods to access, interact with, and export metadata (e.g., artist name, track title) and musicological features (e.g., instrument list, voice type, key/mode) for 1 million events streaming on 10,000 internet radio stations across the globe. To that end, Section 2 summarizes previous research on the development of digitized music corpora and cultural databases. Next, Section 3 presents the MIRAGE-MetaCorpus, Section 4 introduces the MIRAGE online dashboard, and Section 5 offers a potential use case. Finally, Section 6 discusses limitations and future directions for the MIRAGE project.

2. PREVIOUS RESEARCH

In recent years, researchers in music theory, music information retrieval (MIR), and radio/media studies have developed digitized music corpora and cultural databases that represent data in machine-readable symbolic and audio formats.

In computational music theory, heavily curated corpora (100s of songs) like the McGill Billboard and Rolling Stone-200 data sets include expert annotations for musical parameters like harmony, meter, and melody, for example, but remain restricted to Anglophone popular music traditions [8,9]. What is more, the limited size of symbolic corpora makes comparative research especially difficult [10].

In MIR, corpora like the Million Song data set address issues of scale while avoiding copyright infringement by providing researchers with publicly available metadata and musicological features protected under fair use for a large collection of songs hosted on commercial music-streaming services like last.fm [11]. Nevertheless, the size, scope, and format of these projects require extensive training in distant-reading (i.e., computational) methods [12–14]. As a result, MIR corpora sometimes eschew the kinds of musical engagements favored by scholars in humanities disciplines using close-reading methodologies. Finally, the projects referenced above do not include information about the geographic location of the music encountered by listeners in everyday life.

Finally, in radio/media studies, researchers routinely employ interview and survey methodologies to explore radio stations across the globe [15, 16], in some cases by selecting samples from radio-station directories hosted online [17]. The now defunct ComFM, for example, included a catalogue of web-radio stations classified according to

Continent	Radio Stations	Sovereign States
Africa	392 (4%)	39 (58%)
Asia	653 (7%)	38 (59%)
Europe	5,161 (52%)	49 (60%)
North America	2,243 (22%)	33 (67%)
Oceania	222 (2%)	5 (17%)
South America	1,329 (13%)	13 (87%)
TOTAL	10,000	177

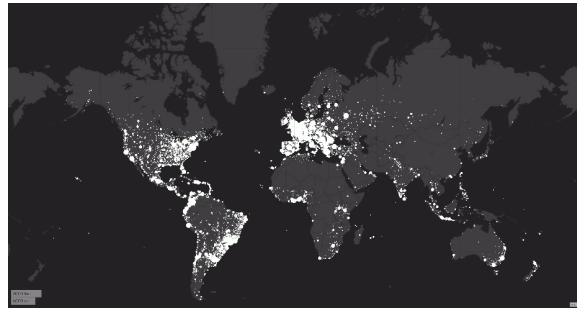

Figure 1. Descriptive statistics (left) and geographic map (right) of the radio stations in MIRAGE-MetaCorpus. The size of each bubble represents the number of stations at that location.

geographic region and type of programming. Other current internet radio directories like radio.co and internet-radio.com offer searchable databases consisting of several thousand stations, but they do not permit users to access or export the entire database for further analysis.

The MIRAGE online dashboard addresses these issues by offering a global archive of the musical traditions encountered on internet radio. For this reason, the dashboard’s database could serve MIR tasks like music recommendation and genre classification, but the dashboard itself also allows researchers with potentially little training in computational methods to select and analyze a subset of events or stations (i.e., to develop their own sub-corpora). Finally, like previous MIR projects [11], the MIRAGE online dashboard avoids copyright infringement by including publicly available metadata and musicological features protected under fair use while enabling users to stream recordings using embedded links to commercial services like Spotify and YouTube.

3. MIRAGE METACORPUS

The core database for the MIRAGE online dashboard is MIRAGE-MetaCorpus, which currently consists of metadata and musicological features for 1 million events that streamed on 10,000 internet radio stations across the globe. In this context, an ‘event’ could represent a musical work of some kind, or a radio program like a podcast or a call-in show.

3.1 Collecting MetaData

Following [12], data collection consisted of three stages: station-list and event-list collection (*Stage 1*), station-list review (*Stage 2*), and event-list parsing (*Stage 3*).

3.1.1 Stage 1: Collecting Station/Event Lists

Toward Stage 1, the research team collected metadata for an initial list of internet radio stations and then monitored the station streams to obtain additional metadata from the stream encoder. To that end, we monitored radio stations in real time on Radio Garden,¹ a streaming service with an open-access application programming interface (API)

that allows users to select and play publicly available radio streams using an interactive representation of the globe.

Between the months October to January 2022-2023, a random sample of 10,000 stations from the initial station list was monitored throughout the 24-hour day – but avoiding each ten-minute period at the top and bottom of the hour when advertising is most frequent – in order to obtain additional metadata from the stream encoder for 100 events from each station, resulting in an initial list of 1 million events. The monitoring algorithm also excluded an event if the stream description did not include metadata, or if the metadata featured advertising terms or reflected a station blackout period (e.g., ‘advert’, ‘commercial’, ‘unknown’, ‘blackout’, etc.).

During event-list collection, additional metadata for each location in the initial station list was also included from the Natural Earth map data set,² which provides public-domain vector and map raster data along with accompanying metadata.

Shown in Figure 1, the selected station list represents 177 of the globe’s 305 sovereign states. As a random sample of Radio Garden’s station list (i.e., the *Radio Garden sample*), this release of the MIRAGE-MetaCorpus (v0.2) therefore reflects the prevalence of internet radio stations across the globe on the Radio Garden streaming service.

3.1.2 Stage 2: Reviewing Stations

Toward Stage 2, a team of six human annotators began reviewing station-level metadata from the Radio Garden API and radio-station stream encoder in 2023-2024. For each station, an annotator reviewed the station’s website url, station name, city, and country for incorrect/missing spelling, capitalization, punctuation, and diacritics. Next, the list of genres, formats, and terrestrial (FM/AM) station frequencies (if applicable) were reviewed and/or included using information on the station website. Finally, the annotator reviewed the corresponding event list for each station to determine the percentage of events that featured reliable stream-description metadata (i.e., artist name, track title).

Currently, the research team has reviewed over 6,000 stations and plans to complete station-list review by 2025.

Table 1. Left: Selected variables from the encoding scheme for MIRAGE-MetaCorpus, expressed in pseudocode. Metadata were obtained from the following sources: ^a Radio Garden API; ^b Natural Earth map data set; ^c Internet Radio Station Stream Encoder; ^d Annotator Review; ^e Monitoring/Matching Algorithm; ^f Online Music Libraries. Right: An example of the metadata for an event in MIRAGE-MetaCorpus.

3.1.3 Stage 3: Parsing Events

Toward Stage 3, additional metadata were collected for each event using the Spotify and WikiData online music libraries.³ Specifically, the team queried each API using each event’s stream description. The obtained list of matching queries was then filtered using a normalized edit distance measure. Query lists featuring more than one matching entry based on normalized edit distance were then ranked by release date, and the track with the oldest release date was selected.

3.2 MetaData Variables

Each event in MIRAGE-MetaCorpus includes metadata for 100 variables obtained from the Radio Garden API (RG), the Natural Earth map data set (NE), the internet radio station stream encoder (SE), annotator review (AR), or using the online music libraries WikiData (WD), MusicBrainz (MB), Spotify (SP), Musixmatch (MX), YouTube (YT), Genius (GE), and AZlyrics (AZ). Shown in Table 1, these metadata reflect information about each event’s location, station, event, artist, and track. For

³ <https://open.spotify.com>; <https://www.wikidata.org>.

example, location metadata includes variables like the city, country, and geographic coordinates of the monitored event, as well as demographic data like the country’s population and GDP. Station metadata includes its name, form (a webcast stream, or a stream simulcast on the internet and terrestrial radio frequencies), formats (e.g., Top 40), and the station’s website url. Event metadata includes variables like the local time when the station was monitored and the event’s identifying metadata, such as the name of the artist and title of the recording. Finally, artist and track metadata include variables like the name and type of the artist, and if the artist is a group, a list of the group’s members and their demographic information (their listed genders, sexual orientations, and ethnicities), the group’s country of origin by birth and/or citizenship, the title and duration of the track, and its year of release.

3.3 MetaData Access & Export

Users may access the complete MIRAGE-Metacorp with the online dashboard.⁴ In addition, public-domain metadata from MIRAGE-MetaCorpus are available for download in an open-access repository on Zenodo [18], which includes both the complete data set and a subset of the data set for which the metadata obtained from the station’s stream encoder and the corresponding metadata provided by online music libraries was deemed a reliable match (i.e., where the normalized edit distance measure between the two metadata character strings was $\geq .90$ on a 0–1 scale).

4. MIRAGE ONLINE DASHBOARD

The MIRAGE online dashboard is an open-access web application that enables users to effortlessly navigate and engage with radio-station metadata and musicological features at various levels of detail. The dashboard’s layout consists of fully interactive panes displaying relevant information from MIRAGE-MetaCorpus. The dashboard is also compatible with multiple platforms and operating systems, so users may access and interact with the dashboard from any internet-connected device.

The complete technology stack of the dashboard includes Node.js for the server, MongoDB for the database, and React for the front end. This integration of technology guarantees a smooth user experience and effective data processing. Moreover, the dashboard may be tailored to accommodate individual users’ distinct requirements and inclinations, rendering it a versatile instrument for analyzing radio stations. What is more, incorporating these technologies enables instantaneous data updates and interactive functionalities, thereby boosting the overall user experience over subsequent versions of the dashboard. In addition, the MIRAGE dashboard offers sophisticated search and filtering tools and the ability to export metadata and visualizations in URL, CSV, PNG, and SVG formats, allowing users to study and share data easily.

⁴ The MIRAGE online dashboard is available at <https://pearl-laboratory.github.io/mirage-mc/>.

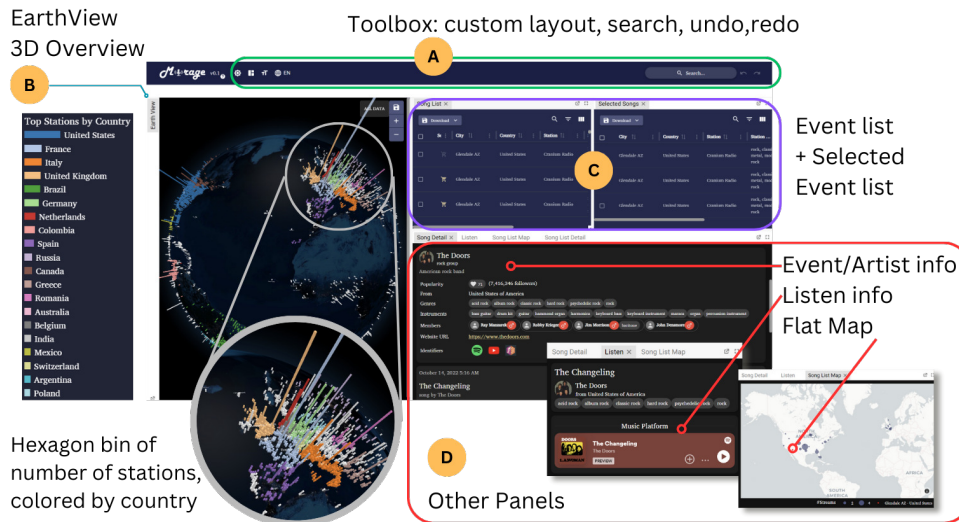

Figure 2. An overview of the MIRAGE online dashboard (v0.2).

4.1 Structure & Processing

Shown in Figure 2, the MIRAGE dashboard’s layout is divided into two groups: a toolbox on the top (A) and data-visualization panels below (B-D), making it easy for users to navigate and analyze information. The toolbox at the top includes options for language preference, panel-display customization, and searching. The data visualization panels show the data in various formats, such as charts, graphs, and tables, for straightforward interpretation and analysis. The panels can also dock to allow the user to create a customized layout, or open to another window (or undock) to permit a more detailed view suitable for multiple-screen presentations.

Shown in Figure 3, the database is partitioned into five tables: location, station, event, artist, and track. The data are structured in this manner to facilitate convenient retrieval and examination of each category while minimizing duplication. In this way, the database allows for easy filtering and sorting based on specific criteria, enhancing the overall efficiency of data analysis. Additionally, partitioning of data into separate tables helps to prevent errors and inconsistencies in data entry and manipulation.

4.2 Layout

4.2.1 Earth-View Panel

The 3D interactive Earth-view (or ‘globe’) panel visualizes the number of stations across the globe. Shown in Figure 2, each hexagonal-shaped vertical bar identifies the locations where radio stations reside. The height of each bar represents the number of stations at that geographic location, and the bars are also color-coded by country. The Earth-view panel is also linked to the event-list panel such that when a user selects a specific location on the Earth view, the event-list panel automatically filters (i.e., restricts) the station- and event-level metadata to the selected location.

In this way, users may compare the number of stations in various regions and discern any recurring patterns or trends.

4.2.2 Event-List Panels

Once users have selected a specific location on the interactive Earth-view panel or using the search function on the toolbox, they can retrieve metadata for the top 1,000 most recent entries in the event-list panel. Users can also select and add events to the selected event-list panel for further analysis and/or export, enabling users to revise their search parameters without losing selected metadata. The event-list panels also allow users to download the contents of either table in CSV format, or obtain a URL to share the

Figure 3. Database tables and connections for the MIRAGE online dashboard.

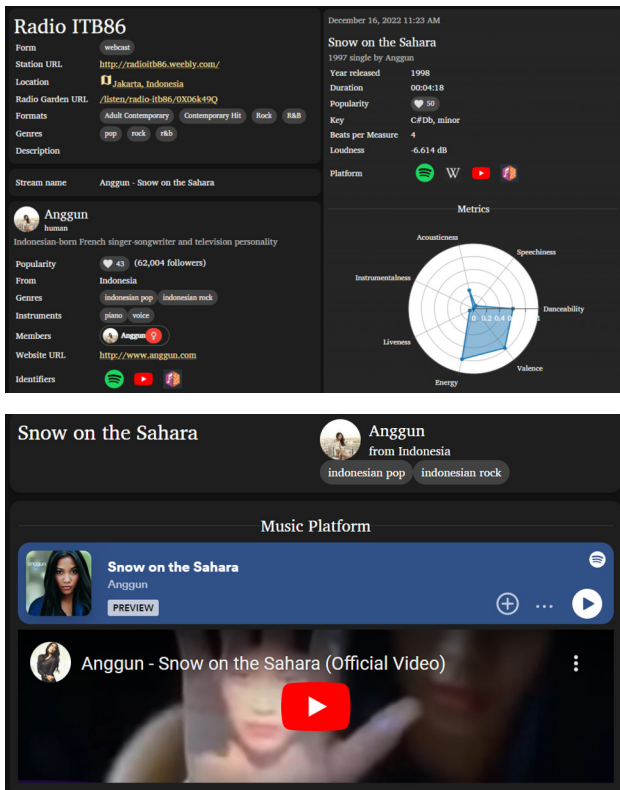

Figure 4. Top: Examples of the event-detail (top) and listen (bottom) panels in the MIRAGE online dashboard.

results of their most recent search with another user.

4.2.3 Map Panel

The map panel enables users to readily visualize the events’ geographic distribution in the event-list panel. Each dot on the map reflects the precise position of a particular event, and the size of the dot represents the number of events at that position. If the user selects an event from the event-list panel, that event will be represented by a red dot in the map panel. In this way, the map panel offers users a distinctive method for visualizing the geographical variety of the events in the event-list panel.

4.2.4 Event-Detail & Listen Panels

Shown in Figure 4, the event-detail panel displays the currently selected event from the event-list panel. The content is categorized into four sections: radio-station metadata (e.g., name, location, formats, url, etc.), event metadata (i.e., stream description), artist details (e.g., name(s), gender(s), group affiliations, instrument(s), etc.), and track metadata (e.g., track title, duration, key/mode, etc.). Figure 4, for example, presents all available metadata for Indonesian singer Anggun’s “Snow on the Sahara,” which streamed on Radio ITB86 in Jakarta, Indonesia on December 16, 2022. Note that users can obtain a list of demographic (e.g., gender, nationality, etc.) and musicological (e.g., list of instruments, vocal type, associated genres, etc.) information about Anggun, review additional metadata about the song itself (year released, language, the song’s lyricist(s), etc.), and finally navigate to other web-

sites and online music libraries using the provided hyperlinks.

Finally, the listen panel allows users to stream available recordings using embedded links to the integrated Spotify and YouTube platforms. Although not all events are available on both platforms, the dashboard is regularly updated to ensure that the provided information is current.

4.2.5 Event-List Visualization Panel

Shown in Figure 5, the event-list visualization panel allows users to explore the searched or selected event list using interactive bar, scatter, and histogram plots. For each plot, users may select the appropriate metadata variable(s) from a dropdown list, edit the plot using Plotly Chart Studio,⁵ and finally export the plot in SVG format.

5. EXAMPLE USE CASE

The metadata and visualizations produced by the MIRAGE online dashboard have numerous applications for users. Figure 5, for example, examines Anggun’s “Snow on the Sahara” within the context of events produced by Indonesian artists across the globe (left), or streaming on Indonesian radio stations (right). The MIRAGE-MetaCorpus features 37 events (and 12 tracks) produced by Anggun, of which 21 were “Snow on the Sahara” (or its French language version, “La neige au Sahara”).

Among Indonesian artists, music genres familiar to western listeners like pop, pop-rock, and alternative rock rank in the top 10, along with characteristic southeast Asian genres like dangdut and koplo. Among events streaming on Indonesian stations, music by Indonesian artists also ranks first, though several Anglophone countries also rank in the top ten (USA, UK, etc.). Scatter plots of a two-dimensional arousal-valence emotion space and a two-component solution from a principal components analysis of the track’s danceability, speechiness, acousticness, liveness, and instrumentality further reveal the track’s unconventional expressive and musical characteristics relative to the other tracks produced by Indonesian artists or streaming on Indonesian stations. Finally, histograms of the track’s popularity and year of release reflect the song’s enduring popularity more than two decades after its initial release.

6. CONCLUSION & ETHICAL CONSIDERATIONS

This development release (v0.2) of the MIRAGE online dashboard provides a snapshot of the contemporary global listening landscape for scholars across the (digital) humanities. Our purpose in doing so is to facilitate cross-cultural, comparative research, which has become a pressing concern in several music disciplines [1, 19–21]. To that end, the MIRAGE-MetaCorpus features metadata for 1 million events that streamed on 10,000 radio stations across the globe, and the dashboard is interoperable with several platforms and operating systems [22, 23].

⁵ chart-studio.plotly.com.

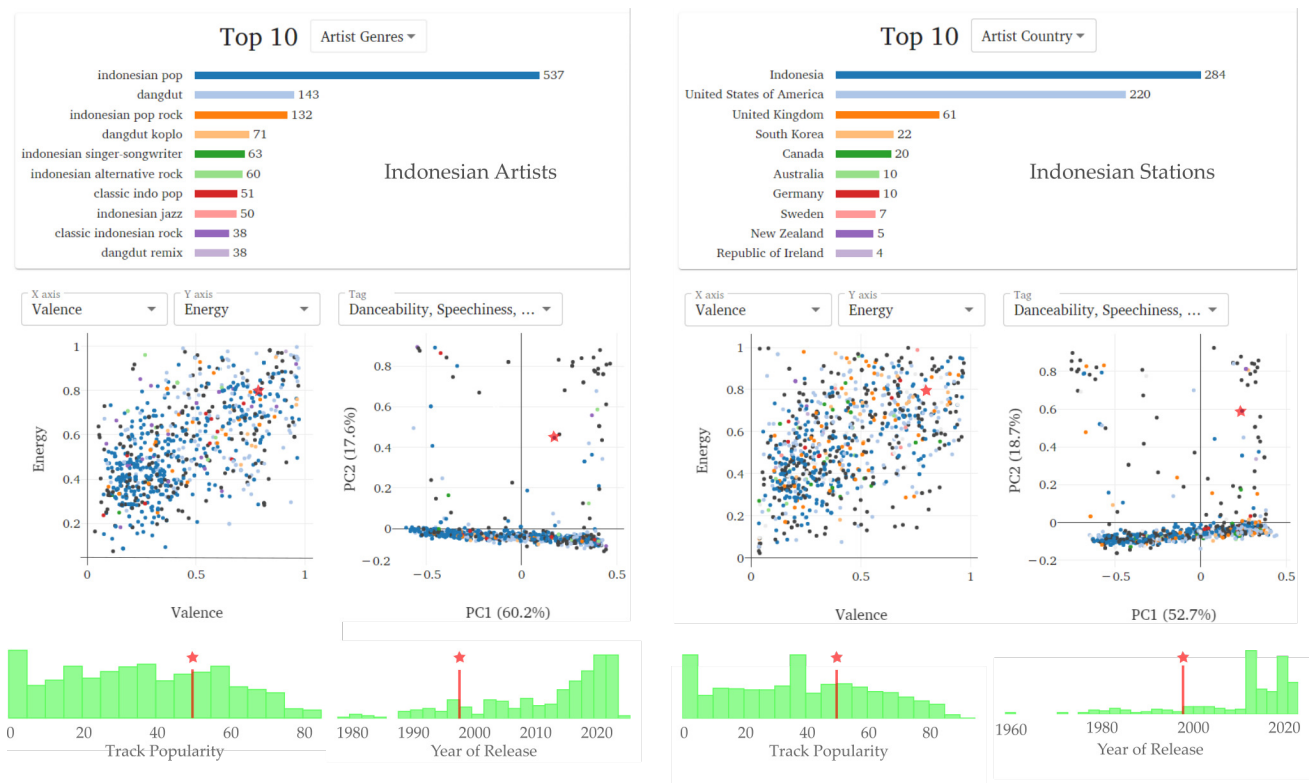

Figure 5. Event-List Visualization Pane for events by Indonesian artists (left) or Indonesian stations (right) in the MIRAGE online dashboard. The red star indicates the position of Anggun’s “Snow on the Sahara.”

As a metadata repository, the MIRAGE-MetaCorpus contains links to online resources that we do not control. To mitigate the potential for dataset degradation over time, the research team plans to update (and collect additional) metadata annually. Nevertheless, the attribution metadata provided by the radio station’s stream encoder does not always reliably match metadata provided by online music libraries. In our view, nonmatching (or ‘unreliable’) metadata allow the research community to evaluate the coverage (i.e., bias) of online music libraries for the music found on internet radio. Nevertheless, MIRAGE users should be aware of the potential for matching errors. For tasks where higher match quality is important, users may search for reliable metadata in the online dashboard, or export reliable subsets of the MIRAGE-MetaCorpus.

Similarly, this project provides access to metadata and musicological features produced by proprietary (or otherwise undisclosed) algorithms, often trained on western musical traditions and their associated organizational principles. As a result, we encourage the research community to treat the attribution metadata in MIRAGE as a starting point for developing corpora and methodologies involving other musical traditions [24, 25].

In developing the MIRAGE online dashboard, the research team has attempted to protect the interests of copyright holders by only including publicly available metadata protected under fair use while enabling users to stream recordings using embedded links to commercial services like Spotify or YouTube. The dashboard also adheres to the user agreements from the libraries and streaming ser-

vices mentioned above (e.g., Radio Garden, Spotify, WikiData), according to which users may access and interact with all data on the online dashboard, but they may only export public-domain data for further analysis and study (i.e., from the Radio Garden API, the Natural Earth data set, station stream encoder, and WikiData). Perhaps most importantly, this project did not directly record/store audio from station streams at any point in the data-collection pipeline.

Nevertheless, we acknowledge the concerns of copyright holders (artists, radio stations, online music libraries, and streaming services) who do not wish to share attribution metadata about their work (e.g., artist demographics, track details, etc.). We only provide links to publicly available sources and do not own the copyright for any music referenced in the MIRAGE-MetaCorpus. For that reason, copyright holders may request the removal of metadata from the MIRAGE project.⁶

In addition to completing station-list review for the remaining stations in MIRAGE-MetaCorpus, future versions of the dashboard will transition from React+Nodejs to Remix in order to enhance the speed of queries and allow users to access and review more than 1,000 events simultaneously in the event-list panel. The team also plans to conduct a usability study to examine the dashboard’s practical utility, as well as incorporate additional customizable sampling and visualization tools like statistical surface maps to enhance the user’s exploration of metadata variables in MIRAGE [26]. In doing so, we hope future versions of

⁶ Please contact miragedashboard@gmail.com.

this dashboard will facilitate cross-cultural, comparative research for a medium that places diversity center stage.

MIDI-TO-TAB: GUITAR TABLATURE INFERENCE VIA MASKED LANGUAGE MODELING

Drew Edwards Xavier Riley Pedro Sarmento Simon Dixon

{a.c.edwards, j.x.riley, p.p.sarmento, s.e.dixon}@qmul.ac.uk

ABSTRACT

Guitar tablatures enrich the structure of traditional music notation by assigning each note to a string and fret of a guitar in a particular tuning, indicating precisely where to play the note on the instrument. The problem of generating tablature from a symbolic music representation involves inferring this string and fret assignment per note across an entire composition or performance. On the guitar, multiple string-fret assignments are possible for most pitches, which leads to a large combinatorial space that prevents exhaustive search approaches. Most modern methods use constraint-based dynamic programming to minimize some cost function (e.g. hand position movement). In this work, we introduce a novel deep learning solution to symbolic guitar tablature estimation. We train an encoder-decoder Transformer model in a masked language modeling paradigm to assign notes to strings. The model is first pre-trained on DadaGP, a dataset of over 25K tablatures, and then fine-tuned on a curated set of professionally transcribed guitar performances. Given the subjective nature of assessing tablature quality, we conduct a user study amongst guitarists, wherein we ask participants to rate the playability of multiple versions of tablature for the same four-bar excerpt. The results indicate our system significantly outperforms competing algorithms.

1. INTRODUCTION

Tablatures (tabs) are a type of music notation where each played note is indicated by its physical position on the instrument, as opposed to merely its pitch. Whereas on (e.g.) the piano, each pitch can be played in exactly one location on the instrument, most playable pitches on stringed instruments like the guitar or violin can be played in multiple positions [1]. This redundancy introduces an additional layer of analysis to derive mechanics of a performance from raw pitches. In traditional music scores, e.g. for classical guitar, it is the burden of the performer to select appropriate fingerings and positions for the notes in the sheet music. Similarly, a MIDI transcription of a guitar recording lacks

this crucial information for a guitarist to replicate the performance.

In this research we examine the problem of mapping a symbolic representation of a musical performance to guitar tablature. There are few recent publications on this topic (see Section 2), although there are commercial solutions available. Most existing methods propose a manually defined objective function, often related to the difficulty of hand stretches to play chords and distances between hand positions, and seek a solution that minimizes the cost. We take a different approach and provide a modern machine learning treatment of the problem.

We cover the following aspects of our research in this paper: first, we provide a background on the research related to guitar transcription and tablature estimation. Then we formally define the problem of tablature inference from symbolic music notation. Next, we describe the methods of our research, which include: a simple tokenization, a masked language model learning task, a Transformer model solution, pre-training and fine-tuning phases, and a custom beam search inference. Finally, we characterize the performance of our system with quantitative and qualitative metrics, including a detailed user study with 15 guitarists rating various tablatures for short solo guitar excerpts. Our results indicate that guitarists significantly prefer our automatic tablatures versus the commercial alternatives we benchmark.

2. RELATED WORK

The earliest algorithmic approaches to automatic guitar tablature systems date back to Sayegh [2]. His approaches include an expert system approach assigning rules of permissible transitions between hand positions. These are encoded and enforced via Prolog and its native constraint solver. The second approach described assigns costs to transitions between fingerings and uses dynamic programming (Viterbi [3]) to find an optimal path through the constructed weighted graph. This latter approach represents the standard classical benchmark for tablature inference. Alternate approaches include genetic algorithms [4], hybrid expert systems [5], and hidden Markov models [6]. Hori and Sagayama [7] extend the dynamic programming approach by finding a path that minimizes the maximum cost of a local transition across a phrase, as opposed to minimizing the global cost as in Sayegh. Radicioni [8] estimates the fingers employed as well as the fret-string

Figure 1. Overview of the training procedure. Guitar Pro files from DadaGP are converted to six-track MIDI files, one file per distinct guitar part and one track per string. These are tokenized into the Structured tokenization of MidiTok. We train a BART model in a simple masked language modeling task where the string tokens are masked out. Only the predictions for the string tokens are used for loss signal propagation.

combinations, using a graph search paradigm to optimize the bio-mechanical comfort of rendering a piece.

In addition to purely symbolic approaches, there is considerable research on the topic of automatic guitar transcription from audio input. Yazawa et al. [9] follow a two-stage approach which uses latent harmonic allocation for multi-pitch estimation (MPE) and then removes unplayable pitches as determined by a fingering cost algorithm similar to Sayegh. Wiggins and Kim [10] apply a convolutional neural network to jointly perform MPE and tablature fingering. The strongest performing MPE methods for guitar [11, 12] leverage the vast amount of transcription material from other instruments (particularly piano) to enlarge the training dataset, but they fall short in offering no tablature estimations.

The most similar approach to our own is described in the master’s thesis of Mistler [13], where recurrent neural networks are trained to predict guitar tablatures. However, the training dataset used only contained 74 songs and uses hand-crafted features extracted from the input MusicXML. In contrast, we train on tens of thousands of tabs and process a raw, MIDI-derived tokenization of the input score. The data used for training our network comes from the DadaGP dataset [14], comprising 26,181 song scores in the Guitar Pro format.

3. PROBLEM FORMULATION

We simplify the task of guitar tablature estimation to the task of assigning notes to strings. For a specific guitar tuning, the combination of pitch, string, and fret has only two degrees of freedom. Thus, since the pitch is known a priori, we may predict the string and compute the resulting fret for the assignment. This essentially reduces the problem to *se-*

quence labeling. In order to increase the flexibility of our system to process a variety of data sources, we begin with MIDI data. Any digital score can be converted to MIDI, and most automatic transcription systems produce MIDI data as well, enabling our tablature system to be composed with any MPE algorithm.

The problem is formally structured as follows: given a one-track MIDI file M , the system produces a six-track MIDI file M_S , where each track contains the notes assigned to a particular string. Let

$$\mathcal{O} = \{64, 59, 55, 50, 45, 40\}$$

denote the list of MIDI note numbers for the open strings of the guitar in standard tuning, corresponding to $E_4, B_3, G_3, D_3, A_2, E_2$, respectively. Thus, to derive the fret of a note with MIDI note number n assigned to a string s , where $s \in \{1, 2, 3, 4, 5, 6\}$, the fret f is calculated by:

$$f = n - \mathcal{O}[s]$$

Although our derivation of the fret value assumes a standard tuning, this approach could be easily modified to permit alternate tunings by changing the values of \mathcal{O} .

4. METHODS

4.1 Architecture

Our solution to the problem uses a Transformer with a bi-directional auto-encoder and a left-to-right decoder, based on the BART model architecture [15]. Using such an approach requires a tokenization of the input data. For this, we use the *Structured* tokenization scheme of Huang and Yang [16]. For each MIDI note, we produce five tokens: time shift, string (i.e. track), pitch, velocity, and duration.

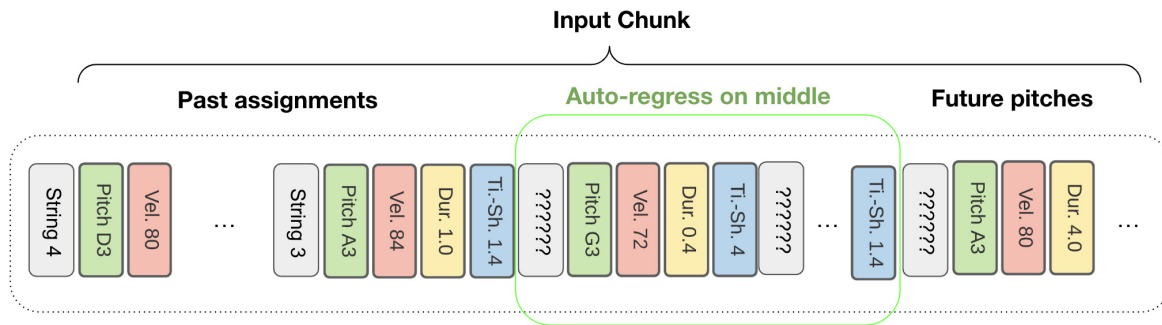

Figure 2. A diagram of our quintile inference algorithm. The middle fifth of the attention window is predicted in an auto-regressive fashion. String assignments from earlier quintiles are fixed. Future notes are available in the context window but will not be assigned until the processing window places them in the center. The beam search is not depicted.

During training, we use a simple masked language modeling supervision scheme, masking the string tokens. This permits both past and future note values to be available for the network during inference, but only past string assignments can be seen. During training, we only compute the loss for string token predictions. We use the Hugging Face Transformers package to define the network, using hyperparameter settings that simply halve the `bert-base` configuration: 384-dimensional hidden size, 6 hidden layers, 6 attention heads, 1536-dimensional intermediate size, dropout probability of 10%. These hyperparameter values were not finetuned.

4.2 Training

Training takes a two-phase approach (see Figure 1): first we train from scratch on 27,619 guitar tablatures derived from DadaGP¹. We use the pre-processing code from the SynthTab project [17] to produce a six-track MIDI file for each guitar part in the Guitar Pro files. Training is performed with the AdamW optimizer of PyTorch, employing a linear decay schedule with warm-up and an initial learning rate of 1×10^{-4} and runs for 100 epochs. The second phase of training is a finetuning on precisely annotated guitar performances from the training splits of Riley et al. [12] and GuitarSet [18]. The fine-tuning stage is motivated by the concern of data quality in the DadaGP annotations, which were scraped from the online, crowd-sourced tab library Ultimate Guitar². Here we fine-tune with a learning rate of 1×10^{-5} , again for 100 epochs, on the much smaller data of 281 tabs. Examples are fed into the network in note sequences of length 50, corresponding to 250 tokens per example.

4.3 Inference

A common problem when training Transformer models for auto-regressive tasks is an asymmetry between training and inference regarding previously predicted sequence values. To leverage the parallelism of the Transformer architecture, ground truth labels must be used as decoder input for

masked preceding values. However, during inference on unseen data, these labels are unavailable.

We implement a novel inference mechanism for our algorithm. We break up the input segment into quintiles (10 notes or 50 tokens per quintile). Excluding boundary cases, we only make predictions for the center quintile (see Figure 2). This allows our network to have the ability to see the 20 previous note-string assignments and the next 20 future note values. The attention window is advanced by 10 notes per inference step. Additionally, we implement a custom beam search inference. For each string prediction in a quintile, we retain the top two string values for the note. We limit the number of potential paths to 32. The paths are batched to keep inference times nearly equivalent to naive autoregression. Paths are pruned by taking the maximum probability computed by summing the logits of the string predictions. While this does not fully resolve the asymmetry between inference and training, the beam search and additional context provide more probable decoder input values than naive autoregression.

4.4 Post-processing

Thus far we have not imposed any constraints on the output of the network. Ideally, we would take the string predictions and directly augment the score information with the resulting tablature. However, in our qualitative assessment of the system, there are occasions where a string-fret prediction can lead to invalid or unplayable notes. To address these outliers, we attempt to relocate the note to a more suitable string.

The heuristic algorithm is as follows:

1. Merge and sort notes from all strings by start time.
2. Set maximum allowable deviation from the average fret position ($MAX_DEVIATION = 5$) and the highest playable fret ($MAX_FRET = 21$).
3. For each run of 11 notes (5 past, 1 middle, 5 future):
 - (a) Find the average fret value of the run, excluding open strings from the computation.
 - (b) If the middle note has a fret value exceeding MAX_FRET or $MAX_DEVIATION$:

¹ Some pieces in DadaGP have multiple guitar parts, and some tracks are filtered out in the conversion process.

² <https://www.ultimate-guitar.com/>

Figure 3. Heatmaps of the fret-string distributions for three of the five tablature systems (ground truth, ours, and Guitar Pro 8). Overall, our system has a similar distribution to the ground truth, but the output appears to be biased away from open strings. Guitar Pro 8 shows a heavy skew to low frets, which perhaps suggest a bias towards playing in “first position” (playing primarily on frets 1 to 4).

- i. Define the available strings to be those with no notes intersecting with the note under consideration.
- ii. If an open string is available, select it.
- iii. Else, select the string yielding a fret value closest to the neighborhood mean.

Ultimately, in our test set from Riley et al. [12], our post-processing algorithm only modifies 0.53% of all notes. However rare, addressing these failures is important to ensure the resulting tab is playable.

5. RESULTS

5.1 Quantitative Results

We use the training splits from Riley et al. [12], with 61 pieces in the training set, 8 in the validation set, and 9 in the test set, corresponding to 58,080, 7,031, and 8,451 notes respectively. At the end of finetuning, our next note accuracy on the validation set is 94.35%. This is the probability of correctly inferring the next note-string assignment given ground truth labels up to the point of prediction. When evaluating autoregressively on the held-out test set across 50-note³ examples, our network agrees with ground truth on 82.52% of predictions. This discrepancy highlights the difference between teacher-forcing and errors accumulated in auto-regressive inference. We measure the impact of the finetuning step by evaluating the pre-trained model without finetuning, which gives 78.48% agreement, corresponding to a 4.04 percentage point difference due to finetuning.

To compare our algorithm to existing technologies, we use one commercially available and two open-source implementations of automatic tablature systems. Guitar Pro 8⁴ is a music software program designed for editing, visualizing, and sharing guitar, bass, and other stringed instruments’ tablatures, and includes an algorithm to automatically produce tablature from score or MIDI. MuseScore⁵ is an open-source score editor with a similar functionality for generating tablature. TuxGuitar⁶ is free, open-source

software for creating and playing guitar tablature and standard musical notation. We use each of these systems to generate MusicXML files with tablature for our 9 held-out test scores from our finetuning dataset, which are then used for evaluation.

Objective evaluation of guitar tablature is difficult, as we will discuss further in Section 5.2. We provide three metrics that illustrate the strength of our system. The first metric is a measure of agreement between the ground truth note-string assignment and each algorithm’s assignment for the corresponding note. The metric is computed by matching⁷ notes from each measure of the ground truth with the notes from the inferred tablature’s corresponding measure. An agreement occurs when the ground truth and the inferred tab assign the same string. The total number of agreements is counted across all examples and then divided by the total number of notes compared. Our system shows the highest agreement of 73.18% (see Table 1). This falls below our 84.42% agreement from the 50-note examples, because early disagreements on fretboard location for a group of notes will likely cause subsequent note assignments to continue to disagree.

The other two metrics relate to the “stretch” values across chords in the MusicXML. Chords are extracted as note onsets occurring at the exact same time. For all such groups of notes, we define the stretch as the maximum fret-wise distance between any two notes in the chord. For example, a chord with notes F3, C4, E4, and A4 played on the string-fret locations⁸ (4, 3), (3, 5), (2, 5), (1, 5) will have a stretch value of 2. Open strings do not restrict hand positions so they do not contribute to the stretch. We report the maximum and average stretch across the chords in the test set. The ground truth has the lowest maximum stretch of 6. Our system demonstrates occasional erratic behavior of assigning high notes to lower strings, resulting in a shifted mean and larger maximum stretch value of 12. In Figure 4, we compare frequencies of maximum fret distances between our system and the ground truth. An example failure is shown in Figure 5. The mean and median values indicate that, in general, all algorithms attempt to place chords

³ Recall the model has a context window of 50 notes.

⁴ <https://www.guitar-pro.com/>

⁵ <https://musescore.com/>

⁶ <https://www.tuxguitar.app/>

⁷ Matching is required due to reordering of simultaneous notes.

⁸ String 1 is the High E string, and fret values start at 0 for open strings.

Figure 4. Comparison of the distributions of stretch distances between chords in the test set.

Figure 5. An example failure of our system. Ground truth is left, ours is right. The assignment of B2 to the fifth string creates an 8-fret stretch, which is essentially unplayable.

within a narrow band of frets. The presence of these large stretches motivates future work to better inform our algorithm about the importance of physical playability.

As a final quantitative comparison, we compute fret-string distributions for all five sets of tablatures. For each distribution, we compute the Kullback–Leibler divergence against the ground truth distribution. Our system has the lowest value of 0.099; the other values are: 0.462 for Guitar Pro 8, 0.635 for MuseScore, and 1.286 for TuxGuitar. Three of these distributions are shown in Figure 3.

5.2 User Study

A purely quantitative evaluation of automatic guitar tablature systems is problematic because there may be multiple ways to play the same phrase or excerpt of music. For example, in Figure 6, we show two distinct tablatures for the same one-bar phrase. The top is the ground truth transcription

Table 1. Summary of quantitative analysis, showing maximum, mean and median “stretch” of chords in the tablature, defined as the maximum fret distance between any two notes in the chord. We also report the percent agreement with the ground truth note-string assignment. All metrics are averaged over the entire withheld test set.

Source	Max Stretch	Mean Stretch	Median Stretch	% Agree
Ground Truth	6	1.04	0	–
Ours	12	1.84	1	73.58
MuseScore	10	1.19	1	62.51
Guitar Pro 8	12	0.78	0	62.27
TuxGuitar	18	2.03	1	55.42

tion and the bottom is the layout from our system. At a glance, both provide reasonable fretboard fingerings. The ground truth shows a preference for open strings, but our system better minimizes the maximum span between successive notes (2 frets versus 4 frets). However, in this example, our system only agrees with the ground truth on two notes, which corresponds to an accuracy of 16.67%. On the other hand, hand-crafted metrics (such as maximum or average span between notes) fail to capture complex preferences of guitar tablature – otherwise existing systems that minimize these values as cost functions would suffice.

To complement the quantitative analysis and circumvent some of the potential limitations of the approach, we conducted a study to assess guitarists’ opinions on the playability and overall preferences for tablatures. Participants were exposed to 30 audio excerpts consisting of 4-bars of solo jazz guitar audio, and for each were shown 5 distinct tablature transcriptions from the following groups: TuxGuitar (*TG*), MuseScore (*MS*), Guitar Pro 8 (*GP*), our system (*Ours*) and ground truth (*GT*), which was created by a professional transcriber. The stimuli were selected by randomly sampling the test split of Riley et al. [12]. Via an online listening study, we probed how guitar players deem the tablatures generated by our system, and how they rank them against the ground truth and the outputs from other tablature generation software (i.e. *TG*, *MS* and *GP*).

The online listening study took approximately 1.5 hours to complete and both the order of audio excerpts and the order of tablature transcriptions were randomized. As conditions to take part in the study we proposed that participants should be guitar players and have a familiarity with reading tablatures, access to headphones or speakers and normal hearing. Subjects were instructed to ignore the difficulty of the music excerpts as they rated the playability of the tablatures. Overall, we recruited 15 guitarists and invited them to attempt to play each of the tablature examples on the guitar during the study, while rating each of the tablature transcription groups on a scale from 1 to 10. Participants, with an age distribution of 39 ± 14 years, reported a median value of 10 years of daily regular engagement with practice of the guitar, and a median value of 3 hours of guitar practice per day at the peak of their interest. The study received ethical approval from the Queen Mary University of London Ethics of Research Committee (QMERC20.565.DSEEC24.012), and participants were compensated with an Amazon gift voucher. Results for the listening test can be observed in Figure 7.

Figure 6. Two tablatures for the same musical excerpt. The top is ground truth, the bottom is from our system.

Figure 7. Box plots of the results of the listening study on the playability of tablatures. Bars indicate median values and triangles indicate mean values, for each group.

As expected, the ground truth group ranks highest (7.45 ± 2.62). We hypothesise that the reason why the ground truth falls well short of a “perfect” score is linked to the subjective preferences of participants in terms of fingerings and note position choices, which are inherently linked to their guitar playing techniques and overall style. Furthermore, the ground truth represents professional transcriptions of jazz recordings, where perfect information of the original tablature is not available. As discussed above and illustrated in Figure 6, there can be multiple reasonable ways to play a phrase, and we observed that the ratings for our system were higher than those of the ground truth group for 101 ratings out of 450 in total. The results show that participants tend to rate the playability and overall preference of the tablatures from our system (6.04 ± 2.67) higher than the ones from the competing software (*TG*: 3.32 ± 2.87 ; *MS*: 4.67 ± 2.88 ; *GP*: 4.69 ± 2.64).

Of the 2,250 data points collected (30 excerpts \times 5 tabs \times 15 participants), a Shapiro-Wilk test showed that data was not normally distributed within groups. Due to the repeated measurements characteristic of the test (every participant rates all the stimuli), we use a Friedman test to investigate the effects of the type of tablature transcription system on the perceived playability of tablatures, with a Type I error α of 0.05. The statistical results showed a highly significant effect of the tablature transcription system in the participants’ responses amongst groups ($\chi^2(4) = 532.09$, $p < .001$). Finally, in order to determine if there were statistically significant differences between groups, we conducted a post-hoc pairwise Wilcoxon test, Bonferroni-adjusted α level of 0.005 ($.05/10$). This yielded highly significant differences in ratings between groups, except for (*MS*, *GP*).

6. DISCUSSION

Our results suggest a data-driven approach to guitar tablature inference can yield predictions that are significantly more aligned with guitarists’ preferences than existing methods. These results are very encouraging given the simplicity of our approach. Our system imposes no con-

straints on the predicted tablatures until the final post-processing, during which less than 1% of note-string assignments are modified. Future research in this direction may benefit from more directly encoding positional fretboard locations and physical limitations as input to the network.

Despite the strong results, our system has several limitations to be addressed. Guitar tuning is never explicitly encoded as input to the model. Since we only predict string values, our fret predictions are always derived from the note-string assignment and an assumption of standard tuning. Similarly, our system does not handle the use of capos. The system is unaware of many guitar specific articulations, such as harmonics, hammer-ons, pull-offs, and pitch bends. Finally, we make no attempt to assign individual notes to the fingers of a guitarist, which is occasionally done in professional scores or transcriptions, and would be a necessary step in order to estimate playability explicitly.

Another criticism of our approach is that it does not use visual and audio cues for fretboard prediction. As shown by Bastas et al. [19], inharmonicity analysis of a particular instrument can improve string predictions. Likewise, Duke and Salgian [20] demonstrate how computer vision models can be used for accurate and real-time tablature transcription. Both of these directions of research offer a more faithful reproduction of a particular performance, since a symbolic approach simply has no access to disambiguating signals such as hand position or string inharmonicity. However, this shortcoming can also be viewed as a strength: our system does not need access to video nor audio. From this perspective, our approach can be viewed as an automatic arranging system for guitar tablature performance.

The main failure mode of our system is the assignment of unplayable chords at a small but significant frequency (2.4% of chords have a maximum fret distance exceeding 7). Future research may explore different tokenization schemes: encoding fret values as input, physically inspired loss functions, or more carefully designed post-processing to handle these cases. However, the vast majority of the mass of the distribution of chord stretch distances falls within playable limits, which indicates that the algorithm is implicitly modeling some of the physical constraints that classical systems use to derive tablatures.

7. CONCLUSION

We present a deep learning algorithm to predict guitar tablature from symbolic music notation. Our methodology trains an encoder-decoder Transformer to learn tablature assignment from raw note events. Drawing inspiration from natural language processing, we begin by pre-training on a dataset of tens of thousands of tablatures and then fine-tune on a curated dataset of professional guitar scores. We evaluate our system against commercially available software and demonstrate a significant preference for our system through a user study among guitarists. Our MIDI-to-Tab system represents a first step towards achieving human-level tablature inference via machine learning.

TRANSCRIPTION-BASED LYRICS EMBEDDINGS: SIMPLE EXTRACTION OF EFFECTIVE LYRICS EMBEDDINGS FROM AUDIO

Jaehun Kim Florian Henkel Camilo Landau Samuel E. Sandberg Andreas F. Ehmann

firstname.lastname@siriusxm.com

ABSTRACT

The majority of Western popular music contains lyrics. Previous studies have shown that lyrics are a rich source of information and are complementary to other information sources, such as audio. One factor that hinders the research and application of lyrics on a large scale is their availability. To mitigate this, we propose the use of *transcription-based lyrics embeddings* (TLE). These estimate ‘ground-truth’ lyrics embeddings given only audio as input. Central to this approach is the use of transcripts derived from an automatic lyrics transcription (ALT) system instead of human-transcribed, ‘ground-truth’ lyrics, making them substantially more accessible. We conduct an experiment to assess the effectiveness of TLEs across various music information retrieval (MIR) tasks. Our results indicate that TLEs can improve the performance of audio embeddings alone, especially when combined, closing the gap with cases where ground-truth lyrics information is available.

1. INTRODUCTION

Lyrics play an important role in music consumption [1–3], often providing additional context to the perceived audio, such as lyrical themes and semantic meaning. As such, lyrics also have a wide range of applications in MIR, including mood/sentiment prediction [4–8], recommendation [2, 9], genre [2, 10–12] and music tag prediction [11].

However, the absence of lyrics on a large scale poses a significant challenge. While they are often available for popular music, this might not be the case for the majority of songs in a music catalog, either because they are non-existent, i.e., not yet transcribed by a human, or due to missing copyrights. Automatic lyrics transcription (ALT) systems are an important step towards alleviating this problem by directly transcribing the lyrical content from a piece of audio [13–17]. Still, these systems are not infallible and some efforts have been made to further refine the resulting (potentially faulty) transcriptions, e.g., by using large language models (LLMs) [15].

In this work, we investigate the use of lyrics embeddings on a variety of MIR downstream tasks, ranging from music tagging to recommendation. We focus on a comparison between embeddings stemming from human-transcribed or ‘ground-truth’ lyrics and their machine-transcribed counterparts, which we refer to as transcription-based lyrics embeddings (TLE) throughout this work. In particular, we are interested in the effectiveness of two TLE variants compared to audio embeddings and ‘ground-truth’ lyrics embeddings, where we assume the performance of the latter as an upper bound to TLE. To that end, we answer the following research questions:

- **RQ1** Do TLE provide useful additional information compared to audio embeddings alone?
- **RQ2** Can TLE be efficiently refined to close the gap to ‘ground-truth’ lyrics embeddings?

The remainder of the paper is structured as follows. Section 2 discusses related work on lyrics embeddings and automatic lyrics transcription. In Section 3 we introduce the concept and types of TLEs we evaluate in this work. Section 4 covers our experimental setup including choices of audio/lyrics embeddings as well as datasets and tasks. In Section 5 we investigate and discuss the aforementioned research questions. Finally, we conclude this work in Section 6 and highlight potential future work directions.

2. RELATED WORK

Extracting information from lyrics has long been studied in the MIR community. In particular, representing such information quantitatively, e.g., with feature or latent vectors, has been a strong focus. For instance, linguistic features (e.g., rhyme and stylistic features) are shown to be useful in various tasks [6, 8, 18], as well as approaches using psychologically validated dictionaries [2, 19].

For representation modelling, bag-of-words (BoW) [20] and term frequency inverse document frequency (TF-IDF) have been common and effective choices for lyrics [6, 12], which is further extended to latent document or topic modeling that has been successful in lyrics similarity estimation and exploration [21, 22], as well as genre and mood classification [6, 11, 12]. Another successful method is to employ word2vec [4, 18, 23], where lyrics documents are typically represented as the average of word vectors.

Lately, deep learning (DL) has been a popular choice for lyrics representation learning. In supervised learning,

it typically is accomplished implicitly within hidden layers via end-to-end learning, which proves to be effective on a range of downstream tasks [10, 11, 18]. More recently, LLMs have introduced self-supervised learning based latent text representations, which are shown to be effective on several MIR tasks [24, 25].

Regardless, ALT remains a challenging problem today [15, 16, 26, 27]. Along with efforts in building lyrics-specific transcription systems [16, 17], Automatic Speech Recognition (ASR) applied to the ALT task has also been shown to be effective [27–29].

3. TRANSCRIPTION-BASED LYRICS EMBEDDINGS

Figure 1. The diagram of proposed lyrics embedding estimation. The models in the green-colored boxes ($\{t, h, f\}$) are assumed to be pre-trained, whereas lyrics enhancement model g is trained employing embeddings obtained from those pre-trained models.

In this work, we propose a system that estimates lyrics embeddings (LE) independent of ‘ground-truth’ lyrics data $y \in \mathcal{Y}$ by only relying on audio data $x \in \mathcal{X}$, which we generally refer to as transcription-based lyrics embeddings (TLE) in the following. To achieve this, we consider several off-the-shelf pre-trained models, including an ALT model $t : \mathcal{X} \rightarrow \hat{\mathcal{Y}}$, an audio embedding model $h : \mathcal{X} \rightarrow \mathcal{A}$, and finally a lyrics embedding model $f : \mathcal{Y} \rightarrow \mathcal{Z}$.

Given the availability of a pre-trained ALT as well as word or sentence embedding models, it is straight-forward to devise a sequential system that allows one to directly input audio data and obtain high-quality lyrics embeddings that are ready to be used for a variety of downstream music tasks. We propose such an ALT based embedding as the first type of TLE, which is further referred to as \mathbf{TLE}_T and denoted as \hat{z} in Figure 1.

Despite remarkable recent improvements, ALT models are not yet completely error-free, due to the challenging nature of this task [15]. As a result the transcription $\hat{y} \in \hat{\mathcal{Y}}$, and hence an embedding computed from it may contain a certain degree of error when compared to ‘ground-truth’ lyrics embeddings. We aim to improve the fidelity of \mathbf{TLE}_T by introducing an ‘enhancement’ model which regresses to the ground-truth lyrics embeddings from noisy transcription-based embeddings by using audio embeddings as an additional input. In the following we refer to this approach as \mathbf{TLE}_R (denoted as \hat{z} in Figure 1).

Given pre-configured audio $a \in \mathcal{A} \subset \mathbb{R}^{d_a}$ and lyrics embedding $z \in \mathcal{Z} \subset \mathbb{R}^{d_z}$ spaces, the main goal of ‘enhancement’ is to find a function $g : \Phi \rightarrow \mathcal{Z}$ which maps

the concatenated audio-lyrics embedding $\phi = [a; \hat{z}] \in \Phi \subset \mathbb{R}^{(d_a+d_z)}$ to the lyrics embedding space $z' \in \mathbb{R}^{d_z}$. Specifically, we minimize the sum of squared error between the estimated and ground-truth lyrics embedding as the main learning objective:

$$\min_{\Theta} \sum_{(z,x) \sim \mathcal{D}_{\text{train}}} \|z - g(\phi; \Theta)\|^2 + \alpha \mathcal{R}(\Theta) \quad (1)$$

where Θ are the parameters of the regressor g and $\mathcal{D}_{\text{train}}$ denotes the training dataset where we have access to both the audio x and lyrics y as well as their corresponding embeddings a and z . Finally, \mathcal{R} is the regularizer for the parameters Θ which is controlled by coefficient α .

4. EXPERIMENTAL SETUP

The main hypotheses correspond to each RQ: 1) \mathbf{TLE}_T effectively provides lyrics information that is complementary to audio 2) \mathbf{TLE}_R improves the effect of \mathbf{TLE}_T . Concretely, we design an experiment comparing the performance of three treatments, \mathbf{LE} , \mathbf{TLE}_T , and \mathbf{TLE}_R , on relevant downstream tasks, with respect to a range of lyrics and audio embeddings. In the experiment, we define a treatment as a scenario where a single type of (transcription-based) lyrics embeddings is employed to represent text information, both in the training and testing phase of the machine learning (ML) experiment.¹ The rest of this section describes each component of the experimental design.

4.1 Machine Transcription

Similar to [15], we rely on a Whisper-based model [28] to transcribe the lyrics of a song from its audio recording. In contrast to [15], we do not perform a correction step in the form of ChatGPT², as this would be too costly on a large scale. Instead we directly create embeddings from the potentially faulty transcriptions (\mathbf{TLE}_T) and subsequently try to improve the embeddings using a learned correction function (\mathbf{TLE}_R).

Considering that we aim to transcribe a large set of audio recordings (see Table 1), we employ Distil-Whisper for an efficient transcription process without significant performance losses [32, 33]. As suggested in [15] we use “lyrics:” as a prefix prompt.

4.2 Embeddings

In the following, we introduce the different embeddings for each modality used in our experiments. While each embedding is tested separately, we also test *combined cases*, where both audio and lyrics embeddings are provided in the downstream task as a concatenated embedding vector.

¹ We do not consider the scenarios where different treatments are used in training and testing phase to control for a possible data drift [30, 31] and to simplify the experimental design.

² <https://openai.com/blog/chatgpt>

4.2.1 Lyrics Embeddings

We consider three text embeddings, ranging from conventional to more modern transformer-based embeddings to ensure the generality of the study.

Bag-of-Words embeddings (BE): BE embeddings serve as the baseline lyrics embedding approach within the experimental design. Unless the lyrics data is pre-tokenized by words such as the MSD-MusiXmatch (MSD-MXM) dataset [34], we employ the Byte-Pair Encoding (BPE) tokenization [35] instead of actual words. The resulting representation is a sparse song-token count matrix on which we apply TF-IDF [36] and randomized singular value decomposition (rSVD) [37] with a dimensionality of $d = 300$ to subsequently obtain a dense, low-rank vector representation of each lyrics.

Wasserstein embeddings (WE): WE embeddings are learned by applying linear optimal transport which minimizes the Wasserstein distance between distributions of the learned embeddings and given reference vectors [38]. For the reference vectors, we train token embeddings using their co-occurrence matrix. This provides token-to-token transition frequency information on top of the document-token frequency which is the only information source to BE. We choose an embedding dimensionality of $d = 300$.

Sentence BERT embeddings (sBERT): We use a pre-trained sentence BERT model [39], which is fine-tuned using a general language model called MPNet [40, 41]. In particular, the fine-tuning training involved a large scale text corpora to effectively estimate the semantic similarity between paraphrased sentences. Such a property can be crucial for lyrics data, which often is highly abstract and irregular compared to conversational language. The embedding has a dimensionality of $d = 768$.

4.2.2 Audio Embeddings

We employ two open-source and one proprietary music audio embedding models.

OpenL3: is a video-audio multimodal representation trained using self-supervised learning. Specifically, the model encodes video and audio features in respective embeddings, and minimizes the matching error between them, assuming the best matches happen when they are extracted from the same video clip [42,43]. We employ the audio encoding sub-network from the ‘music’ variant of OpenL3 as the embedding encoder with a dimensionality of $d = 6144$ and 128-band mel spectrograms as input.

MULE: is an open-source music audio embedding model trained in a self-supervised way by using contrastive learning on MusicSet, a large-scale proprietary music audio dataset [44]. We choose this for representing a modern, generic music audio embedding which is effective on wide range of downstream tasks.

MSLE: is the supervised counterpart to MULE where the music labels of MusicSet are used for its supervised learning [44]. We employ it for the proprietary datasets (i.e., InternalLT, InternalRec, see following section). Both embeddings have the same dimensionality $d = 1728$.

4.3 Tasks and Datasets

4.3.1 Automatic Music Tagging (AMT)

AMT has been a popular downstream task in MIR [45]. While there are several datasets [34, 46–48], few of them focus on lyrics specifically. To measure the effect of lyrics more clearly, we devise a subset of the Million Song Dataset (MSD) for tagging [34] that is more relevant for lyrics data, which we refer to as **MSDSnippetLT**.

It is composed as the subset of social tags that MSD provides and that are specifically relevant to the lyrics’ subject matter and language. It involves a machine-assisted tag selection process, where we first identify lyric-relevant tags by ranking MSD tags using the correlation with approximately a dozen privately-curated lyric-related tags and language metadata, with songs matched to an annotated proprietary music catalog. Among the top 200 MSD tags per each proprietary lyrics tag, three researchers voted³ for a final subset based on the following selection rules: 1) the MSD tag has to be clearly related to the targeted proprietary lyrics tag, 2) the MSD tag is not a music genre, 3) the MSD tag is not an artist. After filtering songs that map to the MSD-MXM subset which provides lyrics data for a subset of MSD songs, the resulting dataset contains 74,545 MSD songs and 87 unique tags in total, where approximately half of them center around the lyrical subject (i.e., “melancholy”, “political”), while the other half are related to the lyrics’ language (i.e., “british”, “Español”). We also experiment with a proprietary subset that we refer to as **MSDFullLT** where we have access to the full lyrics. The dataset consists of 35,264 songs and is a complete subset of MSDSnippetLT. We hypothesize that the dataset can provide useful insights on the effect of incompleteness of the snippet/preview lyrics.

Additionally, we experiment with two popular tagging datasets and one proprietary lyrics subject tagging dataset: **MSDSnippetMT** is a subset of the popular MSD tagging dataset, [34] where we select the commonly used 50 tags [45] to compare to the MSDSnippetLT dataset. As we have to consider the availability of lyrics within MSD, the resulting subset includes a total of 68,363 songs. We further test with **JamendoMood** dataset which is a subset of the MTG-Jamendo dataset [47] specifically focused on music mood. The main purpose of this dataset is to show how effective TLEs are for general music mood tagging when ‘ground-truth’ lyrics are not available. It contains 17,982 songs annotated with 56 music mood tags. Finally, **InternalLT** is the subset of a proprietary lyrics-subject dataset providing a set of high-quality lyrics-subject tags as well as full ‘ground-truth’ lyrics.

We apply 5-fold cross validation for all datasets except JamendoMood, where we use the provided pre-defined split. The model performance is evaluated by the sample-weighted mean average precision (wmAP) averaged across all tags. The main motivation of applying sample weights

³ A weighted majority voting is conducted where one of three researchers has three times larger weight than the other two, considering the substantial musical experience and training. For further details on the dataset creation, we kindly refer readers to the supplementary material.

Dataset	task	#songs	#tags	text	audio
MSDSnippetMT	music tagging	68,363	50	BoW5k	preview
MSDSnippetLT	lyrics tagging	75,545	87	BoW5k	preview
MSDFullLT	lyrics tagging	35,264	87	full-text	preview
JamendoMood	mood tagging	17,982	56	N/A	full-audio
InternalLT	lyrics tagging	51,240	15	full-text	full-audio
MSDSnippetRec	RecSys	112,769	N/A	BoW5k	preview
InternalRec	RecSys	138,984	N/A	full-text	full-audio

Table 1. Details on the datasets.

is that the majority of the datasets, except JamendoMood, provide the tagging confidence values, which is useful to both training and evaluating the task. The sample weight $w_{i,j} \in [0, 1]$ is defined as the normalized confidence value for the observed annotation of tag j on song i . For all other pairs of i and j (unannotated tags on songs) we set it to 1.

4.3.2 Music Recommendation

We further explore the effectiveness of lyrics embeddings within a music recommendation system (RecSys) problem. To maximize the effect of music content in a RecSys task, we experiment with the ‘item cold-start’ scenario; a subset of songs lack user interactions (e.g., new releases) hence a content-based recommendation is more effective than collaborative filtering [49, 50].

The dataset consists of triplets of {user, song, listening count} which is translated into a user-song matrix. The interaction data is split into five sets of *train*, *validation* and *test* set by songs in approximately 3:1:1 ratio via 5-fold cross-validation. The user-song interactions within the training (song) set is assumed as ‘observed’ and thus can be used as the training data, while those within the test (song) set are treated as ‘future’ interactions which the recommendation system is expected to rank higher. An effective measure commonly used is the binary normalized discounted cumulative gain (nDCG) [51] applied on a truncated list of the top 500 recommended songs.⁴

We employ two datasets for the RecSys task: MSD-Echonest subset⁵ is a popular recommendation dataset which contains {user, song, listening count} triplets. We derived a subset by including songs overlapping with the MSD-MXM subset only, which we refer to as **MSDSnippetRec**. We apply 5-core filtering, i.e., we filter out users who interacted with less than or equal to five unique songs, and vice versa. Similarly, we derived a subset of proprietary streaming listening data in the aforementioned format and apply the same pre-processing steps. We refer to this dataset as **InternalRec**.

4.3.3 Pre-processing on Text Representation

The subset of datasets involving MSD-MXM data only provide a pre-tokenized BoW representation, while for the rest we have access to a natural text representation of lyrics, except for JamendoMood where we do not have access to any ‘ground-truth’ lyrics. We refer to the pre-tokenized BoW representation as *BoW5K* as it specifically

is limited to the 5000 most frequent words. This applies to MSDSnippetLT, MSDSnippetMT, MSDSnippetRec.

Furthermore, as the transcription of music previews tend to be substantially shorter, the BoW5K representation of those has less counts compared to the one provided by MSD-MXM, which is extracted from the full-text lyrics. To correct this bias, we apply the following adjustment to the transcription based word count a :

$$\tilde{a}_{i,b} = \tilde{N}_i(\gamma p_{i,b}^a + (1 - \gamma)p_{i,b}^{\text{prior}}) \quad (2)$$

where $p_{i,b}^a$ denotes the normalized frequency of a word b on the i th lyrics based on the transcription, while $p_{i,b}^{\text{prior}}$ represents the global probability of a word b based on the MSD-MXM corpus. $\tilde{N}_i = r_i N_i$ denotes the estimated word count of the full text based on the length ratio r_i between full audio and snippet audio, and the observed word count from the transcription N_i . Based on a preliminary study, we choose the mixing coefficient $\gamma = 0.8$ which yielded the best adjustment quality.⁶

Given that MSDFullLT, InternalLT, InternalRec, and JamendoMood (via transcription) directly provide full text lyrics for the embedding encoding, they do not require any of the aforementioned pre-processing steps. An overview of the datasets can be found in Table 1.

4.4 Experimental Setup Details

4.4.1 Lyrics Embedding Models

Unlike sBERT, for which we use a pre-trained model, we train BE and WE models either with the MSD-MXM dataset or a proprietary lyrics corpus.⁷ As discussed in section 4.3.3, downstream task datasets based on MSD-MXM are pre-processed with the BoW5K representation, which lacks the token sequential dependency information. As WE requires the reference embeddings where typically pre-trained token/word embeddings are used, we employ *glove-840B* [52] word embeddings. For training BE and WE embeddings, we only use half of the songs uniformly sampled from MSD-MXM (118, 831/237, 662) to consider the scenario where lyrics are only available for a subset of songs. For datasets with the full texts available, we employ BE and WE pre-trained on a subset of a proprietary lyrics corpus containing 3 million unique lyrics.

⁴ For efficient evaluation, we compute estimates per fold by averaging nDCG over 5 randomly sampled subsets of 3000 users. It is shown that the estimation error is marginal, not impacting the overall conclusion.

⁵ <http://millionsongdataset.com/tasteprofile/>

⁶ The BoW5K matrix becomes dense after this adjustment, which still is tractable for computing BE and WE, due to the word truncation at 5000. However, for a large scale dataset, we suggest to set $\gamma = 1$, which disregards the prior but significantly improves computational efficiency.

⁷ We use implementations from the vectorizers package.

4.4.2 Regression Model for TLE_R

For the enhancement model for TLE_R , we apply multivariate linear ridge regression where the regularizer $\mathcal{R}(\Theta) = \|\Theta\|$ and the optimal α is selected from the range $\{10^p : p = [-6, -5, \dots, 5, 6]\}$ via cross-validation.

4.4.3 Downstream Task Pre-processing & Models

We apply standardization followed by Principal Component Analysis (PCA) to embeddings at 99.9% explained variance ratio with whitening. This is especially useful for combined audio-lyrics embeddings in order to balance the contribution of each modality.

For *Tagging* tasks, we apply ridge logistic regression, populated per tag to handle the multi-label classification problem. The regularization coefficient is found by cross-validation, from the same range used for the regressor described in Section 4.4.2.

For the *RecSys* task, we employ item K-Nearest Neighbor (itemKNN) [53]. For each song, it computes and caches the K most similar songs by measuring cosine distances between song embedding vectors, which results in a sparse song-song similarity matrix. Later, it serves songs that are most similar to the users previously listened songs by employing this similarity matrix. Finally, the optimal K is found by cross validation per fold in each feature/dataset combination from the range of [20, 50, 100, 200, 500, 1000, 2000].

5. RESULTS & DISCUSSION

5.1 Are LE in general useful for MIR tasks?

Although our main focus is the effectiveness of TLEs on MIR tasks, we briefly discuss its ideal counterpart, LE. Our main interest is whether LE outperforms the baseline scenario where *only the audio embedding is used*, compared to scenarios where LE is either used alone or in combination with audio embeddings for downstream tasks. As Figure 2 suggests, LE (round points in pink) outperforms the baseline (dashed horizontal line) particularly when the task is lyrics focused (i.e., MSDSnippetLT, MSDFullLT, InternalLT), or when the combined lyrics and audio embedding is given to downstream task models (i.e., the three “+Audio” columns to the right of each grouping). It is notable that a performance improvement is observed on most of the tagging datasets and one RecSys scenario (i.e., InternalRec using MSLE) when LE is combined with audio embeddings. However, overall we observe a smaller effect for RecSys tasks. We assume that this is due to the smaller relative effect of LE against the baseline in those cases.

Comparing audio baselines, OpenL3 performs worse than MULE and MSLE on most tagging tasks (except MSDFullLT), while performing better in RecSys tasks. Despite these differences, we observe similar trends regarding the performance of LEs compared to those baselines.

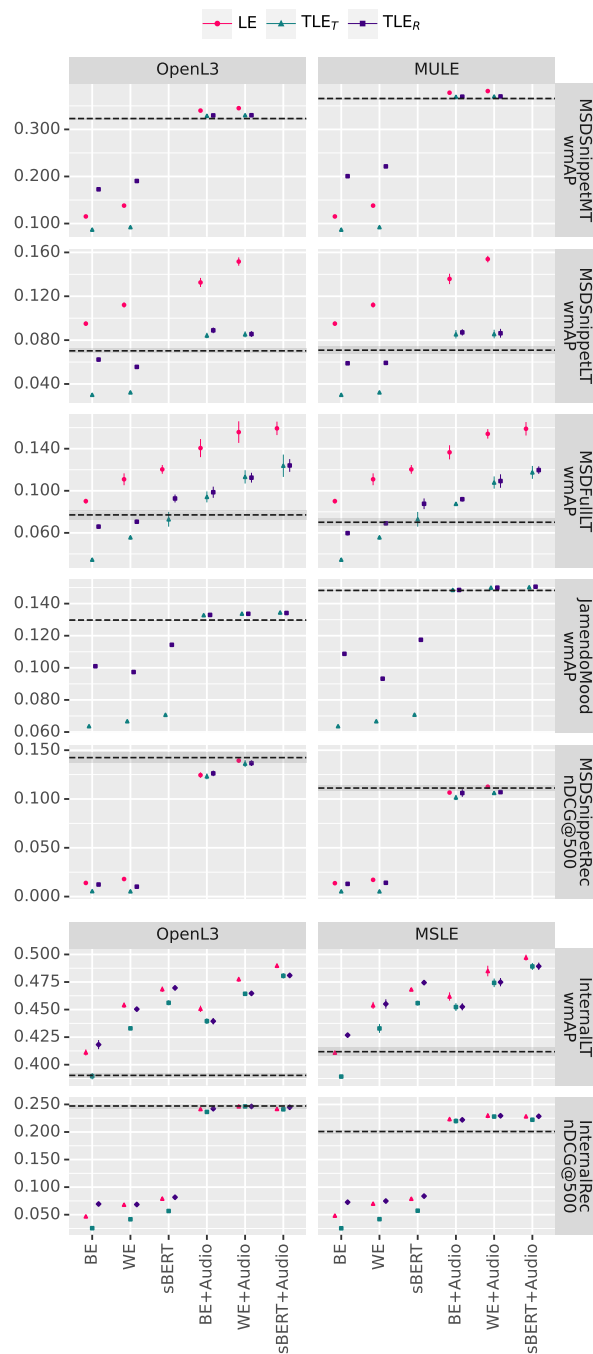

Figure 2. Each sub-figure corresponds to one dataset (row) and audio embedding (column). x and y axes represent embedding combinations and performance measures per task, respectively. Dashed horizontal lines and the shaded gray area in each figure represents the average performance and confidence interval when only the audio embedding is used. Each other point and vertical bar indicates the average performance and confidence interval of an embedding combination. We set confidence intervals at 95%.

5.2 Does TLE_T provide complementary information to audio embeddings?

In practice, the confirmed effectiveness of LE is unlikely to be helpful due to limited access to ‘ground-truth’ lyrics. Regardless, our results indicate that TLE_T can also achieve better testing performance compared to audio-only base-

lines, similar to LE.

We observe degradation of performance compared to LE in most of the cases, which is expected due to the transcription error of the ALT process. The error can be seen in Figure 3, where we measure the cosine similarity between corresponding pairs of LE and TLEs. This suggests that the transcription error can be severe such that the cosine similarity of a large number of pairs approaches 0 (i.e., MSDSnippetLT, MSDFullLT).

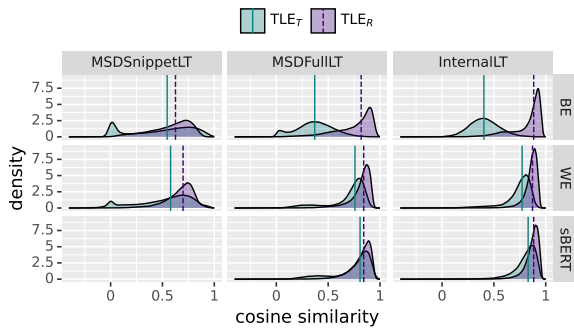

Figure 3. Distribution of cosine similarities measured between pairs of TLE_T – LE and TLE_R – LE, respectively. Each sub-figure represents the result per dataset and lyrics embeddings tested. Vertical bars denote the median.

However, TLE_T , even with such transcription errors and hence a loss of fidelity in the resulting embeddings, still provides meaningful performance gains when compared to an audio-embedding-only scenario. This is especially true on lyrics focused tasks or when combining the audio and (noisy) lyrics embeddings. In JamendoMood and MSDSnippetMT, where the lyrics data is not available upfront or the task is not focused on lyrics, we still observe that TLE_T combined with audio features outperforms audio embeddings alone.

This implies that one can build lyrics-based ML systems that can be applied to all the songs in the catalog of interest, with an expectation of a performance gain compared to models solely dependent on audio embeddings.

Comparing the performance of TLE_T between MSDSnippetLT and MSDFullLT, it is notable that the truncation of transcribed lyrics influences the effectiveness of the resulting embeddings. This suggests that providing full-length lyrics transcripts where possible is important.

5.3 Does TLE_R further improve TLE_T ?

Next, we focus on TLE_R which applies regression on top of TLE_T . Ideally, we would expect that the regression improves the fidelity of TLE_T , which likely results in an improved downstream task performance. First, we can confirm that the regression indeed improves the fidelity, as suggested by Figure 3. Measured on the testing samples of matching pairs of LE and TLE_R , the average cosine similarity is improved in all the cases. The effect is more obvious when the initial TLE_T has lower fidelity (i.e., BE, MSDSnippetLT). This indicates that the regression does increase the fidelity to some degree.

However, on the downstream tasks, the effect is not as consistent as in the cosine similarity (fidelity) result. In the case where the audio embedding is not included as input, the result indicates that TLE_R improves the downstream performance over TLE_T , sometimes even outperforming corresponding LEs (i.e., MSDSnippetMT, InternalLT). However, once combined with audio embeddings, the effect is not as distinct. While overall a small positive effect is observed in the RecSys datasets, the effect in the tagging datasets seems to be less clear, with TLE_R generally performing on par with TLE_T .

One explanation could be that the concatenation of audio embeddings for downstream tasks would eventually provide the same degree of audio information for TLE_T as already provided for TLE_R . The regression of TLE_R is conditioned both by TLE_T and the audio embedding, and thus would likely inherit the audio information. This is a possible explanation for the cases where TLE_R outperforms both LE and TLE_T . Similarly, TLE_T combined with the audio embedding explicitly fusing the two modalities via concatenation, shows performance that is on par with TLE_R in most of the cases.

6. CONCLUSION & FUTURE WORK

In this work, we introduce and assess transcription-based lyrics embeddings which tackles the problem of lyrics availability. An experiment is conducted to evaluate the effectiveness of TLEs in popular MIR downstream tasks, assessed against two comparisons, namely ‘ground-truth’ lyrics embeddings and audio embeddings. The result indicates that TLEs perform generally in between these two contenders, especially when combined with audio embedding and on the lyrics-focused tasks. This implies that TLEs can be an effective approach to be applied in lyrics-relevant MIR tasks where lyrics are often unavailable.

In particular, our results suggest that TLE_T is a simple, yet effective method for various downstream tasks when combined with audio embeddings. It is shown to complement audio embeddings by improving performance when combined with them. These gains can be achieved by using only off-the-shelf pre-trained models, while not requiring any access to ‘ground-truth’ lyrics whatsoever. Additionally, this approach does not require any subsequent refinement processes as is the case with TLE_R .

Furthermore, we identify some areas of exploration by which TLE could be improved: 1) end-to-end learning that directly associates the audio and LE to potentially improve the quality of TLE_R and avoids the transcription process, 2) instead of a simple linear regression model, more advanced methods such as semi-supervised learning [54] could further improve the fidelity of TLE_R . Additionally, 3) using context vectors from DL-based ALT models could be a viable alternative TLE, which bypasses the lyrics text embedding models. Finally, 4) while not the main focus due to the prevalence of English language in the data, multi-lingual transcription and embedding models could further improve the results in a more general setup.

ABSTRACT

It is a well known fact that the dynamics in piano performance gives significant effect in expressiveness. Taking the polyphonic nature of the instrument into account, analysing information to form dynamics for each performed note has significant meaning to understand piano performance in a quantitative way. It is also a key element in an education context for piano learners.

In this study, we developed a model for estimating MIDI velocity for each note, as one of indicators to represent loudness, with a condition of score assuming educational use case, by a Deep Neural Network (DNN) utilizing a U-Net with Scaled Dot-Product Attention (Attention) and Feature-wise Linear Modulation (FiLM) conditioning. As a result, we prove that effectiveness of Attention and FiLM conditioning, improved estimation accuracy and achieved the best result among previous researches using DNNs and showed its robustness across the various domain of test data.

1. INTRODUCTION

In the realm of piano performance, the loudness of each note plays a pivotal role, alongside other factors such as tempo and precise keystrokes [1]. When analyzing piano performances, the loudness of each note is quantitatively represented by MIDI velocity. Given the polyphonic nature of the piano, measuring the overall loudness within a specific timeframe fails to provide meaningful insights into the performance's quality. Loudness can be observed at various granularities, ranging from note-level loudness and frame-level aggregated loudness to the transcription of symbolic loudness representations. Each note in a piano performance can exhibit varying loudness levels, contingent on the music's texture [2, 3]. The unique loudness of each note, especially in the context of the piano's polyphonic attributes, holds significant meaning. Mastery over the loudness of individual notes is paramount, particularly in educational settings. To hone this control, score information serves as an essential benchmark. Visualization

further enhances this educational endeavor [4]. Consequently, this study operates under the assumption that score information is accessible.

To ensure clarity in our terminology, we define "loudness" as the aggregated MIDI velocities within a designated timeframe, as gauged by an electronic piano device. In contrast, "intensity" refers to the peak value of the frequency sum for a note frame, as delineated in [5]. It is imperative to recognize that MIDI velocity does not directly correspond to the loudness as perceived by the human auditory system. Previous research has probed the relationship between MIDI velocity and perceived loudness in decibels (dB) [6,7]. These investigations consistently reveal a non-linear relationship, where an increase in MIDI velocity corresponds to a rise in perceived loudness.

Furthermore, studies such as those by [8, 9] have explored the mapping from perceptual loudness values in dB scale to dynamic symbols in piano performance, including symbols like *forte*, *mezzoforte*, *piano*, *pianissimo*, *crescendo*, and so forth. The dynamics and expressiveness of a musical composition are shaped by the loudness values attributed to each note in the score [1]. Notably, MIDI velocity offers a more nuanced prediction of loudness compared to traditional dynamic markings found in most music scores. These markings provide relative directives on the loudness with which a piece should be played. The loudness of individual notes in a piano performance can fluctuate based on the texture of the music [2,3]. Given the polyphonic characteristics of piano performances, note-level loudness is of paramount importance.

Recognizing the significance of delving into note-level loudness granularity, this study primarily centers on MIDI velocity estimation, particularly within an educational context where score information is presumed available.

2. RELATED WORK

In this section, we delve into pertinent works within the domain of Machine Learning methods and their applications for the task.

Note Level Intensity Estimation: The task of note-level loudness estimation has been the focus of multiple studies [5, 10–13]. These investigations have utilized both Non-Negative Matrix Factorization (NMF) and DNN methodologies to segregate piano performance audio into 88 distinct keys, subsequently estimating MIDI velocity or intensity for each note. This research domain can be

viewed as an extension of Automatic Music Transcription (AMT) and Music Performance Assessment, with potential applications in modeling performance expressiveness. The task of piano note-level MIDI velocity estimation is multifaceted, encompassing both a regression problem, where MIDI velocity values within the 0-127 range are estimated, and an audio classification challenge, which categorizes audio into one of the typical 88 piano keys. A limited number of studies have tackled the note-level MIDI velocity estimation task for an actual piano performance data, employing techniques like NMF [5] and DNN methods [13, 14]. The study by [5] integrated with score information to estimate note-level intensity, subsequently developing a linear regression model for note-level MIDI velocity estimation. The DNN methods [13] have sought to address the estimation challenge by incorporating AMT techniques and score conditioning. These DNN architectures amalgamate convolution blocks and GRU blocks, introducing FiLM conditioning generated by a fully connected linear layer. A diffusion model together with FiLM conditioning [14] inserts a score and performance audio information for its generative task to express note frames with MIDI velocity information. While the DNN approach did not outperform the NMF method, it marked a pioneering effort to estimate MIDI velocity using DNNs, aiming to create a model that could generalize to unseen classical music inputs, in contrast to the NMF method that optimizes parameters for individual test data. In our research, we juxtapose our findings with these preceding studies.

U-Net: The U-Net architecture incorporates layered residual connections. The concept of a residual network emerged as a solution to counteract the vanishing or exploding gradient issues encountered during the DNN training phase. U-Net has been employed for piano performance transcription, specifically for reconstructing spectrograms [15]. Its efficacy in music source separation tasks within the field of music information retrieval is well-documented. Notably, research has been conducted on a FiLM-conditioned U-Net for music source separation [16]. In our study, we leverage a U-Net structure with convolutional layers to process the mel spectrogram, a two-dimensional representation of audio. We anticipate that the U-Net will enhance classification accuracy, converting audio to the 88 piano keys.

Feature-wise Linear Modulation (FiLM): Our study employs FiLM conditioning to integrate score information, aiming to estimate note-level MIDI velocity for piano performances [17]. Historically, FiLM conditioning has found applications in image processing, yielding enhanced results when conditioned with natural language for tasks like object detection [17]. This concept has been extended to audio source separation tasks, where audio is conditioned with supplementary information such as video and scores [18]. Structurally, FiLM encompasses neural network layers that produce an affine transformation for a specified input layer. It integrates a base DNN, trained in a supervised manner, with a condition generator. This generator processes conditions, such as scores, to produce the

parameters β and γ for an element-wise affine transformation in the latent space of the base DNN. Mathematically, this is represented as: $FiLM(x) = \gamma(z) \cdot x + \beta(z)$. Here, the vector z serves as the conditional vector. Figure 1 visually represents the FiLM conditioning architecture, illustrating how the condition embedding model generates the parameters β and γ for the affine transformation on the latent vector x derived from the base DNN.

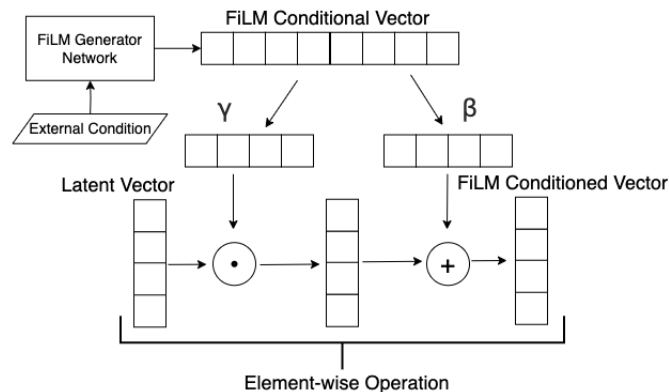

Figure 1. Visualization of FiLM operation

The Scaled Dot-Product Attention (Attention): The Attention, introduced by [19], has been instrumental in advancing the field of deep learning. This mechanism computes attention weights by scaling the dot products of queries and keys, which facilitates a dynamic focusing of the model on relevant parts of the input data. Its efficiency and simplicity allow for significant improvements in model performance by enabling the capture of long-range dependencies within the data, without the constraints imposed by previous sequence processing models. The architecture is utilised in an image processing area [20] and a speech processing area [21] together with U-Nets. This mechanism has also been applied to music information retrieval such as source separation [22] and showed its performance together with computational efficiency for the task. These researches show that the Attention mechanism works for capturing its target information from complex input data.

Our model incorporates this Attention within the U-Net architecture to leverage its proven benefits, thereby enhancing our model’s ability to understand and generate nuanced responses based on the context provided by the input sequence in a musical sense.

3. METHOD

Figure 2 illustrates the comprehensive architecture of our proposed model. Initially, the model processes audio input, transforming it into a Log Mel-frequency Spectrogram. This transformation facilitates the conversion of the waveform into an image-like format. The audio processing parameters include a window length of two seconds, a hop size of one second, and a sampling rate of 16k Hz, resulting in a model output resolution of 100 frames per second. The overarching model architecture can be cate-

Figure 2. The entire architecture of the proposed model.

gorized into three distinct convolutional blocks, as showcased in Figure 3.

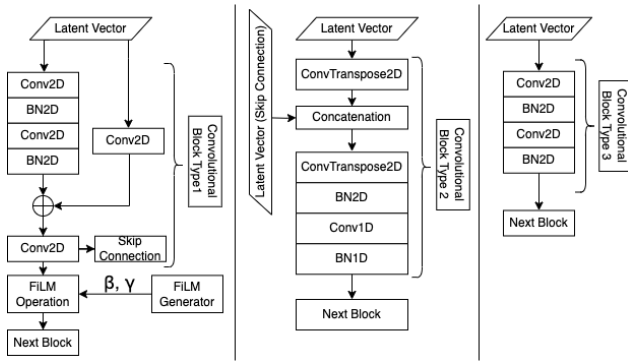

Figure 3. Schematic of the three convolutional blocks utilized in the model.

Convolutional blocks of type 1 and 2 collectively form the U-Net structure. Type 1 blocks also play a pivotal role in encoding note frame information. In this study, note frames are derived from a MIDI roll. Corresponding blocks in the encoding phase generate FiLM conditioning parameters, denoted as β and γ , for each affine transformation. Several methods for inserting FiLM parameters are described in [16]. In our model, through empirical study, we generate parameters to ensure element-wise correspondence for each latent space vector, as depicted in Figure 1. Consequently, each output from the score encoders generates twice as many parameters for the output of each block in the encoder of the U-Net.

To ensure uniformity in the processed latent features, we employ convolutional layers of the same hierarchical level to produce FiLM parameters for each layer within the U-Net. For the skip connections, non-conditioned latent vectors from each block are relayed to the corresponding type 2 block, while FiLM-conditioned latent vectors are channeled to the subsequent layer of the type 1 block.

In the decoder section of the U-Net architecture, Attention modules are incorporated before each convolutional

block type 2. This configuration enhances the network’s ability to focus on relevant features by dynamically adjusting the importance of different areas of the input image. The Attention mechanism, which calculates attention scores by scaling the dot-product of queries and keys, enables the model to prioritize specific features over others, improving the precision of MIDI velocity estimation.

The construction block consists of convolutional block type 3 followed by the block containing bi-directional GRU. It processes inputs through a sequence of layers including linear transformations for dimensionality reduction based on the input feature type, batch normalization, and a bidirectional GRU for capturing temporal dynamics. The network concludes with a fully connected layer applying a sigmoid function to output note frames with velocity information. Dropout and ReLU activations are utilized throughout to enhance performance and prevent overfitting.

For training our model, we employed the MAESTRO dataset [23]. MAESTRO is a dataset composed of about 200 hours of virtuosic piano performances captured with fine alignment (up to 3 ms) between note labels and audio waveforms. Notably, other DNN models targeting MIDI velocity estimation, such as [13] and [14], have also employed this dataset. This usage facilitates a more legitimate comparison of model performance across different studies.

Our chosen loss function, represented by Eq. 1, amalgamates the $l1$ loss and the Binary Cross-Entropy (BCE) loss. This design facilitates back-propagation of losses for both classification and regression tasks.

$$Loss = \theta \cdot l1 \text{ loss} + (1 - \theta) \cdot BCE \text{ loss} \quad (1)$$

Here, $\theta \in [0, 1]$ signifies the weight for the $l1$ and the BCE loss. For our empirical setup, we set θ to 0.5. The $l1$ loss function, as defined in Eq. 2, is articulated as:

$$l1 \text{ loss} = \frac{\sum_i |V(i)_{\text{ground truth}} - V(i)_{\text{model output}}|}{N} \quad (2)$$

In this equation, $V(i)$ represents MIDI velocity with the index i of corresponding notes between the ground truth and the model output within a specified window, while N denotes the total number of notes present in that window. Each input data point spans two seconds, with each frame encompassing 100 segments per second to depict the MIDI roll. The velocities used to compute the loss are normalized to the range $[0, 1]$ to match the scale of the BCE.

For the evaluation phase, we employed the Saarland Music Data (SMD) dataset [24]. SMD provides audio recordings along with perfectly synchronized MIDI files for various piano pieces. The pieces were performed by students of the Hochschule für Musik Saar on a hybrid acoustic/digital piano (Yamaha Disklavier). We selected 49 excerpts from this dataset, consistent with the test sets used in prior studies [5, 13, 14], ensuring a fair and comparable assessment. The model's error is quantified using the formula presented in Eq. 3:

$$Error = \frac{\sum_i |V(i)_{\text{ground truth}} - V(i)_{\text{inference}}|}{N} \quad (3)$$

In this equation, i represents individual notes, and N denotes the total number of notes accurately identified in the score. The inferred MIDI velocity is determined by the peak value within the interval of each detected and categorized velocity frame, juxtaposed with the ground truth velocity frame for the respective note. This approach is adopted because the detected velocity typically exhibits a peak followed by a decline in the estimated MIDI velocity within a note frame, mirroring the attack and decay patterns of each note's loudness. Differently from loss function, the output values are not normalised but are scaled to the range $[0, 127]$. The recall score serves as our primary evaluation metric for classification accuracy, given that the model's output is constrained by the provided score information.

4. RESULTS AND DISCUSSION

Result and Comparison: Table 1 presents the comparative outcomes of our model against previous works in the field. The proposed model consistently outperforms other DNN-based methods across all metrics, demonstrating notable improvements. The enhancements are particularly evident when comparing the best and worst outcomes of our model with those of other models. The results highlight that the U-Net designed with Attention and FiLM conditioning with score information significantly boosts performance.

Among the test set, the most favorable outcome is observed for "Bach BWV875-01 002," which recorded mean error, standard deviation, and recall values of 4.6, 3.3, and 95.6%, respectively. Conversely, "Chopin Op028-17" exhibited the least favorable results for mean error and standard deviation, with values of 16.0 and 11.9 respectively, and a recall of 87.5%. Additionally, "Ravel Jeux d'eau" demonstrated the lowest recall score in the dataset

Model	Mean	SD	Recall
DNN Based Model			
DiffVel [14]	19.7	13.1	53.0%
Convolutional Net [13]	15.1	12.3	85.8%
Proposed Model	9.9	7.8	89.7%
NMF Based Model			
Score-Informed NMF [5]	4.1	5.0	N.A.

Table 1. Comparative results of models for note-level MIDI velocity estimation with score information. SD: Standard Deviation

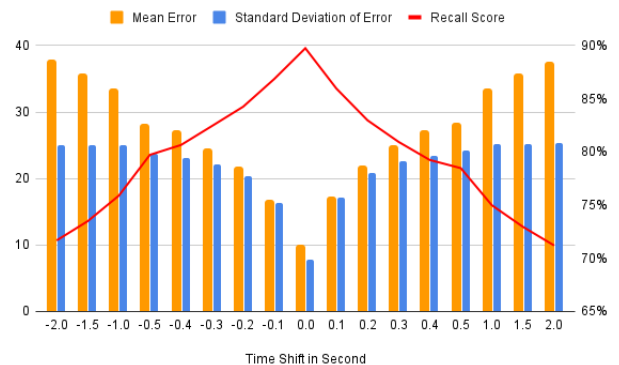

Figure 4. Mean and SD of errors for misaligned score information

at 80.7%, with corresponding mean error and standard deviation values of 12.1 and 10.2. These results illustrate the varied performance of our model across different musical pieces, underscoring its effectiveness as well as areas for potential improvement.

The analysis also highlights the strengths and weaknesses of both DNN and NMF-based methods. DNNs are capable of capturing complex relationships within the training data due to their nonlinear nature, but they are computationally demanding and require extensive data to optimize parameters effectively. In contrast, NMF-based methods, such as the one described by [5], optimize parameters for individual excerpts using score information in the test set, offering a more tailored approach. This specificity, however, can limit their generalizability compared to DNNs, which aim to develop a more generic model suitable for diverse musical excerpts. Notably, the proposed model is trained on a distinct domain, specifically a piano performance dataset different from the test set, to ensure a fair comparison and robust assessment of its performance. This strategy helps in evaluating the model's ability to generalize across different musical contexts effectively.

Misaligned Condition Insertion: In real-world applications, alignment discrepancies frequently occur between scores and their corresponding audio, affecting the accurate feeding of note frames. Figure 4 elucidates the model's sensitivity to temporal misalignments, exhibiting a correlation between the degree of time shift and the model's performance metrics.

These shifts are synthetically generated by inserting the

conditions a specified number of seconds ahead or behind each input frame, with a two-second duration per input. It is clear that misaligned data affects to the model accuracy proportionally. Addressing this misalignment, data augmentation can be employed during the training phase to acclimate the model to varying degrees of data condition misalignments, thereby enhancing its flexibility.

Nonetheless, this alignment challenge may become negligible with the integration of a dedicated note frame detection model, as delineated by models like the one in [25]. Utilizing such models for precise note frame detection allows for a subsequent, more accurate analysis of MIDI velocity estimation by the proposed model, streamlining the workflow and potentially increasing performance accuracy.

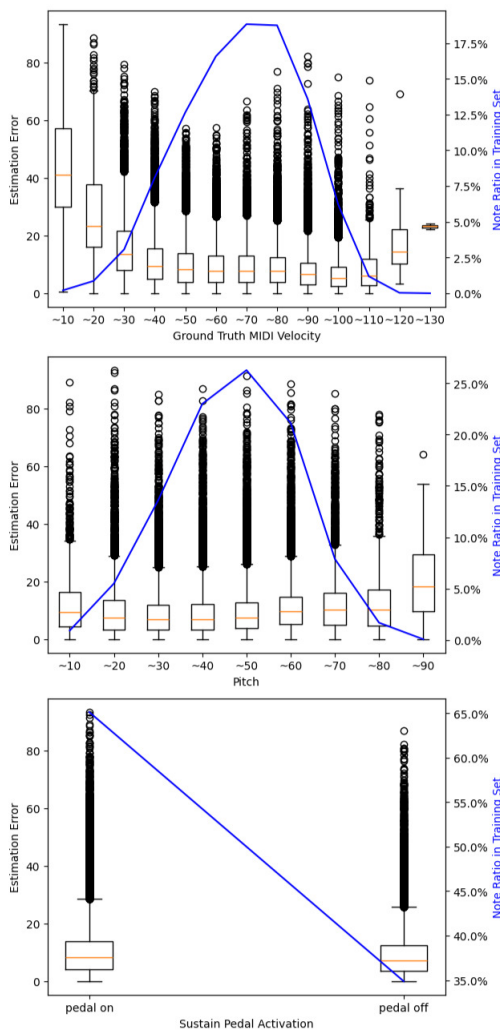

Figure 5. Error distributions based on various ground truth aspects: pitch, sustain pedal activation, and MIDI velocity intervals together with the ratio of notes appeared in the training set.

Error Analysis: Further analysis was conducted to evaluate the error distribution across different pitch groups, ground truth MIDI velocities, and sustain pedal activation states, as depicted in Figure 5. The analysis indicates that error is inversely correlated with the volume of data in the

training set: the greater the quantity of data processed by the model, the more accurate the MIDI velocity estimates, highlighting the benefits of extensive data representation.

The results further reveal that enhanced training data volumes lead to improved estimation outcomes across various data dimensions. This suggests that applying data augmentation to achieve a balanced distribution in pitch and velocity bins can result in higher estimation accuracy. However, such augmentation must maintain the musico-logical context, including harmony and expressiveness, making this a complex yet critical task for effective model training.

Ablation Study: In our ablation study, we evaluate the individual and combined contributions of FiLM conditioning and the Attention modules to our model’s performance, based on the U-Net architecture. These components were chosen for their theoretical abilities to enhance feature representation and focusing mechanisms, respectively. The study aims to clarify their roles within our proposed deep neural network architecture. We examine four configurations of our model: (i) with both FiLM and Attention (proposed model), (ii) with FiLM but without Attention, (iii) with Attention but without FiLM, and (iv) without either FiLM or Attention, as shown in Table 2.

Model Configuration	Mean	SD	Recall
With FiLM:			
With Attention	9.9	7.8	89.7%
Without Attention	10.0	7.8	89.4%
Without FiLM:			
With Attention	12.1	10.5	73.0%
Without Attention	13.0	10.5	68.5%

Table 2. Ablation Study: Detailed Performance Comparison Highlighting the Impact of FiLM Conditioning and Attention.

The ablation study highlights the significant impact of FiLM Conditioning and a relatively lesser contribution from the Attention in enhancing the performance of the proposed model. The observed synergy when integrating these modules indicates a promising avenue for future research and development in deep neural network architectures. While the Attention module improves model performance, its effectiveness is not as pronounced as that of FiLM Conditioning. This suggests that the model’s ability to concentrate on relevant features, and thereby its predictive performance, is significantly enhanced by FiLM Conditioning. Notably, we could see universal improvement on the recall score on all the excepts on the test set in any comparison among combination of (i) to (iv).

According to Table 1, the study also demonstrates that incorporating a U-Net mechanism, particularly its skip connections, can enhance accuracy for the task at hand, outperforming previous models.

Robustness of the Model: We conducted a comparative analysis against the state-of-the-art transcription model that additionally estimates the MIDI velocity [26]. The results, detailed in Table 3, indicate that our proposed

model achieves comparable performance in MIDI velocity estimation. Notably, our model demonstrates enhanced robustness across various test datasets, as evidenced by the recall scores, in comparison to the model proposed by [26] which is also trained on the MAESTRO dataset.

Model	Mean	SD	Recall
Proposed Model	9.9	7.8	89.7%
The hFT Model [26]	9.9	7.3	78.0%

Table 3. Comparison to the SOTA Transcription Model

This comparison highlights the efficacy of our model, particularly in its ability to generalize across different datasets, which is crucial for practical applications. The fact that both models yield identical mean scores for MIDI velocity estimation but our model exhibits a higher recall rate suggests our model’s capability in accurately capturing the nuances of musical expression. Furthermore, despite the slightly higher standard deviation in our model’s performance, the significantly higher recall rate underscores its robustness and reliability in diverse testing scenarios. This finding is particularly relevant for applications requiring high fidelity in musical transcription and velocity estimation, indicating a promising direction for future research and development in music transcription technologies. Also the ablation study indicates that adding FiLM conditioning can improve the model accuracy for the task, after experimental process of designing the parameter generators and methods to insert the parameters, which yields another research topic.

5. CONCLUSION AND FUTURE WORKS

In this study, we explored the complexities of MIDI velocity estimation, leveraging an U-Net architecture enriched with the Attention and FiLM conditioning to integrate score information. Our results underscore the superiority of this approach among DNN methodologies. Our empirical evaluations further attest to the pivotal role of FiLM conditioning in bolstering result accuracy. This enhancement transcends specific model architectures, with FiLM conditioning amplifying precision across various models, ranging from feed-forward designs with convolution and GRU blocks to diffusion models, combining the previous researches [13, 14]. The Attention also contributes to improve on both MIDI velocity estimation and recall score. The model also showed that comparable results towards SoTA transcription model and the robustness across the sources of test set compared to other state of the art transcription models which also estimates MIDI velocity.

Generally, FiLM conditioning has proven effective for MIDI velocity estimation tasks. Enhanced transcription of note onset, offset, and frames could further refine performance, positioning this model as a robust solution for MIDI velocity estimation across diverse datasets. This suggests that utilizing DNN models, such as the onsets and frames model proposed by [25], which demonstrates superior accuracy in note frame detection without FiLM

conditioning, could be advantageous. In situations where score data are not available, a cascaded approach can be employed: first, use a DNN for accurate note frame detection, and then leverage the detected MIDI for FiLM conditioning, circumventing the need for score-to-audio alignment.

As we look to the future, our objective is to expand the range of score information, transitioning from MIDI note frame to more comprehensive formats, MusicXML to be encoded. Such a shift is anticipated to offer increased resilience, especially in situations where achieving precise alignments poses challenges. Data augmentation on training data is also considered as crucial task for obtaining more robust estimation, as mentioned. Additionally, addressing issues such as omitted notes and extraneous notes is essential to tailor the model more effectively for educational applications, catering to both novice learners and seasoned professionals, considering currently the set up only considers the student is god enough to follow the score for performance visualization purposes.

The potential applications of this research are manifold, extending from the development of visualization tools that bolster musical communication to advanced transcription techniques. Such annotations, especially those denoting expressiveness, carry significant implications, particularly in pedagogical contexts where teacher-student interactions are crucial.

The code and model developed for this study are available upon request.

ABSTRACT

Existing text-to-music models can produce high-quality audio with great diversity. However, textual prompts alone cannot precisely control temporal musical features such as chords and rhythm of the generated music. To address this challenge, we introduce MusiConGen, a temporally-conditioned Transformer-based text-to-music model that builds upon the pretrained MusicGen framework. Our innovation lies in an efficient finetuning mechanism, tailored for consumer-grade GPUs, that integrates automatically-extracted rhythm and chords as the condition signal. During inference, the condition can either be musical features extracted from a reference audio signal, or be user-defined symbolic chord sequence, BPM, and textual prompts. Our performance evaluation on two datasets—one derived from extracted features and the other from user-created inputs—demonstrates that MusiConGen can generate realistic backing track music that aligns well with the specified conditions. We open-source the code and model checkpoints, and provide audio examples online, https://musicongen.github.io/musicongen_demo/.

1. INTRODUCTION

The realm of text-to-music generation has seen significant progress over the recent years [1–11]. These models span various genres and styles, largely leveraging textual prompts to guide the creative process. There have been two primary methodological frameworks so far. The first employs *Transformer* architectures to model audio tokens [12] derived from pre-trained audio codec models [13–15]; noted examples include MusicLM [1] and MusicGen [2]. The second employs *diffusion* models to represent audio through spectrograms or audio features, such as AudioLDM 2 [4] and JEN-1 [5].

Text-to-music generation model generally relies on the global textual conditions to guide the music generation process. Textual prompts serving as high-level conceptual guides, however, introduce a degree of ambiguity and verbosity into the music generation for describing the musi-

Model	Chord control	Rhythm control	Do not need reference audio

Music ControlNet [7]		✓	✓
Ours	✓	✓	✓

Table 1. The comparison for conditions and condition type of related temporally-conditioned text-to-music models.

cal features [7]. This inherent vagueness poses a challenge in precisely controlling temporal musical features such as melody, chords and rhythm, which are crucial for music creation. Building on the success of MusicGen-melody [2] in melody control, our focus now shifts to enhancing chord and rhythm control, aiming to create a more integrated approach to music generation that captures the full spectrum of musical elements.

Table 1 tabulates two existing studies that have explored the incorporation of time-varying chord- and rhythm-related attributes in text-to-music generation. Coco-Mulla [6] is a Transformer-based model that employs a large-scale, 3.3B-parameter MusicGen model, finetuned with an adapted LLaMA-adapter [16] for chord and rhythm control. For rhythm control in particular, Coco-Mulla uses drum audio codec tokens extracted from a reference drum audio signal as a condition for guiding the music generation, thereby demanding *reference audio* for control. While it is appropriate to assume the availability of such *reference audio* in some scenarios, for broader use cases we desire to have a model that can take user-provided *text*-like inputs as well, such as the intended beats-per-minute (BPM) value (for rhythm) and the chord progression as a series of chord symbols (for chords). This function is not supported by Coco-Mulla.

The other model, Music ControlNet [7], leverages a diffusion model architecture and the adapter-based conditioning mechanism of ControlNet [17] to manipulate text-like, symbolic melody, dynamics, and rhythm conditions. This diffusion model creates a spectrogram based on the provided conditions, which is then transformed into audio using their pretrained vocoder. For musical conditions, a 12-pitch-class chromagram representation is used for the melody, combined with beat and downbeat probability curves concatenation for rhythm control, and an energy curve to adjust the dynamic volume. However, Music ControlNet does not deal with chord conditions.

Yang, “MusiConGen: Rhythm and Chord Control for Transformer-Based Text-to-Music Generation”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

In view of the limits of the prior works, we introduce in this paper MusiConGen, a Transformer-based text-to-music model that applies temporal conditioning to enhance control over rhythm and chord. MusiConGen is finetuned from the pretrained MusicGen framework [2]. We design our temporal condition controls in a way that it supports not only musical features extracted from reference *audio* signals, but also the aforementioned user-provided *text-like* symbolic inputs such as BPM value and chord progression. For effective conditioning of such time-varying features, we propose “adaptive in-attention” conditioning by extending the in-attention mechanism proposed in the MuseMorphose model [18]. Table 1 includes a conceptual comparison of MusiConGen with existing models in terms of the conditions and their types.

In our implementation, we train MusiConGen on a dataset of *backing track music* comprising 5,000 text-audio pairs obtained from YouTube. This training utilizes beat tracking and chord recognition models to extract necessary condition signals without the need for manual labeling. We note that rhythm and chord controls are inherently critical for backing tracks, for backing tracks often do not include the primary melody and their purpose is mainly to provide accompaniment for a lead performer.

Moreover, instead of using the adapter-based finetuning methods [16, 17, 19], we apply the straightforward “direct finetuning” approach to accommodate the domain shift from general instrumental music (on which MusicGen was trained) to the intended backing track music. We leave the use of adapter-based finetuning as future work. To make our approach suited for operations on consumer-grade GPUs, we propose a mechanism referred to as “jump finetuning” instead of finetuning the full MusicGen model.

We present a comprehensive performance study involving objective and subjective evaluation using two public-domain datasets, MUSDB18 [20] and RWC-pop-100 [21]. Our evaluation demonstrates MusiConGen’s enhanced ability to offer nuanced temporal control, surpassing the original MusicGen model in producing music that aligns more faithfully with the given conditions.

The contributions of this work are two-fold. First, to our best knowledge, this work presents the first Transformer-based text-to-music generation model that follows user-provided rhythm and chords conditions, requiring no reference audio signals. Second, we present efficient training configuration allowing such a model to be built by finetuning the publicly-available MusicGen model with customer-level GPU, specifically 4x RTX-3090 in all our experiments. We open-source the code, checkpoint, and information about the training data of MusiConGen on GitHub.¹

2. BACKGROUND

2.1 Codec Models for Audio Representation

In contemporary music generation tasks, audio signals are typically compressed into more compact representations

using two main methods: Mel spectrograms and codec tokens. Mel spectrograms provide a two-dimensional time-frequency representation, adjusting the frequency axis to the Mel scale to better align with human auditory perception. Codec tokens, on the other hand, are often residual vector quantization (RVQ) tokens that are encoded from audio signals by a codec model [13–15]. Following MusicGen, we employ in our work the Encodec (32k) [14] as the pretrained codec model to encode audio data at a sample rate of 32,000 Hz. This Encodec model comprises 4 codebooks, each containing 2,048 codes, and operates at a code frame rate f_s of 50 Hz.

2.2 Classifier-Free Guidance

Classifier-free guidance [22] is a technique initially developed for diffusion models in generative modeling to enhance the quality and relevance of the outputs without the need for an external classifier. This approach involves training the generative model in both a conditional and an unconditional manner, combining the output score estimates from both methods during the inference stage. The mathematical expression is as $\nabla_x \log \tilde{p}_\theta(x|c) = (1-\gamma)\nabla_x \log p_\theta(x) + \gamma\nabla_x \log p_\theta(x|c)$. Here, γ represents the guidance scale, which adjusts the influence of the conditioning information. We perform a weighted average of $f_\theta(x, c)$ and $f_\theta(x)$ when sampling from the output logits.

2.3 Pretrained MusicGen Model

The pretrained model used in our study is a MusicGen model with 1.5B parameters, equipped with melody control (i.e., MusicGen-Melody). The melody condition employs a chromagram of 12 pitch classes at a frame rate f_M , denoted as $\mathcal{M} \in \mathbb{R}^{T_{f_M} \times 12 \times 1}$, derived from the linear spectrogram of the provided reference audio. For text encoding, the model leverages the FLAN-T5 [23] as a text encoder to generate conditioning text embeddings, represented as $\mathcal{T} \in \mathbb{R}^{T_{t5} \times d_{t5} \times 1}$. Both the melody and text conditions undergo linear projection into a D -dimensional space before being prepended to the input audio embedding. Regarding the input audio for training, audio signals are initially encoded into RVQ tokens, $X_{rvq} \in \mathbb{R}^{T_{f_s} \times 1 \times 4}$, using the pretrained Encodec model. These tokens are then formatted into a “delay pattern” [2], maintaining the same sequence length. Subsequently, an embedding lookup table, $W_{emb} \in \mathbb{R}^{N \times D \times 4}$, where N represents for numbers of codes in a codebook, is used to represent the associated codes, summing contributions from each codebook of X_{rvq} to form the audio embedding $X_{emb} \in \mathbb{R}^{T_{f_s} \times D \times 1}$. The input representation is then fed to the self-attention layers via additive sinusoidal encoding.

3. METHODOLOGY

Our method seeks to efficiently finetune the foundational MusicGen model using time-varying symbolic rhythm and chord conditions as guiding conditions. To achieve this, we must carefully consider both the representation of these conditions and the finetuning mechanism as follows:

¹ <https://github.com/Cyan0731/MusiConGen>

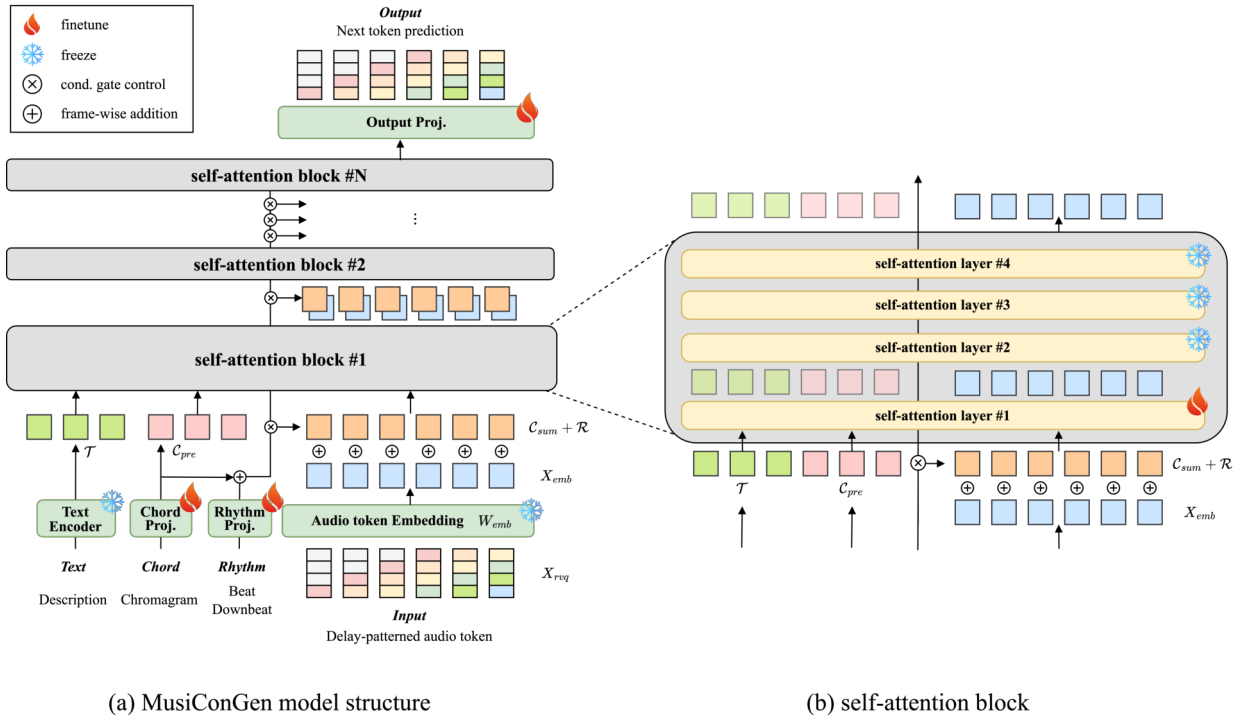

Figure 1. The model structure of MusiConGen and the self-attention block. a) MusiConGen takes text \mathcal{T} , downsampled chord C_{pre} as prepended condition and frame-wise chord C_{sum} and rhythm \mathcal{R} as additive condition. The addition operation of frame-wise conditions to each self-attention block is regulated by the condition gate control (\otimes). b) Each self-attention block consists of four layers. In our proposed model, only the first layer is finetuned, which is also called jump finetuning.

3.1 Representing Temporal & Symbolic Conditions

Chords. For chord condition, we employ two methods. The first **prepend** method is similar to the melody control method of MusicGen, denoted as $C_{pre} \in \mathbb{R}^{T_{f_M} \times 12}$ where C_{pre} maintains the same resolution (i.e. frame rate f_M and sequence length) as MusicGen’s melody condition \mathcal{M} . This allows us to utilize the pretrained melody projection weights from MusicGen as initial weights. Furthermore, we have noted that chord transitions can lead to asynchronization issues. To address this, we introduce a second **frame-wise** chord condition, $C_{sum} \in \mathbb{R}^{T_{f_s} \times 12 \times 1}$, which matches the resolution of the audio codec tokens, thus providing a solution for the synchronization problem.

Rhythm. To control rhythm, we derive conditions from both the beat and the downbeat. The beat represents the consistent pulse within a piece of music, and the downbeat signifies the first and most emphasized beat of each measure, forming the piece’s rhythmic backbone. We encode beat and downbeat information into one-hot embedding each at a frame rate of f_s . For the beat embedding, a soft kernel is applied to allow for a tolerance of 70ms. Subsequently, the beat and downbeat arrays are summed to yield the **frame-wise** rhythm condition $\mathcal{R} \in \mathbb{R}^{T_{f_s} \times 1}$.

3.2 Finetuning Mechanisms

The finetuning mechanism we employ consists of two parts: 1) jump finetuning, and 2) an adaptive in-attention mechanism. As illustrated in Figure 1, our proposed model activates condition gates at the “block” level, treating four

consecutive self-attention layers as a block.

Jump finetuning is designed to specifically target the *first* self-attention layer *within each block* for finetuning, while freezing the remaining three self-attention layers of the same block, as shown in Figure 1 (b). Doing so reduces the number of parameters of finetuning while maintaining the flexibility to learn to respond to the new conditions by refining the first self-attention layer per block.

The adaptive in-attention mechanism is designed to improve control over chords and rhythm. It is an adaptation of the in-attention technique of MuseMorphose [18], whose main idea is to augment every intermediate output of the self-attention layers with copies of the condition. Unlike the original implementation that augment all the self-attention layers, we selectively apply it to the first three-quarters of self-attention blocks (e.g., for a model with 12 blocks, in-attention is applied to first 9 blocks) to relax the control in the last few blocks for better balancing on rhythm and chords. This leads to better result empirically, as will be shown in Section 5.2 and Table 3.

4. EXPERIMENTAL SETUP

4.1 Datasets

We finetuned the model using a dataset of ~ 250 hours backing track music sourced from YouTube, comprising 5K songs across five genres: Rock, Funk, Jazz, Blues, and Metal, with 1K songs per genre. After preprocessing (see Section 4.2), the training data contained 80,871 clips.

For evaluation, we used the rhythm and chords from two public-domain datasets—MUSDB18 [20] and RWC-pop-100 [21]. For MUSDB18, the rhythm and chords are *extracted* from the audio signals, so this dataset reflects the case where the condition signals are from a *reference audio*. There are 150 songs with four isolated stems: vocal, bass, drum, and others. For each song, we dropped the vocals and divided the mix of the remaining tracks into 30-second clips, resulting in a total of 1,089 clips.

The RWC comprises 100 Japanese pop songs with human annotated chord progressions and BPM labels. We simply use the *human labels* as the conditions here, reflecting the case where the condition signals are user provided *in a text-like format*. We similarly divided each song into 30-second clips, leading to 755 clips in total.

4.2 Dataset Pre-processing Details

The training and evaluation datasets consist of full-song data, with durations ranging from 2 to 5 minutes per song. Below are the preprocessing details for each type of input:

Audios: All audio data have vocals removed. For the training and RWC dataset, we employed the source separation model Demucs [24, 25] to eliminate the vocal stem. In the MUSDB18 dataset, which already features isolated stems, we combined the bass, drum, and others stems to form the dataset. Each song was segmented into 30-second clips, ensuring each clip starts at a downbeat.

Descriptions: For the training set, the text prompts were simply extracted from the titles of the corresponding YouTube videos. For the two evaluation datasets, we tasked ChatGPT [26] to generate 16 distinct text prompts, covering the five genres included by the training set. Here is an example—“A smooth acid Jazz track with a laid-back groove, silky electric piano, and a cool bass, providing a modern take on Jazz. Instruments: electric piano, bass, drums.” At inference time, we randomly selected one of the 16 text prompts in a uniform distribution.

Chords: The RWC dataset comes with ground truth labeled chords. For both the training set and MUSDB18, we used the BTC model [27] as the chord extraction model to predict symbolic chords with time tags for each clip. The detailed chord quality extends to the seventh note. We then translated the extracted chord symbols with time tags into a 12-pitch chromagram in the order of C, C#, ..., B. The chromagram’s frame rate for the frame-wise condition \mathcal{C}_{sum} is f_s , and for the prepend condition \mathcal{C}_{pre} it is f_M .

Rhythm: Except for RWC, beat and downbeat were extracted using the RNN+HMM model [28] from the Madmom library [29]. The timing format for beats and downbeats was transformed into a one-hot representation matching the audio token frame rate f_s . A soft kernel was applied to the one-hot beat array to create a softened beat array. The rhythm representation \mathcal{R} was the frame-wise summation of the softened beat array and downbeat array.

4.3 Training Configuration

The proposed rhythm and chord-conditioned Transformer was built upon the architecture of the medium-sized (1.5B)

MusicGen-melody, featuring $L = 48$ self-attention layers with dimension $D = 1,536$ and 24 multi-head attention units. The condition dropout rate is 0.5 and guidance scale is set to be $\gamma = 3$ for classifier-free guidance. We finetuned only a quarter of the full model, which corresponds to 352 million parameters, while keeping both the audio token embedding lookup table and the FLAN-T5 text encoder frozen. The training involved 100K finetuning steps, carried out over approximately 2 days on 4 RTX-3090 GPUs, with a batch size of 2 per GPU for each experiment.

4.4 Objective Evaluation Metrics

We employed metrics to evaluate controllability of chords and rhythm, textual adherence and audio fidelity. For the first two metrics, we used the rhythm and chord conditions from a clip in a evaluation dataset to generate music (along with a text prompt generated by ChatGPT; see Section 4.2), applied the Madmom and BTC models on the generated audio to estimate beats and chords, and evaluated how they reflect the given conditions. See Figure 2 for examples.

Chord. We used the *mir_eval* [30] package to measure 3 different degrees of frame-wise chord correctness: **majmin**, **triads** and **tetrads**. The majmin function compares chords in major-minor rule ignoring chord qualities outside major/minor/no-chord. The triads function compares chords along triad (root & quality to #5), while the tetrads compares chords along tetrad (root & full quality).

Rhythm F1 measurement follows the standard methodology for beat evaluation. We measured the beat accuracy also via *mir_eval*, assessing the alignment between the beat timestamps of the generated music and the reference rhythm music data, with a tolerance window of 70ms.

CLAP [31, 32] score examines the textual adherence by the cosine similarity between the embedding of the text prompt and that of the generated audio in a text-audio joint embedding space learned by contrastive learning. Here, we used the LAION CLAP model trained for music [33], *music_audioset_epoch_15_esc_90.14.pt*.

FAD is the Fréchet distance between the embeddings distribution from a set of reference audios and that from the generated audios [34, 35]. The metric represent how realistic the generated audios are compared to the given reference audios. The audio encoder of FAD we used is VGGish [36] model which trained on an audio classification task. The reference set of audios was from MUSDB18 or RWC depending on the evaluation set.

4.5 Subjective Evaluation Metrics

We also did a listening test to evaluate the followings aspects: text relevance, rhythm consistency, and chord relevance. Text relevance concerns how the generated audio clips reflect the given text prompts. Rhythm consistency is about how steady the beats is within an audio clip. (We found that, unlike the case of objective evaluations, minor out-of-sync beats at the beginning of a clip were deemed acceptable here perceptually.) Chord relevance concerns how a generated clip follows the given chord progressions.

Model	Evaluation dataset	Rhythm	Chord			FAD	CLAP
		F-measure(%)	majmin(%)	triads(%)	tetrads(%)		
proposed ($\mathcal{C}_{pre} + \mathcal{C}_{sum} + \mathcal{R}$)	MUSDB18	69.76	67.03	66.19	56.91	1.29	0.34
	RWC	79.40	73.03	68.42	54.12	0.96	0.34
chords only ($\mathcal{C}_{pre} + \mathcal{C}_{sum}$)	MUSDB18	39.47	73.25	72.29	60.89	1.91	0.34
	RWC	49.85	73.30	68.50	50.66	2.18	0.34
rhythm only (\mathcal{R})	MUSDB18	61.37	5.84	5.76	3.84	1.95	0.32
	RWC	58.39	5.40	5.08	2.90	2.67	0.32
no frame-wise chords ($\mathcal{C}_{pre} + \mathcal{R}$)	MUSDB18	61.68	57.39	56.65	47.17	1.44	0.35
	RWC	69.30	60.95	57.19	44.21	1.29	0.35
baseline (no finetuning; \mathcal{M} for \mathcal{C}_{pre})	MUSDB18	26.14	53.13	52.31	44.83	2.01	0.34
	RWC	30.67	51.90	48.54	35.81	2.30	0.35

Table 2. Objective evaluation results for models with different conditions on two different test sets MUSDB18 and RWC. With the proposed condition representation, we can achieve better performance both in rhythm and chord controls.

Model	Evaluation dataset	Rhythm	Chord			FAD	CLAP
		F-measure(%)	majmin(%)	triads(%)	tetrads(%)		
proposed (jump+adaptive in-attn)	MUSDB18	69.76	67.03	66.19	56.91	1.29	0.34
	RWC	79.40	73.03	68.42	54.12	0.96	0.34
ablation 1 (jump finetuning only)	MUSDB18	42.28	71.06	70.21	61.58	1.39	0.36
	RWC	53.14	76.04	71.33	57.52	1.27	0.36
ablation 2 (jump+full in-attn)	MUSDB18	67.23	66.47	65.60	56.37	1.59	0.35
	RWC	71.13	64.82	60.77	48.07	1.47	0.35
finetuned baseline (jump only; no \mathcal{C}_{sum} no \mathcal{R})	MUSDB18	40.15	55.65	54.88	45.52	1.94	0.36
	RWC	49.25	56.49	52.66	38.07	2.24	0.36

Table 3. Objective evaluation results for models trained with different finetuning mechanisms. We see that the proposed jump finetuning with adaptive (partial) in-attention achieves better result on rhythm and chord controls.

5. EXPERIMENTAL RESULTS

5.1 Objective Evaluation: Temporal Conditions

We assessed the audio generated under various condition combinations applied to the training model, including the proposed method and its **ablations** with either chord- or rhythm-only as the temporal condition, or using both but without the frame-wise chord condition. The finetuning configurations and mechanisms for these models were the same. Moreover, we considered the **baseline** as follows. The pretrained MusicGen-melody model originally processes text and melody conditions \mathcal{T} , \mathcal{M} . We simply used the prepend chord condition \mathcal{C}_{pre} as input to the linear projection layers originally pretrained to take the melody condition, without finetuning the entire model at all. In addition, we appended to the end of the text prompt BPM information (e.g., “at BPM 90”) as the rhythm condition.

Result shown in Table 2 leads to many findings. Firstly, a comparison between the result of the proposed model (first row) and the baseline (last row) demonstrates nicely the effectiveness of the proposed design. The proposed model leads to much higher scores in almost all the met-

rics. Moreover, it performs similarly well for the two evaluation datasets, suggesting that MusiConGen can deal with both conditions extracted from a reference audio signals or provided by creators in a symbolic text-like format.

Secondly, although the baseline model does not perform well, it still exhibits some level of chord control, showing the knowledge of melody can be transferred to chords.

Finally, from the ablations (middle three rows), chord-only and rhythm-only did not work well for rhythm and chord control respectively, which is expected. Compared to the proposed model, excluding per-frame chord condition degrades both chord and rhythm controllability, showing that chord and rhythm are interrelated.

5.2 Objective Evaluation: Finetuning Mechanisms

Besides the proposed finetuning method, we evaluated the following alternatives. **Finetuned baseline** is a baseline model that was finetuned using the prepended chords (\mathcal{C}_{pre}) instead of melody \mathcal{M} the frame-level conditions, employing the jump finetuning mechanism but no in-attention. **Jump finetuning without in-attention** (ablation 1) and **jump finetuning with full in-attention** (abal-

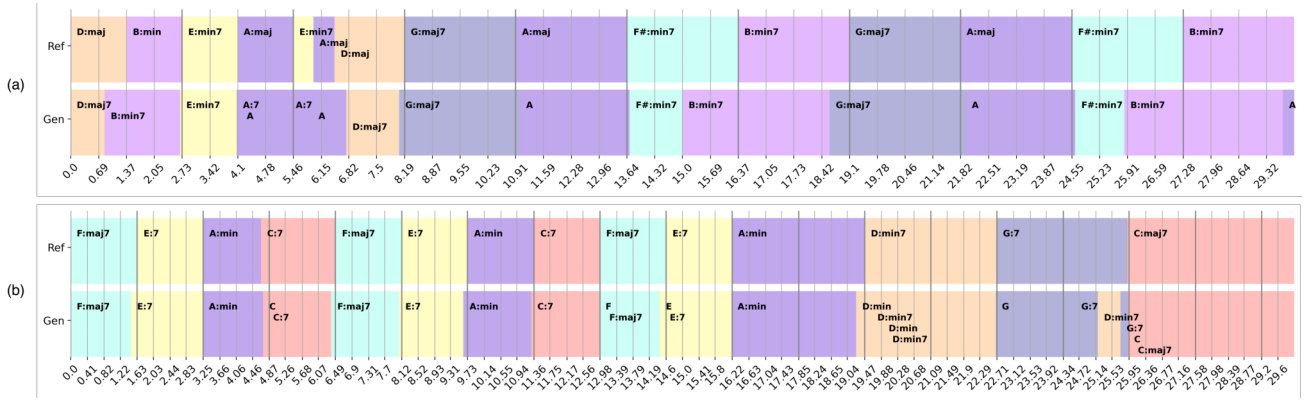

Figure 2. Comparison on chord progression and beats of ground truth and generated samples, using the conditions from RWC. For each example (a) or (b), the top row is ground truth chords and the bottom row is extracted chords from generated samples. The thick and light gray lines indicate the times of the downbeat and the beat, respectively.

Figure 3. Subjective evaluation of condition controls—5-scale mean opinion score with 95% confidence interval.

ation 2) are ablations which use full conditions (prepended chord C_{pre} , frame-wise chord C_{sum} , and rhythm \mathcal{R}), but we either dropped in-attention entirely, or employed in-attention to every self-attention block, instead of only the first three-quarter blocks as done by the proposed method.

The result is tabulated in Table 3. Among the four methods, the proposed method leads to the best rhythm control and very competitive chord control. Comparing the results of the proposed method and the two ablations reveals a trade-off in rhythm and chord control when we go from no in-attention, adaptive (partial) in-attention, to full in-attention. The proposed method strikes an effective balance between rhythm and chord controls.

Comparing the last row of Table 2 and that of Table 3 shows that the finetuned baseline outperforms the baseline (with no finetuning at all) mainly in the rhythm control. This is notable as the finetuned baseline is actually trained with only the prepend chord condition C_{pre} , not using the rhythm condition \mathcal{R} , suggesting again the interrelation of chord and rhythm. Moreover, although the finetuned baseline is better than the baseline, it is still much inferior to the proposed method in both chord and rhythm controls.

5.3 Subjective Evaluation

We evaluated three models in the listening test: the baseline, the finetuned baseline, and the proposed model. Each model generates a music clip using the ChatGPT-generated text prompts, along with the BPM and chords

from the RWC dataset, namely considering text-like symbolic rhythm and chord conditions. Besides the audios generated by the three models, we also included real audios from the RWC dataset as the **real audio**. We note that the real audios would have perfect rhythm and chord controllability (for they are where the conditions are from), but the textual adherence would be bad because RWC songs are J-Pop rather than any of the five genres (i.e., Rock, Funk, Jazz, Blues, and Metal) described by the text prompts.

We had 23 participants in the user study, 85% of whom have over three years of musical training. Each time, we displayed the given text, rhythm and chord conditions, and asked a participant to rate the generated audio and the real audio (anonymized and in random order) on a five-point Likert scale. The result is shown in Figure 3.

Several findings emerged. Firstly, the proposed model demonstrated superior chord control compared to the other two models, although it still fell short of matching the real audio. Secondly, the proposed model has no significant advantage on rhythm consistency against the finetuned baseline. As suggested by the examples on our demo page, we found that being on the precise beat onset does not significantly impact rhythm perception. Thirdly, our model had lower text relevance than the finetuned baseline, suggesting that our model may have traded text control for increased temporal control of rhythm and chords.

6. CONCLUSION AND FUTURE WORK

This paper has presented conditioning mechanisms and finetuning techniques to adapt MusicGen for better rhythm and chord control. Our evaluation on backing track generation shows that the model can take condition signals from either a reference audio or a symbolic input. For future work, our user study shows room to further improve the rhythm and chord controllability while keeping the text relevance. This might be done by scaling up the model size, better language model, or audio codecs. It is also interesting to incorporate additional conditions, such as symbolic melody, instrumentation, vocal audio, and video clips.

7. ACKNOWLEDGEMENTS

We are grateful to the discussions and feedbacks from the research team of Positive Grid, a leading global guitar amp and effect modeling company, during the initial phase of the project. We also thank the comments from the anonymous reviewers and meta-reviewer. The work is also partially supported by grants from the National Science and Technology Council (NSTC 112-2222-E-002-005-MY2), (NSTC 113-2628-E-002-029), and from the Ministry of Education of Taiwan (NTU-112V1904-5).

ABSTRACT

The automated creation of accurate musical notation from an expressive human performance is a fundamental task in computational musicology. To this end, we present an end-to-end deep learning approach that constructs detailed musical scores directly from real-world piano performance-MIDI files. We introduce a modern transformer-based architecture with a novel tokenized representation for symbolic music data. Framing the task as sequence-to-sequence translation rather than note-wise classification reduces alignment requirements and annotation costs, while allowing the prediction of more concise and accurate notation. To serialize symbolic music data, we design a custom tokenization stage based on compound tokens that carefully quantizes continuous values. This technique preserves more score information while reducing sequence lengths by $3.5\times$ compared to prior approaches. Using the transformer backbone, our method demonstrates better understanding of note values, rhythmic structure, and details such as staff assignment. When evaluated end-to-end using transcription metrics such as MUSTER, we achieve significant improvements over previous deep learning approaches and complex HMM-based state-of-the-art pipelines. Our method is also the first to directly predict notational details like trill marks or stem direction from performance data. Code and models are available on [GitHub](#).

1. INTRODUCTION

Creating structured musical scores from human performance recordings is a challenging task with a significant number of downstream applications in areas such as alignment [1], score-following, education, and archiving.

Human performances are typically represented as performance-MIDI (P-MIDI) files, as they can be easily recorded from MIDI instruments or generated from audio by automated transcription systems [2, 3]. In contrast, high-quality scores in standard sheet music formats such as MusicXML [4] are much less commonly available and generally require creation by human experts.

Performance-MIDI-to-Score conversion (PM2S) is complex, encompassing several lower-level tasks like note

value prediction, tempo regression, rhythm quantization, voice assignment, and typesetting details, including ornaments and note stems. As a result, PM2S and its sub-tasks have remained an active research topic and popular application of computational methods for over 30 years [5].

While early approaches relied on classical modeling and hand-crafted processing [6], research gradually shifted towards statistical methods based on Hidden Markov Models (HMMs) augmented with heuristics.

Cogliati et al. [7] run an HMM-based meter estimation [8] with beat-snapping heuristics to quantize note timings, before outputting LilyPond [9] notation. HMM variants were also used for estimating staff placement [10] and rhythm quantization [11, 12], where the outputs of multiple models are merged into a final prediction with improved accuracy. To complement onset timing quantization, a method for note value recognition based on Markov random fields was introduced by Nakamura et al. [13]. Building upon these advances, Shibata et al. [14] combined prior systems with hand-crafted non-local statistics to improve estimates of global attributes such as piece tempo and time signatures. While these approaches yield state-of-the-art performance, they are composed of a complex web of interdependent components, rely on human-designed priors, and are not trained end-to-end. Thus, more recent work has attempted to tackle PM2S using deep learning.

So far, the scarcity of high-quality labeled data has limited its use to scenarios with cheaper labels, leading to a focus on synthetic data [15, 16], sub-tasks like pitch-spelling [17], note value quantization and voicing [18], or beat tracking [19, 20]. Beat tracking, in particular, has seen significant progress by combining CRNNs with beat in-filling via dynamic programming [19]. The CRNN also predicts other score attributes such as key and time signatures. Unfortunately, beat-tracking makes overly restrictive assumptions about the regularity of the underlying performance data and struggles with real-world human recordings.

Another challenge is the representation of symbolic music data for machine learning models. Monophonic sequences are often captured as Lilypond [9, 15], ABC [21], Humdrum-derived [16, 22], or custom CTC-friendly [16] character sequences. For polyphonic data, piano rolls [2, 23], MIDI-derived tokens [24–26], and custom MusicXML tokens [27] are the most common representations. To create more compact encodings, Zeng et al. [28] and Dong et al. [29] use compound tokens and represent MIDI attributes in separate streams, shortening sequence lengths.

Our proposed approach continues the progression of PM2S systems towards end-to-end learned approaches and overcomes several limitations of prior systems based on deep learning, making the following key contributions:

- We cast PM2S as an end-to-end sequence-to-sequence translation task, developing a transformer to enable accurate prediction of global attributes (e.g., meter) that require understanding of long-term dependencies.
- Relaxed annotation requirements compared to prior deep learning methods, using only beat-level alignment for training. We can additionally leverage unmatched MusicXML data without corresponding P-MIDI.
- We introduce a compact and extensible tokenization scheme for P-MIDI and MusicXML data, allowing the backbone model to directly translate tokenized P-MIDI into MusicXML tokens and enabling the generation of detailed score features such as ornaments.
- We demonstrate superior performance on quantitative error metrics like MUSTER, with our approach surpassing prior deep learning models and the highly optimized, complex state-of-the-art.

2. METHODOLOGY

2.1 Task definition

Our end-to-end PM2S system directly converts an unstructured P-MIDI file into a highly readable MusicXML score. P-MIDI files only contain information about note timing (onsets, offsets), pitch, and velocity. The input to a PM2S system is thus defined by the following sequence:

$$\mathbf{X} = \{(p_i, o_i, d_i, v_i)\}_{i=1}^{N_{\text{perf}}}, \quad (1)$$

with MIDI pitch p_i , onset o_i and duration d_i in seconds, and velocity v_i for each of the N_{perf} performance notes.

In contrast to existing methods, which often cast PM2S as a note-wise classification task [18, 19], we do not assume a one-to-one correspondence between notes in the performance and the score. This is crucial in scenarios with trills or misplayed notes, where one-to-one matchings are impossible. Consequently, we predict a new output note sequence from scratch that includes a full set of MusicXML attributes for each note in the score:

$$\mathbf{Y}_{\mathbf{q}} = \{(p_j, mo_j, md_j, ml_j)\}_{j=1}^{N_{\text{score}}} \quad (2)$$

$$\mathbf{Y}_{\mathbf{v}} = \{(h_j, vo_j)\}_{j=1}^{N_{\text{score}}} \quad (3)$$

$$\mathbf{Y}_{\mathbf{o}} = \{(t_j, s_j, sd_j, g_j, a_j)\}_{j=1}^{N_{\text{score}}} \quad (4)$$

$$\mathbf{Y} = (\mathbf{Y}_{\mathbf{q}}, \mathbf{Y}_{\mathbf{v}}, \mathbf{Y}_{\mathbf{o}}), \quad (5)$$

where $\mathbf{Y}_{\mathbf{q}}$ comprises attributes related to pitch p_j and quantized timings for the musical onset time mo_j , musical duration md_j , and measure length ml_j . $\mathbf{Y}_{\mathbf{v}}$ collects vertical positioning information, such as staff placement/hand h_j , and MusicXML voice number vo_j . Finally, $\mathbf{Y}_{\mathbf{o}}$ covers performance annotations, ornamentation, and typesetting details like trill t_j , staccato s_j , stem direction sd_j , grace note g_j , and accidentals a_j . Predicting these additional attributes enables creating more concise and accurate notation. \mathbf{X} and \mathbf{Y} are sorted by ascending onset/offset, pitch, and duration, yielding a unique serialized representation even for complex polyphony.

2.2 Tokenization scheme

To efficiently represent input \mathbf{X} and output \mathbf{Y} , we introduce a systematic tokenization for P-MIDI files and MusicXML scores. The key objective of a tokenization algorithm is to retain as much information from the original sequence as possible within a compact sequence length and vocabulary size. Thus, we adopt a parallel token stream paradigm [28]; a separate token stream is constructed for each of the four input attributes given in Eq. (1) and the eleven output attributes in Eq. (5). As a result, each note occupies only one timeslot. The final vocabulary sizes and parameter ranges are shown in Table 1.

For P-MIDI, we adopt a strategy similar to [19] and use 128 pitch tokens, 8 quantized velocity tokens, and quantize delta onsets and durations into 200 buckets. To achieve high resolution for small values while covering times up to 8 seconds without clipping, we apply a *log*-transform before bucketing onsets and durations, implementing a continuous version of multi-resolution quantization [28].

We pay particular attention to the MusicXML tokenization. While binary and categorical attributes, such as stem direction and staff assignment, are easily tokenized, continuous values like onsets and durations demand more care. The encoding of musical timing and positioning significantly impacts score quality. To find a good trade-off between vocabulary size and the ability to correctly represent common note durations and onsets, we conducted a search over bucket sizes. Consequently, we opt to quantize musical time into $\frac{1}{24}$ th fractions, diverging from previous approaches, which rely on powers of 2 or smaller denominators [18, 28, 30]. Our parameterization accurately represents 98.6% of notes in the ASAP dataset with 97 tokens, compared to just 85.4% using powers of 2 up to 256.

Encoding absolute musical onsets into tokens poses another challenge. Direct quantization of absolute positions is infeasible due to the large range of positions required, while delta encoding similar to MIDI quickly leads to drift issues and misalignment with measure boundaries and the

Parameter	N_{vocab}	Range/Values
<i>Input Parameters</i>		
Pitch (p_i)	128	[0, 127]
Onset (o_i)	200	[0, 8]
Duration (d_i)	200	[0, 8]
Velocity (v_i)	8	[0, 127]
<i>Output Parameters</i>		
Pitch (p_j)	128	[0, 127]
Musical Onset (mo_j)	145	[0, 6]
Musical Duration (md_j)	97	[0, 4]
Measure Length (ml_j)	146	[0, 6] \cup {false}
Hand/Staff (h_j), Trill (t_j), Grace (g_j), Staccato (s_j)	2 each	boolean
Voice (vo_j)	8	[1, 8]
Stem (sd_j)	3	{up, down, none}
Accidental (a_j)	6	{bb, b, ♮, #, x, none}

Table 1. Parameter specifications for input/output representations. The rightmost column details the range or set of representable values for each attribute. Continuous values outside the range are clipped before tokenization.

Figure 1. Model architecture overview. We use a standard Roformer encoder-decoder model [31] with custom token embedding and projection layers. Each token stream is embedded separately, then a constant-size shared embedding is created via summation. The backbone model architecture remains unchanged compared to models applied to NLP or other sequence-to-sequence learning tasks. In this illustration, depth symbolizes the time direction.

musical grid. Thus, we adopt a hybrid approach representing absolute positions using two tokens; mo_j encodes the note’s position relative to the start of the current measure, and ml_j stores the preceding measure’s length for the first note in each measure or is set to `false` otherwise. Combined, mo_j and ml_j enable the reconstruction of absolute musical times, including correct bar lines and most time signatures. During score creation, bar lines are used to split and tie notes crossing measure boundaries, recovering most ties, and rests are added to fill any gaps in voices.

Since input and output streams are not necessarily the same length, we also insert space tokens (sp_j) where required for alignment (see also Section 3.1.2). The space tokens differ from typical end-of-sequence padding or masking tokens in Transformers, as they are predicted during inference and attention to these positions is not masked.

2.3 Model architecture

By adopting a unified autoregressive Transformer encoder-decoder model [32] to directly translate tokenized P-MIDI into MusicXML tokens (as depicted in Figure 1), we diverge from existing deep learning models for PM2S, which used subtask-specific LSTMs [33] or CRNNs. Our choice is driven by the transformer’s ability to scale to large datasets and to handle long-range dependencies, which are crucial for predicting piece-wide attributes like meter.

To interface with parallel token streams, our model introduces custom embedding and projection modules. First, each attribute-specific token stream is mapped into a constant-size 512-dimensional embedding space. The results are then summed and normalized using LayerNorm [34] to form a constant-size shared embedding, independent of the token stream count.

The backbone model itself follows the original architecture described by Vaswani et al. [32] and consists of symmetrically arranged encoder and decoder stacks. Each stack comprises four layers, eight attention heads, and a model dimension of 512. To optimize performance, we adopt rotary positional encodings [31], pre-norm [35], and SwiGLU activations [36] with an inner dimension of 3072 for the position-wise feed-forward network. At the end of the decoder, a set of linear layers projects the final hidden state into one output logit distribution per token stream.

2.4 Training & inference details

To optimize our model parameters, we break down the loss computation into two stages and first compute per-timestep

losses \mathcal{L}_j , before summing along the sequence position. At each timestep j , our model performs 12 separate classification tasks, one for every token stream in \mathbf{Y} and one for the space token sp_j .

We compute the cross entropy (CE) loss for each output token stream y and the space token stream. For timesteps with spacing token sp_j , the loss is calculated only for the space token stream since the labels for all other tokens are undefined. The full loss computation is thus:

$$\mathcal{L}_{y,j} = \text{CE}(\hat{y}_j, y_j) \quad (6)$$

$$\mathcal{L}_j = \begin{cases} \text{CE}(\hat{sp}_j, 1) & \text{for } sp_j = 1, \\ \sum_{y \in \mathbf{Y}} \mathcal{L}_{y,j} + \text{CE}(\hat{sp}_j, 0) & \text{otherwise.} \end{cases} \quad (7)$$

$$\mathcal{L} = \sum_{j=1}^{N_{\text{score}}} \mathcal{L}_j. \quad (8)$$

We train our model for 40,000 steps using the AdamW optimizer [37]. The learning rate follows a cosine learning rate decay schedule with linear warmup over the first 4,000 steps to a maximum learning rate of $3e-4$. Gradients are clipped to a maximum value of 0.5. We use a batch size of 32 and the training sequence length is 512 timesteps.

To parallelize training, transformers are often trained with teacher forcing. However, exposure bias [38] can lead to lower-than-expected performance at inference time, especially in the low-data regime. We find that heavy dropout [39] during training to expose the model to only 25% of the preceding output tokens addresses this problem.

During inference, we employ greedy top-1 decoding as it provides better performance than alternatives. To handle songs with more than 512 notes, we partition the input into chunks of 512 notes each, ensuring a 64-note overlap between consecutive segments. Sufficient overlap eliminates abrupt changes at the segment boundaries and is essential for generating temporally coherent scores.

3. EXPERIMENTS

3.1 Data

3.1.1 Datasets

Unlike prior PM2S systems [14, 18, 19], we do not use the MAPS [40] dataset in our experiments, as performance data contained therein is not representative of real-world P-MIDI¹. Furthermore, its musical scores are only available

¹ The underlying data is score-derived and has been manually adjusted to represent aspects of performance and score at the same time. This leads

in the MIDI format, which lacks representational capacity compared to MusicXML. Thus, MAPS scores do not effectively capture many aspects of musical notation.

To overcome these limitations, we use the ASAP dataset [41] for training and evaluation. It contains 1067 pieces of P-MIDI recorded from expert piano performances and corresponding high-fidelity MusicXML scores. Performance and scores are aligned with beat-level annotations, which are significantly cheaper to obtain than note-level alignments. We also observed that, on average, MusicXML scores contain 2.6% fewer notes than associated P-MIDI. These discrepancies are typically caused by misplayed notes and trills, again highlighting the importance of a flexible approach that is not reliant on one-to-one correspondences and can handle a wide variety of notation features.

After manually inspecting the dataset, we reject 100 instances due to poor alignment or data corruption, leaving 967 performances. We perform only minimal preprocessing, focusing on removing non-sounding notes from the score. This includes merging tied notes into a single, longer note and removing notes with the MusicXML `print-object=no` attribute, as they would not be visible to a human performer.

To guarantee non-overlapping sets with robust evaluation across all composers in the dataset, dataset splits are created using the following procedure:

For each composer, we select one piece as a test piece and use all performances of this piece for the test set, yielding 59 instances. 90% of all remaining pieces are used in the training set and 10% in the validation set. Table 2 shows the resulting full dataset split statistics.

To complement this labeled dataset, we also construct an unpaired dataset consisting of 58,646 public domain MusicXML files from Muscores, without corresponding P-MIDI. These scores are filtered for overlap with the labeled dataset to avoid data leakage.

Dataset	Train	Validation	Test	Total
Performances	822	86	59	967
Distinct pieces	176	16	14	206
P-MIDI Notes (10^3)	2510	300	220	3030
Score Notes (10^3)	2462	295	215	2972

Table 2. Dataset statistics for ASAP [41] after excluding instances with mismatched annotations.

3.1.2 Training batch construction

All training batches consist of 32 sequences of 512 notes each, equally split between labeled and unpaired datasets. To sample instances from these heterogeneous datasets, we adopt two different procedures.

Labeled data. We first use the beat-level correspondences to coarsely align input and output sequences by sorting notes into inter-beat intervals according to their onset time. Although this correspondence is exact for the Mu-

to information leakage as highly regular onset/offset alignment remains in the ‘performance’ data. Details of the laborious alignment process are available at <http://www.piano-midi.de/technic.htm>.

sicXML score data, human performances introduce variations to the P-MIDI data, causing some notes to not align perfectly with annotated beats. As a result, performance notes that occur shortly before the annotated beat time may musically belong into the next inter-beat interval and vice-versa. To solve this issue, we follow a greedy optimization strategy that minimizes mismatched pitches between performance and score in each beat interval. If a performed note occurred within 50ms of a beat, and moving it to the previous/next inter-beat-interval reduces the number of mismatched pitches in both intervals, the move is performed. Where necessary for alignment, we add spacing tokens (sp_j) at the end of inter-beat intervals. Given correct beat annotations, this procedure yields good alignment even in non-trivial situations like trills, where multiple MIDI notes correspond to just one MusicXML note.

Unpaired data. In this case, only MusicXML data is available. This could be used to simply pre-train the decoder stack in an autoregressive fashion; however, we found this procedure to be ineffective. We thus aim to incorporate the encoder into the training process and construct a surrogate input token stream by reusing the output pitch tokens p_j as input for the encoder model p_i and mark the input sequence using conditioning tokens c_i . All other input tokens (o_i , d_i , and v_i) are masked. As demonstrated in Section 3.4, this significantly enhances the effectiveness of training on unpaired data. Without input timing and velocity streams, the model has far less information to make predictions. To make the learning objective more feasible, we decrease the prior-token dropout probability to 50% (compared to 75% for paired data), improving training efficiency without compromising inference time behavior (see also Section 2.4). Similar to conditioning masks in diffusion models, we also feed a binary token (c_i) to the encoder which indicates that no real P-MIDI conditioning information from the labeled dataset is provided, resolving ambiguity about whether input tokens are masked/dropped out or simply not available. The addition of this token improves the effectiveness of training on unlabeled data (see Table 6). When training on labeled data and during inference, its embedding is set to 0 and can thus be omitted.

3.1.3 Data augmentation

During training, four types of data augmentation are used to combat overfitting:

- **Transposition:** Shift all pitches in the input and output up or down by up to 12 semitones; notes falling outside the MIDI pitch range are shifted inward by one octave. Accidentals are modified accordingly, following [17].
- **Global tempo:** Change the timing data of the input MIDI notes by a factor of $\lambda \sim \mathcal{U}(0.8, 1.2)$.
- **Duration jitter:** To simulate human performance variations, performed note durations are additionally rescaled by a small amount of noise $\sim \mathcal{U}(0.95, 1.05)$.
- **Onset jitter:** All between-note intervals of the input MIDI are changed according to $\tilde{o}_{i+1} - \tilde{o}_i = (o_{i+1} - o_i) \cdot \mathcal{N}(1, 0.05^2)$.

Method	MUSTER [14]						ScoreSimilarity [27,42]

Table 3. Comparative quantitative evaluation on the ASAP test set. All prior methods produce quantized MIDI and require MuseScore 4 to perform typesetting and conversion to MusicXML. [†]: the reported metrics are slightly optimistic as some pieces of the test set appeared in the training data for subcomponents of this method only.

3.2 Metrics

To conduct fine-grained comparisons, we use both MUSTER [12, 18] and ScoreSimilarity [27, 42] as evaluation metrics for PM2S performance².

MUSTER especially focuses on high-level accuracy and rhythmic structure, with sub-metrics for note-level edit-distance (\mathcal{E}_p , \mathcal{E}_{miss} , \mathcal{E}_{extra}), rhythm correction (\mathcal{E}_{onset}), defined by the amount of scale and shift operations required to correctly align every note’s onset with the ground truth sequence, and \mathcal{E}_{offset} , which measures the accuracy of the predicted note’s musical durations. While edit-distance metrics primarily reflect the melodic correctness of a score, \mathcal{E}_{onset} and \mathcal{E}_{offset} serve as good indicators of rhythmic understanding and visual clarity of the resulting notation.

ScoreSimilarity also tracks edit-distances (\mathcal{E}_{miss} , \mathcal{E}_{extra}) but additionally allows the evaluation of notational details such as stem direction (\mathcal{E}_{stem}), pitch spelling ($\mathcal{E}_{spell.}$), or hand/staff assignment (\mathcal{E}_{staff}). We extend ScoreSimilarity to ornaments by adding F1-scores for grace, staccato, and trill. To harmonize the scores reported by both metrics, we opt to report normalized error scores and F1-scores instead of absolute error counts as originally proposed in [42].

	ScoreSimilarity [27, 42]					
	\mathcal{E}_{staff}	\mathcal{E}_{stem}	$\mathcal{E}_{spell.}$	$F1_{grace}$	$F1_{staccato}$	$F1_{trill}$
SOTA [19, 43, 44]	6.86	26.74	9.69	-	-	-
Ours	6.62	25.03	8.69	27.80	18.19	54.64

Table 5. Comparison of score representation schemes by sequence lengths and representation error rates.

² MV2H [45] was also considered, but its alignment procedure was prohibitively slow on real-world scores with thousands of notes. Alignment is necessitated by the lack of one-to-one correspondence labels.

³ The MIDI files were created from MusicXML with MuseScore 4.0.

3.3 Comparative experiments

PM2S. In Table 3, we compare our model to the best publicly available PM2S systems. Our baselines include the popular commercial programs MuseScore [43] and Finale [44], the strongest HMM-based approach [14], and the highest-performance deep learning model [19], which relies on neural beat tracking. Where necessary for evaluation, MuseScore 4 is employed to convert quantized score MIDI predictions to MusicXML. We also compare with an improved version of the reference implementation of [19], which removes the time-signature⁴ and note-value prediction modules. However, as noted in Section 3.1.1, beat-tracking still struggles on real-world P-MIDI, lagging behind [14] and other options in rhythm quantization.

In contrast, our method predicts notation with significantly more accurate rhythm ($\mathcal{E}_{onset/offset}$), note values ($\mathcal{E}_{offset/duration}$), and fewer extraneous notes (\mathcal{E}_{extra}). In practice, this is reflected in better alignment of notes with barlines and more concise notation than alternative approaches. While all baselines pass the input pitch sequence directly to the output, our setup requires the model to rebuild the full sequence from scratch, leading to more missed notes ($\mathcal{E}_{p/miss}$). Decoupling the output pitch sequence from the input is key to our method, enabling training without one-to-one correspondences and predicting many-to-one relationships like trills. In fact, many ‘misses’ occur because our approach notated a trill where the ground truth score contains multiple alternating notes, with minimal impact on the resulting score’s quality from a human perspective.

For sample scores and visual comparisons with baseline approaches, we refer to the supplementary material.

Notation details. To our knowledge, our method is the first PM2S system to predict note-level attributes beyond timing, pitch, and staff assignment. The model also estimates staccato, grace notes, and trill marks, which are crucial for human performers. Given the data imbalance – for instance, trills account for only 0.15% of notes – achieving high F1 scores is extremely challenging. Table 4 shows that our approach predicts more accurate stem directions, pitch-spelling, and staff assignments, while exhibiting relatively good performance on grace and trill notes.

Tokenization scheme. We evaluate our MusicXML to-

⁴ We found that assuming a fixed $\frac{4}{4}$ time signature improves results.

Table 6. Ablation study for key design decisions. Grayed out values do not reflect the true model performance as a large fraction of notes are misaligned during metric computations, leading to incorrect results. Rows are organized by \mathcal{E}_{avg} .

kenization against prior methods and score-derived MIDI files by converting ground-truth scores to a new format and then comparing the reconstructions to the originals.

Table 5 shows that our approach yields $3.5\times$ shorter sequence lengths than prior MusicXML tokenizations while maintaining more detail than alternatives. Furthermore, it highlights MIDI’s shortcomings as a notation format; both ground-truth MIDI scores and MIDI-based tokenizations [28] exhibit lower fidelity than MusicXML-derived tokenizations and particularly high error rates for details like stem directions, which are not supported by MIDI.

3.4 Ablation study

Our ablation study in Table 6 shows the impact of key design choices.

Backbone architecture. The transformer architecture is much stronger than classic recurrent networks like bidirectional LSTMs [33] and GRUs [46] when trained on the same data (rows 3 & 2). We also evaluate the effectiveness of the conditioning token (row 11) and demonstrate the impact of feeding surrogate pitch information to the encoder for unpaired data (row 8).

Positional encoding. We compare rotary embeddings with standard sinusoidal embeddings [32] (row 13) and ALiBi [47] (row 7) and find that sinusoidal embeddings perform slightly weaker than rotary encoding while ALiBi yields significantly worse results.

Tokenization. We demonstrate the impact of our tokenization scheme’s quantization by changing the encoding scheme to quantize durations by 32nd-divisions instead of 24th (row 6). This has a particularly strong impact on metrics for rhythm and note values (\mathcal{E}_{onset} , \mathcal{E}_{offset} , $\mathcal{E}_{duration}$).

Data augmentation & alignment. Data augmentation is crucial to the effectiveness of our approach (row 1). Rows 5, 9, 10, and 12 show that using all 4 augmentation types combined yields the best results. We also demonstrate that using our greedy beat-level note alignment algorithm significantly improves performance compared to unoptimized input and output sequence alignment (row 4).

3.5 Scaling

To assess model performance as datasets grow, we conduct experiments with varying amounts of paired and unpaired data (see Table 7). We observe a clear trend where increasing the amount of paired and unpaired data improves final performance across most metrics. The benefits of adding 10,000 unpaired scores are similar to expanding from 100 paired to 822 paired training pieces. While training on unpaired data is less sample-efficient, the labeling cost-savings may make it worthwhile nonetheless. The results suggest that our method is able to leverage additional data well and that training on larger (paired & unpaired) datasets could lead to significant further improvements.

Number of pieces		ScoreSimilarity [42]				
Paired	Unpaired	\mathcal{E}_{miss}	\mathcal{E}_{extra}	$\mathcal{E}_{duration}$	\mathcal{E}_{staff}	\mathcal{E}_{stem}
100	-	22.04	17.78	54.22	8.77	28.43
822	-	14.44	10.11	50.77	7.78	27.56
100	10,000	15.40	12.03	55.98	7.53	26.93
822	10,000	13.44	9.49	49.18	8.22	27.85
822	58,686	12.69	9.06	51.86	6.62	25.03

4. CONCLUSION

We presented a flexible, robust, and conceptually simple approach to convert P-MIDI into musical notation and showed that a standard sequence-to-sequence transformer model can outperform existing methods that benefit from extensive domain-specific optimizations. We also introduced a compact tokenization method for symbolic music data that is extensible to further notational elements in the future. Furthermore, we demonstrate that leveraging large unpaired training datasets can improve model performance and enhance the fidelity of predicted scores. Future efforts could add features like explicit key and time signature prediction, tempo marks, and expand to other musical genres, instruments, and notation systems.

5. ETHICS STATEMENT

The proposed system is primarily trained on classical piano music by European composers engraved in standard Western musical notation. While preliminary experiments show that the method generalizes out-of-genre to modern piano pop music, our approach nonetheless excludes a large body of musical work notated in different formats. Future work should aim to address this imbalance and create systems that can be useful to an even wider audience.

6. ACKNOWLEDGEMENTS

We would like to thank Andrew McLeod for his assistance and feedback on a draft of this work via the New-to-ISMIR paper mentoring program. This work was partially supported by the ERC Starting Grant SpatialSem (101076253).

FROM REAL TO CLONED SINGER IDENTIFICATION

Dorian Desblancs Gabriel Meseguer-Brocal Romain Hennequin Manuel Moussallam
Deezer Research, Paris, France

research@deezer.com

ABSTRACT

Cloned voices of popular singers sound increasingly realistic and have gained popularity over the past few years. They however pose a threat to the industry due to personality rights concerns. As such, methods to identify the original singer in synthetic voices are needed. In this paper, we investigate how singer identification methods could be used for such a task. We present three embedding models that are trained using a singer-level contrastive learning scheme, where positive pairs consist of segments with vocals from the same singers. These segments can be mixtures for the first model, vocals for the second, and both for the third. We demonstrate that all three models are highly capable of identifying real singers. However, their performance deteriorates when classifying cloned versions of singers in our evaluation set. This is especially true for models that use mixtures as an input. These findings highlight the need to understand the biases that exist within singer identification systems, and how they can influence the identification of voice deepfakes in music.

1. INTRODUCTION

In April 2023, the track “Heart on my Sleeve” by an anonymous TikTok user Ghostwriter977 put the music industry in a frenzy [1, 2]. The artist used artificial intelligence (AI) based cloning technologies to turn their voice into Drake and the Weeknd’s [3], two of the most popular singers in the world. The song became very popular across music streaming platforms, before being removed by demand of the original artists’ right owners. This situation raised the need for singer identification systems that can also identify the original singer a synthetic voice was generated from.

In this paper, we train three embedding models for singer identification using a singer-level contrastive learning scheme, where positive pairs consist of segments with vocals of the same singers whilst negatives come from different singers. These samples can be mixtures for the first model, vocals for the second, and both for the third. The models are then evaluated on real singers using novel splits of two open datasets, the Free Music Archive (FMA) [4, 5]

and MTG-Jamendo (MTG) [6], and a closed dataset consisting of 176,141 songs that span 7500 popular singers. We use this dataset due to its scale and the fact that its singers are often the target of music voice deepfakes, some of which we use in this paper. We demonstrate that all three models are highly capable of classifying real voices, though genres that use effects on vocals, such as hip-hop, pop, and electronic music, and singers with long discographies can be much harder to classify. We then test whether the performance of our models generalizes to cloned voices of singers present in our closed dataset, using songs from YouTube. In this context, singers are often cloned onto famous instrumentals, or instrumentals that differ greatly from their usual environments. We find that the performance of all three models deteriorates quite significantly. This is especially true for models that use mixtures as inputs. We hope that these findings can be useful for future singer identification works. We believe that these should aim to design systems that can identify both a singer’s real and synthetic voice, in the hopes of combating the growing problem of voice deepfakes in music.

We summarize the contributions of this work as follows:

- 1) We evaluate singer identification systems on songs with real singers and cloned voices of some of the same singers.
- 2) We offer a detailed inspection of their performance, and demonstrate that these systems struggle to classify synthetic voices, genres where audio effects are applied to natural voices, and singers with long discographies. For synthetic voices, this decline is even greater when instrumental information is present during training, and highlights the need to understand the biases that exist within singer identification systems.
- 3) We open source singer identification splits of two open datasets, the FMA and MTG, that can serve as future performance benchmarks for the task of singer identification in polyphonic mixtures.¹

2. RELATED WORK

Singer identification, has been a staple of the music information retrieval (MIR) community for more than twenty years [7, 8]. Early approaches aimed to attenuate the instrumental parts of a song through the use of vocal melody or pitch extraction and voice re-synthesis and detection algorithms [9–11]. Classic features, such as mel-frequency cepstral coefficients (MFCCs), were then computed on these signals and used as inputs for a classifier. The improvements in music source separation [12, 13] then led re-

¹ <https://github.com/deezer/real-cloned-singer-id>

searchers to build models that classify singers using the vocals of each song [14, 15]. More recently, self-supervised methods that process the vocal stem of each track have been shown to be effective for singer identification [16, 17]. However, source separation is computationally costly. As such, these algorithms are hard to deploy on catalogues that span millions of tracks. Several works have attempted to build embedding models for singer identification that use mixtures as inputs [18, 19], most notably by using triplet learning where anchors and positives come from the same singers in different instrumental environments.

The work in this paper focuses on testing whether singer identification systems trained on real voices generalize to cloned voices of the same singers. This task must not be confused with the task of singing voice deepfake detection, which has very recently emerged in the signal processing community [20, 21]. Both works introduce datasets for Chinese singing voice spoofing detection, and demonstrate that state-of-the-art speech deepfake detectors fail to accurately predict whether the songs in their datasets are deepfakes. After supervised training, their performance is improved. However, [21] also finds that the classifiers are not robust to unseen singers, languages, or musical contexts, suggesting the need for more complex methods.

Finally, audio embeddings learned using artist-based sampling scheme have been used in [22]. The authors used metric learning, with anchors and positives coming from the same artists, to train a neural network for artist disambiguation. More recently, [23] used sampling at the artist level for contrastive learning and downstream tasks such as genre and mood classification or music tagging.

3. EXPERIMENTAL SETUP

In this section, we first present the datasets used throughout this paper. We then present the setup used to train an embedding model for singer disambiguation using contrastive learning. Finally, we present how this model is used for singer identification.

3.1 Datasets

We collect a vast number of popular, commercial, and annotated songs for both training and evaluating the embedding models. The data and their singer annotations come from four sources: Deezer, MusicBrainz, Wikidata, and Discogs [24]. The latter three are publicly available. In total, we collect more than four million tracks that span ~ 2.6 million artists. We then filter out all tracks that are not comprised of vocal segments at least 75% of the time. For this, we use a simple deep learning model that classifies three-second segments into either an instrumental class or a vocal class across all songs. We then filter out all unique singers that do not have at least two tracks. This leaves us with 37,525 singers. 7500 of the ones that have at least seven tracks are used for our singer identification task. The remaining 30,025 are used to train and validate our embedding models using contrastive learning.

We then gather 377 tracks, from YouTube, with cloned

Dataset	No. Singers	No. Songs	Songs/Singer
Train	25929	181989	≥ 2
Validation	4096	8192	2
Closed	7500	176141	≥ 7
FMA	1019	11676	≥ 5
MTG	572	7710	≥ 5
Cloned	67	377	N.A.

Table 1. Attributes of each dataset used in this paper. The train and validation sets are used for training the embedding models. Upon initial collection, validation singers can have more than two mostly-vocal tracks; we however randomly select a segment with vocals from two tracks to keep the set constant. The closed, FMA, and MTG datasets are used for real singer identification. The cloned dataset contains songs collected from YouTube in which synthesized voices of real singers are used. The original singers in this dataset are present in the closed dataset.

voices from 67 singers in our closed dataset. These are used to test our embedding models on music voice deepfakes. We also test our models on two open music tagging datasets for real singer identification: the FMA and MTG. For these, we first gather their artist tags. We then filter out songs that are not comprised of segments with vocals at least 50% of the time. Artists with less than five songs are also removed. This leaves us with 1019 artists for the FMA and 572 artists for the MTG. Unlike the commercial, closed dataset, each song can contain more than one singer. We however postulate that the trends observed in the results are highly indicative of our models’ performances on the singer identification task. We publish the subsets of data we used on these datasets for reproducibility and to serve as future benchmarks. To the best of our knowledge, other open singer identification datasets, such as the VocalSet [25] and M4Singer [26], only contain snippets of a capella singing voices. We hope future singer identification systems will also be evaluated on our proposed, more authentic musical data: singers singing to an instrumental. Table 1 displays the attributes of each of these sets of data.

3.2 Singer-Level Contrastive Learning

We train the embedding models in a contrastive learning way to predict whether two songs are from the same singer. During each training iteration, we begin by drawing a batch of $B = 128$ positive pairs, which correspond to pairs of segments with singing. These pairs are drawn on the fly from different songs of the same singer. For our Mixture model, these segments come from songs’ mixtures. For our Vocal model, these segments come from the vocal stem generated by Demucs [27, 28]. Finally, for our Hybrid model, these segments are randomly sampled from either; the following positive pairings are possible during the contrastive learning task: vocal-vocal, vocal-mixture, mixture-vocal, and mixture-mixture. This is done to better disambiguate singing voices, without the need for source separation during the downstream singer identification task. All segments are sampled at 16000 Hz and have a six-

second duration. We then compute their mel-spectrograms and pass these through the small version of the transformer model from [29]. We use a FFT size of 800, a hop length of 400, and a total of 128 mel bins for our mel-spectrogram operation. The transformer model then maps the resulting 128×240 tensor to an embedding of size 2048. Similarly to [30–32], these embeddings are passed through a fully-connected projector head. In our case, this head maps our embeddings to outputs of dimension 2048, 1024, and 2048, and uses batch-normalization [33] and ReLU activations. Let us denote the resulting projections by y_i , where $i \in [1, 2B]$. For each positive pair (i, j) , we compute, and aim to minimize, the normalized temperature-scaled cross-entropy, or NT-Xent [30], loss function, defined as:

$$\ell_{i,j} = -\log \frac{\exp\left(\frac{1}{T} S(y_i, y_j)\right)}{\sum_{k=1}^{2B} \mathbb{1}_{[k \neq i]} \exp\left(\frac{1}{T} S(y_i, y_k)\right)}, \quad (1)$$

where the indicator function $\mathbb{1}_{[k \neq i]}$ evaluates to 1 iff $k \neq i$. T is a temperature parameter that helps the model learn from hard negatives. In our case, we set $T = 0.2$ following [34]. $S(u, v)$ denotes the cosine similarity between vectors u and v . The average loss value is then backpropagated to the model. We use the ADAM optimizer [35] throughout training, with an initial learning rate of 0.0001. This value is decreased by a factor of 0.5 at every 25-epoch validation loss plateau. Note that one epoch corresponds to 32 training and validation iterations. We stop training when the validation loss has plateaued for 100 epochs.

3.3 Singer Identification

We then train classifiers with the same architecture as the projector head from the previous section upon the frozen transformer models. We evaluate these classifiers on two sets of data for real singer identification: the FMA and MTG open datasets and the closed set. For all of these, we randomly set aside one track for testing and one track for validation per singer. These are constant throughout all our experiments for reproducibility purposes. Note that four segments from each validation track are selected randomly at the beginning of each singer identification experiment to keep the validation set constant. At least three tracks per singer are then used for training. During each training iteration, we select a segment with vocals on the fly to construct batches of size 100. We minimize a Cross Entropy loss [36] using the ADAM optimizer with an initial learning rate of 0.01. This value is decreased by a factor of 0.1 every 10-epoch validation loss plateau. Here, one epoch is, again, equal to 32 training and validation iterations. We stop training when the validation loss has plateaued for 20 epochs. For each dataset’s test tracks, the final singer prediction is obtained using a majority vote scheme, where each segment with vocals is passed through the frozen embedding model and classification head. The singer with the most “votes” is then used as the track’s final output.

We report all our results using 10 runs. For both open datasets, we report results using all singers. On the other hand, for our 7500-singer closed set, we report results from

100 to 1000 classes. During each run, we randomly sample a subset of singers, on which we then train and evaluate a classifier. Finally, for the cloned singers dataset, we: 1) train models to classify 100 to 1000 singers using the closed dataset; 67 of these are cloned singers, whilst the remainder are randomly sampled from the rest of our closed dataset. 2) try to classify the cloned singer of our deepfake tracks. Our goal is to evaluate whether singer identification systems trained on real singer data can correctly classify the singers’ voice deepfakes.

4. RESULTS

4.1 Open Datasets

Dataset	Model	Top-1 Acc.	Top-5 Acc.
FMA	CLMR	73.2 +/- 0.6	73.6 +/- 0.6
	Mixture	76.6 +/- 0.5	84.1 +/- 0.6
	Hybrid	77.6 +/- 0.3	85.1 +/- 0.6
	Vocal	79.9 +/- 0.4	85.7 +/- 0.3
MTG	CLMR	67.9 +/- 1.1	68.0 +/- 1.1
	Mixture	78.5 +/- 0.5	88.4 +/- 0.6
	Hybrid	79.3 +/- 1.1	88.7 +/- 0.6
	Vocal	83.2 +/- 0.6	91.3 +/- 0.6

Table 2. Singer identification results obtained on the open datasets (%). For each dataset, we report the top-1 and top-5 accuracies generated by the three models we train using singer-level contrastive learning. We also use the embeddings from [37], called CLMR, as a baseline. These embeddings are trained in a similar fashion to [31], but on $\sim 4M$ tracks, and are used for both training and testing our classification heads to generate these results. We display the means and standard deviations over 10 runs.

The results obtained on open datasets can be visualised in Table 2. One can immediately notice that the CLMR [37] results are inferior to the singer-level embedding models’ results by at least a few percentage points. On the FMA dataset, we notice a 3.4% top-1 gap between the CLMR and Mixture models. This gap grows to more than 10 percentage points using a top-5 accuracy and is even more exacerbated on the MTG dataset and with the Hybrid and Vocal models. This highlights the fact that sampling at the singer-level is much more adapted than classic, high-performing self-supervised learning methods for pre-training a model for singer identification. We observe these gaps even though the contrastive model from [37] is trained on more than $20\times$ more tracks than the embedding models we trained for this paper.

We can also notice that the Vocal model outperforms the models that use mixtures as an input by a few percentage points. More specifically: for the MTG dataset, we observe a 3.9% gap compared to the Hybrid model on top-1 accuracy and a 2.6% gap on top-5 accuracy. The gap is less pronounced on the FMA data. We can also notice that the Hybrid model, which samples both mixtures and vocal stems during pre-training, is slightly better-performing than the mixture model, though the performance gap never exceeds

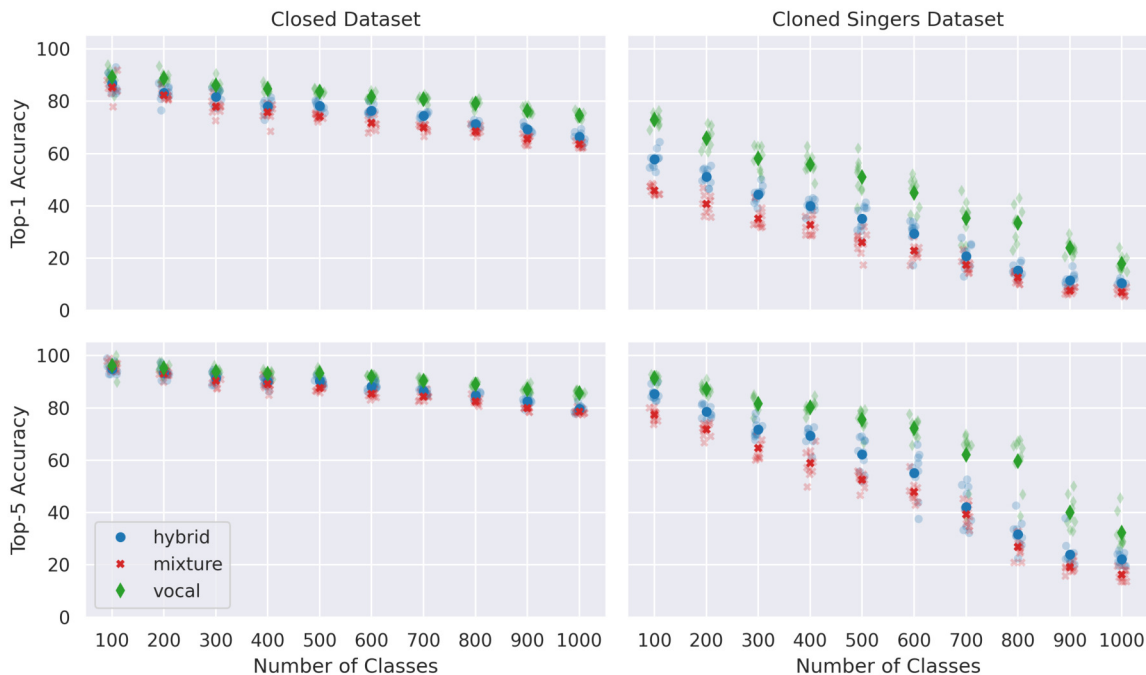

Figure 1. Singer identification results obtained on the closed (left) and cloned (right) datasets. We display results over 10 runs for 100 to 1000 singer classes. For each number of classes, we display the top-1 and top-5 accuracies for each run (pale markers), and the mean results between all runs (prominent markers). On the closed dataset, we randomly sample a subset of the 7500 singers on every run and display results on their test tracks. For the cloned dataset, we train our models to classify the 67 cloned singers and other randomly selected singers. We then display the results on the 377 spoofed tracks.

a percentage point. This highlights one of our main findings: separating vocals from the rest of the track clearly helps our models disambiguate singers between each other. However, we can obtain good performance using mixtures too. In the realm of production, where source separation can be costly memory and time-wise, the results obtained using the Hybrid or Mixture models may suffice; they may not justify the need to separate vocal stems beforehand. The results obtained on the closed dataset in the next section further emphasize this idea.

4.2 Closed Dataset

The results obtained on the closed dataset can be found on the left side of Figure 1. We observe a similar trend to the one observed on the open datasets: the Vocal model outperforms both models that use mixtures as inputs by a few percentage points. Then, the Hybrid model outperforms the Mixture model, though the gap is narrow. For example, for 400 classes, we observe mean top-5 accuracies of 89.2% for the Mixture model, 90.1% for the Hybrid model, and 93.2% for the Vocal model. For 700 classes, we observe mean top-1 accuracies of 69.8% for the Mixture model, 74.5% for the Hybrid model, and 80.9% for the Vocal model. As the number of classes grows, the gaps in performance are more pronounced, especially on the top-1 accuracy metric. We however suggest that the gap between the Vocal model and models that work on mixtures does not warrant the need for source separation in production-like environments for real-singer identification.

No. Singers	Method	Dataset	Top-1	Top-5
300	[19]	MSD	39.5	69.2
	Mixture	Closed	78.0	90.4
500	[16, 18]	MSD	47.9	71.2
	[16]	MSD	63.1	82.2
	Mixture	Closed	74.2	87.6

Table 3. Singer identification results for the same number of singers in this and previous works of the field (%).

Comparing our results to previous works in the field of music singer identification is quite difficult. These report results on private datasets [16] or on the Million Song Dataset (MSD) [18, 19, 38], a dataset whose audio is not publicly available. That is why we hope future works in singer identification will also be evaluated on the open splits we report results on in Section 4.1. We however report our worst and previous works’ results for the same number of singers in Table 3. These highlight that our methodology is at the very least on par with previous works and validate sampling at the singer level for contrastive learning when the downstream task is singer identification.

We should however point out that, even though our models identify real singers quite well, there remain open challenges. As displayed in Figure 2, our performance over musical genres is not uniform. For example, for Country and Folk music, the mean top-5 accuracies are 86.3% and 86.6%. On the other hand, for Hip-hop and Pop music, the

Figure 2. Vocal model performance by genre when trying to classify 1500 singers. The macro genre tags are gathered from Deezer and are unique for each test track. We display the mean top-5 accuracy for each run with the orange dots. The boxes then display the median and interquartile range (IQR) between runs. The whiskers extend to points that lie within 1.5 IQRs of the lower and upper quantiles. Finally, outlier runs have circles drawn around them. Genres containing less than 100 test tracks are omitted from this plot.

mean top-5 accuracies are 72.7% and 72.7%. The performance drops even further for Electronic music, where we observe a mean top-5 accuracy of 41.6%. The same trends can be observed for top-1 accuracy, our other models, and different numbers of classes. Hip-hop, Pop, and Electronic genres tend to employ effects such as reverb and vocoder on singing voices. These effects can change a voice’s timbre quite substantially, and seem to have an effect on our singer identification performance. On the other hand, Folk and Country tend to have natural-sounding singing voices. We suggest that future singer classification works should aim to lessen the gap between these genres, perhaps by introducing augmentations during either the embedding or classifier’s training. We also did experiments on the influence of language on performance, and did not find our results to be biased towards any of these. We found all 10, commonly-represented languages to have a median top-5 accuracy between 68 and 82% for 1500-singer identification, with substantial overlaps in distribution.

One can also notice the following trend from Figure 3: when we are trying to classify a small number of singers, having more tracks per singer for training leads to higher performance; on the other hand, when we are trying to classify a large number of singers, having fewer tracks for training leads to higher performance. For example, for 500-singer identification, we merely observe a top-1 accuracy of 78.5% when singers have 5 to 9 training tracks. This top-1 accuracy grows to 88.5% when singers have 20

Figure 3. Vocal model performance over 500, 1000, and 1500-singer identification. We report results from each run in buckets that describe the number of training tracks per singer, that are used to train our classifiers. In the first, we display the top-1 accuracies observed for singers with only 5 to 9 training tracks. In the second, we display the top-1 accuracies observed for singers with 10 to 19 training tracks. Finally, in the last, we display the top-1 accuracies observed for singers with 20 or more training tracks. We report results using violin plots, where, for each bucket, the inner figure is a box plot similar to that in Figure 2 and the outer figure is a kernel density estimation of the data.

or more training tracks. On the other hand, for 1500-singer identification, we observe top-1 accuracies of 68.1% and 51.5% for these same buckets. These trends can also be observed on our other models and for top-5 accuracy. They suggest that, as the singer identification task gets harder, singers with more songs to their name, and most likely much longer careers, get harder to correctly classify than singers with just an extended play (EP) or album to their name. This could be due to changes in style, mixing effects, or even singing voice. We hope that future works in the field will design systems that are more robust to singing voice evolution over a variety of musical projects.

4.3 Cloned Voices

The results on our cloned dataset can be found on the right side of Figure 1. One can immediately notice a sharp decline between the performance we observed on real singers and synthetic ones. For 200-singer identification, the worst-performing model on real singers, the Mixture one, has a mean top-1 accuracy of 82.3%. In compar-

Figure 4. Mean all-pairs cosine similarity between each of the closed set singers’ test track embeddings and: in purple (test/other), the embeddings from a random track from another singer; in red (test/val), their validation track embeddings; in green (test/vocal), their test track’s vocal stem embeddings; in orange (test/instru), their test track’s instrumental stem embeddings; in blue (test/test), the other embeddings from the same track. All embeddings are generated on segments with vocals.

ison, the best-performing model on synthetic voices, the Vocal one, has a top-1 accuracy of 65.8%. For 600-singer identification, their respective top-5 accuracies are 85.3% and 72.3%. The decline in performance on cloned singers is hence quite dramatic. However, in a lot of ways, it is to be expected. Synthetic voices can sometimes be quite unrealistic depending on the voice conversion or generation techniques used, which should obviously lead to deterioration in singer identification performance.

The more striking decline is that which we observe between models themselves. More notably, the Vocal model performs substantially better than the models that use mixtures as inputs. Starting at 100 classes, the mean top-1 accuracy of the Vocal model is 65.8% versus 51.2% for the Hybrid model and 40.1% for the Mixture model. For 800 classes, we observe accuracies of 33.4% versus 15.3% and 12.7%. On the one hand, for real singers, we found the gap in performance between the Vocal and Hybrid to be minimal enough to justify using mixtures over vocal stems, and hence avoid using source separation pre-processing. Here, however, the answer is much more clear cut: the Vocal model is the only one with decent performance on cloned singer identification task, whilst the models that use mixture inputs see a very significant drop in performance.

The reason behind the performance drop between models is illustrated in Figure 4. When comparing the embed-

dings of each closed set test track to other embeddings of the same track, we see that these are very similar, with cosine similarities of $\sim 95\%$. However, the comparison with the test tracks’ stem embeddings can differ significantly. For the Mixture model, we see that the instrumental embeddings are actually more similar to the “ground truth” test track embeddings (GTEs) than the vocal embeddings, with mean similarities of 90.8% and 89.1%. Even worse, the instrumental embeddings are closer to the GTEs than the validation track’s. Hence, even though our Mixture model, like the Hybrid and Vocal models, is pre-trained to disambiguate singers, we find that its embeddings are more suitable for finding similar songs based on instrumental information than vocal information. This problem is partly solved in the Hybrid model and fully solved in the Vocal model. Note that these results extend to other vector similarity measures such as Euclidean distance.

These findings outline why the models that are trained using mixtures drop off significantly on spoofed versions of famous artists. On these tracks, singers are often used on an instrumental which is either from another famous track, or an instrumental which is very different from their usual environment. Some of the cloned tracks’ instrumentals are even present in their original tracks during training on real singers, which leads to obvious misclassifications. As such, models that bias singers towards certain types of musical backgrounds fail to correctly identify them in altered contexts. Source separation allows us to better disambiguate voices only during training, and thus classify synthetic versions of performers. In the future, perhaps reintegrating mashups to alter a singer’s context on the fly, such as was done in [18], could lead to more robust singer identification models. These could solve the two main remaining problems in the field: 1) the need for source separation pre-processing and 2) the identification of cloned versions of existing singers.

5. CONCLUSION

In this paper, we train three models using singer-level contrastive learning. The first is only trained using mixtures, the second is only trained using vocal stems, while the third is trained using both. We find that all three models are highly capable of classifying real singers, though there remain open challenges, such as classifying genres that use more vocal effects and singers with long discographies. However, all three models’ performance decreases drastically when trying to identify cloned voices of existing singers. This decrease is much more pronounced for models that are trained using mixtures. These models bias singers towards certain types of instrumentals. They therefore struggle to correctly classify them in different background music environments, such as those offered by singing voice deepfakes. By publishing our results and novel, singer identification splits of the FMA and MTG datasets, we aim to generate more research in this field of MIR. Future works could notably incorporate cloned voices in a few-shot fashion in the hopes of minimizing the gap between real and synthetic singer identification.

6. ETHICS STATEMENT

Our work offers a glimpse into how we, as a field, can identify the original singers in music voice deepfakes. It is important that outputs of systems like ours not be used as justification to make important decisions, however, such as content removal from platforms. As demonstrated in this paper, singer identification systems are often wrong; they often return false positives. This is even more true on deepfakes. As such, human emotion and decision-making should still be at the heart of the music deepfake battle. Creative, talented singers should never see their work deplatformed because a machine learning model falsely said so. The outputs of these models should always be interpreted with caution, as an indication but not a truth.

ABSTRACT

Managing the emotional aspect remains a challenge in automatic music generation. Prior works aim to learn various emotions at once, leading to inadequate modeling. This paper explores the disentanglement of emotions in piano performance generation through a two-stage framework. The first stage focuses on valence modeling of lead sheet, and the second stage addresses arousal modeling by introducing performance-level attributes. To further capture features that shape valence, an aspect less explored by previous approaches, we introduce a novel functional representation of symbolic music. This representation aims to capture the emotional impact of major-minor tonality, as well as the interactions among notes, chords, and key signatures. Objective and subjective experiments validate the effectiveness of our framework in both emotional valence and arousal modeling. We further leverage our framework in a novel application of emotional controls, showing a broad potential in emotion-driven music generation.

1. INTRODUCTION

With the recent advancements in symbolic music generation [1–6], there has been a growing interest in controlling high-level musical features throughout the generation process. Among these features, *emotion-driven music generation* [7–13] aims to generate music that conveys specific emotions, representing a crucial aspect for music appreciation and analysis. The downstream applications of such models have also been explored, such as music therapy for healthcare and educational purposes [14] and soundtrack generation for videos and movies [15].

Emotion could be represented in two dimensions from the literature [16]: *valence* and *arousal*. Valence refers to the positiveness of an emotion and arousal refers to energy or activation [17–19]. These two dimensions can be further divided into four quadrants (4Q), namely high valence high arousal (Q1), low valence high arousal (Q2), low valence low arousal (Q3), and high valence low arousal (Q4).

In this paper, we focus on the emotion-driven *piano performance generation* of these four quadrants. Throughout prior works, we observe crucial challenges from the perspectives of both model design and musical inductive bias.

First, previous emotion-driven piano performance generation models [7, 8] attempt to learn emotion quadrants and expressions in an *end-to-end* paradigm. In terms of model design, this approach poses training difficulty on the generation model, leading to the instability in achieving results of desired emotions. For example, many existing works [7, 9, 11] could effectively control the arousal levels of music, while their performance of *valence modeling*, especially in generating low valence (i.e., negative) music, is still poor. In terms of music, the creation process of music typically involves multiple stages, such as the *lead sheet composition* for melodies and chord progressions, and *performance generation* for textures and expressiveness. Consistently, emotion can be evoked through a combination of musical elements (e.g., melody, chord, texture). For example, major/minor chords have been found to seize different valence trends in psychological studies [20] and performance-level attributes like articulation, tempo, and velocity are more related to arousal [21, 22]. It is worth to explore the potential relation between the *disentanglement* of the generation process and the emotion expression.

Second, previous emotion-driven generation models have received limited attention regarding the influence of *tonality* on emotion modeling. It has been widely shown that major-minor tonality in composition is highly related to valence perception [22–25]. For example, as depicted in Figure 1, the histogram of musical keys derived from the emotion-labeled music dataset EMOPIA [7] supports the distribution skews to major keys for high valence clips and opposite trend for low valence ones. Furthermore, different tonalities may reveal similar patterns in the relative relationships between melodies and chords, while the distribution of melodies, chords, and tonalities can exhibit distinct shapes across different emotions. Current representations of symbolic music, such as REMI [2] and CP-Word [26], do not explicitly incorporate such interactions nor address its connection to emotion adequately. Therefore, it is necessary to consider a functional format of symbolic music representation considering the relationships between notes, chords and key signatures to better model the tonality in the emotion-driven music generation process.

In this paper, we contribute to combat above challenges:

Figure 1. Key histogram of high/low valence clips from the emotion-labeled piano music dataset EMOPIA [7].

- We employ a two-stage Transformer-based model on emotion-driven piano performance generation. The first stage focuses on valence modeling via lead sheet composition, while the second stage addresses arousal modeling by introducing performance-level attributes.
- We propose a novel functional representation for symbolic music, encoding both melody and chords with Roman numerals relative to musical keys, to consider the interactions among notes, chords and tonalities [27].
- Experiments demonstrate the effectiveness of our framework and representation on emotion modeling. Additionally, our method enables new capabilities to control the arousal levels of generation under the same lead sheet, leading to more flexible emotion controls.

As a minor contribution, we also refine key signature labels and extract lead sheet annotations for the EMOPIA dataset [7] to ensure the correct training of the two-stage framework. We share the data, open source our code¹ and present generation samples in the demo page.²

2. RELATED WORK

2.1 Emotion-driven Piano Performance Generation

Prior works apply emotion conditions on deep-learning models to guide the generation of piano performance [7, 8, 11], or develop searching methods to generate music of desired emotions [28, 29]. Musical elements via feature disentanglement [9] or supervised clustering [10] can further be regarded as a bridge between emotion labels and performances for generation. In contrast, our framework employs a two-stage generation approach to reduce the complexities of one-stage generation, fostering a more nature process of music creation as well as a better incorporation between emotion labels and generation results.

2.2 Tonality, Functional Harmony, and Emotion

Musical keys and functional harmony have been explored in the field of roman numeral analysis [30–32]. The analysis of how modes and tonalities relate to mid-level perceptual features (e.g., dissonance, tonal stability, minoriness) and affect the emotional perception of music pieces has also been discovered [22, 24].

While some music generation works attempted to combine key information into data representation [33], loss

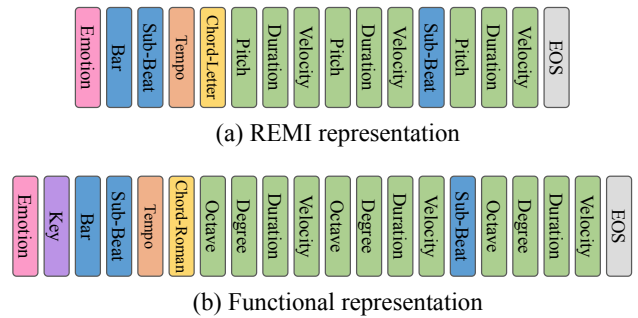

Figure 2. Illustration of (a) REMI [2], (b) the proposed functional representation, and their differences.

function [34] and text conditions [6], none of them explore the relation between musical keys and emotional perception. In this paper, we leverage both functional harmony knowledge and class-octave based pitch representation [35] to design a new data representation, incorporating the relationships between notes, chords and keys for emotion-driven music generation.

3. METHOD

In this section, we will first introduce the functional representation of symbolic music as the main generation unit. Then we introduce the two-stage model as the main component of the emotion disentanglement and generation.

3.1 Functional Representation

Figure 2 illustrates our proposed functional representation. Its design is initially based on REMI [2], a widely used event-based representation for symbolic music. We incorporate different note and chord events assisting to better learn the joint information of emotion and key signature.

3.1.1 Emotion and Key Events

We follow CTRL [36] to set up the condition within the autoregressive generation process in Transformer architecture. To denote distinct emotions and affect overall properties, we begin the event sequence with `<Emotion_*>` event to indicate the emotion label of music clips. The `<Key_*>` event is appended after `<Emotion_*>` to provide the musical key property, with the total of 24 keys (12 tonic notes with two modes in EMOPIA [7]).

3.1.2 Bar, Sub-Beat, Tempo and EOS Events

Similar to REMI, a `<Bar>` event denotes the new start of a bar; a `<Sub-Beat_*>` event denotes one of 16 possible discrete beat locations within a bar; a `<Tempo_*>` event denotes local tempo changes every four beats; and an `<EOS>` event denotes the end of sequence.

3.1.3 Chord Events

A musical chord name typically consists of root note and chord quality. For example, `Fmaj` represents the chord F–A–C with root F and major quality. Such symbols describe correct note information in chord within the tonality,

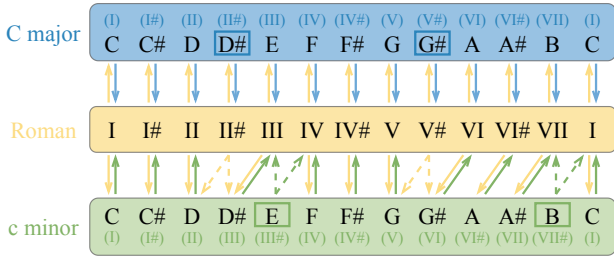

Figure 3. The conversion between letters and Roman numerals in the cases of C major and c minor scales. Solid arrows denote strict one-to-one conversions, and dotted arrows denote optional one-to-either conversions.

but they overlook the variations in *chord functions* of the same chord across different tonalities. For example, while Fmaj serves the tonic function in F major scale, it serves the subdominant function in C major scale. Moreover, the chord progression follows these functional harmony rules to establish tonality and convey musical emotion [27].

To introduce chord functions in the emotion modeling, we adopt Roman numerals from *Roman Numeral Analysis* [31] to notate chord roots in Figure 3. Given the $\langle \text{Key}_* \rangle$ event, root notes in the absolute pitch are directly converted into Roman numerals based on their scale degrees relative to the key (i.e., relative pitch). For roots outside the scale, we employ a direct conversion for I#, II#, IV#, V# and VI# appearing in major keys, but randomly assign III# and VII#, which only appear in minor keys, as one of their neighboring degrees during the encoding and decoding process. This design ensures the notation to be key-independent and make every conversion of notes reasonable to the music theory. The notations of chord qualities remain unchanged, and the chord event $\langle \text{Chord}_* \rangle$ appears every four beats.

3.1.4 Note-related Events

A note is denoted by $\langle \text{Pitch}_* \rangle$, $\langle \text{Duration}_* \rangle$ and $\langle \text{Velocity}_* \rangle$ events, where $\langle \text{Pitch}_* \rangle$ event indicates the onset of pitches from A0 to C8. Inspired by [35, 37], we decompose $\langle \text{Pitch}_* \rangle$ into $\langle \text{Octave}_* \rangle$ and $\langle \text{Degree}_* \rangle$ events according to the note octave and degree in the certain key scale. The conversion rule from $\langle \text{Pitch}_* \rangle$ to $\langle \text{Degree}_* \rangle$ is the same as that of chord roots in Figure 3. For example, pitch D#4 is decomposed into $\langle \text{Octave}_4 \rangle$ and $\langle \text{Degree}_{III} \rangle$ in c minor scale, but $\langle \text{Degree}_I \rangle$ in D# major scale. Such degree-octave pitch representation narrows the difference between melodies, thus improves the learning of connections between emotions, chords, and melodies, as demonstrated in Figure 4.

3.2 Two-stage Emotion Disentanglement

We use the idea of Compose & Embellish [38] to generate music in two stages: lead sheet first, and then piano performance. While Compose & Embellish is emotion-agnostic, we extend it so that the lead sheet model involves *valence modeling* and the performance model *arousal modeling*.

Figure 4. Two lead sheet examples from different songs in EMOPIA. In our functional representation, they have the same melody events (green), but different chord events (yellow) by different emotions (Positive and Negative by pink) and keys (D major or c minor by purple).

3.2.1 Valence Modeling

The top left section of Figure 5 denotes the first stage, where only emotion events $\langle \text{Emotion_Positive} \rangle$ and $\langle \text{Emotion_Negative} \rangle$ are considered as conditions. The former includes music pieces of Q1 and Q4 (high valence) and the latter includes those of Q2 and Q3 (low valence). The lead sheet model first predicts a key event k conditioned on the given emotion event e , and then generates the lead sheet sequence $M = \{m_1, \dots, m_T\}$ of length T , as melody and chord progression, conditioned on previous tokens step-by-step:

$$p(k, M|e) = p(k|e) \prod_{t=1}^T p(m_t|e, k, M_{<t}), \quad (1)$$

where $p(k|e)$ and $p(m_t|e, k, M_{<t})$ are jointly learned through the Transformer-based generation model [26, 38]. Performance-related events $\langle \text{Velocity}_* \rangle$ and $\langle \text{Tempo}_* \rangle$ are removed in the first stage (i.e., lead sheet generation), as we mainly focus on the contributions of key, pitch and chord for valence perception.

3.2.2 Arousal Modeling

The top right section of Figure 5 denotes the second stage. Given the lead sheet M , the performance model generates performance X conditioned on the true emotion label (Q1 to Q4). As the valence aspect has already been modeling in the first stage, this stage focuses on the generation of musical textures for the lead sheet, and more importantly, on how to perform it through variations of tempo, velocity, articulation, and other performance-level attributes that largely influence perceived arousal [21, 22]. During the training and inference phases, with the positions of $\langle \text{Bar} \rangle$ events, M and X are further segmented into $\{M_1, \dots, M_b\}$ and $\{X_1, \dots, X_b\}$, where b is the number of bars. The segmented sequences are “interleaved” in the form of $\{\dots \langle \text{Track}_M \rangle, M_i, \langle \text{Track}_X \rangle, X_i \dots\}$ with additional $\langle \text{Track}_* \rangle$ events to distinguish M and X tracks. In that, the target performance bar X_i is appended to its corresponding conditions M_i , as mapping each lead sheet segment to its corresponding performance segment [26]. With the emotion condition and key event from lead sheet as prefix tokens, the performance model is summarized as

$$p(X|e, k, M) = \prod_{i=1}^b p(X_i|e, k, M_{\leq i}, X_{<i}). \quad (2)$$

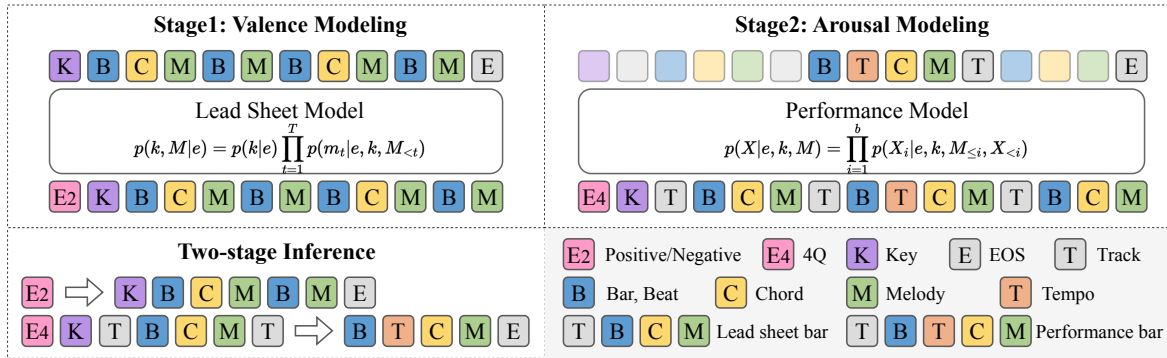

Figure 5. The two-stage framework of emotion-driven piano performance generation. Squares with transparent background denote the tokens that are not included in the loss computation during the training phase.

3.2.3 Training Objectives

Lead sheet and performance models are trained separately by both optimizing the negative log-likelihood loss of the sequence. Since existing emotion-labeled music datasets are not large, we leverage large-scale music datasets without emotion annotations to *pretrain* both models for better music understanding. During pretraining, the emotion event is marked as `<Emotion_None>`. We then finetune two models on the emotion-labeled dataset (detail in Section 4) to learn composition and performance styles specific to different emotion contexts.

3.2.4 Two-stage Inference

The left bottom section of Figure 5 denotes the inference process of both models. In the first stage, the lead sheet model predicts the key event and generates the lead sheet sequence step-by-step given `<Emotion_Positive>` or `<Emotion_Negative>` event, creating a musical motif for the specific valence preference. Even though our framework has the capability to generate any-key music of specific emotions, we observe that some generation results, such as a high-valence and high-arousal song with a minor key scale, may go beyond the current definition of emotion in [16], where the valence naturally has a strong correlation to the major-minor tonality (Figure 1). Therefore, we limit major keys to `<Emotion_Positive>` and minor keys to `<Emotion_Negative>` during the inference stage. We acknowledge that this can be overly simplifying. Since this paper focuses mainly on the valence-arousal disentanglement during the generation process, we leave this exploration of generating any emotion within any key as an advanced topic for future research.

In the second stage, the performance model generates piano performance with desired valence and arousal combination given the lead sheet from the first stage. For example, to generate a music piece of Q3, a “Negative” lead sheet and a “Q3” emotion event are selected as conditions. Additionally, this two-stage framework enables the flexibility to generate different arousal levels of piano performance under the same lead sheet, delivering some scenarios when the music need to shift quickly to complement the scenes in movies or daily videos (detail in Section 4 and the demo page).

4. EXPERIMENTS

4.1 Datasets and Preprocessing

As presented in Table 1, we collect different datasets for pretraining and finetuning phases as mentioned in Section 3.2.3. For pretraining the lead sheet model, we use the HookTheory dataset [39,40], where we choose 18,206 lead sheets with high-quality and human-transcribed melody, chord and key annotations in 4/4 time signature. We simplify 249 chord quality classes into 11 types³ as the same set in the other datasets below. For pretraining the performance model, we use the Pop1k7 dataset [26], consisting of 1747 transcribed pop piano performances. Since Pop1k7 does not contain lead sheet annotations, we refer [38] to extract melodies using the skyline algorithm [41], recognize chords using the chorder library [42], and detect key signatures using [43] in MIDI Toolbox [44].

For finetuning the models with emotion conditions, we use the EMOPIA dataset [7], consisting of 1,071 music clips with human-annotated emotion labels. Similar to Pop1k7, we obtain the lead sheets of EMOPIA by extracting melodies using the algorithm in [45] and recognizing chords using the algorithm in [46]. Empirically, we observe that specifically in the EMOPIA dataset, melodies and chords extracted by these alternative algorithms are more correct compared to the skyline algorithm and the chorder library. Additionally, we found the key signature labels in EMOPIA are not fully correct since they are also obtained by the detection algorithm with error rates. Since the valence modeling is strongly related to the musical keys and modes, we manually correct the key annotations of 367 clips in EMOPIA to ensure a high quality of lead sheets.

All datasets are randomly divided into respective training and validation sets at the ratio of 9:1. As a result in our functional representation, the vocabulary size of events is 215 for lead sheet and 324 for piano performance.

4.2 Model Settings

The lead sheet model is a 12-layer Transformer Decoder [47] with 8 heads, 512 hidden dimensions and relative positional encoding [48]. The performance model is

³ Major, minor, augment, diminish, suspend2, suspend4, major7, minor7, dominant7, diminish7, half-diminish7

Dataset	# clips (major)	# bars	# events
HookTheory [40]	18,206 (9,737)	10.84	282.81
Pop1k7 [26]	1,747 (1,264)	104.82	6794.86
EMOPIA(L) [7]	1,071 (618)	16.94	435.22
EMOPIA [7]	1,071 (618)	17.09	1311.47

Table 1. The datasets. (major) denotes the number of clips in major key (and the left is in minor key). The #bars and #events are average numbers across a dataset. EMOPIA(L) refers to EMOPIA lead sheets.

similar to the lead sheet model except with Performer attention [49]. The total parameter sizes are 41 million and 38 million respectively.

Both models are trained with the batch size of 4, the maximum sequence length of 512 (lead sheet model) or 3072 (performance model), and the Adam optimizer with $\beta = (0.99, 0.9)$. We adopt a 200-step warm-up to achieve the maximum learning rate of $1e-4$ for pretraining and $1e-5$ for finetune. All models are implemented by PyTorch and trained on one NVIDIA Tesla V100 GPU. The lead sheet model took around 180,000 steps to converge and the performance model took around 200,000 steps. Nucleus sampling [50] is employed in the inference phase. We referred [38, 51] to choose the sampling hyperparameters $\tau = 1.2$, $p = 0.97$ for the lead sheet model and $\tau = 1.1$, $p = 0.99$ for the performance model.

4.3 Baseline and Ablations

We consider the emotion-driven piano performance generation model in EMOPIA [7] as our baseline, which generates music in an end-to-end paradigm instead of two stages. To ensure the fair comparison of generation performance, we trained the baseline model under the same datasets in both pretraining and finetune phases, and replaced the original CP-Word representation with REMI as the former usually yields better generation performance and more comparable to our proposed functional representation. Two other related works [8, 9] are not included in comparison due to the main reason that we focus more on the evaluation of the two-stage framework in valence and arousal modeling; and the partial reason that they are not open-source or releasing the reproducible model weights.

We conduct a comprehensive ablation study to evaluate if each proposed design benefits the emotion modeling of music generation. Specially, these designs include: 1) the two-stage generation, 2) the functional representation, and 3) the dataset pretraining. In the following sections, models are denoted as **<representation(stage)>**. For example, REMI(one) denotes the one-stage generation model with REMI representation as the baseline, and REMI(two) denotes the two-stage generation as one variant.

4.4 Objective Evaluation and Results

Even though previous studies [7–9] employ metrics, such as Pitch Range (PR) and Number of Pitch Classes (NPC), to evaluate the generation performance, they do not pro-

	M	C	M+C	P
REMI+key (two)	0.465	0.065	0.075	0.418
–w/o. pretrain	0.350	0.105	0.130	0.343
functional (two)	0.505	0.700	0.735	0.548
–w/o. pretrain	0.400	0.570	0.625	0.430
Real data	0.578	0.695	0.746	0.812

Table 2. Key consistency calculated across all components, including melody (M), chord (C), lead sheet (M+C) and performance (P).

vide any evidences on the superiority of melody development, chord progression, and texture arrangement of music. Therefore, a model with more similar PR and NPC values to those of the target dataset does not necessarily promise a better generation quality than others.

Instead of using such metrics, we wish to evaluate the consistency between the input musical conditions and the generation results. We introduce **key consistency** to assess if a model can generate music pieces that adhere to the desired input key signatures, which is highly correlated to the lead sheet development and valence modeling. Specifically, key consistency measures the match between the key condition $\langle \text{Key}_* \rangle$ and the actual key detected in the generation using the algorithm [44] with an 81% accuracy rate. We compare REMI and our functional representation to determine if the functional representation can improve the key consistency via more close and interactive designs on key, melody, and chord. Since this metric requires the key as conditions, we add the $\langle \text{Key}_* \rangle$ event in REMI after $\langle \text{Emotion}_* \rangle$ (as REMI+key in Table 2) when training the model. The non-pretrained versions are also included for comparison. Each model generates 200 lead sheets (100 high and 100 low valence) and 400 performance samples (100 per emotion quadrant) for evaluation.

From Table 2, the functional representation outperforms REMI (i.e., REMI+key) across all components and even achieves compatible accuracy to real data over the lead sheet component. This demonstrates the effectiveness of the functional representation, by representing notes and chord roots relative to key events for key modeling. In contrast, REMI struggles with associating chord events with keys due to the ignorance of chord labels serving different functions in different key scales. Moreover, pretraining process introduces musical priors to enhance the learning of key relationships with other musical elements, improving key consistency for both representations.

4.5 Subjective Evaluation and Results

We leverage an online listening test to assess the emotion modeling ability of models. The test was conducted to collect user responses on three parts: 1) valence modeling, 2) arousal modeling, and 3) 4Q emotion modeling. During this test, the quality of the generated music has also been assessed implicitly as it is a prerequisite to the emotion expression in the music. 22 participants were engaging in this test, 5 with less than 2 years of musical training, 8 with 2-5 years, 3 with 5-10 years, and 6 with more than 10 years.

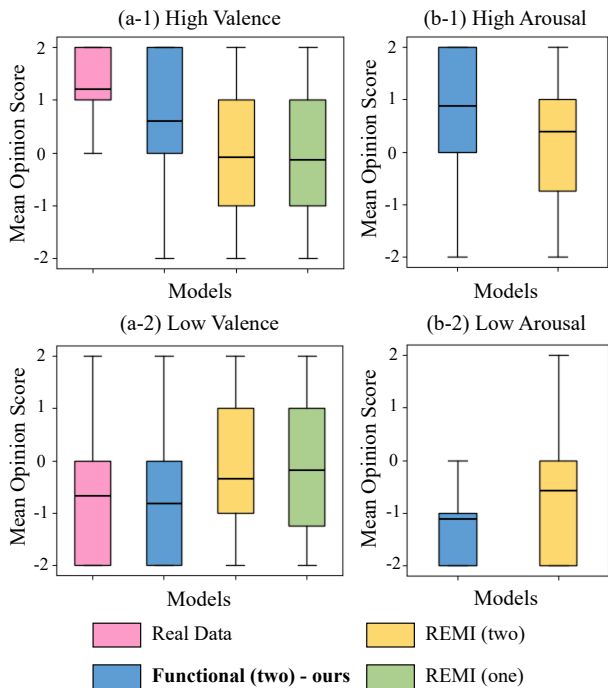

Figure 6. The mean opinion score performance on the valence-oriented and arousal-oriented listening tests. For (a-1) and (b-1), the higher score the better performance; for (a-2) and (b-2), the lower score the better performance.

4.5.1 Valence Modeling

In this part, each participant listened to 16 generated tracks of piano performance from four models [four tracks (two high valence and two low valence) per model]: 1) Real data; 2) REMI (one); 3) REMI (two); 4) Functional (two). For each track, participants rated its positiveness from -2 (low valence) to 2 (high valence) with the step size 1.

The left of Figure 6 (‘a’) presents the mean opinion scores for the valence-oriented test, where the Functional (two) model significantly outperforms both REMI (two) and REMI (one) models. The REMI (two) model shows a slight improvement over REMI (one) due to its two-stage design. Our proposed Functional (two) model even marginally exceeds real data in low valence scores, which could be due to the potential subjective biases in the negative emotion as discussed in [10]. And our model achieves both great performance in high valence and low valence results, demonstrating a good balance in valence modeling.

4.5.2 Arousal Modeling

In the second part, the functional (two) and REMI (two) models are chosen to compare their arousal modeling performance. Specifically, we wish to explore whether they can generate piano performance with either high or low arousal under the same lead sheet based on the given conditions (Q1 and Q4 for positive lead sheets, Q2 and Q3 for negative ones). Two pairs of generated tracks are randomly drawn for each model and each valence level, where every pair includes two tracks of different arousal conditions. For each track, participants rated its arousal level from -2 (low arousal) to 2 (high arousal) with the step size 1.

Figure 7. The confusion matrices on the 4Q listening tests.

The right of Figure 6 (‘b’) presents the results. The Functional (two) model surpasses REMI (two) by an average of 0.5 point, highlighting its superior ability to differentiate between the musical features of the two arousal levels through performance. Additionally, it is rare for Functional (two) to be incorrectly identified as high arousal under low arousal conditions (Figure 6 (b-2)).

4.5.3 4Q Emotion Judgement

In the last part, participants needed to choose the best option from four options (4Q) for each track, with 8 tracks in total for the two models the last section (4 tracks per model and 1 track per emotion).

Figure 7 presents the confusion matrices of two models. The Functional (two) model achieves the higher overall accuracy than that of REMI (two) (71.5% vs. 31.0%). When examining each emotion category, Functional(two) demonstrates superior performance in Q3 and Q4 than Q1 and Q2. Furthermore, music pieces generated from it with high valence conditions are misidentified almost based on their arousal levels; for instance, pieces intended for Q1 are almost mistaken for Q4 and vice versa. In contrast, for REMI(two), the misclassifications are across all categories, demonstrating its limitations in modeling the four emotion classes although through two-stage generation.

All above evaluations support that the combination of two-stage framework and functional representation is effective in controlling the emotion of the music it generates to a certain extent.

5. CONCLUSION AND FUTURE WORK

In this paper, we first explore emotion disentanglement through a two-stage Transformer-based framework for emotion-driven piano performance generation. Then we propose a novel functional representation for symbolic music to capture the interactions among musical keys, modes, chords, and melodies in relation to the emotion contexts. An objective metric is designed to qualify the key modeling of the proposed method, and subjective evaluations further confirm its ability to convey desired emotional perception. In the future, we wish to focus on enhancing the flexibility of emotional music generation across all musical keys and investigating new applications fostered by our framework, such as the controls of valence and arousal attributes under similar music motifs.

6. ACKNOWLEDGMENT

The work is supported by a grant from the National Science and Technology Council of Taiwan (NSTC 112-2222-E-002-005-MY2). This work also benefits from the review comments of an unpublished work [52], which is an early version of the present study. While the concept of functional representation has been mentioned in that previous work [52], its focus was on emotion-driven melody harmonization and the effectiveness of the functional representation in that context was unclear, as the melody was pre-given and fixed. In the current work, melody and chords are generated together, allowing more flexibility for emotion control with the proposed functional representation. The source code of that previous work can be found at the GitHub repo: https://github.com/Yuer867/EMO_Harmonizer.

ABSTRACT

Singing voice beat tracking is a challenging task, due to the lack of musical accompaniment that often contains robust rhythmic and harmonic patterns, something most existing beat tracking systems utilize and can be essential for estimating beats. In this paper, a novel temporal convolutional network-based beat-tracking approach featuring self-supervised learning (SSL) representations and adapter tuning is proposed to track the beat and downbeat of singing voices jointly. The SSL DistilHuBERT representations are utilized to capture the semantic information of singing voices and are further fused with the generic spectral features to facilitate beat estimation. Sources of variabilities that are particularly prominent with the non-homogeneous singing voice data are reduced by the efficient adapter tuning. Extensive experiments show that feature fusion and adapter tuning improve the performance individually, and the combination of both leads to significantly better performances than the un-adapted baseline system, with up to 31.6% and 42.4% absolute F1-score improvements on beat and downbeat tracking, respectively.

1. INTRODUCTION

Singing voice beat tracking is an important music information retrieval (MIR) task that can serve many downstream applications. For example, singing transcription can utilize beats to finetune the onsets of the transcribed notes for better accuracies [1] as well as automatic accompaniment generation, where the beat information can be instrumental for drum arrangements [2]. However, existing literature on beat tracking mostly focused on music with instrumental accompaniment [3–11], and tracking beats of singing voice is largely unaddressed and remains a key challenge to date. Its difficulty can be attributed to the lack of musical accompaniment that contains rhythmic and harmonic

patterns vital for beat tracking in general. This leads to several challenges in developing effective singing voice beat tracking systems.

First, the existing state-of-the-art music beat tracking systems deliver poor performances on singing voices due to the notable inherent disparities between complete music songs and singing voices [12]. For example, the traditional music beat tracking system often learns latent mapping based on acoustic clues such as the spectrogram magnitude [13–15], which is often caused by the reoccurring drums or bass. Such clues, however, are barely present in singing voices. Inspired by the similarity between the singing voice and speech [16], the self-supervised learning (SSL) speech representations are utilized and demonstrate advantages over spectral features in singing voices [12].

Second, the naturalistic singing voice data is generally highly non-homogeneous due to its inherent variabilities from different conditions, such as genres, singers, recording devices, or languages [17]. The resulting high degree of singing voice heterogeneity may cause a large mismatch between training and test distributions, which can significantly degrade system performances. This issue is particularly prominent with the singing voice beat tracking that lacks musical accompaniment, as opposed to music beat tracking containing rich percussive and harmonic profiles.

To this end, we present a novel singing voice beat and downbeat tracking system using a temporal convolutional network featuring SSL representations and adapter tuning. More specifically, the SSL DistilHuBERT representations are utilized to capture the essential para-linguistics, semantic, and phonemic level characteristics and are further fused with the generic spectral features to facilitate beat estimations. A series of parameter-efficient adapters are performed to compensate for mismatch arising from the inherent variabilities among diverse singing voice datasets. The main contributions of the paper are summarized below:

1) To our knowledge, this paper is the first to investigate the joint beat and downbeat tracking task featuring the fusion of SSL representations and spectral features. In contrast, similar prior research was conducted in the context of only beat estimations [12] or beat/downbeat tracking using spectral features only [18].

2) Extensive experiments show that the train-test

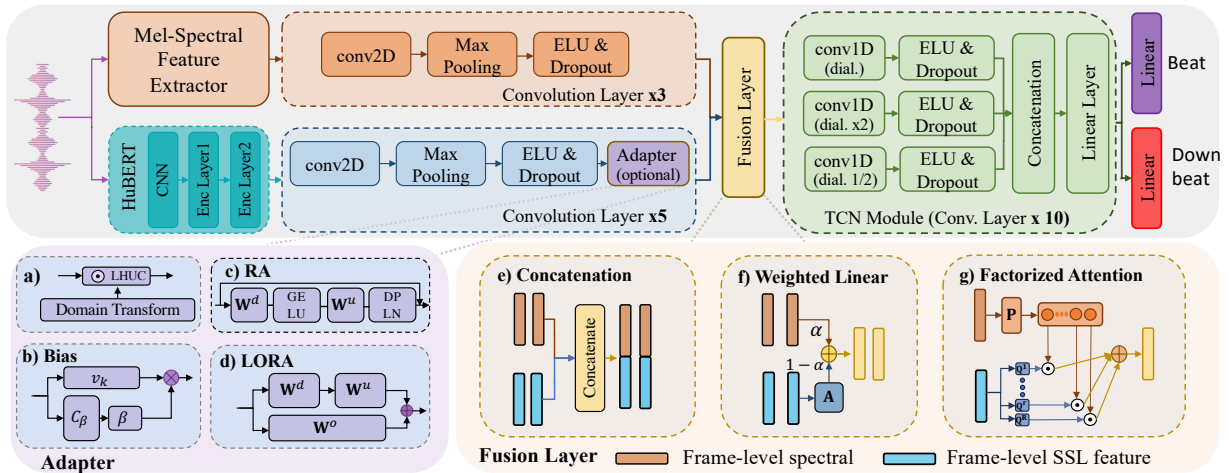

Figure 1. Examples of joint beat and downbeat tracking systems using Temporal Convolutional Network (TCN) shown in the light grey box (top). The pre-trained self-supervised DistilHuBERT model is shown in the deep cyan-blue box (top left). The parameter-efficient adapters described in Section 4 are shown in the light purple colored box (bottom left corner), which includes **a)** Learning Hidden Unit Contributions adaptation, **b)** Bias Adapter adaptation, **c)** Residual Adapter (RA) adaptation and **d)** Low-Rank Adaptation (LoRA). The fusion layer described in Section 3 is shown in the light orange box (bottom right), which includes **e)** Concatenation, **f)** Weighted linear interpolation fusion, and **g)** Factorized attention fusion.

data distribution mismatch issue presented in the non-homogeneous singing voice data significantly degrades the beat-tracking performance, particularly in downbeat estimation. To this end, inspired by the use of parameter-efficient adaptation techniques in machine learning fields [19–24], this paper presents the first work that successfully employs efficient adapter tuning approaches for singing voice beat-tracking tasks to address the mismatch above.

3) The efficacy of the proposed beat tracking approach is consistently demonstrated across various public datasets over the un-adapted baseline beat tracking system. In addition, the inherent generality of the proposed approach and the accompanying implementation details outlined in this paper allow their further application to other beat-tracking systems or MIR tasks.

2. TCN-BASED BEAT TRACKING SYSTEMS

In this paper, we adopt temporal convolutional network (TCN) as the backbone for singing voice beat tracking for two reasons: **1)** TCN has shown solid performances in the traditional beat tracking involving musical accompaniment. First proposed by [25], TCN achieved superior performances to the previous SOTA bi-directional LSTM and has been widely used for beat tracking since then [26, 27]. **2)** Although SpecTNT has recently outperformed TCN [9], TCN is still lightweight with way fewer parameters than SpecTNT, making it easy for deployment and cost-efficient as commercial applications.

2.1 Architecture

The conventional TCN-based beat tracking system consists of a front-end convolution module and a TCN module, connected by a fusion layer shown in Fig. 1 (light grey box, top). Each convolution layer in the front-end module has 20 channels, a stride of one, and kernels with various sizes. Max-pooling, exponential linear unit (ELU) acti-

vation [28], and dropout neural operations are applied to each convolution layer in sequence. The TCN module is stacked by ten dilated convolutional layers with exponentially increased dilation factors $2^0, 2^1, \dots, 2^9$ resulting in a large receptive to capture long temporal contexts. Each dilated convolutional layer contains three dilated convolution blocks, each with different dilation rates (one dilation factor, half the dilation factor, and twice the dilation factor) and 20 channels. ELU activation and dropout operations are applied to each dilated convolution block, followed by an output linear layer shown in Fig. 1 (green box, top right).

2.2 Multi-task Learning

Based on the above TCN-based architecture, the beat-tracking task can be cast as a binary classification through time, for example, classifying the presence or absence of a beat for each frame. To perform the joint beat and downbeat tracking in a single system [26, 27], an auxiliary downbeat tracking task by introducing a separate binary classification linear layer is carried out to produce the downbeat. Thus a multi-task criterion that interpolates between the beat and downbeat binary cross entropy (BCE) costs is adopted for training, which can be formulated as

$$\mathcal{L}_{MTL} = \eta \mathcal{L}_{BEAT} + (1 - \eta) \mathcal{L}_{DBEAT}, \quad (1)$$

where $\eta \in [0, 1]$ is the tunable hyper-parameter for balancing the beat BCE cost \mathcal{L}_{BEAT} and downbeat BCE cost \mathcal{L}_{DBEAT} . Both beat and downbeat prediction outputs are post-processed with a dynamic Bayesian network (DBN) [29–31] to produce the final sequence of predictions [15].

2.3 Input Features

Two types of feature embeddings are fed into the TCN-based beat-tracking system. The first is the traditional 81-dim log-magnitude mel-frequency spectrogram features,

which are widely adopted in the music beat tracking tasks [9, 27, 32]. Another is the SSL DistilHuBERT features. DistilHuBERT [33, 34] is a lightweight self-supervised pre-trained speech foundation model. Its lighter architecture enables faster inference than other pre-trained foundation models. The 768-dim DistilHuBERT feature representations extracted from the last HuBERT layer are proven to serve as beneficial feature embeddings in analyzing singing rhythms [12] due to the acoustic and linguistic similarities between singing voices and speech.

3. FEATURE FUSION

The process of combining diverse feature representations, named feature fusion, plays a vital role in determining the effectiveness of beat-tracking systems [35]. To this end, several fusion approaches are introduced in this section to integrate the traditional spectrogram and pre-trained HuBERT feature representations effectively.

3.1 Early Feature Fusion

Early feature fusion is the combination of diverse feature representations performed early in a neural network [36]. For example, the features are fused at the network's input layer. Let $\mathbf{x} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_T] \in \mathbb{R}^{m \times T}$ and $\mathbf{u} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_T] \in \mathbb{R}^{n \times T}$ denote the spectrogram and HuBERT feature representations with T frames, respectively. Two forms of early feature fusion are investigated.

a) Input concatenation refers to directly concatenating the spectrogram and HuBERT features at the frame level. The concatenated feature representation \mathbf{z} at t -th frame can be expressed as $\mathbf{z}_t = [\mathbf{x}_t; \mathbf{u}_t] \in \mathbb{R}^{n+m}$.

b) Weighted linear interpolation refers to interpolating the frame-level spectrogram and HuBERT feature representations with a learnable hyper-parameter $\alpha \in [0, 1]$. The interpolated feature representation at t -th frame can be formulated as $\mathbf{z}_t = \alpha \mathbf{x}_t + (1 - \alpha) \mathbf{A} \mathbf{u}_t$, where $\mathbf{A} \in \mathbb{R}^{n \times m}$ is a learnable projection matrix to enable the dimension of HuBERT features to be consistent with that of the spectrogram features.

3.2 Late Feature Fusion

The combination of diverse features at a later network layer leads to late feature fusion [37]. This allows the model to leverage high-level, abstract representations, leading to more informed decisions and improved performance. As shown in Fig. 1, the spectrogram and pre-trained HuBERT features are first fed into a separate CNN module before being further combined using different fusion schemes. Let $\hat{\mathbf{x}} = [\hat{\mathbf{x}}_1, \hat{\mathbf{x}}_2, \dots, \hat{\mathbf{x}}_T] \in \mathbb{R}^{k \times T}$ and $\hat{\mathbf{u}} = [\hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2, \dots, \hat{\mathbf{u}}_T] \in \mathbb{R}^{k \times T}$ denote the high-level CNN output hidden representations with T frames using the spectrogram and HuBERT features, respectively. The concatenation and weighted combination operations can also be performed in a late fusion style, which is illustrated as **a)** late concatenation fusion $\hat{\mathbf{z}}_t = [\hat{\mathbf{x}}_t; \hat{\mathbf{u}}_t] \in \mathbb{R}^{2k}$ and **b)** late weighted linear interpolation fusion $\hat{\mathbf{z}}_t = \alpha \hat{\mathbf{x}}_t + (1 - \alpha) \hat{\mathbf{u}}_t$.

3.3 Factorized Attention Fusion

In order to focus on relevant selective representations while suppressing less important ones, factorized attention fusion is performed in a late fusion fashion. The SSL hidden representation at t -th frame $\hat{\mathbf{u}}_t$ are first factorized into R subspace representations $[\mathbf{v}_t^1, \mathbf{v}_t^2, \dots, \mathbf{v}_t^R] \in \mathbb{R}^{k \times R}$ using a series of parallel linear transforms, which is expressed as

$$[\mathbf{v}_t^1, \mathbf{v}_t^2, \dots, \mathbf{v}_t^R] = [\mathbf{Q}^1, \mathbf{Q}^2, \dots, \mathbf{Q}^R] \hat{\mathbf{u}}_t, \quad (2)$$

where $\mathbf{Q}^r \in \mathbb{R}^{k \times k}$ is the linear transformations for r -th subspace. The spectrogram hidden embedding at t -th frame $\hat{\mathbf{x}}_t$ is projected into a R -dim interpolation vector $\mathbf{w}_t = [w_t^1, w_t^2, \dots, w_t^R] \in \mathbb{R}^R$ using a projection matrix $\mathbf{P} \in \mathbb{R}^{R \times k}$, which is given as $\mathbf{w}_t = \text{Softmax}(\mathbf{P} \hat{\mathbf{x}}_t)$. Subsequently, the fused feature representation can be obtained by an attention mechanism [38],

$$\hat{\mathbf{z}}_t = \text{Sigmoid}\left(\sum_{r=1}^R w_t^r \mathbf{v}_t^r\right). \quad (3)$$

4. PARAMETER EFFICIENT ADAPTATION

A straightforward solution to reduce the mismatch between training and evaluation distributions is to directly fine-tune the entire system using the target-domain singing voice data. However, this adaptation scheme not only encounters overfitting problems due to the scarcity of singing voices but also poses key challenges to adaptation parameter storage. Parameter-efficient adaptation approaches [39–41] that introduce limited adaptation parameters with the original model parameters unchanged have been proposed to tail for the above overfitting and parameter storage issues. Inspired by this idea, several prominent parameter-efficient adapters are explored for singing voice beat-tracking systems in this section.

4.1 Learning Hidden Unit Contributions

Learning hidden unit contributions (LHUC) adaptation is an effective speaker adaptation solution that accounts for speaker variation of speech [42]. The basic idea of LHUC adaptation is to modify the amplitudes of activation outputs using a scaling vector. Let $\mathbf{r}_{l,e} \in \mathbb{R}^u$ denote the adaptation parameters for the e -th domain in the l -th hidden layer, where u is the dimension of adaptation parameters. The adapted hidden output $\mathbf{h}_{l,k}$ can be given as

$$\mathbf{h}_{l,k} = \mathbf{h}_l \odot \xi(\mathbf{r}_{l,k}), \quad (4)$$

where \mathbf{h}_l is the original hidden activation output at the l -th hidden layer, \odot is the Hadamard product operation, $\xi(\mathbf{r}_{l,e})$ is the scaling vector parameterized by $\mathbf{r}_{l,e}$, and $\xi(\cdot)$ is the element-wise $2 \times \text{Sigmoid}(\cdot)$ function with a range of $(0, 2)$. During adaptation, the adaptation parameters $\mathbf{r}_{l,k}$ for each domain are initialized as zeros vector. An example of LHUC adaptation is shown in Fig. 1(a).

4.2 Bias Adaptation

The bias adapter adaptation [43] adds frame-level bias to the hidden representation shifts using a domain-dependent shift vector $\mathbf{v}_e \in \mathbb{R}^u$ and a linear layer C_β , which is shown in Fig. 1(b). The frames crucial for beat tracking should be assigned a larger representation shift compared to other frames. The linear layer produces a frame-level weight vector $\boldsymbol{\beta} = C_\beta \mathbf{h}_l = [\beta_1, \beta_2, \dots, \beta_T] \in \mathbb{R}^T$, where β_t denotes the weight of the t -th frame hidden representation. Therefore, the domain-dependent representation shifts \mathbf{v}_e can be enhanced by applying frame-level weights, and the adapted hidden layer output can be expressed as

$$\mathbf{h}_{l,e} = \mathbf{h}_l + \mathbf{v}_e \otimes \boldsymbol{\beta}, \quad (5)$$

where \otimes is the outer product operation, and the outer product of shift-vector \mathbf{v} and the weight $\boldsymbol{\beta}$ can be expressed as $\mathbf{v} \otimes \boldsymbol{\beta} = [\beta_1 \mathbf{v}_e, \beta_2 \mathbf{v}_e, \dots, \beta_T \mathbf{v}_e] \in \mathbb{R}^{u \times T}$.

4.3 Residual Adapter

Inspired by the residual idea [44], a residual adapter (RA) with slight modifications is designed for beat tracking. The adapter starts with a down-linear projection $\mathbf{W}_e^d \in \mathbb{R}^{r \times u}$, followed by a non-linear GeLU activation function $\zeta(\cdot)$, and an up-linear projection $\mathbf{W}_e^u \in \mathbb{R}^{u \times r}$. Let $f_{RA}(\cdot; \boldsymbol{\Theta}_{l,e})$ denote the residual adapter function for e -th domain in the l -th hidden layer, where $\boldsymbol{\Theta}_{l,e}$ is the adaptation parameters for e -th domain. The adapted hidden outputs are given as

$$\mathbf{h}_{l,k} = \mathbf{h}_l + f_{RA}(\mathbf{h}_l; \boldsymbol{\Theta}_{l,e}), \quad (6)$$

$$f_{RA}(\mathbf{h}_l; \boldsymbol{\Theta}_{l,e}) = \text{LN}(\text{DP}(\mathbf{W}_{l,e}^u \zeta(\mathbf{W}_{l,e}^d \mathbf{h}_l))), \quad (7)$$

where $\text{DP}(\cdot)$ and $\text{LN}(\cdot)$ denote the dropout and layernorm operations, respectively. The adaptation capacity can be controlled by managing the number of parameters in each adapter module through controlling the bottleneck dimension r . An example of an RA adapter is shown in Fig. 1(c).

4.4 Low-rank Adaptation

Instead of the non-parallel nature of adapter modules that consumes additional GPU time mentioned above, Low-rank adaptation (LoRA) [45] reduces the number of adaptation parameters by learning rank-decomposition matrix pairs $\{\mathbf{W}^d, \mathbf{W}^u\}$ while freezing the original weights. The LoRA-adapted linear hidden output can be expressed as

$$\mathbf{h}_{l,k} = f_{LoRA}(\mathbf{h}_{l-1}; \boldsymbol{\Theta}_{l,e}), \quad (8)$$

$$= (\mathbf{W}_l^o + \mathbf{W}_{l,e}^u \mathbf{W}_{l,e}^d) \mathbf{h}_{l-1}, \quad (9)$$

where $f_{LoRA}(\cdot; \boldsymbol{\Theta}_{l,e})$ is the LoRA adapter, $\mathbf{W}_l^o \in \mathbb{R}^{n \times u}$ is the original pre-trained weight matrix, $\mathbf{W}_{l,e}^d \in \mathbb{R}^{r \times u}$ and $\mathbf{W}_{l,e}^u \in \mathbb{R}^{n \times r}$ are the trainable low-rank decomposition matrices. It is noted that the rank $r \ll \min(u, n)$ is far less than the dimension of the original matrix, which allows for reducing the number of adaptation parameters. An example of a LoRA adapter is shown in Fig. 1(d).

Table 1. Description of the singing voice beat tracking datasets. † and * represent the music beat tracking dataset and the music source separation dataset, respectively.

Dataset	# Hours	# Excerpts	Genres
GTZAN† [48]	5.9	754	Blues, Country, Disco, Hiphop, etc.
RWC Pop† [49]	5.4	273	Japanese Pop., etc.
Ballroom† [50]	2.8	313	Rumba, Tango, Waltz, Jive, etc.
Hainsworth† [51]	1.9	173	Jazz, Metal, Rock, Opera, etc.
MUSDB18* [52]	6.4	144	Pop., Country, Rock, etc.
URSinger* [53]	3.4	142	Chinese Pop., etc.

4.5 Estimation of Adaptation Parameters

Let $\mathcal{D}_e = \{\mathbf{X}_e, \mathbf{Y}_e\}$ denote the adaptation data for e -th domain, where \mathbf{X}_e and \mathbf{Y}_e stand for the singing voice waveform and the corresponding beat/downbeat sequences, respectively. Without loss of generality and for simplicity, let $\boldsymbol{\Theta}$ denote the original model parameters. In the context of adaptation, the adaptation parameters $\boldsymbol{\Theta}_e$ conditioned on the e -th domain can be estimated by minimizing the loss function in Eqn. (1), which is given by

$$\hat{\boldsymbol{\Theta}}_e = \arg \min_{\boldsymbol{\Theta}_e} \{\mathcal{L}_{MTL}(\mathcal{D}_e; \boldsymbol{\Theta}, \boldsymbol{\Theta}_e)\}. \quad (10)$$

5. EXPERIMENTS

5.1 Datasets and Evaluation Metrics

To the best of our knowledge, there are no publicly available datasets that include pristine vocal audio alongside beats and downbeats annotations. Annotating beats and downbeats based solely on vocal signals can be arduous and subjective, even by human experts, since there are no evident rhythmic cues like percussive instruments to accurately comprehend the singer’s rhythmic intentions.

Therefore, we follow the strategy described in [12] to utilize the existing public MIR datasets and systems to create the singing voice data with beat/downbeat annotations. This includes **a) four music beat tracking datasets** with available beat annotations, where the singing signals are extracted by the Demucs source separation model [46], and **b) two music source separation datasets** with available isolated singing tracks, where the preliminary beats and downbeats annotations are generated by the existing TCN-based beat tracking system [25] using the full music mix (singing with musical accompaniment), then manual revision is further performed to correct the potential annotation errors. Altogether, six datasets are used in this paper as shown in Table 1, where a silence-stripping technique is applied to each dataset to remove the long chunks of silence. The 90% of the whole data randomly selected from a uniform distribution is used for training, while the remaining 10% is used for evaluation. The evaluation metric of F1-score with a tolerance window of ± 70 ms, a typical setting commonly used in the traditional beat tracking [25], is adopted for our performance evaluation. We also adopt P-score, Cemgil, and Goto [47] as additional evaluation metrics to further demonstrate the advantages of the proposed approaches in the final experiments (Table 4).

Table 2. Beat and downbeat tracking performance of TCN systems using different feature fusion methods evaluated on the GTZAN, RWC pop (RWCPO), and MUSDB18 (MUSDB) datasets in terms of F1-score.

ID	Input Features	Fusion Methods	GTZAN	RWCPO	MUSDB
Beat/Downbeat Tracking F1 Scores					
1	Spectrogram	-	0.48/0.26	0.65/0.53	0.31/0.15
2	DistilHuBERT	-	0.74/0.47	0.76/0.68	0.38/0.17
3	Spectrogram & DistilHuBERT	Input Concatenation	0.78/0.56	0.83/0.79	0.41/0.25
4		Input Weighted	0.77/0.55	0.86/0.81	0.43/0.25
5		Late Concatenation	0.81/0.53	0.87/0.81	0.45/0.25
6		Late Weighted	0.79/0.58	0.88/0.84	0.47/0.26
7		Factorized Attention	0.80/0.51	0.91/0.82	0.48/0.23

5.2 Implementation Details

Two feature extractors, including the mel-spectrogram feature extractor and the pre-trained SSL DistilHuBERT feature extractor [34], are employed to generate the 81-dimensional spectral features and 768-dimensional SSL feature representations of vocal signals. In this paper, the vocal signals of all datasets are resampled to 16000 Hz. As illustrated in Section 2, the temporal convolution network consists of a front-end convolution and TCN modules. The front-end convolution module tailored for late feature fusion consists of a 3-layer convolution network¹ and a 5-layer convolution network² for processing the spectral and SSL feature representations, respectively. The kernel size and stride for the Max-pooling operation are 1×3 for all convolution layers. The TCN module consists of ten dilated convolution layers, wherein the dilation factors increase exponentially.

During the TCN-based beat tracking system training, all weights of the system are randomly initialized. The Ranger optimizer [54] with an initial learning rate of 0.001, the ReduceLRonPlateau scheduler with a factor of 0.9 and patience of 5, and a dropout rate of 0.1 are used for training and adaptation. The training and adaptation epochs are set as 100 and 30, respectively. The hyper-parameter of multi-task learning in Eqn. (1) is empirically set as $\eta = 0.2$. Since the ratio of positive and negative examples in the beat-tracking task is often imbalanced, the weighted binary cross-entropy loss is applied, and the weights of positive examples for the beat and downbeat costs are set to be 10 and 20, respectively.

5.3 Performance of Feature Fusion

Table 2 shows the beat and downbeat tracking F1 scores of TCN systems using different feature representation fusion methods. Several important findings can be observed. **a)** The systems using SSL DistilHuBERT features (ID.2) show better F1 performance than those using the traditional spectral features (ID.1) in all three evaluation sets. This demonstrates that the semantic information captured by SSL speech representation is crucial for singing voice beat

¹ The channel, kernel size, stride, and padding of Conv2D used in 3-layer convolution network for each convolution layer are {20, 20, 20}, {3x3, 1x12, 1x3}, {1, 1, 1} and {1x0, 0x0, 1x0} respectively.

² The channel, kernel size, stride, and padding of Conv2D used in 5-layer convolution network for each convolution layer are {20, 20, 20, 20, 20}, {3x3, 1x12, 1x3, 3x3, 1x12, 3x3}, {1, 1, 1, 1, 1} and {1x0, 0x0, 1x0, 0x0, 1x0} respectively.

Figure 2. F1-score of the beat (upper) and downbeat (bottom) tracking when training data and test data are collected from the same (diagonal value) or different sources.

tracking. **b)** All systems that leverage feature fusion approaches (ID.3-7) outperform the systems using only one single spectral (ID.1) or SSL feature (ID.2). This confirms our motivation that spectral and SSL features are complementary as they capture different characteristics of vocal signals. **c)** The late weighted linear interpolation fusion method (ID.6) achieves the best F1 results on the downbeat tracking and competitive beat tracking performance among all fusion approaches, therefore we selected it for the following experiments.

5.4 Performance of Adaptation

The mismatch across different datasets is revealed in Fig. 2. **a)** When the system is trained on singing voice data from the same source as the test data, the best beat and downbeat tracking performance are obtained (diagonal value). **b)** The mismatch between training and test distributions (non-diagonal) significantly degrades the beat tracking performance, especially in downbeat tracking. This confirms our assumption that the mismatch across different datasets is particularly prominent in singing voice beat tracking due to the lack of robust rhythmic and harmonic patterns. Therefore, mismatch is an essential issue that needs to be addressed in multi-condition training.

Table 3 shows the beat and downbeat tracking performance of the TCN systems configured with different adapters using only DistilHuBERT features. Several trends can be found. **a)** It is not surprising that multi-condition systems (ID.2) trained on all six datasets do not always outperform the in-domain systems (ID.1) trained on the well-controlled data from the same source as test data because of the mismatch issue. This demonstrates that

Table 3. Beat and downbeat tracking performance of TCN systems configured with different adapters on the GTZAN, RWCPO, Ballroom (BROOM), Hainsworth (HAINS), MUSDB, and URSing (URSIN) datasets in terms of F1-score.

ID	Systems	Adapter			Datasets

blindly expanding the training data is insufficient to enhance the system’s generalization. **b)** All systems configured with adapters (ID.4-7) improve the performance over both multi-condition systems (ID.2) and in-domain systems (ID.1), which suggests that parameter-efficient adapter tuning methods can address the mismatch issue effectively. **c)** The residual adapter (RA) (ID.7) applied at the first CNN layer achieves the best results relative to other adaptation approaches. It is noteworthy that RA adaptation using only 20% of adaptation parameters shows comparable performance to fully fine-tuned techniques (ID.3). In addition, the observation that the performance gain of downbeat tracking is greater than that of beat tracking is consistent with our finding in Fig. 2 that the downbeat tracking performance is more sensitive to the mismatch issue. **d)** When incorporating adapters into the second or third CNN layer (ID.8,9), with acceptable performance degradation, RA adaptation delivers a much lighter architecture with fewer parameters.

5.5 Performance of The Proposed Method

The advantages of the proposed method incorporating both late weighted linear interpolation feature fusion and RA adapter are demonstrated in Table 4. The evaluation results are the overall performance of all six evaluation sets using micro averaging. Two main observations can be found.

First, the multi-condition system using the proposed feature fusion approaches (ID.3) still outperforms the systems (ID.1,2) using only one spectral or SSL feature. Of particular interest, this system (ID.3) is compared to the existing singing voice beat tracking system [12], where the same evaluation protocol is followed by using the entire 5.9-hrs GTZAN dataset for testing³. As a result, our system achieved beat tracking F1-score of 0.784 on GTZAN, a significant **5.1%** absolute improvement compared to 0.733

³ The remaining five datasets are therefore used for training our system, which is less data compared to [12].

from [12] even using less training data.

Second, consistent performance improvements across all evaluation metrics are observed when the adapter tuning scheme (ID.4) is applied. Overall significant F1-score improvements of up to **31.6%** and **42.4%** absolute were obtained over the baseline un-adapted system using only one feature on the beat and downbeat tracking, respectively. In particular, the beat/downbeat performances of 0.87/0.78, 0.95/0.87, 0.85/0.75, 0.66/0.49, 0.68/0.49, and 0.79/0.41 are achieved by the proposed approach (ID.4) on the test split of GTZAN, RWC pop, Ballroom, Hainsworth, MUSDB, and URSing datasets, respectively.

6. CONCLUSIONS

This paper proposed a temporal convolution network based beat-tracking framework featuring self-supervised learning (SSL) representations and efficient adapter tuning to track the beat and downbeat of singing voices jointly. Feature fusion strategies were performed to leverage the advantages of the generic spectral and SSL speech feature representations. Efficient adapter tuning was utilized to mitigate the sources of variabilities of the non-homogeneous singing voice data. Experimental results showed that the proposed approach significantly outperforms the un-adapted baseline system using only spectral or SSL features. The inherent generality of the proposed approaches allows their further application to other beat-tracking systems or MIR tasks. Future work will focus on solving the data sparsity issue of the singing voice beat tracking task.

ABSTRACT

Are composers' emotional intentions conveyed to listeners through audio features? In the field of Music Emotion Recognition (MER), recent efforts have been made to predict listeners' time-varying perceived emotions using machine-learning models. However, interpreting these models has been challenging due to their black-box nature. To increase the explainability of models for subjective emotional experiences, we focus on composers' emotional intentions. Our study aims to determine which audio features effectively predict both composers' time-varying emotions and listeners' perceived emotions. Seven composers performed 18 piano improvisations expressing three types of emotions (*joy/happiness*, *sadness*, and *anger*), which were then listened to by 36 participants in a laboratory setting. Both composers and listeners continuously assessed the emotional valence of the music clips on a 9-point scale (1: 'very negative' to 9: 'very positive'). Linear mixed-effect models analysis revealed that listeners significantly perceived the composers' intended emotions. Regarding audio features, the RMS was found to modulate the degree to which the listener's perceived emotion resembled the composer's emotion across all emotions. Moreover, the significant audio features that influenced this relationship varied depending on the emotion type. We propose that audio features related to the emotional responses of composers-listeners can be considered key factors in predicting listeners' emotional responses.

1. INTRODUCTION

Music holds the power to convey emotions and evoke strong emotional responses in its listeners. There is a growing interest in utilizing Music Emotion Recognition (MER) systems for personalized music experiences, such as music recommendations, automated music generation, and diverse multimodal experiences. However, identifying the

variables that effectively predict listeners' emotional experiences is a challenging problem due to the complexity of its mechanisms [1]. While recent MER studies employ machine learning techniques to predict emotions based on dynamic listener annotations [2, 3], they often lack an interpretation of the underlying factors driving emotions.

This study aims to explain the prediction of musical emotions by empirically investigating the relationship between the composer's intended emotion, the listener's perceived emotion, and various audio features of music through time-series data. We specifically focus on the composer's emotional intentions during the music creation process, prior to listener exposure.

1.1 Background

MER tasks are inherently user-centered [4], bringing researchers from interdisciplinary fields such as musicology, cognitive science, and computer science. A range of factors, including individual traits (*e.g.*, personality, mood regulation strategies, etc.) and musical elements (*e.g.*, timbre, rhythm, harmony, etc.) [1], can impact the MER systems, posing challenges for enhancing model performance. Many MER studies rely on emotion datasets where listeners annotate their perceived or felt emotions [5, 6]. Given this, the outcome of the study can be significantly influenced by the taxonomy used to define emotions and the methods used to identify listeners' annotations [4, 7]. While previous studies have often relied on discrete emotion ratings [8–11], the latest trends favor continuous assessments that capture emotional fluctuations during music listening, reflecting the nature of music experiences [2, 3].

Recent studies on Music Emotion Recognition (MER) face several limitations. First, they often overlook the potential influence of emotions expressed by composers or performers on listeners' emotional experiences. Second, MER models commonly encounter challenges in accurately predicting valence compared to arousal [3].

The emotional intentions of composers/performers can play an important role in predicting listeners' emotions, but their significance is often underestimated. Composers or performers express their emotions through musical features such as tempo, dynamics, and timbre [12–14]. Listeners then perceive these cues and interpret the emotions conveyed by the music. When the emotions perceived by

© E.J. Oh, H. Kim, and K.M. Lee. Licensed under a Creative Commons Attribution 4.0 International License (CC BY 4.0). **Attribution:** E.J. Oh, H. Kim, and K.M. Lee, "Which audio features can predict the dynamic musical emotions of both composers and listeners?", in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

the listener align closely with those expressed by the composer or performer, it can foster a strong connection between the listener and the composer/performer, which can positively impact listeners' emotional experiences [15]. This connection can also be observed in physiological responses; a previous study [16] has shown that the similarity of brain activity between audiences and violinists can predict the audiences' fondness for the performance.

Taken together, the relationship between listeners' and composers/performers' emotions is highly correlated with the emotional responses that listeners experience from music, such as music engagement and enjoyment. Therefore, we propose that composers' intentions may play an important role in MER systems that seek to predict listeners' emotions. To determine the impact of composers' intentions on predicting listeners' perceived emotions, we aim to compare prediction outcomes using only audio features against those utilizing both audio features and composers' emotional intentions.

Despite the potential importance of this relationship, there is a lack of research exploring the link between listeners and musical intentions. While some studies investigated how accurately emotional intentions were conveyed to listeners through discrete emotion ratings [8, 17, 18], there is a need to investigate the dynamic emotional responses of composer/performer and listener as the music unfolds over time.

1.2 Research Question

To examine the predictive role of audio features and emotional intentions in shaping listeners' perceived emotions, as well as the significance of time-varying emotional data in this context, we set the following research questions:

RQ1. Do the predictors of listeners' perceived emotions (audio features and composer's emotions) vary based on the methodology, discrete vs. dynamic emotional ratings?

RQ2 Which audio features predict the dynamics of the composer/performer's emotional intentions and listener-perceived emotions, respectively?

RQ3 Which audio features reflect both the composer/performer's and listeners' emotions?

To address these questions, we initially recruited composers to create emotionally expressive piano improvisations. We then collected composers' real-time assessments of the emotions they intended to convey during their performances. The emotional valence scale was only used for the assessments to reduce the complexity of predicting emotions. This approach may reduce cognitive overload for lay participants, who might find 2D emotion mapping (*arousal-valence*) unfamiliar.

For listeners' emotional data, we played the composers' music clips and instructed listeners to continuously infer the expressed emotion. Audio features were extracted via the *librosa* library, including root-mean-square (*RMS*), *flatness*, *zero-crossing*, *spectral centroid*, and *roll-off*, chosen based on previous research on audio features and emo-

tions [3, 9, 19].

We employed Linear Mixed-Effects (LME) models for multi-level regression analysis, which are suitable for handling hierarchical, non-independent time-series data. By accounting for variability within and between music clips, we investigated whether listeners effectively captured changes in the composer's intentions, independent of the specific characteristics of individual clips [20].

2. MATERIALS

2.1 Composers' Emotion Data

2.1.1 Participants

We recruited eight composers from various composition departments in the College of Music, Republic of Korea (4 males and 4 females, $M = 26.88$, $SD = 1.73$). These participants were either undergraduate students or recent graduates with a bachelor's degree in Western classical music composition. On average, they had 14.13 years of formal music training ($SD = 5.72$), with an average of 10.25 years of piano experience ($SD = 3.28$). All composers had prior experience in improvised performances.

2.1.2 Music Performance Setting

Composers were instructed to prepare three semi-improvised piano performances, each lasting 1-2 minutes, expressing primary emotions: *joy/happiness*, *sadness*, and *anger*. These emotions were chosen based on prior literature [10, 20–22] for their distinctiveness in conveying or interpreting emotions through music.

Performances took place in a soundproof booth using a Casio Contemporary CDP-120 digital keyboard, with default piano sound and fixed volume settings. Video recordings were made using a Canon EOS 5D Mark IV Full Frame DSLR, capturing audio via the built-in microphone. The recordings were in .mp4 format, with a resolution of 1920 x 1080, 25 fps, and an audio sampling rate of 48 kHz.

2.1.3 Recording Procedure

Composers were briefed about the experiment and provided consent. They had 15 minutes to prepare, followed by a 30-second sample performance for technical setup. The order of recording for the three performances was randomized, with breaks between each to refresh emotions.

After each performance, composers rated their expressed emotions using arousal, valence, and dominance on a 9-point Likert scale (discrete ratings). Following the recording session, they watched videos of themselves in a randomized order, continuously rating the emotions they expressed during the performance on a 9-point valence scale (1: 'very negative' - 9: 'very positive') in real-time, mirroring the setup described in Section 3.2.

2.1.4 Music Selection

Twenty-four music clips were initially recorded, featuring performances of three emotions by eight composers. Five authors and colleagues participated in the decision-making process for music selection. The selection criteria ensured

	joy/happiness	sadness	anger
arousal	6.33 (2.16)	3 (1.87)	7.57 (1.27)
valence	8.33 (0.82)	3.6 (0.55)	2.14 (0.69)
dominance	6.17 (1.94)	4.8 (1.64)	7.71 (1.60)

Table 1. The *mean* (*SD*) scores of emotion provided by composers for the final 18 music clips ($n = 6$ for each emotion). They were assessed with a 9-point Likert scale.

that 1) each clip effectively conveyed its intended emotion (e.g., a performance expressing sadness was excluded since some researchers felt it was positive valenced music) and 2) was free from distracting noise (e.g., the sound of fingernails on keyboards). An equal distribution of male and female composers per emotion was maintained resulting in 18 chosen clips (six per emotion) from four males and three females.

All 18 clips were pre-processed using Adobe Premiere Pro, ensuring .wav format, 44.1 kHz sampling rate, 16-bit depth, stereo, and normalization according to ITU BS.1770-3 standards¹. The mean clip length was 97.5 seconds (*SD* 14.50), ranging from 73 to 125 seconds. The mean scores of discrete emotional ratings provided by composers are shown in Table 1.

2.2 MIR Audio Features

To select the audio features, we reviewed prior research on emotion perception and acoustic features. Studies highlighted the importance of timbre, tempo, mode, harmony, loudness, and pitch in emotional communication [2, 9, 23, 24]. In particular, tonality, pitch, harmony, articulation, and timbre (e.g., brightness, roughness) were crucial for predicting emotion valence [25, 26]. Machine-learning methods have shown that valence emotion prediction models achieve high explanatory power when incorporating spectral [3, 19] and rhythmic features [19] available in the *librosa* package [27]. Based on this, we used *librosa* to extract audio features from 18 music clips, focusing on loudness (root-mean-square; *RMS*), timbre (*flatness*, *zero-crossing*, *spectral centroid*, and *roll-off*), harmony (Mel-Scale Frequency Cepstral Coefficients; *MFCC*, *chroma*, *spectral contrast*), and rhythm (*dynamic tempo*). To compare audio features with 2D data (*time-valence*) of composers' and listeners' emotional ratings, we selected five features: *RMS*, *flatness*, *zero-crossing*, *spectral centroid*, and *roll-off*. These features were computed using non-overlapping 500 ms windows to match the 2 Hz sampling rate of the emotional ratings.

2.3 Linear Mixed-Effect Models

The linear mixed-effects (LME) model to predict the dynamics of listeners' perceived emotions based on composers' emotional intentions is formulated as:

$$y_{ij} = \alpha + \beta x_{ij} + a_i + b_i x_{ij} + \epsilon_{ij} \quad (1)$$

This equation describes how listeners' perceived emotions (y_{ij}) relate to composers' emotional intentions (x_{ij}) for each music clip (i) at each time point (j). α , β , a_i , and b_i represent the intercept, coefficient for composers' emotional intentions, random intercept for each clip, and random slope for composers' emotional intentions within each clip, respectively. Terms (a_i, b_i) follow a bivariate normal distribution, while ϵ_{ij} represents the residual error.

To investigate the influence of a specific audio feature on this relationship, we employed a LME model:

$$y_{ij} = \alpha + \beta_1 x_{ij} + \beta_2 \cdot feature_{ij} + \beta_3 x_{ij} \cdot feature_{ij} + a_i + b_i x_{ij} + \epsilon_{ij} \quad (2)$$

The terms y_{ij} and x_{ij} represent listeners' perceived emotions and composers' emotional intentions, respectively, for each music clip (i) at each time point (j). α , β_1 , β_2 , and β_3 denote the intercept, composer's emotional intention coefficient, audio feature coefficient, and their interaction coefficient. Random intercept (a_i) and slope (b_i) account for variation within each clip, while ϵ_{ij} represents the residual error.

3. EXPERIMENT

3.1 Participants

We recruited 36 participants (19 males, 17 females; *mean* age 26.06, *SD* 3.56) through campus mail and online bulletin boards. Except for one participant, who held a master's degree in piano performance, all others were non-musicians. On average, they had about 5.81 years of musical training (*SD* 3.91).

To minimize cultural influences on emotional judgments, only native Korean speakers were included in the experiment. Participants had to meet certain criteria: aged 20 or older, normal vision and hearing, no hand movement disabilities, no diagnosed neurological or psychiatric conditions, and no current use of psychiatric medications.

3.2 Emotional Ratings

The experiment was primarily designed to examine the modality effects on musical emotion inference [28, 29]. Using a counterbalanced design, each participant rated six out of 18 music clips per modality (audio-only, video-only, and video-and-audio), with two clips per emotion (joy/happiness, sadness, and anger). This resulted in 216 emotional ratings for each modality and a total of 648 ratings collected across all clips. We used the 216 emotional ratings from the audio-only condition for the analysis to investigate listeners' emotional experiences during music listening in a more ecological setting.

The dynamic emotional rating task was conducted using *PsychoPy* software, mirroring the dynamic emotional ratings by composers described in Section 2.1.3. Participants,

¹ Sample music clips and supplementary materials are available at https://osf.io/4dcxu/?view_only=3f1d818e5c4f4e698ebca357daa656cc.

Figure 1. Screenshot of participants' emotional rating task on a valence scale (1: 'very negative' and 9: 'very positive', labels in Korean).

referred to as *listeners*, were instructed to infer the emotional states of composers expressed in the music. While listening, listeners moved a red dot (initially positioned at 5) along a valence scale (1: 'very negative' - 9: 'very positive') whenever they perceived a change in the composer's emotional state [20, 30] (see Figure 1). Ratings were recorded at a sampling rate of 2 Hz, with timestamps every 0.5 seconds.

After each clip, participants evaluated their psychological state using a 9-point Likert scale for arousal, valence, dominance, flow, and empathy. These assessments aimed to minimize the influence of previous emotional experiences on subsequent ratings, and the results were not included in this paper.

3.3 Experiment Procedure

Participants arrived at the lab, completed consent forms, and filled out questionnaires about their music experience. In a soundproof booth, they then performed an emotional inference task. After a practice trial, they listened to six predetermined music clips, inferring the composer's expressed emotion by adjusting a red circle on a scale. Following each clip, they answered five questions about their psychological state and could take breaks. The task was conducted using headphones, with participants adjusting the volume to their preference.

3.4 Data Analysis

All behavior ratings were interpolated using the *scipy* package in Python to maintain consistent time intervals. Silent sections were manually removed from the beginning and end of each audio file before analysis. Audio features were normalized between 0 and 1 at the composer level using min-max normalization. We found strong multicollinearity between spectral centroid and roll-off, so the roll-off feature was excluded from the final analysis to avoid potential overfitting.

For the analysis of listeners' perceived emotions, we selected one representative emotional rating from the responses of 12 listeners for each music clip. The representative value was calculated as the median of 12 ratings for each time point of each clip (see Figure 2). Thus, one time-

Figure 2. Emotional ratings for a sample joy/happiness music clip: time (x-axis), valence (y-axis, 1: 'very negative' to 9: 'very positive'). Red line shows the composer's ratings, black line the median of 12 listeners, and gray lines individual listener ratings.

series data per music stimulus was used for data analysis as *listeners'* emotions. This means that each music clip retained one composer emotion rating, one listener rating, and four audio features. Additionally, the average of listener ratings was used as discrete emotions for comparison with composers' discrete ratings and audio features, as listeners' discrete ratings were not collected (see section 4.2).

Intra-class correlation (ICC) was computed to assess agreement over time among the listener data using the 'ICC' function in the R package *psych*. A two-way mixed, average score ICC was employed for consistency in the 12 valence ratings, following prior research on continuous emotional annotations [2, 31]. The results of this analysis can be found in the supplementary material.

Linear mixed-effects (LME) models were fitted using the *lme4* [32] and the *lmerTest* package [33] in R. Random effects were included in the model structure, and it was found that the random slope of composers' emotions significantly improved the model fit. The random slope was added since the relationship between listeners' perceived emotions and composers' expressed emotions may vary depending on the music clips.

4. RESULTS

4.1 Composers-Listeners Discrete Emotions

To assess the predictability of listeners' perceived emotions using discrete values, we used an LME model analysis. The dependent variable was the average emotional rating from listeners' representative data per music clip. We compared two models: *Model 1* used four audio features (RMS, flatness, zero-crossing, and spectral centroid; the average value of each music clip) as predictors, while *Model 2* added composers' discrete emotional ratings (arousal, valence, and dominance) with four audio features. P-values for fixed effects were obtained using Satterthwaite's approximations, and confidence intervals were computed using the Wald method. Refer to the supplementary material for detailed results of each model.

Model 1 showed that all four audio features sig-

Figure 3. Plot of the effect size of two models.

Metric	Model 1	Model 2	P-value
MAE	2.11	1.17	0.012*
MSE	6.29	2.10	0.009**
RMSE	2.24	1.33	0.009**
MAPE	0.62	0.32	0.012*

Table 2. The mean metric values of each model’s leave-one-song-out cross-validation for 18 music stimuli. The values were compared using the Wilcoxon signed-rank test.

nificantly predicted listeners’ perceived emotions (see Figure 3). In Model 2, only composers’ arousal and valence were significant predictors, with no significant fixed effects for the audio features (see Figure 3). Using leave-one-song-out cross-validation, we confirmed that Model 2 predicted more accurately than Model 1, even for unseen data (see Table 2). This is indicated by its better performance across four metrics: mean absolute error (MAE), mean squared error (MSE), root mean squared error (RMSE), and mean percentage error (MPE).

4.2 Composers-Listeners Continuous Emotions

4.2.1 All Emotions

The relationships between dynamic composers’ emotional intentions and listeners’ perceived emotions were analyzed with an LME model (Equation 1 from Section 2.3). The dependent variable was listeners’ emotional representative ratings, and composers’ emotion ratings served as the predictor across all music clips (total observations, $N = 3438$; music clips, $N = 18$). The LME analysis revealed that composers’ emotional intentions significantly predicted listeners’ perceived emotions ($\beta = 0.26$, $p < 0.001$; see Figure 4). Separate analyses for each emotion indicated a significant association between composer-listener emotions except for *joy/happiness* ($p = 0.144$).

4.3 Audio Features & Musical Emotions

LME models were employed to predict composers’ and listeners’ emotions (see Table 3). For composers’ emotions, spectral centroid significantly predicted *all emotions* ($\beta = 0.74$, $p < 0.001$) and for *joy/happiness*, RMS, zero-crossing, and spectral centroid were significant predictors (RMS: $\beta = 0.60$, $p < 0.001$; zero-crossing: $\beta = -1.11$, $p < 0.001$; spectral centroid: $\beta = 1.09$, $p = 0.020$). For

Figure 4. Plot showing listeners’ emotions predicted by composers’ emotions, with a regression line indicating a slope ($\beta = 0.26$) of the fixed effect for composers.

sadness, RMS was significant ($\beta = -0.33$, $p = 0.016$), and for *anger*, RMS and spectral centroid were significant predictors (RMS: $\beta = -0.35$, $p = 0.042$; spectral centroid ($\beta = 1.51$, $p < 0.001$).

In the LME model predicting listeners’ emotions, adding composers’ emotional ratings with audio features significantly improved the model fit across all 18 music clips and for each emotion-specific model. RMS consistently predicted listeners’ emotions, and zero-crossing emerged as a significant predictor for *anger* music ($\beta = 0.38$, $p = 0.045$).

4.3.1 All Emotions

Building on previous findings, we explored whether audio features that significantly predicted composers’ and listeners’ emotions could simultaneously predict both subjects’ emotions (Equation 2 from Section 2.3). An LME model with listeners’ ratings as the dependent variable, and composers ratings, RMS, and their interaction term for predictors (N total observations = 3438; AIC = 5970.1, LogLik = -2977.0), outperformed the model in Section 4.2.1 ($X^2 = 57.24$, $p < 0.001$).

All fixed effects terms were statistically significant in predicting listeners’ emotions, particularly the interaction term between composer ratings and RMS ($\beta = 0.15$, $p < 0.001$). This suggests that the relationship between composer and listener emotions varied significantly with changes in RMS levels (see Figure 5), highlighting RMS’s role in modulating both composer and listener emotions. Conversely, the interaction term with spectral centroid was not statistically significant ($\beta = -0.06$, $p = 0.055$).

4.3.2 Joy/Happiness

As in Section 4.3.1, we assessed interaction terms between audio features and composers in LME models for each emotion, focusing on *joy/happiness*. Using RMS, zero-crossing, and spectral centroid as predictors, each including an interaction term with composer ratings. Results indicated statistically significant interaction effects across all models: *composer x RMS* ($\beta = -0.55$, $p < 0.001$), *composer x zero-crossing* ($\beta = 0.58$, $p < 0.001$), and *composer x spectral centroid* ($\beta = 0.74$, $p < 0.001$).

	Composer	Listener	Composer & Listener
<i>All Emotions</i>	Spectral centroid	Composer, & RMS	RMS
<i>Joy/Happiness</i>	RMS, Zero-crossing, & Spectral centroid	Composer, & RMS	RMS, Zero-crossing, & Spectral centroid
<i>Sadness</i>	RMS	Composer, & RMS	-
<i>Anger</i>	RMS, & Spectral centroid	Composer, RMS, & Zero-crossing	RMS, & Zero-crossing

Table 3. Significant predictors included four audio features for composers’ emotional intentions and listeners’ perceived emotions. Composers’ emotions were added as predictors in the models predicting listeners’ emotions.

Figure 5. An interaction plot illustrating the model predicting listeners’ emotions with composers’ emotions and RMS. The solid line depicts the slope of the fixed effect of *composer*, varying with changes in RMS values.

4.3.3 Sadness

For *sadness*, an LME model was fitted with the RMS feature and the interaction term between RMS and composer as predictors. The results showed that neither the interaction term ($p = 0.409$) nor the fixed effect of the RMS feature ($p = 0.365$) were statistically significant.

4.3.4 Anger

The LME model for *anger* music included fixed effects and interaction terms for RMS, zero-crossing, and spectral centroid features. Results showed that the interaction terms for RMS (beta = -0.32 , $p < 0.001$) and zero-crossing (beta = 0.53 , $p < 0.001$) were statistically significant. However, the spectral centroid model did not show significant results upon model comparison ($p = 0.222$).

5. DISCUSSION

In this study, we employed linear mixed-effects (LME) models to explore how spectral features of music predict both the composer’s real-time intended emotional expression during piano improvisations and the listener’s perceived emotion. This included gathering emotional ratings empirically from composers and also listeners on a valence scale. We then examined the relationship between these ratings and the features extracted from the music clips.

We found that composers’ emotional intentions were conveyed to listeners’ perceptions of musical emotions. Discrete emotional ratings showed that composers’ intentions were stronger predictors of listeners’ perceived emotions than other audio features. Conversely, continuous emotional data emphasized the importance of both composers’ intentions and RMS features. These results un-

derscored the impact of emotional assessment methodologies, suggesting that discrete emotion ratings may overlook acoustic cues conveying composers’ intentions.

Overall, RMS was identified as a primary predictor for conveying composers’ intentions and also served as an indicator of listeners’ emotional perceptions. While RMS was the key feature for predicting listeners’ emotions, the features that indicated composers’ emotions varied with different emotional categories. For *joy/happiness* and *anger*, the spectral centroid emerged as the main predictor of the composers’ intentions, likely due to its association with timbral brightness, which helps detect changes in the valence [26].

Our findings highlight RMS as a crucial audio feature for predicting the emotions of both composers and listeners. RMS was strongly associated with emotional dynamics in *joy/happiness* and *anger*, but not in *sadness*. This is consistent with prior research [9], which also found RMS to be an effective predictor of *happiness* and *anger*, but not *sadness*. Additionally, zero-crossing emerged as a significant predictor of the emotional relationship between composers and listeners for both *joy/happiness* and *anger*, further aligning with the findings of previous studies on speech emotion recognition [34].

However, we found no audio features capable of predicting composer-listener emotions for *sadness*, which typically involves lower arousal compared to *joy/happiness* and *anger*. In music with low arousal, features related to valence may not be as prominent. For instance, in *sad* music, changes in loudness (i.e., RMS) may not be as pronounced as in *joy/happiness* or *anger*, thus potentially not serving as cues for both composers’ emotional intentions and listeners’ perceptions of valence.

Future research should further explore more audio features related to other musical factors (e.g., tempo, pitch, harmony, etc.) that are known to be associated with emotional experiences in music. Additionally, it is needed to determine whether the features identified in this study enhance the performance of MER models. Expanding the sample size of participants and utilizing a larger pool of music stimuli, while considering individual and cultural variations, will also be essential to enhance generalizability and gain more comprehensive insights.

This study offers insights into factors influencing MER system predictions of emotional valence, enhancing machine-learning models’ ability to predict listeners’ emotions by considering feature importance across different emotions. Additionally, incorporating time-series emotional data, including composers’ intentions, adds further significance to the research.

EXPLORING MUSICAL ROOTS: APPLYING AUDIO EMBEDDINGS TO EMPOWER INFLUENCE ATTRIBUTION FOR A GENERATIVE MUSIC MODEL

Julia Barnett

Hugo Flores García
Northwestern University

Bryan Pardo
Northwestern University

ABSTRACT

Every artist has a creative process that draws inspiration from previous artists and their works. Today, “inspiration” has been automated by generative music models. The black box nature of these models obscures the identity of the works that influence their creative output. As a result, users may inadvertently appropriate or copy existing artists’ works. We establish a replicable methodology to systematically identify similar pieces of music audio in a manner that is useful for understanding training data attribution. We compare the effect of applying CLMR [1] and CLAP [2] embeddings to similarity measurement in a set of 5 million audio clips used to train VampNet [3], a recent open source generative music model. We validate this approach with a human listening study. We also explore the effect that modifications of an audio example (e.g., pitch shifting) have on similarity measurements. This work is foundational to incorporating automated influence attribution into generative modeling, which promises to let model creators and users move from ignorant appropriation to informed creation. Audio samples accompanying this paper are available at tinyurl.com/exploring-musical-roots.

1. INTRODUCTION

For creators and users of generative models to be informed and responsible, there needs to be a mechanism that provides information about works in the model’s training data that were highly influential upon generated outputs. This would enable both citation of existing work and offer the opportunity to learn about the influences of their creation. We assume a model-generated product that is a copy or near-copy of a work in the model’s training set indicates the model was influenced by that work. To develop methods to automatically detect the influences upon model-generated products it is, therefore, essential to develop good measures of similarity between works.

We define a measure of approximate memorization in deep generative audio models by establishing a thresh-

old for high similarity and memorization of training data against a large repertoire of 5,000,000+ song clips. We take inspiration from the “split-product” measure for image similarity from Somepalli et al. [4], which breaks the embedded feature vector of images into smaller chunks to compare inner products of corresponding localized features. In our work, every audio file is split into 3-second segments (a.k.a. clips), each of which is encoded as a feature vector (either a CLMR [1] or CLAP [2] embedding) produced by a machine learning model trained to encode audio for the purpose of measuring similarity. See Section 3.3.2 for details. We measure similarity between generated clips and training data clips to find similarity between subportions of songs (e.g., a single musical phrase), returning the songs with the most similar clips. We also evaluate the extent to which similarity measured in this way agrees with similarity assessments by human listeners (Section 4).

We apply our approach to VampNet [3], an open-source music audio generation model trained on 795k music songs. VampNet is representative of a widely-used class of generative models: language-model-style generation. This approach is used in AudioLM [5], JukeBox [6], Musi-cLM [7], SoundStorm [8], among others [9, 10]. While we utilize VampNet as a case study, our evaluation framework is both model and training data agnostic.

This paper makes the following **key contributions**. Primarily, it establishes **an easily replicable methodology and framework to perform training data attribution for a generative music model** (Section 3), which has been **validated in a human-listener study** (Section 4). Second, **we systematically explore the robustness of embedding-based similarity measures for music audio (CLMR and CLAP) to audio perturbations such as pitch shift, time stretch, and mixture with different types of noise** (Section 5.1). Generative models, even when creating near-copies of training data, are likely to add some form of variation to the outputs, making it essential to understand how robust this method is to such anticipated perturbations.

Our formal research questions are:

1. Can we measure similarity between generated music and music in the training data in a way that human listeners would agree with?
2. How do different perturbation types and amounts affect the ability of the evaluated similarity measure(s) to quantitatively identify similar pieces of music?

2. RELEVANT LITERATURE

2.1 Memorization in Non-Audio Generative Models

It is well established that large language models (LLMs) applied to text are capable of memorizing part of their training data [11–18]. LLMs like the 6 billion parameter GPT-J model can memorize at least 1% of training data [19]. If access to the training data is available, it is relatively straightforward to detect when language models copy strings of text verbatim due to the ability to check for exact sequences of tokens.

Memorized images created by generative models pose risks similar to memorized training data from text LLMs such as sensitive data leaks and copyright infringement. Detecting memorization and duplication by image models is fundamentally different from detecting duplication from a text-based language model; instead of memorizing and reproducing items verbatim from the training data, image models create images that are not identical to the training data, but are sufficiently similar to warrant being called content replication [4].

Carlini et al. [20] propose an approximation of a distance metric for memorization in the image space. A generated image whose nearest neighbor in the training data falls closer than a determined threshold (δ), when embedded in the appropriate manifold, is labeled as a memorized example even if not a verbatim copy. Somepalli et al. [4] demonstrate that diffusion models replicate images from training data with high fidelity, setting a lower bound for memorization of Stable Diffusion at 1.88% of generations [21]. We extend this methodology [4, 20] into the audio domain for our paper.

2.2 Audio Retrieval and Music Similarity

2.2.1 Music Similarity in Generative Audio Models

Popularized in the early 2000s, audio fingerprinting [22, 23] aims to detect exact copies of a given piece of audio. In 2006, Shazam popularized this method for the general public with a system utilizing query-by-example for everyday users [24]. Traditional audio fingerprinting (e.g., Shazam [25]) depends on low-level structural details that are not typically regenerated by generative models, so it is not a relevant approach for our methodology.

Most of the limited work examining similarity of audio made by generative models has been in the context of a different purpose, rather than the focus of an in-depth exploration. Examples include creating new strategies for text-to-music generation in order to create more novel songs [26] or brief ad-hoc memorization evaluations at time of release [7, 9]. Perhaps the closest work to our own is by Bralios et al. [27], who examined replication of audio utilizing text-to-audio latent diffusion models for general audio sounds, such as explosions or people cheering. They define replication of training data as “nearly-identical complex spectro-temporal patterns.” They did not perform any subjective evaluation by human listeners to validate their approach to measuring similarity. Our work instead focuses on music, uses a much larger dataset, and is intended

to be easily adoptable by any model creator.

2.2.2 Measuring Audio Similarity with Embeddings

The key to measuring similarity effectively is to have a representation that highlights the task-relevant features. Most popular right now in the age of generative modeling is measuring audio similarity with embeddings. Audio embeddings are continuous vector representations for excerpts of audio that are based on the internal representations of a neural model trained on a proxy task like generative pre-training [28], contrastive learning [1, 2], classification [29], autoencoding [30, 31], and other methods [32, 33].

To use an audio embedding model to measure the similarity of a collection of audio excerpts, we pass the audio signals through the embedding network, which gives us a multi-dimensional vector output for each audio signal: the “audio embedding”. To obtain a list of the most similar audio signals for a given query audio signal, we extract the embeddings for each audio signal using an embedding model of our choice. We then compute a cosine or L1 distance between our query audio signal and the signals in the database, returning a ranked list, where audio signals with higher similarity to the query audio are ranked higher.

The choice of audio embedding model can have a large impact on the results. There are a variety of embeddings capturing different features of audio, such as [1, 2, 28–30, 32, 33]. We focus on CLAP [2] and CLMR [1] embeddings for this work. Both are state-of-the-art (SOTA), produce human-validated similarity in our listening tests, are robust to perturbation, and are able to return relevant top songs.

3. DATA AND METHODOLOGY

3.1 Scope of Analysis

We want to create a system that identifies music both quantitatively similar and subjectively similar to humans. We do not focus on measuring similarity of any individual feature of music (e.g., timber, rhythm, lyrics), but rather use one of two embedding approaches (CLAP or CLMR) to encode audio and examine whether similarity in these embedding spaces aligns with human subjective evaluation (Sec. 4).

3.2 Data and Models Used

Though our approach is model agnostic, we validate our framework on VampNet [3], a generative model trained on 795k songs collected from the internet. VampNet takes a masked acoustic token modeling approach to music audio generation. In the first stage, a Descript Audio Codec (DAC) [31] learns to encode the audio data in a discrete vocabulary of “tokens”, of which it is then trained to model sequences. To create audio files, the token sequence is converted back into the input domain via the DAC decoder. VampNet adopts a masked generative modeling approach with a parallel iterative decoding procedure. Conditioning is done through example audio, either with a prefix (generating a continuation), postfix (generating an introduction) or as infill (masking the middle). We denote musical outputs of VampNet as “vamps.”

We chose VampNet because, at the time of writing, no other model made available both the training data and model weights. We trained another version of VampNet on a smaller training data and found no noticeable differences. While VampNet has a diverse set of music for the training set, our companion website also includes a small analysis of efficacy on various genres in the GTZAN [34] dataset.

3.3 Methodology

3.3.1 Similarity Metric

We define a measure of approximate memorization in generative audio models by establishing a threshold for high similarity and memorization of training data against a large collection of 5 million 3-second song clips drawn from the 795k songs in VampNet’s [3] training data. We take inspiration from the “split-product” measure for image similarity [4, 20], which breaks the images into smaller chunks to compare inner products of corresponding localized features. In our work, every audio file is split into 3-second clips, each of which is encoded as a feature vector. We measure the cosine similarity between generated clips and training data clips to find similarity between sub-portions of songs, returning the most similar songs.

3.3.2 Embeddings

We focus on two main embeddings: (1) contrastive learning of musical representations (CLMR) embeddings [1] and (2) contrastive language-audio pretraining (CLAP) embeddings [2]. We use both CLAP and CLMR embeddings because they can be applied to any dataset of raw music audio without the need for any transformation or fine-tuning, generalize well to out-of-domain datasets, and can be used as a baseline across different models and genres. Utilizing publicly available embeddings that generalize to any dataset is helpful in encouraging adoption.

We put all of the embeddings and their corresponding musical metadata in a vector database (Pinecone) that lets us quickly and efficiently search through millions of embeddings and return the top k similar songs by a chosen similarity metric (e.g., cosine similarity) in milliseconds.

3.3.3 Code and Tools Used

To recreate this study, use the following code and tools. To generate audio using VampNet: github.com/hugofloresgarcia/vampnet. To put audio in a format suitable for Pinecone and to add noise to clips (see Section 5.1) use: github.com/julbarnett/exploring-musical-roots.

4. LISTENING TEST: EXPERIMENTAL DESIGN

Presumably, output that is highly similar to a training audio clip was influenced by that clip. Of course, similarity is in the ear of the listener and many similarity measures do not align with human opinions. To build a replicable framework that will not require other audio researchers to conduct costly and cumbersome human listening tests, we conduct an experiment with human listeners to demonstrate the alignment of our quantitative technique with hu-

man listening. We utilize ReSEval, a framework that enables us to build subjective evaluation of audio tasks deployed on crowdworker platforms [35].

4.1 Dataset Preparation

To create the data for our study we take a random sample of 1,000 3-second clips from VampNet’s training data. For each of these 1,000 clips, we rank its top 10,000 closest clips in the training dataset by cosine similarity. For each embedding (CLAP and CLMR), we fit a Gaussian to the distribution of similarity scores of the top 10,000 clips (histograms in Table 1). The further above the mean a similarity score is, the more similar the clips are. We segment the data into 4 meaningful bins: the mean cosine similarity of the top 10,000 (CLAP: 0.815; CLMR: 0.693), $+1\sigma$ (CLAP: 0.885; CLMR: 0.784), $+2\sigma$ (CLAP: 0.955; CLMR: 0.875) and “random” (CLAP: 0.513; CLMR: 0.151). For the random bin, we take two random sets of 1,000 clips from the full 5 million clip dataset and measure pairwise cosine similarity; the mean similarity of this distribution gives the expected similarity score of random song pairs. We use these bin centers to create bins ± 0.02 for these similarity scores.

4.2 ABX Trials

Cartwright et al. [36, 37] overcame the difficulties of deploying time-consuming lab-based listener studies by utilizing pairwise comparison performed over the web, duplicating the findings of a lab-based test. We leverage these findings and employ a pairwise comparison study design, performing the study on Mechanical Turk (MTurk).

In our study, listeners are asked to perform ABX trials. The target audio clip (X) is presented, along with two other clips (A and B). The listener is asked to rate which clip (A or B) is more like the target X. The proportion of listeners that find A more similar than B is an estimate of the probability that people find A more similar to X than B.

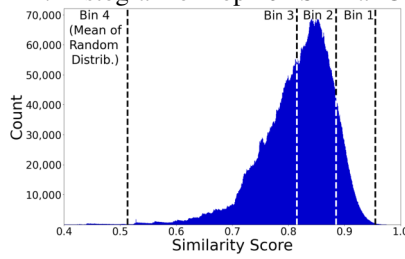

Given a clip X drawn from a random sample of 1,000 clips, one can then create a pair of examples A and B by selecting them randomly from different bins (see Section 4.1). This lets us create ABX trials with known differences in cosine similarity to X between the paired examples A and B. We can then collect statistics on the probability that users will find A more similar to X than B is to X. The greater the difference in cosine similarity, the more skewed we expect the listening results to be. If true, our objective measure’s similarity rankings align with human rankings.

We have 4 bins, resulting in 6 different pair-wise comparisons (bin 1 vs. bin 2, 1v3, 1v4, 2v3, 2v4, and 3v4). To have 150 evaluations per bin (900 evaluations total), we need 90 people to listen to 10 ABX comparisons each. We randomly choose 15 prompt “X” clips from the training data, with their respective 4 clips within the bins chosen as detailed above for the A and B comparison. An example set of clips for an ABX evaluation is at tinyurl.com/exploring-musical-roots.

4.3 Participant Recruitment

We utilized MTurk to recruit 150 participants each to evaluate similarity scores of CLAP and CLMR embeddings.

Human Evaluation Results: ABX Listening Test

		CLAP Embeddings			
		Bin 2	Bin 3	Bin 4	Total
		(0.885 ±0.02)	(0.815 ±0.02)	(0.513 ±0.02)	(All Trials)
CLAP: Histogram of Top 10k Similar Clips 	B				
	A				
	Bin 1	96.2%	98.0%	98.1%	97.4%
	(0.955 ±0.02)	(n = 156)	(n = 150)	(n = 162)	(n = 468)
Bin 2		73.3%	93.6%	83.7%	
(0.885 ±0.02)		(n = 135)	(n = 141)	(n = 276)	
Bin 3			81.5%	81.5%	
(0.815 ±0.02)			(n = 178)	(n = 178)	

		CLMR Embeddings			
		Bin 2	Bin 3	Bin 4	Total
		(0.784 ±0.02)	(0.693 ±0.02)	(0.151 ±0.02)	(All Trials)
CLMR: Histogram of Top 10k Similar Clips 	B				
	A				
	Bin 1	90.7%	91.0%	98.5%	93.2%
	(0.875 ±0.02)	(n = 150)	(n = 156)	(n = 135)	(n = 441)
Bin 2		71.6%	93.6%	82.7%	
(0.784 ±0.02)		(n = 155)	(n = 157)	(n = 312)	
Bin 3			80.7%	80.7%	
(0.693 ±0.02)			(n = 140)	(n = 140)	

Table 1. Results from the listening experiment. Results show the percent of time listeners rated clip “A” (the clips with higher similarity scores to the prompt “X”) as more similar to the prompt clip “X” than clip “B” (those with lower similarity scores to prompt “X”). Histograms of the top 10k similar songs can be found to the left of the table. Bin regions are shown on these histograms. Bin 3 is centered on the mean of the top 10,000 most similar clips, Bin 2 = +1σ, Bin 1 = +2σ, and Bin 4 is the mean similarity score of a randomly selected clip from the entire training data (not just the top 10k).

We paid each evaluator \$1.50 to annotate 1 set of 10 ABX trials (estimated \$22.50/hour). We recruited US residents with an approval rating of at least 98 and 1,000 approved tasks. We filtered out bots by excluding evaluations that failed a pre-screening listening test. There were no requirements for music expertise beyond passing a listening test.

4.4 Results

Table 1 contains the results of our listening experiment. We found that human evaluations closely aligned with our quantitative metrics. For both CLAP and CLMR evaluations, listeners affirm by a wide margin that clips with higher similarity scores (lower bin numbers) sound more similar to the prompt clip than those with lower scores (higher bin numbers). Clips drawn from the most-similar bin (Bin 1) to the prompt track “X” were rated as more similar to the prompt clip than clips from any other bin 97.4% of the time for CLAP (93.2% for CLMR). For both embeddings, the vast majority of listeners ranked the clips with high similarity to the prompt track (“A”: Bins 1-3) as sounding more similar than the random song (“B”: Bin 4).

5. ANALYSIS OF OBJECTIVE MEASURES

5.1 Robustness to Perturbations

Our second research question focuses on the effect of different perturbations on our methodology’s ability to correctly return similar songs. Any generative music model will add some degree of variation to a training example during the generation process—the aim of these models is

not to replicate the training data exactly. This variation could take many forms (e.g., changing the pitch, speed). Therefore, in this section we evaluate the ability of our methodology to return target songs that have been modified by given perturbations. For varying amounts of each perturbation, we evaluate how frequently the target song (the unmodified clip) is returned as the most similar, within the top 5 similar songs, and within the top 10 most similar songs. The 7 types of perturbations we evaluate are:

- **Pitch shift** (in semitones; range: -12 to 12)
- **Time stretch** (in % of song; range: -20% to +20%)
- **White noise** overlaid on top of music (in dB; range: -30 to 30 dB in relation to original audio clip)
- **“Mash-up”** of two clips from training data (range: 5/95% to 95/5%; e.g., 60/40%)
- **“Mash-up”** of one clip from inside and one outside training data (range: 5/95% to 95/5%; e.g., 60/40%)
- **“Mash-up”** of a prompt clip and the generated vamp (range: 5/95% to 95/5%; e.g., 60/40%)

We selected these because we envision them as common alterations to music that would not render it unrecognizable by a human listener. We are not seeking to evaluate all types of adversarial noise since we are assuming users and creators are working cooperatively with these generative models to create something novel—not acting maliciously.

We evaluate all of the audio perturbations for both CLAP and CLMR embeddings to understand the robustness of our methodology while utilizing different embedding networks. For all perturbations except higher levels

Figure 1. Plots of various amounts of noise perturbations to clips and the percent of the time they were returned in the top $k = 10$, $k = 5$, and $k = 1$ song using our methodology for CLMR embeddings. Displays pitch shift in semitones, time stretch as percent shortened/elongated, white noise overlay in decibels to target clip, and mash-ups of 2 songs in training data, 1 song in training data and one random, and a prompt song and its generated vamp.

of time stretch, CLMR embeddings are more robust than CLAP embeddings; all of the results using CLMR are presented in Figure 1. Example perturbations available at tinyurl.com/exploring-musical-roots.

Pitch shift is a common perturbation to audio that involves raising or lowering the original pitch of an audio clip without adjusting the length of the clip. Notably, human perception is extremely robust to pitch shift. Both embedding types were robust to small pitch shifts; for changes of ± 3 semitones the target song was returned the vast majority of the time. Both embedding types had a lower recall of the target song for larger pitch shifts.

Time stretching audio clips involves speeding up or slowing down audio while keeping the pitch constant. For this perturbation, we evaluate stretching the clip from 20% slower to 20% faster. Both embeddings consistently returned the target song for small amounts of time stretch, but were impacted by larger amounts ($> \pm 10\%$).

White noise overlay involves adding randomly generated white noise to audio clips. We evaluate the noise level in relation to the amplitude of the original clip in decibels, ranging from -30 to 30dB (-30dB being the quietest). Though we were only able to consistently return the target song at quiet levels of white noise overlay (≤ -18 dB) barely perceptible to the human ear, this perturbation has the largest impact on our method’s ability to identify the target track. Luckily, this is not an anticipated type of noise; generative models will add more “musical” variation to songs rather than white noise.

“Mash-ups” of two combined songs are defined here as splicing two clips together at different percentage levels (e.g., for 75/25% the first 2.25 seconds are the target song

and the last 0.75 seconds are some other song). We evaluate three types of “mash-ups”: combining (1) two clips from the training data, (2) one clip from the training data and one outside of the training data, and (3) a prompt track and its generated vamp from VampNet. For each mash-up, we seek to identify the percent of time the target (or prompt) track is returned in the top similar songs. CLMR embeddings only need 50-60% of the target song present in the mash-up to consistently return it in the top similar songs (CLAP need $\geq 80\%$). At each mash-up proportion the model returned the target song (prompt song) for mash-ups with vamps more consistently than for combining two different songs, indicating the vamp is more similar to the prompt song than two randomly selected songs are to each other. When the majority of the song analyzed is the vamp (i.e., $x\text{-axis} \leq 50\%$), it does not return the target (prompt) but rather other songs in the training data.

5.2 Systematic Evaluation of Generative Music Model

As a case study, we systematically evaluate VampNet [3] to demonstrate how to employ this technique to understand training data attribution on both individual songs and an entire model. To evaluate VampNet, we generate 10,000 vamps from 1,000 10-second prompt clips (10 different vamps per clip), and evaluate the most similar clips in the training data to the vamps. We embed each of the 10,000 vamps as a feature vector using both CLMR and CLAP embeddings and analyze the most similar 50 clips by cosine similarity (out of the five million+ clips from VampNet’s training data in our vector store). For each of the 10,000 vamps, the prompt that generated the vamp was rarely among the top similar clips returned by our methodology. Thus, we seek to understand the attribution of the

Systematic Evaluation of Generated Music (Vamps)			
Similarity Score		Vamp & Prompt	Vamp & #1 Similar Track
CLAP	Mean	0.393	0.795
	Median	0.402	0.815
	St. Dev.	0.151	0.084
CLMR	Mean	0.166	0.846
	Median	0.153	0.850
	St. Dev.	0.189	0.054

Table 2. Systematic evaluation of VampNet’s generations. Generated pieces of music (vamps) are less similar to the prompt song provided to the model at generation time than they are to other music from the training data.

rest of the training data on generations. For CLAP embeddings, the average cosine similarity between a prompt clip and generated vamp was 0.393, ($\sigma = 0.151$), whereas on average, the closest clip had a similarity score of 0.795 ($\sigma = 0.084$). CLMR had a similar disparity; full descriptive results are in Table 2. As noted in the above analysis on robustness to perturbations in Section 5.1, our methodology utilizing CLMR (rather than CLAP) embeddings is more robust to perturbations combining elements of new clips with clips present in the training data. Thus for the remainder of this section we will focus on CLMR embeddings for this case study using VampNet.

Leveraging insight from our listening study (Section 4), human evaluation affirms that within CLMR embeddings, music clips with a similarity score of ≥ 0.875 sound significantly more similar than clips with lower similarity scores. For this analysis, we utilize that same top bin as a benchmark and evaluate how often the most similar clips have similarity scores ≥ 0.875 . Findings are presented in Table 3. Over 30% of the vamps generated had at least one song with a similarity score ≥ 0.875 . Looking at scores in 0.02 increments above this benchmark similarity score, almost 20% of vamps had at least one song in the training data with a similarity score ≥ 0.895 , 9% ≥ 0.915 , 3% ≥ 0.935 , and almost 1% ≥ 0.955 . Evaluating more broadly among the top 10 songs, songs with these high similarity scores were concentrated among most similar couple clips, as opposed to having the entirety of the top 10 most similar clips have extremely high similarity scores. This indicates that at least 30% of the time, small sets of songs from the training data were highly influential on generated vamps.

6. DISCUSSION

These findings establish that the framework we propose is an effective means to systematically evaluate the training data attribution on any generative music model. This method is replicable and should be employed by model creators so they are able to have a greater understanding of their outputs. If exposed to end users, this framework also enables anyone to verify if they are copying music and learn about influences of their “novel” generations.

The authors first acknowledge the limitations of this ap-

Vamps with Highly Similar Songs in Training Data				
		Count of Songs in Top k		
		$k = 1$		$k = 10$
Similarity Score	k -clips ($n = 10,000$)	% Total		k -clips ($n = 100,000$)
		$k = 1$	$k = 10$	
≥ 0.955	89	0.89%	254	0.25%
≥ 0.935	317	3.17%	1,223	1.22%
≥ 0.915	924	9.24%	3,139	3.14%
≥ 0.895	1,929	19.29%	8,786	8.79%
≥ 0.875	3,201	32.01%	17,291	17.29%

Table 3. For 10,000 vamps, displays how many top k most similar training data songs were at or above given similarity scores for CLMR embeddings. The lowest similarity score in this table (0.875) corresponds to the highest benchmark (Bin 1) from the human listening test (Sec 4).

proach. First, the scope is intentionally limited to exclude lyrics. As generative music models continue to progress this can become an important area of memorization and copyright infringement, and we encourage future research to examine lyric memorization in tandem with our approach. Our scope also did not include any individualized feature levers for similarity (e.g., timbre or rhythm). We did this to both focus on a low-burden implementation for model creators who would follow this methodology as well as to identify encompassing interacting similarities without isolating any musical feature. However, these could be useful for both model creators and users.

Two potential harms of generative audio models are cultural appropriation and copyright infringement [38]. Our work aims to combat these issues both at the time of output generation and prior to model release. Our method can prevent cultural appropriation by giving users the opportunity to engage with the influences of the music, and prevent copyright infringement if the user realizes the generated piece of music is too similar to the identified influences.

7. CONCLUSION

We have proposed an easily-implementable framework for creators of generative music models to evaluate training data attribution. It can be used to prevent appropriation, copyright infringement, and otherwise uninformed creations, enabling model creators and users to understand the influences on their generated outputs by identifying similar songs in the training data. We evaluated a measure of cosine similarity for two embeddings and verified that they align with human perception with a subjective listening test. We also evaluated how robust our framework is to various forms of perturbations we anticipate models adding to training data during the transformation to “novel” output. We perform a case study on VampNet [3] in order to validate the efficacy of our framework. This work is a step towards transforming a generative model from a crutch replacing artistic knowledge to a tool creators and users alike can use to become better and more informed artists.

8. RESEARCH ETHICS AND SOCIAL IMPACT

The authors of this paper took the ethical considerations and social impact of this work seriously. A recent exhaustive study of the ethical implications of generative audio models [38] found that less than 10% of research on generative audio models published discussed any sort of potential negative impact of their work. We took that as inspiration to center our work around the ethical concerns and attempt to build a bridge between ethicists and generative audio engineers.

As mentioned in the discussion (Section 6), among the negative impacts uncovered for generative music models were the potential for cultural appropriation, copyright infringement, and loss of agency and authorship of the creators. This work aims to combat these issues at the time of generation, on a track by track level. By uncovering the roots of a given piece of generated music, we can empower the user of the model to understand where the music came from and learn about the influences.

A primary concern the authors have for this work is that future model creators will simply use this framework as a checkbox to complete their ethical evaluations. They may use this framework and assume since they did so, there are no other potential societal impacts or ethical harms to consider in regard to generative music models. This work only tackles a portion of the issues, and is only a first step in doing so. Though our method can highlight instances of copyright infringement and cultural appropriation, it by no means will catch everything. Though this can assist with educating users about the influences of their work, it will not solve the potential loss of agency and authorship users and musicians could feel when using these models. It does nothing to address creativity stifling, predominance of western bias, overuse of publicly available data, non-consensual use of training data, or job displacement and unemployment. It also requires energy consumption to generate the embeddings and perform searches, so it contributes to the issue of energy consumption of generative models rather than combating it.

In regard to the experiment utilizing human evaluators to subjectively analyze similar pieces of music, we ensured that our study was in line with institutional review board standards (our study was determined to be exempt). We had a thorough consent form for the crowdworkers and ensured they knew they could quit at anytime without any sort of penalty. We timed ourselves taking the survey and attempted to pay them a fair wage (estimated \$22.50 per hour, higher than any minimum wage in the United States). We even paid users who failed the listening pre-screening test for their time and thus were not able to take our survey, even though they did not contribute data to our study. However, we acknowledge that ethical crowdsourcing goes beyond fair pay [39, 40], and tested the listening test thoroughly prior to launch to be certain there would be no burden to crowdworkers beyond potential boredom. The most sensitive data we had access to were the Mechanical Turk IDs of users, but we held these on secure servers.

The authors determined that the positive impact of this

work outweighed these potential harms, especially since the primary motivation of this work is to address a few existing ethical issues in generative audio. However, it is essential to acknowledge these potential risks and where our method falls short.

9. ACKNOWLEDGMENTS

The authors would like to thank the reviewers for their helpful feedback on this work, as well as Max Morrison for his help with the use of Reproducible Subjective Evaluation (ReSEval) [35]. This research is partially supported by USA National Science Foundation award 2222369.

ABSTRACT

The environmental footprint of Generative AI and other Deep Learning (DL) technologies is increasing. To understand the scale of the problem and to identify solutions for avoiding excessive energy use in DL research at communities such as ISMIR, more knowledge is needed of the current energy cost of the undertaken research. In this paper, we provide a scoping inquiry of how the ISMIR research concerning automatic music generation (AMG) and computing-heavy music analysis currently discloses information related to environmental impact. We present a study based on two corpora that document 1) ISMIR papers published in the years 2017–2023 that introduce an AMG model, and 2) ISMIR papers from the years 2022–2023 that propose music analysis models and include heavy computations with GPUs. Our study demonstrates a lack of transparency in model training documentation. It provides the first estimates of energy consumption related to model training at ISMIR, as a baseline for making more systematic estimates about the energy footprint of the ISMIR conference in relation to other machine learning events. Furthermore, we map the geographical distribution of generative model contributions and discuss the corporate role in the funding and model choices in this body of work.

1. INTRODUCTION

Interest in AMG and DL-based analytical models is increasing dramatically at conferences such as ISMIR [1]. Case studies in domains other than music [2–4] have established that the environmental impact of AI technologies can be massive, particularly when it comes to energy consumption. International Energy Agency predicts that the accumulated electricity consumption of data centers, AI, and the cryptocurrency sector will double, reaching the level of whole electricity consumption of Japan by 2026 [5]. In the US, a recent proposal for legislation (Artificial Intelligence Environmental Impacts Act) suggests that AI companies would be urged to start reporting the

environmental impacts of their work [6]. With the increasing investment in AI and the general trend of high compute requirements for training state-of-the-art machine learning systems [7], we expect to see the accumulated energy footprint of the generative music industry and the surrounding research also growing. There is no reason why research around ISMIR would be isolated from these effects. For the community to gain an understanding of the scale of the problem and to identify solutions to avoid excessive energy use in AMG development, more knowledge is needed of the current energy cost of the research conducted. It is, hence, highly relevant and timely to investigate to what extent research at ISMIR acknowledges and documents the environmental impact of energy consumption.

Other research communities around music technology (e.g., NIME [8]) and machine learning technology (e.g., NeurIPS [9]) have shown increasing attention to various aspects of negative ethical impacts, among them environmental. Discussions of such topics continue, however, to be severely underrepresented in the generative music and audio research [10], and entirely absent from the ethics principles and guidelines for AI-music [11, p. 148]. In the context of the ISMIR community, Morreale [12] estimated that between 2011 and 2020, less than 0.5% of ISMIR submissions discussed issues related generally to ethics, of which sustainability could be seen as a subcategory. Our present scoping inquiry demonstrates this lack of concern and transparency in reporting the environmental impacts of AMG and other DL research, with a focus on ISMIR conferences. The title of our paper refers to Schwartz et al. [13], which proposes the concept of *Green AI* as “AI research that is more environmentally friendly and inclusive”. While the concept of Green MIR should be used carefully, as it can lead to practices of greenwashing research, we use this term to raise questions about the current practices and energy impact of MIR.

This study advances a critical discussion in the ISMIR community around the ethical impacts of model development work and the responsibility of MIR research from the underexplored perspective of environmental sustainability. It documents, firstly, the level of transparency in reporting the environmental impact in terms of energy consumption and the computational resource use in the model training process in ISMIR papers in the seven years 2017–2023. Secondly, based on the information documented in these ISMIR publications, we provide preliminary estimates of the energy demands related to training individual AMG

Jääskeläinen, “Green MIR? Investigating computational cost of recent music-AI research in ISMIR”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

and other DL models, as well as an overall estimate of the total energy use and carbon footprint associated with DL training at an ISMIR conference. In this process, we also investigate if AMG models are related to higher energy consumption than other models at ISMIR. Our calculations establish a baseline to set the ISMIR community in relation to other machine learning communities and call for the issue of environmental impact to be addressed more systematically so that the conference can grow and evolve without compromising the environment. Thirdly, we map the geographical distribution of generative model contributions and discuss the role of corporate participation and the consequent political economies in this body of work.

Some limitations of the paper lie within (a) the many uncertainties in estimating the overall energy consumption of developing a DL model based on limited data related to the training process, (b) our focus on model training that leaves a focus on inference processes to future work, and, (c), the reduction of environmental sustainability to energy consumption. In the following two sections, we explain how these limitations emerge from the sparse amount of information and the complexity of the problem. We hope that this paper will motivate both individual authors and the ISMIR conference to take action toward more minute documentation of resource use in DL model development.

2. BACKGROUND

2.1 Environmental Impact of (Music-)AI

The soaring energy cost of AI technology is increasingly discussed in the academic literature [2, 3, 13–19]. Early work on the environmental impact of AI has introduced concepts, such as “green” and its opposite, “red” AI [13], problematized hidden environmental costs in AI [2], and provided methods for quantifying environmental impact [3]. We found only a few works that are related to music-AI (as a term to cover analytic and generative approaches based on – predominantly – deep learning). The first two concern the energy cost of AI models used in music information retrieval [20, 21], and the third focuses on the importance of studying sustainability in arts generally [4].

AI development has been increasingly steering towards Large Language Models (LLMs), which have a particularly high energy expenditure. The popularity of these models is attributed to their success in “generalizing” and performing better in tasks that have traditionally required human labor. But as a consequence, many research papers [22, 23] take a pre-trained foundation model and adapt it. This results in a situation in which the energy cost can be estimated only partially, *i.e.* for the part that extended the pre-trained LLM. Furthermore, it raises questions about how research can account for the environmental cost of using LLMs. Arguably, the researchers who use those LLMs are somewhat responsible for the popularity and increased use of LLMs – through creating demand for their use – which can further aggravate the use of computational resources and energy in LLM development.

Many research works that focus on the environmental

impact of AI take the assumption that energy (computational) cost is the core environmental problem of these technologies, and by reducing energy consumption, it is possible to work towards sustainability. However, this is a simplistic view because sustainability is a complex phenomenon that does not only concern electricity usage. For example, Jääskeläinen et al. [24, 25] discussed the complex networks of environmental harm resulting from resource consumption and capitalistic colonialism that prevail in the case of generative AI. Strengers [26] has generally outlined how behavior change is central to change toward sustainability, and providing metrics such as energy consumption data is insufficient to address change toward sustainability. While keeping this in mind, energy use is a valid starting point for discussing the environmental impact of AI. In this paper, when we refer to *environmental impact*, we explicitly refer to the energy cost and leave out factors such as the life cycle of the technology and water usage of data centers [27], among others.

Technological advances in recent decades have entered the music industry with the promise of reduced material and energy demands. For instance, it was expected that the introduction of mp3, the digitalization of music production, and eventually the platformization of its consumption would diminish the environmental footprint of the industry. As Devine [28] and Brennan [29] have demonstrated, the opposite has historically been the case: while the demand for plastic dropped in the era of the mp3 to a fraction compared the previous music consumption models (CD, cassette, vinyl, etc.), the greenhouse gas emissions of the industry, on the contrary, *increased*. This increase was explained in sustainability research by Hilty’s concept *rebound effects* [30], which describes indirect 2nd and 3rd order effects that result from adopting new technology.

Similar negative effects are emerging in the proliferation of AI in music. Calculations by Holzapfel [31] illustrate that creative applications of LLMs can amount to considerable levels of energy demand. Furthermore, results by Douwes [20, 21] and Ronchini and Serizel [32] indicate that the scale of energy consumption for audio generation and analysis tasks are not in a linear relation with the model performance, thus questioning the assumption that the growth in model complexity and resource demands are a prerequisite for better models. Even more importantly, Holzapfel [31] calls for the focus of inquiry to be expanded from the carbon footprint to the wider questions of political ecology, and to the perspectives of economic gain and power (see also [33]). In this view, we should not only measure the environmental impact but also form a more complete picture by looking at who is causing it, who is financing that work, and who benefits from it.

2.2 Timeliness of Addressing the Environmental Impact of Music-AI

Bringing energy concerns into research practices is still at an early stage in many communities [19], including MIR. In 2023, Morreale et al. [1] ran a systematic survey of the training datasets for AMG models presented at ISMIR

2013–2023. Their work illustrates a dramatic increase in the development of AMG models in the last decade, and especially since 2017. Taken together with the general lack of both breadth and depth of addressing environmental concerns in music and audio research contexts [10], this increase highlights the urgency of addressing the computational cost of the AMG models in ISMIR research.

Conferences such as NIME have already taken a proactive lead in promoting awareness of the environmental impacts of the research conducted around the conference [34], and by making resources available [35] for the research community to adopt more environmentally conscious research and development practices. NeurIPS [36] requires authors to disclose information on the training procedure as well as the amount and type of compute resources used in the development and research of AI models.¹ We argue that such practices of accessible documentation should be part of the submission requirements in ISMIR research publications as well. This is useful for reproducibility and allows examining the energy cost that ISMIR research contributes to when developing AMGs and other models. However, in order to start such a discussion, it is essential to examine the current practices of reporting environmental impact-related information on AMG development at ISMIR.

3. METHOD

This study covers two corpora (total $N = 113$) of papers: 1) ISMIR papers published in the years 2017–2023 that introduce an AMG model, and 2) a complementary corpus of ISMIR papers from the years 2022–2023 that present analysis models and discuss processes that included heavy computations with GPUs. This will provide a perspective on training resource documentation in recent ISMIR conferences beyond AMG.

The **first corpus** was obtained by selecting papers that were specified as introducing an AMG model in the table compiled by Morreale et al. [1]. We extended this initial list by adding all papers from ISMIR 2023 that presented such a model in that year. This resulted in an overall list of 88 papers that present AMG models between 2013 and 2023. An analysis of the older papers revealed that the majority of papers published before 2017 did not involve DL models trained on GPUs, but rather shallow models (e.g., [38, 39]) or no training at all (e.g., [40, 41]). Therefore, we decided to exclude the 8 papers in the list by [1] published before 2017, resulting in 80 papers in this first corpus.

For each of these 80 papers, we documented whether there was information about the training time, whether the number of parameters was specified (search “param*”²), and whether the computational resources used for training were documented (search “GPU*”, “CPU*”, “TPU*”).

¹ Interestingly, the first editions (2021, 2022) of this checklist included a recommendation to use a CO2 emissions tracker [37], but this aspect has been omitted from the latest version of the guidelines.

² The asterisk character (*) is used to find all spelling variations of a search term, e.g. parameter, parameters, parametric etc.

We further searched the papers for discussions on energy consumption and environmental impact of the models, using terms “environment*”, “sustainab*”, “ecolog*”, “carbon”, “energy” and “kWh”. Finally, as an effort to connect these aspects to the wider perspectives of political ecology, we documented whether the paper indicated company connections in the author affiliations, whether funding information was included in the acknowledgments or elsewhere (search “fund*”, “support*”), whether there were indications of full or partial corporate funding, as well as which countries were the author affiliations related to. The full information retrieved is available in a published data table [42]. Whereas our analysis mainly focuses on the documentation of energy consumption, the additional information included in our data collection was intended to facilitate further contextualization and future research investigations.

To account for the most recent work at ISMIR in our **second corpus**, we searched the proceedings documents of 2022 and 2023 for the keywords “GPU*” and “TPU*”. We did not consider papers that discuss CPU usage in order to focus on DL models, and we excluded all papers that are already part of the first corpus. This way, we obtained a corpus of 33 papers that present models for analysis rather than generation, with some consideration of computational resources (15 papers from 2023, 18 papers from 2022). From the papers we obtained, we collected further information relating to training time, computational resources, and company connections. We focused on energy-related aspects in the second corpus in order to facilitate a comparison with AMG models.

For both corpora, the energy used in the training of a model was estimated for papers that provided information about the type and number of GPUs/TPUs used, along with the training time. We found that websites or GitHub sources did not add information for the vast majority of papers and, therefore, focused on information provided in the published papers. The Thermal Design Power (TDP) of each processor type was obtained from the datasheets of the manufacturer, and the energy used for a single training run was computed as the product of a number of processors, computing time in hours, and TDP. Using the TDP as a basis for energy consumption is a rather conservative estimate, as it ignores the energy consumption of the remaining computer hardware [19]. To take these factors into account, the use of tools (e.g. [3, 43]) to measure actual energy consumption during model development and the publication of this overall consumption would be required. We refrain from attempting to estimate the carbon emissions related to the computed energy consumption of individual papers because a reliable estimate would require detailed information about the energy sources used in the specific computation environment [43]. In our analysis, we do not consider the energy consumption related to model inference, but we will discuss insights related to the energy demands of inference.

Authors 1 and 2 collaborated on collecting data from both corpora by dividing the conference years between

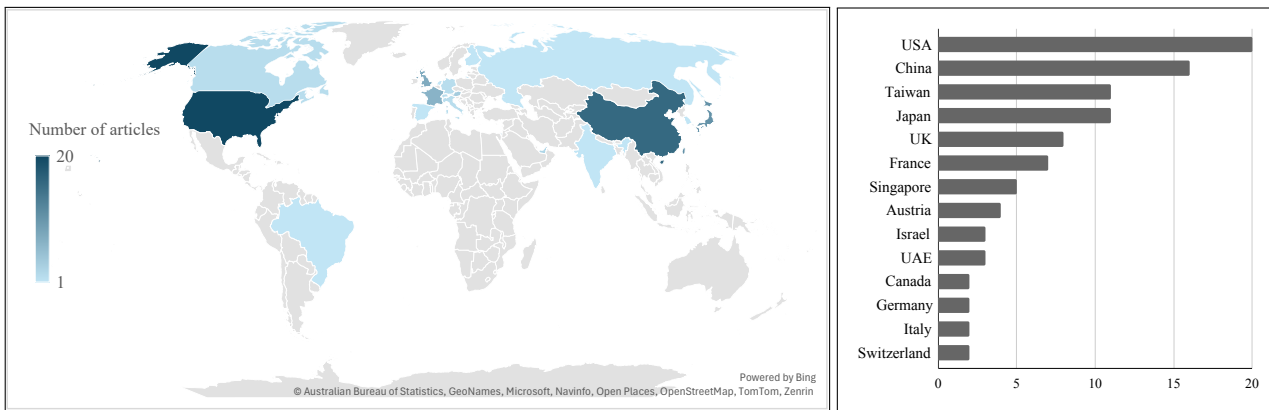

Figure 1. Geographical distribution of the authors in corpus 1 (N=80) at ISMIR 2017–2023, as indicated by the author affiliations. The block chart includes only countries from which at least two publications were found in the corpus.

them. The proceedings’ PDF files were searched for the above-listed terms, and the identified occurrences were analyzed manually without the use of scripts. Papers that presented unclear aspects in the data collection were flagged and discussed between both co-authors. Author 1 conducted the estimates of energy use for models in both corpora.

4. RESULTS

4.1 Results from Corpora 1 and 2

Our analysis revealed that 60 of the 80 papers (75%) in corpus 1 do not provide any information about the time and hardware required to train the model proposed in the paper. Of the remaining 20 papers, seven only provide information about the type and numbers of GPU but do not specify the time required for training. The remaining 13 papers provide full information about GPUs as well as training time. For corpus 2 (33 papers), we identified 13 papers that disclose full information about the computational hardware and training time, another 15 papers that provide partial compute information, and 5 papers that do not include such information. Overall, only 23 % of the papers in corpora 1 and 2 are fully transparent about the hardware and the model training.

When investigating potential change over time in corpus 1, we see that between the years 2017 and 2021, one or two papers annually disclose the full training and hardware data. In 2022, an exceptional six papers provided the full information (30% of the submissions analyzed for that year), whereas, in 2023, only three papers were partially transparent with the information about the GPU budgets. While this may indicate a general trend of increasing transparency in reporting the computational hardware and training cost of the AMG models, it would be misleading to claim this as the current norm in the ISMIR community. The lack of general reflection around the issues of environmental impact is furthermore evident from how the keywords “environment*”, “sustainab*”, “ecolog*”, “carbon”, “energ*”, and “kWh” were completely missing from the analyzed corpus (0 hits for proceedings of 2013–2023).

A few recent papers include reflections regarding increasing computational demands [44–46], but these reflections are motivated by the cost of computing and do not make a relation to environmental impact explicit.

It is also noteworthy how the increase in research engagement with AMG, as documented by Morreale at al. [1], coincides with corporate participation in these efforts. In the years 2020 until 2023, ca. 40 % of the papers in our corpus are co-authored by individuals with affiliations in private companies, compared to 27% in the years before that. This interestingly compares to the 27% of papers with industry-affiliated co-authors in our second corpus, *i.e.* papers that train models for non-generative purposes. Overall, these numbers suggest a certain focus of corporate interest on generative approaches.

Direct corporate funding of the research efforts is, however, rarely documented, with only four papers in the whole analyzed first corpus (N = 80) indicating either involvement of private funding or GPU support from NVIDIA. Overall, a slight majority of papers does not report any funding sources at all. The remainder refers mainly to public funding agencies, most likely as a response to the demands by the agencies for acknowledgment. This suggests an overall situation in which vested financial interests — by private and public stakeholders — are documented in a way that is not very transparent.

As shown in Figure 1, the majority of the AMG model development comes from researchers affiliated with institutions in the US (20 papers) or China (16), followed by Taiwan (11), Japan (11), and the UK (8). In total, these five countries account for over 60% of the ISMIR publications included in corpus 1. These numbers will gain significance in the context of carbon footprint estimates in the next section.

4.2 Energy Use Calculations

For the set of models from corpora 1 and 2 described above that reported the full details of the computational hardware and training time (N = 26), we conducted calculations on the estimated energy use based on the type and number of GPUs/TPUs, the reported training time, and the Thermal

Design Power (TDP) of each processor type, as provided by the manufacturers. The energy used for a single training run was consequently computed as the product of the number of processors, computing time in hours, and TDP. The results of this calculation for each model analyzed are shown in Table 1.

Based on our calculations, the mean/median amount required to train an ISMIR model (for either corpus 1 or 2) is about 224.8kWh (mean) and 18.46kWh (median). This amounts roughly to the energy demand of a single-person household for two months/three days in a Western country, such as Germany.³ As is evident from Table 1, there is no clear distinction between the energy use of generative or analytic models, which implies that the pursued MIR task may not be an important factor. Instead, the distribution of values is strongly focused around smaller values, and only four outlier models require an amount of energy that lies above the average of 225kWh (hence, the large difference between mean and median). Out of these, the three most energy-demanding models in terms of training come from large IT corporations. The amount of energy required to train the models provided in these papers sums to 5.11MWh, which is about 87% of the total energy demand related to all 26 papers with full resource disclosure. In total, taking into account the full range of energy requirements, the papers with industry-affiliated authors demand about 89% of the total resources related to all 26 full-disclosure papers. In contrast, industry-affiliated authors are found only in 40 out of the 113 papers (35%) in our two corpora.

As mentioned in Section 3, an estimate of the actual carbon footprint requires – among other aspects – detailed information about the data centers at which the computation takes place and their energy sources. Nevertheless, we will approach a preliminary estimate of the carbon footprint related to model training at the most recent ISMIR conference. We carefully checked all papers in ISMIR 2023 and determined the number of papers that train a machine learning model, resulting in 62 out of 104 papers (59.6%). We accommodate for the fact that a small amount of these papers train “shallow” machine learning models and use an estimate of 50% of ISMIR papers that train deep learning models in recent years. Assuming the median as the representative statistic for the average energy consumption for training a model, we arrive at an energy consumption of 18.46kWh * 52 papers = 959.92kWh.

Starting from this number, two further obstacles impede a reliable estimate of the carbon footprint: 1) In each paper, the model has not been trained only once, but the total development of the presented model will have required more energy. Strubell et al. [14] have documented how the process of fine-tuning a specific model exceeded the energy demand of one training run by 24 times, and that a whole R&D cycle is three orders more expensive than a single training run. Lacking more precise numbers, it seems, therefore, fair to assume that the actual energy con-

Article	Corpus	Energy cost
Hawthorne et al 2022 [47] ⁴	1	4 375 kWh

Table 1. Energy cost of model training in corpora 1 (N=13) and 2 (N=13).

sumption related to a paper is at least that of fine-tuning an existing model. Hence, with a very conservative assumption of a factor of 20, we arrive at an estimate of $E_{est} = 19.20MWh$ for all model development related to a recent ISMIR conference.

The second obstacle is that the location of the data center at which computation took place is not documented. Therefore, we decided to use the countries of author affiliations as an indicator of where computation took place. In terms of carbon footprint, this has an impact as the USA and China are both on the high end of the carbon intensity spectrum [19]. We retrieved the average carbon intensity of the grids in 2022⁶ for each country depicted in Figure 1, I_c (in gCO₂eq/kWh) and computed the estimate for the total carbon footprint C_{total} of one conference as

$$C_{total} = (E_{est}/N_{total}) \cdot \sum_{c \in C} N_c \cdot I_c \quad (1)$$

with N_c being the number of times co-authors were from

⁴ For the four models in this paper, only the minimum and maximum training times were specified. We use the mean of these two values as an estimate.

³ 5.77kWh per day for a one-person household in 2021 in Germany according to www.destatis.de.

a specific country out of the set C of all countries as depicted in Figure 1, $N_{total} = 96$ is the total count of the histogram. This results in an estimate of $C_{total} = 7.593$ tons of carbon dioxide from training processes related to one recent ISMIR conference.

Putting this number into context, according to the estimates by [43], the training of GPT-3 has caused energy consumption of about 189 MWh. With the carbon intensity of the USA in 2017 (higher than in 2022) of 449.06 gCO₂eq/kWh, this has produced 85 tons of carbon dioxide, one order larger than our estimate for the whole of ISMIR.

5. DISCUSSION

While this paper focused on the training phase of music-AI models, more information is needed about the energy consumption along the full pipeline of model development, inference⁷, and deployment. To this end, authors of ISMIR papers should – at the very least – clearly document the resources (compute time; type and number of processors) needed for training and inference, and – ideally – include more minute documentation of actual energy use during the whole development cycle. We encourage a discussion to adopt standards similar to NeurIPS within the ISMIR submission process.

A commonly used framework that can guide the direction towards considering the environmental impact of ISMIR in a broader sense can be found in the concept of planetary boundaries [71]. There are nine planetary boundaries that can help us to understand and analyze how our actions might influence the environmental systems. These include, for example, biodiversity loss and species extinction, stratospheric ozone depletion, ocean acidification, land-system change/deforestation, freshwater use, and atmospheric aerosol load. Taking the example of freshwater use, these dimensions can be directly applied to ISMIR research to examine the environmental impact in relation to the planetary boundaries. Efforts can be directed toward questions such as what is the level of water use for hardware cooling in computational tasks at ISMIR, and whether the life cycles of the used hardware are contributing to environmental processes such as ocean acidification or species extinction. Unfortunately, six of nine planetary boundaries are currently transgressed [72], and that places us on track for increased climate change and breakage of the prevailing ecosystems.

While energy estimates provide a baseline for understanding the scale of the specific issue of energy consumption and for comparing individual model types to one another, they are not in and of themselves a sufficient solution to the problem of environmental sustainability in model development at ISMIR or elsewhere. In order to address the complexity of the issues in all dimensions of the planetary boundaries, context-specific inquiries into the impact and effect of the ISMIR research and technologies developed

and used by the community are needed. Furthermore, a broader cultural shift in thinking around AI development is necessary to bring environmental sustainability to the ISMIR research agenda. We argue that ISMIR can lead by a good example of more environmentally conscious model development, more mindful and minimalistic energy use, and reflective accounting for the environmental externalities and their political economies in current research and development practices.

We acknowledge that the calculations presented here are necessarily tentative by their nature. This is inherently a result of the lack of transparency in the ISMIR publications. While the information currently provided can provide us with indications of the scale of energy used in training the models, there are several details that may impact the exact values of these variables, which cannot be accounted for due to partial or lacking information. Such inaccuracies may skew the implied environmental impact, with undesirable consequences for social practices in the community. However, we argue that our estimate is very conservative on several points: First, the factor of 20 multiplied with the energy used for one training is below the estimates of [14], second, the use of TDP ignores all additional energy consumption by other hardware, and third, we use the median as a statistic. We would therefore like to point out that the likely underestimated energy costs could lull the research community into a false sense of security and encourage it to refrain from efforts that would be valuable for the environment. These estimates nevertheless provide an important basis upon which further inquiries into the complete environmental and ecological footprint of the conference can build.

Furthermore, we understand that the authors who contributed to our estimates were those who actively documented resource requirements. These papers may seem unfairly a focus of critique in our work, as many other authors who did not volunteer resource information at all were not cited in the paper. We believe it is instrumental to document the need for specifying the use of resources in the ISMIR community, and encourage further proactive efforts toward that goal.

6. CONCLUSION

In the era of acute climate crisis, the interest in resource-demanding music generation and analysis tasks shows signs of acceleration rather than slowing down. It is essential that research communities such as ISMIR apply critical self-reflection and acknowledge their role in promoting practices that may be excessively harmful to the environment. Increased transparency in documentation in ISMIR papers would serve better accounting for the current impacts of the research, steering the community norms and guidelines towards more sustainable practices, and providing a positive example for the wider industry. We encourage the ISMIR community to continue these critical discussions around the ethical impacts of MIR, including environmental sustainability and its political ecologies and beyond.

⁷ Two models in the second corpus discuss the use of GPU resources for inference, but the included information does not allow conclusions about the energy consumption during the experiments.

7. ACKNOWLEDGMENTS

This paper is an outcome of a project funded by the Marianne and Marcus Wallenberg Foundation (MMW 2020.0102).

8. ETHICS STATEMENT

This work is based on secondary data that is publicly accessible in online sources. We acknowledge that our paper presents estimates with many uncertainties. Therefore, the numbers may imply an environmental impact larger or smaller than the actual one, in both cases to the detriment of the community. To mitigate this, we put great effort into clarifying the uncertainties in our method. We also see a risk that a paper focusing on quantitative aspects of environmental impact may fail to motivate larger-scale behavior change, which in the context of global crisis may be seen as an ethical shortcoming.

ABSTRACT

Regular weekly lessons and daily home practice are key for skill development. This paper focuses on identifying the challenges within such practice routines and developing a system to address these issues, thereby enhancing teacher support and elevating student performance in piano. Observations from real-world lessons and an analysis of practice videos spanning 177 days from 30 students reveal successful tactics, including the assignment of suitably challenging pieces and motivational rewards like stickers or stamps. Furthermore, the study underscores issues such as tension in parent-led practice and ineffective repetition. Insights from the field study suggest the potential of third-party feedback, practice segmentation, reporting practice records to teachers, and rewarding practice sessions. We developed a system incorporating these solutions and tested it with 80 children over 4 months. Results showed increased teacher engagement with students' home practice, improved student motivation and practice duration, and enhanced sight-reading skills, demonstrating the system's effectiveness in supporting piano education.

1. INTRODUCTION

Weekly lessons and daily home practice are vital for skill growth in young piano students [1-3]. However, teachers often rely solely on lesson performance to address issues in unseen home practice. Fostering resilience is essential in daily piano education. Research suggests praising not just outcomes, but also effort and perseverance [4]. Therefore, piano instructors should evaluate and commend not only performance outcomes but also efforts during home practice and the ability to overcome difficulties.

Identifying home practice challenges enables efficient skill improvement through targeted interventions and support systems. This paper aims to (1) identify home practice challenges and (2) develop a system to address them. This study aims to address issues and evaluate the system's effectiveness in improving practice outcomes.

Figure 1. (Left) Current practice (Right) Enhanced System with App.

In 2023, with the cooperation of Piano Teachers' National Association of Japan (PTNA) [5], (1a) interviews were conducted with 8 piano teachers, (1b) observations were made of the piano lessons of their 12 students, (1c) survey results regarding home practice were collected from 81 piano teachers, (1d) one-week home practice records were obtained from 37 students (Average age: 7.02), and (1e) the analysis of 177 days of home practice videos from 30 of those students (Average age: 6.93) was performed. (2) Based on these findings, a support system (Fig. 1) was developed and tested over 4 months with 80 students (Average age: 7.11) and 46 teachers, aiming to enhance practice efficiency and outcomes. These students are a different population from the subjects in survey (1a-1e).

The evaluation of the system's effectiveness, based on its usage and surveys conducted before and after the trial, revealed the following:

- Segmenting tasks of target musical score, which is assigned as homework, increased students' practice time and improved their sight-reading skills.
- Reporting practice time and frequency to teachers increased teachers' awareness of home practice.
- Providing incentives for each piece practiced enhanced students' motivation and initiative to practice.

2. FIELD STUDY

2.1 Cultural Background

In Japan, piano lessons are the second most popular extra-curricular activity for elementary school students [6], and almost all students attending piano classes have a piano at home and practice daily. Throughout the 9 years of compulsory education from the first year of elementary school to the third year of middle school, music is consistently a compulsory subject, resulting in high levels of music literacy. Although few children aim to become piano professionals, it is presumed that many parents recognize the educational value of learning music and piano [7]. The educational value of music and piano learning is evident from the fact that many students at major U.S. universities like Harvard and MIT [8] study music as part of their liberal arts education and focus on developing non-cognitive skills [9]. The role of parents in their children's piano learning in Japan is multifaceted. Parents manage the daily practice schedule and maintain their children's motivation through feedback and encouragement. They also work closely with piano teachers, correcting mistakes in place of the teachers to ensure effective practice at home. In this way, active parental involvement significantly impacts the duration and progress of their children's piano learning.

2.2 Lesson Observations and Teacher Interviews

To explore how to maximize the effectiveness of home practice, we invited 8 experienced piano teachers (30s to 60s) to observe 12 lessons across 4 piano classes. These observations, coupled with interviews, highlighted 3 key factors essential for enhancing home practice:

- (1) Receiving objective feedback from a third party to gain a clearer perspective on one's own performance [10].
- (2) Assigning homework that is appropriately challenging, considering the student's age, experience, parental support, and skill level [11-12].
- (3) Rewarding completed assignments with stickers or stamps to motivate students [13].

These teachers, with their deep expertise, foster substantial musical skills, contributing to students' continued engagement with piano through high school and college.

2.3 Teacher and Student Questionnaires

A questionnaire was set up on the website of the Piano Teachers' National Association to clarify teachers' perceptions and students' actual practice conditions at home. Responses were collected from 81 teachers of various ages, genders, and skill levels. The student survey was conducted through teachers, with 37 students from schools reporting their practice status daily for 1 week using Google Forms.

Teacher Questionnaire: The top concern for teachers regarding students' home practice was "insufficient practice days," accounting for 83% of responses. This was followed by 59% of the teachers indicating that students practicing with incorrect sounds and rhythms was a concern.

Student Questionnaire: The home practice records were submitted via Google Form every day after piano practice.

Figure 2. Survey Results on Practice Content for Elementary School Students.

Figure 3. Timeline of home practice for first graders: most of the time was run-through practice.

Days and duration: Out of the total 259 days surveyed (37 students × 7 days), 250 days of responses were received. The number of practice days was 188, averaging 5.08 days per week per person, indicating that they practice on week-days. In addition, 69.1% of the respondents (130 out of 188 days) practiced for more than 15 minutes at a session.

Practice content: An analysis of responses (Fig. 2) to questions about actual practice content revealed that 92.0% (173 out of 188 days) of students reported performing "full run-throughs" of pieces from start to finish. However, only about half of the students practiced "partial sections" such as practicing difficult parts (46.3% or 87 days), practicing parts pointed out in lessons (44.7% or 84 days), or practicing with 1 hand (35.1% or 66 days).

The survey results from both teachers and students revealed a gap in their perceptions. While 83% of the 81 teachers surveyed expressed concerns about the insufficient number of practice days, the student survey results showed that students practiced an average of 5.08 days per week, with 69.1% spending more than 15 minutes per practice session. These results highlight a significant discrepancy between teachers' perceptions and the actual practice conditions of students.

2.4 Analysis of Home Practice Videos from Students

Thirty of the students in the study recorded their home practice for the same week and uploaded the video to Google Drive. As a result, a total of 177 days practice videos were collected. These videos were viewed and analyzed by 5 active teachers, with each teacher assigned a different set of videos to review. The analysis was conducted based on a format that included 5 items: timeline, piece, practice sections, practice methods, and free comments, allowing each teacher to record their observations.

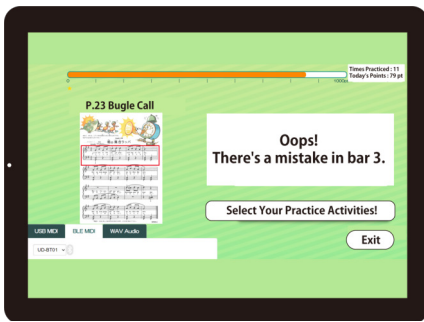

Figure 4. Screenshot of performance assessment.

Figure 5. Example of Part Practice Method B

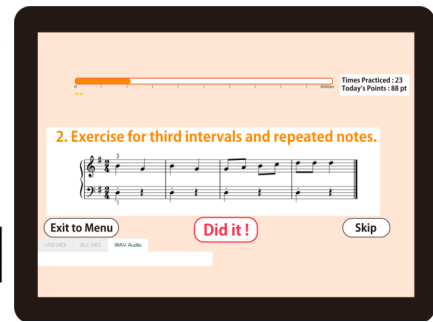

Figure 6. User Interface: students push “Did it !” button after each part practice was completed

For example, Fig. 3 shows a timeline of home practice of first-grade elementary school student who worked on 4 pieces labeled A to D over 5 days of the week. The videos showed the student independently engaging in practice, with a high proportion of full run-throughs in their practice routine. On 1 day, the student repeated a full run-through of the same section 3 times, making the same mistakes each time, but then moved on to the next piece without correcting them. On the day of the lesson (May 25, 2023), the practice time was longer than usual, and the mother's involvement was also observed.

In other videos, various methods of counting the number of plays were observed, such as using an iPad or notebook to keep track, or using educational toys like “Pop-It” to count. There was a tendency to end the practice session after a certain number of repetitions, regardless of whether they could play the sections correctly or not.

Moreover, from the perspective of parental involvement, a correlation was observed between the extent of parental involvement, the completion of assignments, and the students' initiative. Active parental involvement was seen to accelerate technical progress in students, although it tended to suppress their autonomy. While children's skills improved when parents pointed out mistakes in sound or gave prompts similar to those of teachers in lessons, this also led to situations where the child felt pressured and became overly tense. On the other hand, when parents were not overly involved and only supported when prompted by their child, the students tended to practice independently. Although practice often ended based on the number of times played, mistakes sometimes remained uncorrected over time. Furthermore, parents encouraging children to think about the next steps and motivating them through praise and encouragement helped support the children in approaching practice in a relaxed and thoughtful manner.

2.5 Identified Challenges from Field Study

The field study revealed the following challenges: (1) Students themselves find it difficult to objectively view mistakes in sound and rhythm. However, it is challenging for parents, who may not have a deep understanding of piano instruction, to provide appropriate support that is neither too interfering nor disinterested. (2) Merely completing a set number of full run-throughs makes it difficult to overcome sections that are not well-played. (3) There is a gap

between teachers' perceptions and the actual practice conditions of students. (4) Rewards are effective in improving motivation, but since they are only received during weekly lessons, they do not easily motivate home practice.

3. SYSTEM DESCRIPTION

Based on the identified challenges in the previous section, a system was designed to enhance the efficiency of students' home practice. The implemented features in this system are as follows:

- (A) Providing feedback on whether a performance is correct or incorrect by a third party other than parents
- (B) Encouraging targeted practice of difficult sections by segmenting practice pieces [3],[14]
- (C) Enabling teachers to review home practice records at any time
- (D) Motivating students by providing rewards every time they play their practice pieces, visualizing these rewards

3.1 Overview of the Practice App

To achieve the objectives (A) through (D), we implemented the system as follows. It is important to note that while objective (A) is only accessible to users of digital pianos with MIDI output, objectives (B) through (D) are available for both electronic and acoustic piano users.

(A) Design of Performance AI Assessment by System

The system is designed to allow a third party other than parents to provide feedback on the correctness of a performance.

After selecting the homework piece, the student chooses which section of the piece, previously divided into units of about 4 measures, they wish to practice. They start the performance by pressing the “Start” button. The student's performance is recorded in MIDI and converted into a Standard MIDI File (SMF). The recording is done without a metronome or click track to allow the student to play at their own tempo. The student's performance SMF is then compared with a pre-prepared exemplary performance SMF. As a preprocessing step before comparison, the note ON events in the SMF are sorted chronologically. Note ON events within 50 ms of each other are considered

simultaneous and are sorted by MIDI note number in ascending order. The preprocessed SMFs are compared using Dynamic Programming (DP) matching [15] to find corresponding notes between the student's performance and the exemplary performance, and any discrepancies are detected as mistakes. Since this is intended for beginners, a simple method like this is sufficient for now. However, using symbolic music alignment instead of DP matching is a subject for future consideration.

If the performance is flawless, the system responds with "Well played!" If there are mistakes, the system points out the first bar where a mistake occurred (Fig. 4).

(B) Design for Segmenting Practice Pieces

Video observation of home practice sessions revealed that it is difficult to compensate for mistakes and weaknesses by simply practicing through the piece. Therefore, we aimed to encourage segmented practice in order to improve overall mastery of the piece.

Students select their homework piece and, after receiving system feedback on any 4-bars block, they can choose to work on segmented practice pieces using 1 of following 2 methods:

Part Practice Method A: Simplifies the homework piece by concealing parts of the score every 4 measures. This method aims to focus on specific sections by maintaining the original sheet music's staff lines, bar spacing, and note-head sizes, while intentionally hiding parts to help students focus on particular areas.

Part Practice Method B: This method involves identifying key learning elements that are either crucial for learning or where many students stumble. Short 4-bars pieces, simpler than the original, are composed that include some of these learning elements (Fig. 5). The contents were composed by 6 music majors, including three active piano instructors. The following conditions apply to the composition process [16]:

- #1: Include at least one challenging learning element from the original phrase.
 - #2: Maintain the same time signature, position, and key as the original phrase.
 - #3: Include fewer learning elements than the original.
 - #4: Maintain or lower the level of learning elements. Lowering is defined as reverting to already learned related elements.
 - #5: If using elements other than melody and rhythm, employ the same starting note, melody, and rhythm as the practice phrase from the original.
 - #6: Use a melody that the students may have heard before.
- In both Part Practice Method A and B, students can either play the presented 4-bars practice piece or choose to skip it by pressing the skip button located at the bottom right of the sheet and move on to the next original practice piece.

(C&D) Design of Monitoring and Rewarding

Instead of teachers assessing students' home practice solely based on their performance during weekly lessons, the design allows teachers to continuously check daily and cumulative practice time since the start of using the Practice App, the number of times practice pieces are played, and the points earned.

The rewarding design: 1 point for just logging in, 1 to 5 points for pressing the "Did it!" button (Fig. 6), and 10 to

50 points awarded by teachers as a reward. The educational philosophy of this system is "from result-oriented to process-oriented." In a result-oriented approach, perfect performances evaluated by the AI performance assessment would likely earn higher points. However, in a process-oriented approach, value is found in the attempt itself, and regardless of the performance outcome, a consistent 5 points are awarded. Thus, these experimental results are evaluated without a strong AI performance assessment component, other than the simple pitch errors.

3.2 Overview of PoC (Proof of Concept)

Students participating in the PoC were recruited via the website of an organization for piano teachers. The PoC is not an independent experiment but is incorporated into actual students' regular lessons and practice. Participants were selected based on their responses to questions about teaching materials, instruments owned, and devices owned. Additionally, 30 tablets for the PoC were lent out, and it was anticipated that students would use devices (tablets, smartphones, computers) alongside their usual sheet music.

For the performance assessment feature, students who mainly use digital pianos at home were targeted, although some students with acoustic pianos were also accepted. The teaching materials used were "Bastien New Traditions: All In One Piano Course - Level 1A" and "Bastien Piano Basics [17]: Piano - Level 1," both of which have been translated into over 16 languages worldwide.

The PoC was conducted from October 2023 for 4 months. Piano students using the Practice App were introduced by their teachers, and the teachers' surveys were linked to individual students for analysis. To validate the Practice App, a pre-assessment questionnaire was conducted at the beginning and a post-assessment questionnaire after 4 months.

3.3 Results of System Usage

3.3.1 Period and number of participants

Students who participated in the PoC were referred by 46 teachers, and 80 students used the Practice App at least once. The age of the students mainly ranged from first to third grade of elementary school, with a few preschoolers and fourth to 6th graders included. The number of days the Practice App was used ranged from a minimum of 1 day to a maximum of 117 days, with an average usage of 39.2 sessions. The Total points, indicating the level of activity in using the Practice App, ranged from a minimum of 5 points to a maximum of 8,628 points, averaging 1,399 points. 36 teachers monitored their students' practice sessions at least once using the Practice App.

3.3.2 Comparison of Pre/Post PoC Questionnaire

The same questionnaires were administered to students before and after the PoC to validate the effectiveness of the Practice App. The questionnaires used a 5 level Likert scale to ask about students' attitudes towards piano practice and their parent-child relationships. The responses were based on the respondents' subjective perceptions of these aspects. 52 students responded to both the pre and post questionnaires. The students who earned more than 1,000

Questionnaire for HPG Students	Mean	
	before	after
Does your child enjoy daily practice? **	3.20	3.64
Is your child self-motivated in daily piano practice? **	2.76	3.52
How long do you practice each day? *	3.12	3.52
How do you feel about your relationship with your child during daily piano practice?	3.16	3.24

Table 1. Paired t-test of Pre- and Post-PoC Questionnaires for HPG Students (N=25, **p<0.01, *p<0.05)

points with the Practice App were categorized as the High-Practice Group (HPG) with 25 students, and those who earned less than 1,000 points were categorized as the Low-Practice Group (LPG) with 27 students. For the group of 25 HPG participants, a paired t-test was conducted on the pre- and post-assessment questionnaire results. As shown in Table 1, significant improvements were observed in Daily Practice Time, Voluntariness in Practice, and Enjoyment of Practice. However, no significant effect was observed in improving parent-child relationships.

3.3.3 Validation by questionnaire after PoC

Responses to questions included only in the post-PoC questionnaire were collected from 64 participants. These were divided into two groups: 30 in the High-Practice Group (HPG) and 34 in the Low-Practice Group (LPG). The average scores for HPG were listed in descending order in Table 2. Independent sample t-tests were conducted for each question.

In the HPG, half of the 14 question items averaged 4.0 points or higher. Furthermore, HPG received significantly higher scores than LPG in 9 out of the 14 questions. The item “Increased Voluntariness for Practice” in Table 2 corresponds to “Voluntariness in Practice,” which showed significant effects in the paired t-test described in previous section. Therefore, even though there were no significant differences found in the independent samples t-test for items like “Motivated by 'Did it!' Button,” “Supported by AI performance assessment,” and “Supported by Part Practice Method A,” the higher scores in “Increased Voluntariness for Practice” suggest that system was effective. Thus, it is estimated that the system influenced 13 out of the 14 items.

3.3.4 Results of the Teacher Questionnaire

After the PoC, feedback was obtained via a Likert scale questionnaire from 46 teachers, as shown in Table 3. An independent samples t-test was conducted between 26 teachers (HPG) who had at least 1 student scoring over 1,000 points and 20 teachers (LPG) who did not.

Out of 15 questionnaire items, 7 averaged 4.0 points or higher. Moreover, HPG received significantly higher responses in 10 items compared to LPG. The item "Have Students Use Part Practice Method A" scored particularly high for HPG at 4.69 points, with a significant difference from LPG. Conversely, "Have Students Use Part Practice Method B" was the only item among all 15 where both HPG and LPG teachers scored above 4.0 points. Significant responses were also seen in items relating to teacher

Questionnaire for Students	Mean	
	LPG	HPG
Did tracking practice motivate you? **	3.59	4.30
Did Method B support your practice? **	3.50	4.29
Did the "Did it!" button motivate you?	3.76	4.27
Did AI assessment support your practice?	3.67	4.27
Did Method B support your practice?	3.55	4.12
Did practice points motivate you? *	3.41	4.10
Did practicing become more enjoyable? **	3.15	4.00
Did your practice time and frequency increase? *	3.06	3.83
Did your piano skills improve? **	2.85	3.70
Did using Practice App motivate you? **	2.82	3.60
Did it reduce the burden on parents? *	2.85	3.60
Practice independently without parents? **	2.71	3.53
Did your motivation for practicing increase?	3.09	3.43
Did your teacher give you a passing mark earlier?	2.68	3.20

Table 2. Results and Mean Values from Independent Samples t-Test of Post-PoC Student Questionnaires Between HPG and LPG (N ranges from LPG: 9-34, HPG: 11-30, **p<0.01, *p<0.05)

Questionnaire for Teachers	Mean	
	LPG	HPG
Do you want students to use Method A? **	3.85	4.69
Did it spark home practice talks with students? **	3.30	4.42
Do you want students to use Method B?	4.15	4.38
Was Method B effective in improving sight-reading skills? *	3.95	4.38
Any insights from checking students' practice amount? **	3.20	4.27
Any positive changes in students? **	3.25	4.19
Did it help observe students' home practice? **	3.30	4.00
Did lesson efficiency improve? **	3.00	3.92
Did it lead to better lessons?	3.35	3.85
Did students' performance improve by the next lesson? **	2.85	3.85
Did students' sight-reading improve? *	3.20	3.73
Did it change how you assign homework?	3.15	3.65
Did AI assessment reduce pitch and rhythm mistakes?	3.05	3.54
Did points awarded by teachers motivate students? *	2.75	3.50
Did it increase the number of assigned pieces?	2.90	3.23

Table 3. Comparison of Mean Values Between Teachers with 1 or More Students in HPG and Those Without (N=LPG: 20, HPG: 26, **p<0.01, *p<0.05)

engagement with home practice, such as providing opportunities for discussions about home practice and observing the process.

The questions “Have Students Use Part Practice Method A,” “Have Students Use Part Practice Method B,” and “Part Practice Method B is effective for reading skills” reflect teachers' opinions on the functionality rather than the change in students due to implementation, which might explain the higher scores from LPG. As a result, while “Have Students Use Part Practice Method B” did not show a significant difference in scores between HPG and LPG, the high average score of 4.38 points for HPG indicates substantial positive expectations from the teachers.

3.4 Summary of Results

Results from section 3.3.2 indicated that there were significant differences in the Likert scale questionnaire scores

before and after the start of the PoC, demonstrating improvements in “Daily Practice Time,” “Voluntariness in Practice,” and “Enjoyment of Practice.”

From section 3.3.3, significant differences between the High-Practice Group and Low-Practice Group in the post-PoC questionnaire suggest that motivation for practice, practice time and frequency, and the sense of improvement increased while reducing parental burden. Items that scored an average of 4 points or higher in the HPG are considered to indicate the effectiveness of the Practice App. According to the results from section 3.3.4, the significant differences in scores between the HPG and LPG indicated an increase in teachers' awareness of home practice. Both Part Practice Method A and B being highly rated by both groups indicates that these methods are perceived as effective practices by teachers and hold high expectations.

4. DISCUSSION

4.1 Factors Enhancing Engagement

Motivational Effects: The visualization of the effort process has been shown to be effective in motivation in other studies as well [18], but this time, visualizing the efforts of child students at home practice with points confirmed significant motivational effects. For example, a second-grade elementary school monitor student practiced a song from the introductory tutorial book 3 times through, totaling about 2 minutes of practice before the PoC in October. However, two months after starting to use the Practice App, the student began practicing more than 30 minutes every day and was able to progress to “Burgmüller: 25 Progressive Etudes, Op. 100”[19]. This substantial change in motivation was attributed to daily point rewards by teachers, as revealed in interviews. The total points, including both self-reward points and teacher reward points, were always displayed. Students who noticed the addition of teacher points showed increased motivation. Moreover, segmenting practice pieces and increasing the frequency of pressing the “Did it!” button increased opportunities for earning points, enhancing students' autonomy and providing a game-like experience. This led to an increase in frequency and duration, thereby improving sight-reading skills.

Analysis of Part Practice Methods A and B: Field studies show that teachers have traditionally assigned students to practice with one hand or rhythm practice as homework [20], using methods such as writing instructions on the score or using sticky notes. However, in Part Practice Method A, for example, when practicing only with the right hand, the system hides the left-hand part, allowing focus solely on right-hand practice. The system displaying only the part being practiced helps students concentrate on the task without being distracted or overwhelmed by having to cognitively process the whole score first and subsequently disregard some parts. This focus on individual tasks was perceived as effective based on questionnaire results and post-interviews with teachers. Part Practice Method B is not just a specialized part-practice for the assigned homework piece but focuses on learning elements intended to be acquired in that piece, aimed at improving sight-reading skills overall. Interviews and questionnaires

with teachers suggest that compared to adult students aiming to master specific songs, there is a high expectation for child students to improve their sight-reading skills overall to play many pieces in the future.

Feedback and System Impact: In the free-response section of the post-use survey, both students and parents shared feedback such as, “It was helpful that the AI performance assessment could identify mistakes even when parents couldn't supervise the practice,” and “Knowing that the teacher was monitoring daily practice motivated the child (student).” Teachers also provided positive feedback, saying, “The system's suggestion for part practice helped students who tend to play through the entire piece from start to finish to adopt sectional practice,” and “The presence of the system as a third party seemed to reduce parents' frustration.” These responses aligned with the goals of our study, indicating a successful outcome.

4.2 Limitation

This study primarily aimed to conduct a PoC; hence, for the performance assessment, it did not involve using acoustic pianos with automatic musical acoustic alignment [21-24], but instead conducted validations using digital pianos, which offer higher recognition accuracy. Although the effectiveness of segmenting practice pieces was confirmed, the study did not perform detailed analyses such as comparing the impact of Part Practice Method A and B separately or comparing the effects of practice with and without segmentation. The interface was changed to English for the paper, but we use Japanese in practice. Additionally, feedback indicated the current teacher UI is difficult to use in multi-student classrooms. This suggests the need for UI improvements to reduce management costs for actual classroom deployment. Furthermore, while the study has statistically summarized outcomes, reports indicate that some students felt monitored during home practice, and it has not been possible to perform usability evaluations that consider such individual differences.

5. CONCLUSION

This study, through a large scale field study of piano teachers and students, revealed that the challenges in children's home piano practice include not recognizing errors in playing without parental support, repeating inefficient full run-throughs, teachers not understanding the practice process, and maintaining motivation. To address these problems, a system was developed incorporating performance assessment, presentation of segmented practice pieces, reports to teachers, and point allocation, and a PoC was conducted. The results confirmed that (1) the system identified mistakes, reducing parental burden, (2) increased practice time and improved sight-reading skills, (3) increased awareness among teachers about the practice process, and (4) enhanced student motivation and spontaneity. These outcomes suggest that the proposed system has the potential to enhance efficiency and effectiveness in children's piano learning. Challenges such as individual differences in UI and usability, as well as environmental settings, remain for actual deployment and are targeted for future work.

ACKNOWLEDGEMENTS

This work was supported by JSPS KAKENHI Grant number 22H01047. We would like to express our heartfelt thanks to the piano teachers and students who participated in this study by providing survey responses, interviews, home practice videos, and taking part in the PoC (Proof of Concept). Their contributions were essential in making this research possible.

INNER METRIC ANALYSIS AS A MEASURE OF RHYTHMIC SYNCOPATION

Brian Bemman

Durham University

brian.m.bemman@durham.ac.uk

Justin Christensen

University of Sheffield

j.christensen@sheffield.ac.uk

ABSTRACT

Inner Metric Analysis (IMA) is a method for symbolic music analysis that identifies strong and weak metrical positions according to coinciding periodicities within note onsets. These periodicities are visualized with bar graphs known as *metric weight* and *spectral weight profiles*. Analyzing these profiles for the presence of syncopation has thus far required manual inspection. In this paper, we propose a simple measure using chi-squared distance for quantifying the level of syncopation found in IMA weight profiles by considering each as a distribution to be compared against (1) a uniform distribution ‘nominal’ weight profile, and (2) a non-uniform distribution based on beat strength. We apply this measure to the task of predicting perceptual ratings of syncopation using the Song (2014) dataset of 111 single-bar rhythmic patterns and compare its performance to seven existing models of syncopation/complexity. Our results indicate that the proposed measure based on (1) achieves a moderately high Spearman rank correlation ($r_s = 0.80$) to all ratings and is the only single measure that reportedly works across all categories. For so-called polyrhythms in 4/4, the measure based on (2) surpasses all other models and further outperforms five models for monorhythms in 6/8 and three models for monorhythms in 4/4.

1. INTRODUCTION

Much research has gone into understanding the perception of temporal patterns [1–3] and many more recent studies within this scope have focused on the perceived levels of syncopation and complexity in these patterns [4–11]. Subsequently, a number of different computational methods have been proposed for modeling these, including models that are based on a metric hierarchy using tree-based structures [7, 12–14] and those that are not [15–19]. Many of these models have been tested on various perceptual tasks, such as syn-

copation prediction, and their respective performances have been compared [6, 9, 20–23]. However, none of the comparisons carried out to date have considered Inner Metric Analysis [24].

Inner Metric Analysis (IMA) is a method of symbolic music analysis for identifying strong and weak metrical positions in a piece based on coinciding periodicities found in its note onsets [24]. Over the years, IMA has been applied to the tasks of automatic meter detection [25] and dance music classification [26], but it has largely been used in more traditional music analysis contexts [24, 27]. An important feature of IMA is its ability to provide a representation of the *inner* metric structure of a piece rather than a representation tied to its *outer* metric structure—the meter as indicated by the time signature in a score. This feature allows IMA to identify, for example, instances where the notated music conflicts with the implied or perceived meter. For this reason, it has been used to aid in the identification of syncopation [24], which has typically been defined as a temporary displacement of the regular metrical accent [28]. However, until now the use of IMA to identify syncopation in a musical passage has required manual analysis by a music theorist or other domain expert.

In this paper, we propose using chi-squared distance as a first step towards computing a quantifiable measure of syncopation from weight profiles produced by IMA. We apply this method to the task of predicting perceptual ratings of syncopation in the Song (2014) [22] dataset containing 111 one-bar rhythmic patterns in two different meters and rhythm types (i.e., monorhythms in 4/4, monorhythms in 6/8, and so-called polyrhythms in 4/4). In section 2, we explain how IMA produces a metrical analysis of a musical passage and detail the rhythmic patterns in the Song (2014) dataset. In section 3, we introduce our proposed measure based on chi-squared distance for comparing the weight profiles produced by IMA to a uniform distribution or ‘nominal’ weight profile as well as to a non-uniform distribution based on beat strength [29]. We evaluate this measure in section 4 by testing it on the aforementioned dataset and compare its performance to the reported performances of seven existing models of syncopation/complexity. We summarize our findings in section 5 and suggest possible directions for future work.

2. RELATED WORK

2.1 Inner Metric Analysis (IMA)

IMA computes, from the note onsets of a piece, an exhaustive listing of *local meters*—each of which must be a sub-sequence of onsets or *pulses* that are (1) at least 3 in number, (2) separated by a fixed inter-onset interval, called the *period*, (3) not able to be extended further (forwards or backwards in time) within the sequence of all onsets of the piece, and (4) not contained within the pulses belonging to any other local meter. Figure 1 shows the opening two bars of “Twinkle, Twinkle Little Star” with its single local meter. Note that the single local meter (A) contains at least 3—in this case, 7, evenly-spaced pulses (black circles), each aligned with a corresponding onset in the music above. The numbers at the bottom indicate the positions within an underlying “grid” called *time points*, equivalent to *tatums*, upon which the onsets are fitted. Because all adjacent onsets have an equal, constant spacing, represented in the score as quarter-note durations, no time point exists between them. In such passages, there will be only a single local meter as any other possible set of pulses would necessarily be contained within this local meter. For more complex rhythms, this will not be the case.

Following the enumeration of all local meters in a piece, IMA computes a *metric weight* for each onset based on the number of pulses in local meters that coincide with this onset and the lengths of those local meters to which these pulses belong. Formally, let On be the set of all onset time points in a piece and m be a local meter that contains an onset, o , and where k_m denotes the length of m minus 1. $M(l)$ denotes the set of all local meters of length at least l , where in straight-forward implementations of IMA, l is 2 (equal to the minimum number of pulses, 3, minus 1). The metric weight of o is defined as the sum of the values, k_m , of the local meters, m , that contain o . The metric weight of an onset $o \in On$ is thus given by

$$W_{l,p}(o) = \sum_{\{m \in M(l): o \in m\}} (k_m)^p, \quad (1)$$

where p is a weighting parameter typically set to $p = 2$ that is used to control the relative influence of the length of local meters on the metric weight [24]. For example, the metric weight assigned to each of the 7 onsets of the melody shown in Figure 1, using the

Figure 2. Opening bars of a syncopated variation of the “Twinkle, Twinkle Little Star” melody with all ten (A–J) local meters and their extensions (red triangles) generated by Inner Metric Analysis (IMA).

typical weighting parameter of $p = 2$, would be $(7 - 1)^2 = 36$, as each onset has only a single pulse (i.e., no coinciding pulses) belonging to one local meter of length $7 - 1 = 6$.

In addition to the metric weight, IMA also computes a *spectral weight* that considers the *extension* of each local meter to certain time points on the grid that align with either onsets or silence (i.e., rests) in a piece. Formally, an extension, $ext(m)$, of a local meter, m , is defined as the set of time points, $\{s + id, \forall i\}$, where s denotes the time point of the first onset in m , d is the period, and i is an integer time point in the underlying grid. Figure 2 shows a syncopated variation of the melody shown in Figure 1 with all ten of its local meters (A–J) and extensions (red triangles). Note that, in contrast to Figure 1, there are multiple local meters (ten) where no one local meter is contained within the pulses belonging to any other local meter. Take, for example, local meter (E), which shares two of its pulses (time points 1 and 7) with local meter (D), but contains a third (time point 4) that is not shared with (D). The purpose of extensions in IMA is to allow for pulses to contribute to parts of passages where they are not even present. The case for projecting pulses further in time in this way through extensions, for example, is made stronger when one considers the possibility for some latent or persisting pulse in the listener’s perception. The spectral weight is computed in a similar manner to the metric weight (shown in Equation 1), except that it assigns a weight to each time point (rather than only to each onset) based on the pulses and now extensions which coincide with this time point. For a time point, t , the spectral weight is given by

$$SW_{l,p}(t) = \sum_{\{m \in M(l): t \in ext(m)\}} (k_m)^p. \quad (2)$$

Whereas the metric weight of, for example, the first onset (at time point 0) shown in Figure 2, would consider only local meter (H) due to it having the only coinciding pulse, the spectral weight would consider the additional contributions of local meters (A, B, C, G), due to their coinciding extensions.

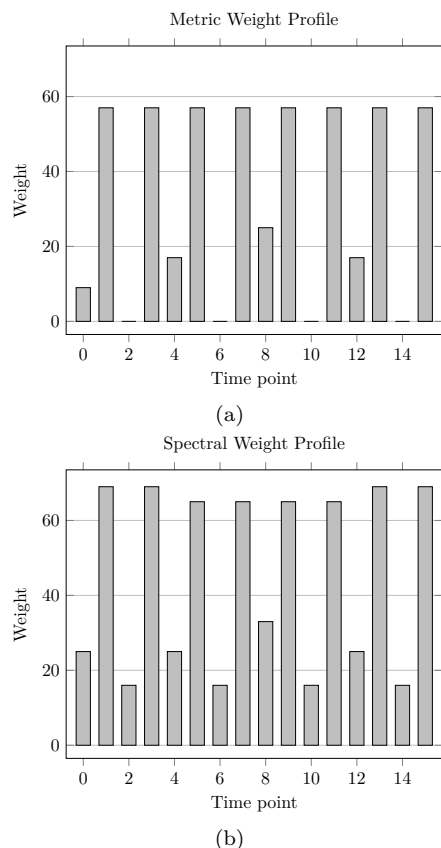

Figure 3. The metric and spectral weight profiles of the opening two bars of the syncopated “Twinkle, Twinkle Little Star” melody from Figure 2 with metric weights shown in (a) and spectral weights shown in (b), as computed by Inner Metric Analysis (IMA).

Whether an analysis of a piece by IMA uses metric weights or spectral weights, it is typical for the weights to be plotted in the form of a bar graph called a *profile*. With a trained eye, musical features of a piece such as a possible meter (whether notated or not) and syncopation often emerge through visual inspection of the profile. Figure 3 shows the *metric weight profile* and *spectral weight profile* for the opening two bars of the syncopated “Twinkle, Twinkle Little Star” melody shown in Figure 2. Given that the actual meter of the syncopated melody in Figure 2 is known, we can see in its corresponding weight profiles, shown in Figure 3, that all lower weights at time points 0, 2, 4, 6, 8, 10, 12, 14 appear at on-beat locations while all higher weights at time points 1, 3, 5, 7, 9, 11, 13, 15 appear at offbeat locations, suggesting a strong possibility for the presence of syncopation.

2.2 The Song (2014) Syncopation Dataset

Datasets containing rhythmic (or temporal) patterns for studying human perception remain relatively few in number and small in size [1–4, 7, 30, 31]. A number of these early datasets were originally constructed as a means for evaluating perceptual complexity and have since been co-opted for the study of syncopation [5,

6]. Even fewer datasets exist for the explicit study of syncopation [7, 22, 32, 33], however, the Song (2014) [22] dataset is arguably one of the largest.

The Song (2014) [22] dataset contains 111 single-bar rhythmic patterns (and their mean listener perceptual ratings from 0 to 4) in two possible meters, 4/4 and 6/8, and of two different rhythm types, mono and poly.¹ There are 27 monorhythm patterns in 4/4 (15 on quarter-note grid; 12 on eighth-note grid), 36 monorhythm patterns in 6/8 (eighth-note grid), and 48 so-called polyrhythm patterns in 4/4 (quarter-note triplet grid)—each of which were preceded for listeners by an audible two-bar metronome in their respective meter. Patterns in each category range from having a single onset (e.g., $\langle 0, 0, 0, 1 \rangle$ monorhythm in 4/4 with an onset on the fourth beat) up to a number of onsets equal to the number of time points in the underlying grid (e.g., $\langle 1, 1, 1, 1, 1, 1 \rangle$ monorhythm in 6/8 of all eighth notes).

3. PROPOSED MEASURE OF SYNCOPATION USING IMA

The central premise motivating our proposed measure is the consideration of weight profiles produced by IMA as distributions through which comparisons with other distributions using chi-squared distance [34] can provide insight into the underlying rhythmic structure that is relevant to predicting syncopation. We consider two possible distributions that we will compare against the weight profiles produced by IMA for a given rhythmic pattern: (1) a uniform distribution based on what we call a ‘nominal’ weight profile that operates conservatively and in the spirit of IMA without knowledge of the underlying meter, and (2) a non-uniform distribution based on beat strength [29] that operates with explicit knowledge of the underlying meter and is nearly analogous to a nominal weight profile but for metrical (hierarchy) structure. A nominal weight profile is the uniform distribution of weights that results from an IMA analysis of any sequence consisting entirely of equally-spaced onsets irrespective of the hierarchical metrical level at which these are expressed. For example, a pattern in 4/4 consisting of all quarter notes, half-notes, or eighth notes will each result in a nominal weight profile. Our motivation for considering nominal weight profiles is based on a simplifying assumption that a less syncopated rhythmic pattern or passage of music will have more equal weighting across its weight profile than a more syncopated pattern or passage. This was observed, for example, in Figures 1 and 2, with the less syncopated melody containing a single local meter resulting in a metric weight profile containing at each onset a constant weight and its syncopated version containing multiple local meters resulting in weight pro-

¹ The complete Song (2014) [22] dataset and perceptual ratings can be found in the following repository: <https://code.soundsoftware.ac.uk/projects/syncopation-dataset>.

files (shown in Figure 3) containing a variable weight that fluctuates over time. Our motivation in (2) for considering non-uniform distributions based on beat strength comes from the fact that clearly not all rhythmic patterns consist of all equally-spaced onsets, and, much like previous models of syncopation, such as Weighted Note-to-Beat Distance (WNBD) [17] or the Longuet-Higgins and Lee (LHL) model [12], providing additional information beyond what is explicitly available in the onsets (e.g., beat locations or rests), can provide relevant (or indeed necessary) information for modelling or predicting syncopation.

The proposed measure adopts two different constructions for handling normalization across patterns and distributions, both of which we will use in our evaluation. The first of these constructions considers a given metric or spectral weight profile produced by IMA as a normalized distribution, P' , scaled to unit length and a second, un-normalized uniform distribution, Q , representing a nominal weight profile having some constant value, Q_i for all i . The measure-normalized (weighted) chi-squared distance, χ_{D1} , between two distributions P' and Q of length n (time points) is given by

$$\text{IMA}_{M,S}\chi_{D1} = \frac{1}{n} \sum_{i=0}^{n-1} \left(\frac{(P'_i - Q_i)^2}{(P'_i + Q_i)} \right)^a, \quad (3)$$

where a is a weighting parameter (discussed in section 4) and $\frac{1}{n}$ serves to normalize the distance by measure length. By calculating the distance of an observed weight profile from a nominal weight profile, we obtain a measure of the overall aperiodicity or irregularity of the rhythmic content (relative to the constant, Q_i , in the uniform distribution), where the higher the overall value, the greater the amount of perceived syncopation there is predicted to be. In principle, while the constant Q_i could be any rational value, for the purposes of this paper, we will utilize a constant value between $[0, 1]$ corresponding to the maximum upper and minimum lower ranges of the P' distribution. In addition to the a weighting parameter, an optimal constant value for Q_i will be learned in section 4.

Whereas the Q uniform distribution in Equation 3 was left un-normalized to allow for various constant values to be learned, which would otherwise disappear with normalization, other distributions, such as our non-uniform distribution based on beat strength, will require normalization for fair comparisons with P' . Thus, an alternative weighted construction, χ_{D2} , of Equation 3 appears below for the same normalized distribution, P' , and another normalized distribution, S' , also of length n and scaled to unit length:

$$\text{IMA}_{M,S}\chi_{D2} = \sum_{i=0}^{n-1} \left(\frac{(P'_i - S'_i)^2}{(P'_i + S'_i)} \right)^a, \quad (4)$$

where a is the same weighting parameter as in

the earlier construction. Note that because both distributions have been scaled to unit length, normalizing by measure length, n , as was done in Equation 3, is no longer necessary. In our use of Equation 4, we consider four different distributions for S' , corresponding to the beat strengths produced by music21 [29] (using the `beatStrength` method) for each of the four different types of meter/rhythm types found in the Song (2014) [22] dataset. The following four (un-normalized) beat strength distributions are those used with this construction: (1) 4/4 meter with quarter-note grid $\langle 1.0, 0.25, 0.5, 0.25 \rangle$, (2) 4/4 meter with eighth-note grid $\langle 1.0, 0.125, 0.25, 0.125, 0.5, 0.125, 0.25, 0.125 \rangle$, (3) 6/8 meter with eighth-note grid $\langle 1.0, 0.25, 0.25, 0.5, 0.25, 0.25 \rangle$, and (4) 4/4 meter with quarter-note triplet grid $\langle 1.0, 0.0625, 0.0625, 0.25, 0.0625, 0.0625, 0.5, 0.0625, 0.0625, 0.25, 0.0625, 0.0625 \rangle$.

4. EVALUATION

We have evaluated our IMA-based measure on the Song (2014) [22] dataset of 111 one-bar rhythmic patterns and their perceptual ratings of syncopation for three reasons: (1) there is a relatively large number of stimuli in comparison to other available datasets, (2) the stimuli were constructed specifically for the purpose of studying syncopation and not, for example, complexity or groove, and (3) there has been significant work already done on evaluating other computational models of syncopation with this dataset. The reader is referred to [22] for an in-depth discussion of the performances of existing models using this dataset.

4.1 Procedure

We have adopted an optimization approach using leave-one-out cross-validation in which we performed a grid search over the pair of parameters, Q_i , and a from Equation 3 for 100^2 value-pairs within the range $[0, 1]$ in increments of 0.01. For each distinct weighting parameter pair, we carried out the procedure below for all rhythmic patterns in the training set:

1. Repeat the time-span note sequence of the given Song (2014) [22] one-bar rhythmic pattern twelve times. As IMA requires at least three pulses to form a local meter, it is generally less effective with short rhythmic patterns having few onsets. For this reason, it has been suggested in [26] to repeat short patterns in this way when using IMA.
2. Convert this extended time-span note sequence from (1) to an ordered set of note onset indices suitable for analysis by IMA e.g., $\langle 0, 1, 0, 1 \rangle$ to $\langle 1, 3 \rangle$ (using 0-based indexing).
3. Compute IMA metric and spectral weight profiles for this extended twelve-bar rhythmic pat-

tern from (2) using an IMA weighting parameter $p = 2$ and minimum local meter length, $l = 2$.

4. ‘Fold’ the metric and spectral weight profiles in (3) into single bars and sum those weights at each time point having equivalent within-bar locations. Then scale each weight profile to unit length such that they each sum to 1.
5. Compute a measure of syncopation from each normalized single-bar metric and spectral weight profile from (4) using Equation 3 and the given weighting parameter pair, Q_i and a .

Following the procedure above for all training rhythmic patterns and a given weighting parameter pair, the respective sets of syncopation scores computed for each of the metric and spectral weight profiles are min-max normalized. The Spearman rank correlation coefficient, r_s , is then computed for each of these sets of syncopation scores and the min-max normalized mean perceptual ratings, in the same way that was done for each of the computational models evaluated in [22, pp. 92–94] so that fair comparisons could be made. The procedure for using Equation 4 and the non-uniform distributions based on beat strength is identical to the steps outlined above, except the grid search was performed across all 100 values between $[0, 1]$ for a only, and the set of beat strengths chosen for any given pattern was that matching in number of time points, n . The weight parameter (Equation 4) or weight parameter pair (Equation 3) that produced the highest mean rank correlation achieved across all k -folds was retained and the final results below are reported using the best parameters across the entire dataset. All syncopation-dependent procedures were implemented in Julia (v. 1.10.0) and all statistical calculations were made with R (v. 4.3.2).

4.2 Results and Discussion

We compare the performance of the proposed measure to the reported performances of seven models of syncopation/complexity previously evaluated in [22] and [21, 23] on the same dataset. These models are Longuet-Higgins and Lee (LHL) [12], Off-Beatness (TOB) [16], Metric Complexity (TMC) [14], Weighted Note-to-Beat Distance (WNBD) [17], Cognitive Complexity (PRS) [13], Off-beat model (KTH) [15], and Sioros et al. (SG) [7]. Table 1 shows the results of our IMA-based measure of syncopation for both the metric and spectral weight profiles using the two proposed distributions across the dataset in comparison to these other models.

In Table 1, the best weighting parameters found for Equation 3 (χ_{D1}) were $a = 1.0$ for both metric and spectral weight and $Q_i = 0.74$ for metric weight and $Q_i = 0.83$ for spectral weight. The best weighting parameters for Equation 4 (χ_{D2}) were $a = 0.82$

³ There may be disagreement as to whether polyrhythms in the Song (2014) [22] dataset are what they claim and whether some existing models are in fact incapable of analyzing these

Table 1. Spearman correlation rank coefficients (r_s) of 9 different models/measures of syncopation for 111 mono- and poly-rhythmic patterns in two meters and their perceptual ratings. For the proposed measures based on IMA (1–4), IMA $_M$ and IMA $_S$ denote use of metric and spectral weight, respectively. Note that results for models 5–11 are the values reported in [22, pp. 92–94]. An asterisk denotes where $p < 0.01$, a hyphen indicates where a given measure is reported as being incapable of providing a result³, and empty cells mark no reported results.

for metric weight and $a = 0.35$ for spectral weight. It is clear from these results that while Equation 3 worked best across the entirety of the dataset (e.g., IMA $_M\chi_{D1}$: $r_s = 0.80^*$; $p < 0.01$ —an improvement over no a weighting parameter and Q_i set to an arbitrary 0.5, $r_s = 0.73^*$; $p < 0.01$), it resulted in relatively poor performance within the individual categories. Perhaps not surprisingly, however, providing additional information about the underlying meter, in the form of beat strengths as done in Equation 4, significantly improved the performance in these individual categories but to the detriment of overall performance (e.g., IMA $_M\chi_{D2}$: $r_s = 0.66^*$; $p < 0.01$ —same as without a). In all cases except monorhythms in 6/8, metric weight performed better than spectral weight. In particular, IMA $_M\chi_{D2}$, outperformed all three of the existing models (TOB, WNBD, KTH) reportedly capable of providing a result for the so-called polyrhythms in 4/4 ($r_s = 0.73^*$; $p < 0.01$); five of the existing models (LHL, TMC, SG, TOB, WNBD) capable of providing a result for monorhythms in 6/8 ($r_s = 0.74^*$; $p < 0.01$); and only three (TOB, WNBD, KTH) of all seven models for monorhythms in 4/4 ($r_s = 0.86^*$; $p < 0.01$; tying with LHL). It should be noted that in [22, p. 139] a so-called weighted-multiple combined (WMC) model using optimized versions of the best combinations of these previous models was able to achieve a rank correlation across the entire dataset of $r_s = 0.89^*$ ($p < 0.01$). While the proposed IMA measure falls short in this regard

without reinterpreting their meter (e.g., 4/4 to 12/8). The reader is referred to [22] for detail on these possible concerns.

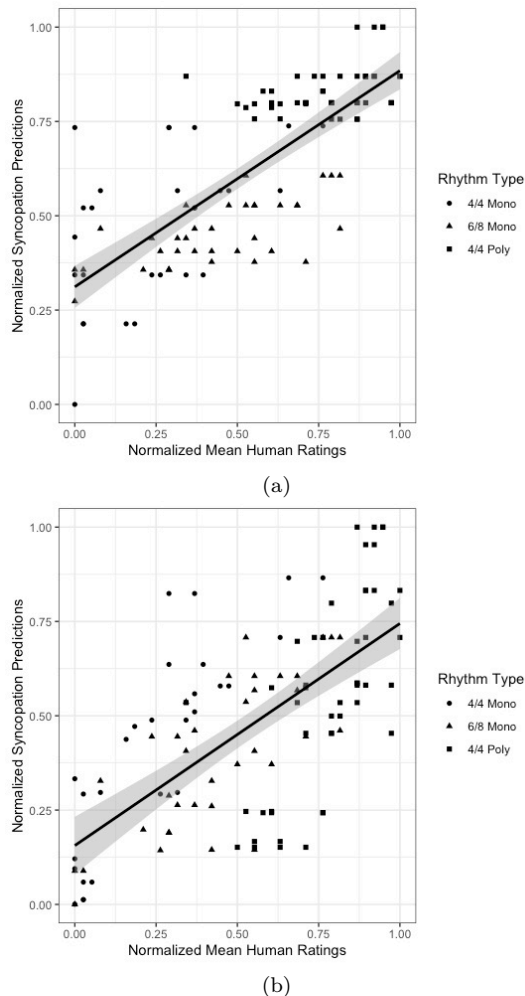

Figure 4. Normalized syncopation predictions produced by $\text{IMA}_M\chi_{D1}$ ($r_s = 0.80^*$; $p < 0.01$) in (a) and $\text{IMA}_M\chi_{D2}$ ($r_s = 0.66^*$; $p < 0.01$) in (b) against the normalized human ratings for the 111 rhythmic patterns in the Song (2014) [22] dataset. Note that regression lines are plotted with shaded areas indicating a 95% confidence interval.

($r_s = 0.80^*$; $p < 0.01$), it remains noteworthy that its performance is close to approaching the performance of a significantly more complex method consisting of many different models. For completeness, Figure 4 shows regression plots of the predicted syncopation scores across the entire dataset for both $\text{IMA}_M\chi_{D1}$ and $\text{IMA}_M\chi_{D2}$ against the human ratings.

The reason for the difference in performances for both constructions across the dataset versus within the individual categories is not immediately clear, however, the use of rank correlation combined with the distributed locations and smaller sizes of the respective sets of rhythm and meter type examples within the dataset is likely a contributing factor. Despite the better overall performance of Equation 3 over Equation 4, one problem with our first construction using this dataset concerns the density of pattern onsets, which has been shown to interact with their perceived displacement from a metrical hierar-

chy in regards to syncopation [33]. Many of the patterns are highly sparse, and Equation 3 is unable to differentiate, for example, between two distinct patterns each having a single onset, such as $\langle 1, 0, 0, 0 \rangle$ and $\langle 0, 1, 0, 0 \rangle$, or the same number of equally-spaced onsets shifted in time, such as $\langle 1, 0, 1, 0 \rangle$ and $\langle 0, 1, 0, 1 \rangle$. This would help to explain its relatively low performance in the individual categories. Equation 4, on the other hand, does not encounter these same difficulties, and its improved performance in the individual categories suggests an informative structural correspondence between the metrical strengths as identified by IMA weight profiles and the beat strengths they were compared against. In an actual piece of music, however, one might expect to find relatively less sparse and more complex examples, so more ecologically valid comparisons may provide deeper insights into whether syncopated patterns have generally less equal weighting in their profiles as un-syncopated patterns, as is assumed by Equation 3. Finally, while the choice of chi-squared distance is motivated by the desire to obtain the best possible results across the entirety of the dataset using the simplest method, multiple other distance measures were tested (e.g., Euclidean and Minkowski) with the relatively more complex Jensen-Shannon divergence [35] performing marginally better across the dataset ($r_s = 0.81^*$; $p < 0.01$) but marginally worse within the individual categories.

5. CONCLUSION

In this paper, we proposed a first step towards using Inner Metric Analysis (IMA) to provide a quantifiable measure of syncopation based on chi-squared distance and comparisons to two different types of distributions. We evaluated our method using a dataset of rhythmic patterns constructed specifically for the task of studying syncopation and compared its performance to the performances of seven existing computational models. Our results indicate that the proposed measure based on comparisons with a uniform distribution achieves a moderately high Spearman rank correlation ($r_s = 0.80$) to all perceptual ratings and is the only single measure that reportedly works across all meters and rhythm types (mono, poly, 4/4 and 6/8). For so-called polyrhythms in 4/4, the measure based on comparisons with a distribution of beat strengths surpasses all other models and further outperforms five models for monorhythms in 6/8 and three models for monorhythms in 4/4. Finally, considering the entirety of a rhythmic sequence as done here rather than summing isolated instances of syncopation as in, for example, the LHL [12] model, appears to have higher validity [36]. In future work, it would be useful to consider other datasets, particularly ones which contain more ecologically valid examples, as well as with other distributions, possibly coming from statistical corpora studies or perceptual profiles, that could be automatically selected for in comparisons.

6. ACKNOWLEDGMENTS

We would like to thank Tuomas Eerola, Mark Gotham, and the anonymous reviewers for their helpful suggestions during the later stages of this paper as well as David Meredith for useful feedback provided during its early stages.

ABSTRACT

The advent of accessible artificial intelligence (AI) tools and systems has begun a new era for creative expression, challenging us to gain a better understanding of human-AI collaboration and creativity. In this paper, we introduce Human–AI Songwriting Processes Dataset (HAISP), consisting of 34 coded submissions from the 2023 AI Song Contest. This dataset offers a resource for exploring the complex dynamics of AI-supported songwriting processes, facilitating investigations into the possibilities and challenges posed by AI in creative endeavors. Overall, HAISP is anticipated to contribute to advancing understanding of human-AI co-creation from the users’ perspective. We suggest potential use cases for the dataset, including examining AI tools used in songwriting and exploring users’ ethical considerations and creative approaches. This could help inform academic research and practical applications in music composition and related fields.

1. INTRODUCTION

Open and easy to access artificial intelligence (AI) technologies have created new opportunities for creativity, challenging conventional notions of authorship, expression, and human-AI creativity [1]. Within this landscape, the AI Song Contest (AISC) has emerged as a unique platform where teams of musicians, data scientists, researchers and AI enthusiasts can leverage AI tools to compose original songs, providing a prolific ground for studying the interplay between human creativity and machine intelligence [2].

In this paper we present the Human-AI Songwriting

Processes Dataset (HAISP), a curated dataset extracted from the written process documentation of participants in the AI Song Contest. This dataset provides a useful resource for exploring various aspects of AI-supported songwriting processes. It consists of 34 submissions from the 2023 AISC teams, cleaned, organized, and cross-annotated by four annotators using our data dictionary. The HAISP dataset includes information on the AI systems utilized, creative and technical inspirations, methodologies for working with AI, teams’ assessments of the songs, and reflections on ethical considerations in AI-generated content. This dataset provides researchers with a unique perspective into the complex relationship between human creativity and AI assistance in songwriting. By analyzing how songwriting processes are affected by the use of AI tools, scholars can gain insights into how AI systems may augment, complement, or challenge creative endeavors. The dataset also supports investigations into the ethical aspects of AI-generated music, including considerations like diversity in training data, intellectual property rights, and accessibility in music creation. It can serve as a valuable resource for scholars, practitioners, and enthusiasts alike, fostering deeper understanding, critical inquiry, and informed discourse in the burgeoning field of human-AI collaboration and creativity. Overall, it provides various insights and opportunities for further research, contributing to our understanding of the interaction between technology and creativity in the digital age.

2. BACKGROUND

2.1 Human–AI Music Creation

Using computational methods for music creation that would be classified as AI today, began in the 1950s, with early examples including Iannis Xenakis using Markov Chains for composition [3] or David Cope’s *Experiments in Musical Intelligence* in the 1980s [4]. For more detail on the history of AI music we refer to *The Oxford Handbook of Algorithmic Music* by Roger Dean and Alex McLean [5]. Although the use of neural networks for mu-

Morris, R. Leger, M. Newman, J. A. Burgoyne, R. Groves, N. Mangal and J. H. Lee, “HAISP: A Dataset of Human–AI Songwriting Processes from the AI Song Contest”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

sic modeling was mentioned as early as 1989 [6], the recent progress in the field of deep learning led to an increase of powerful and easy-to-use AI tools for music creation [7], from accessible applications for a large audience [8], to tools intended for professional musicians (e.g. [9]).

2.2 AI and Music Information Retrieval

In the area of music composition, researchers have developed many methods [10] and machine learning-powered interfaces that enable interactive exploration of musical variations by mapping user inputs to musical structures. Other tools have recently emerged to assist in various aspects of the music creation process, including infilling missing parts of compositions [11–14], creating new instruments [15, 16], counterpoint improvisation [17], and generating and recommending chord progressions [18–20], harmonies [21–23], and even accompaniment [24, 25].

Many AI models have also been created to aid in music information retrieval (MIR) research. With the explosive growth of digital music archives and streaming platforms, the need for effective MIR systems has become increasingly pronounced, driving research efforts to develop more sophisticated methods for understanding and processing music data through AI, such as the utilization of deep learning, neural networks, and large language models [26–29]. Existing datasets in the realm of AI in MIR primarily focus on training data, such as audio features [30, 31], music [32, 33], and metadata [34, 35].

2.3 AI Song Contest

The AI Song Contest is an annual international music competition wherein teams from diverse musical traditions and disciplines collaborate to compose songs using AI methods. It was launched in 2020 by the Dutch public broadcaster VPRO [2], and has been organized independently afterwards every year. There have been 132 teams so far, with 35 from the 2023 edition included in the dataset. We plan to extend the dataset with the other year’s team entries in the future. To participate in the AI Song Contest 2023, teams had to submit their song, a team image, cover art, and an online form in which they described their team, their creative vision, their motivation to participate, the steps of composition, their impression of the human-AI co-creation process, their workflow, all AI tools and databases used and their ethical and cultural considerations. The form has been developed by the AI Song Contest organizing team, slightly modified for each new edition. After successful submission, the songs and process documents are sent to a jury. The top ten entries of the jury voting are open for a public online vote. Whichever team gets the most points from the jury voting combined with the public voting wins the AI Song Contest.

3. OBJECTIVE AND SCOPE

There is a growing recognition of the need for complementary data that provides insights into the qualitative aspects of human-AI collaboration in music creation – the

human side of training and using these AI tools and systems. Recently, researchers have called for a cultural and ethical turn in MIR [36]. Rezwana and Maher [37] and Lee et al. [38] emphasize the importance of understanding not only perspectives but also expectations and ethical concerns of users of AI tools.

To our knowledge, there is no dataset exploring the qualitative processes and reflections of those who have used AI tools for music creation. Recognizing this gap, we were motivated to curate the written submissions of AISC participants into a unique and publicly available dataset that would allow researchers to go behind the scenes and explore the AI-supported songwriting and creation processes of the teams, beyond the final song submissions. By complementing existing quantitative datasets in AI in MIR, the HAISP dataset contributes to a more holistic understanding of the role of AI in creative endeavors and facilitates deeper insights into the collaborative dynamics between human composers and AI systems.

However, there are limitations to the data in this dataset. Firstly, the dataset relies solely on the words of the 34 participants in their written (subjective) process documentation. Compared to other datasets in MIR publications, this qualitative dataset is of limited size which might not lead to conclusions that are broadly applicable. Additionally, the dataset may not capture the full spectrum of AI tools and methodologies employed by participants, as teams may choose not to disclose certain details or may use proprietary technologies. Furthermore, the dataset represents a snapshot of a specific event and a specific outcome, the song, which may not fully generalize to other contexts of AI-supported music creation such as AI tools for jazz improvisation (e.g. see *GenJam* [39]).

Nonetheless, the amount of detail and depth provides an extensive and rich insight into the creative experience of the teams. By compiling and analyzing the teams’ process documentation, we seek to illuminate the landscape of human-AI creative collaboration. Through the creation of this dataset, we aim to facilitate deeper insights into the collaborative dynamics between human composers and AI systems, thereby fostering a richer understanding of the potential, limitations, and societal implications of AI in music production.

4. DATASET DESCRIPTION

The HAISP Dataset is accessible as a .csv and .xlsx on OSF under a Creative Commons Attribution-NonCommercial 4.0 International (CC BY-NC) license, which allows for broad access and utilization for research purposes.¹

4.1 Data Collection

For submission to the contest each team had to fill in the AI Song Contest 2023 Submission Form via Google forms. The form consists of entry fields to upload the song and

¹ <https://creativecommons.org/licenses/by-nc/4.0/>

Category	Subcategory	Definition
Team Data	Team_ID	The given label of the team for the dataset.
	Number of Team Members	The number of team members in a team.
	Type of Affiliation	The given work or personal affiliation of the team members.
	Country	The given country(s) of origin of the team.
	Found Out About Contest	The way that the team discovered or were informed of the AI Song Contest.
	Motivation to Participate in the Contest	The reason the team gave for joining the competition.
Song Data	Song Length	The length of the submitted song given in minutes and seconds.
	Song Description	The short description of the song written for the contest website.
	Final Ranking	Denotes the final ranking of the team's song in the competition.
	Song Title	The title of the song submitted to the AI Song Contest.
	Song Concept	The overarching idea or theme of the song.
Process	Creation Process	The given order in which the separate pieces of the song, or potentially the whole song, was created, as described by the team.
Song Elements Use of AI	Melody	Whether an AI system was used to generate the melody.
	Harmony	Whether an AI system was used to generate the harmony.
	Bassline	Whether an AI system was used to generate the bassline.
	Drums	Whether an AI system was used to generate drum patterns or rhythms.
	Formal Structure	Whether an AI system was used to generate the formal structure.
	Lyrics	Whether an AI system was used to generate the lyrics of the song.
	Voice Synthesis	Whether an AI system was used to generate the singing voice of the song.
Song Process Use of AI	Idea Generation	Whether an AI system was used to generate the idea for the song.
	Composing/Arranging	Whether an AI system was used to organize the elements of the song.
	Evaluation	Whether an AI system was used to evaluate the output or final song.
	Mixing & Mastering	Whether an AI system was used to do the mixing and mastering of the song
	Performance	Whether an AI system is or would be used for live performance.
AI Tools Used	Model Used	The AI models as used and indicated by the teams in the song creation process.
	Database(s) Used	The databases as used and indicated by the teams in the training and song creation process.
Ethical Considerations	Diversity, Ethical, and Cultural Considerations	Ethical and cultural considerations stated by the teams regarding their process and use of AI.
Human Evaluation of AI Co-Creation	Evaluation of Output	The words that teams used to assess the output of the AI system(s).
	Evaluation of Process	The words that teams used to assess the process of working with the AI system(s).
	Ownership	Teams statements regarding ownership of the system output and/or final song.
	Motivation to Use AI	The reasons that teams mentioned why they used AI in the process.
Other	Other	Additional information that does not fit in another category.

Table 1. Categories of HAISP Dataset. The HAISP dataset consists of data collected in 31 categories in total.

visual material (team image and song cover), and a free-text and multiple choice questionnaire. The questions that the teams filled in covered everything in these categories:

- team (bio for the website, location, level of expertise, motivation to participate, how they heard about the AISC);
- song (title, length, link to music video/soundcloud/blogpost, concept/idea, lyrics, live performance);
- human–AI process (short description for the website, models and databases used, steps of the process, creative vision, capabilities/limitations of AI tools in the creative process, workflow, collaboration with team members and AI, input data, ownership and conflict with intellectual property law);
- and diversity, ethical and cultural considerations

All teams had to further give consent for their answers description to be published in a scientific paper.

The answers were collected automatically in a Google Sheet. In total there were 40 submissions collected with one being a corrective submission replacing an existing entry and four submissions being incomplete. After unanswered inquiry these submissions were excluded, leading to 35 participating teams in the 2023 edition. Their complete questionnaires were then handed over to the research group excluding any personal data. One process documentation (teamID: 2023_14) was submitted in Spanish which was excluded from the dataset for linguistic consistency.

4.2 Data Statistics

The HAISP dataset consists of the data from 34 teams of the 2023 edition of the AISC. Looking at the team data, there is a total of 104 team members involved, with an average of three members per team, and 14 countries represented. Of the countries represented, eight teams were based in the United States, six were based in the United Kingdom, and four were based in Guatemala, Sweden, and Germany. Other countries represented included South Korea, Spain, North Macedonia, and more.

Type of affiliation – the given work or personal affiliation of the team members – was determined by coders based on the data, with teams being assigned multiple affiliations based on team members. A majority of the team members (58.8%) were members of academic field (20 mentions), meaning they worked primarily within academic institutions; this included universities, archives, or museums. A partially overlapping 44.1% of the team members were artists or worked in the creative industries, 17.6% worked as researchers outside academia, and 8.8% were classified as independent, (i.e., working in fields unrelated to the study/research/creation of AI or the creation of music but rather participating out of their own curiosity, hobby, or interest).

Teams had primarily heard about the contest from academia (29%), web search, or participation in prior editions of the AISC. The motivation for why teams used AI

in their process and why they decided to take part in the competition can be described as exploratory, while seven teams were also participating in order to display the use of their own or institutionally-created software.

Regarding the AI tools, there were 74 different tools used by teams in the 2023 edition. On average, there were 2.17 tools used per team. Half of the teams used a form of GPT by OpenAI (e.g., ChatGPT) and 38.24% of the teams used tools by Google Magenta (e.g., Magenta Studio, Tensorflow, DDSP). Other tools that were frequently used were TransformerXL [40] (14.1%), AIVA (11.4%) or MusicGen by Meta (3 teams). There were 57 models that have been only used once.

Looking at the use of AI in the compositional process, illustrated in Figure 1, it shows that 21 teams used only AI or co-created with AI for arranging, 18 teams used AI for idea generation and 10 (would) use AI in a performance. Nine teams mentioned the use of AI for mixing/mastering while only four teams used AI for evaluation of the output. Co-creation means this part was created by the human working with AI, human that only human was involved, AI that only AI was involved. Failed attempts to use AI in a specific step of the process were mentioned only in one case. Interestingly, the number of using “AI only” for these steps are low, with most uses (8) for “idea generation”. Only one team, 2023_28, mentioned a failed attempt to use AI in a specific step of the process: mixing and mastering.

Looking at the use of AI to create the elements of the songs – melody, harmony, bassline, drums, formal structure, lyrics, voice – depicted in Figure 2, 29 teams used AI, either in co-creation or solely for melody, while 19 used it for harmony and lyrics. Interestingly, while for melody, harmony, bassline, and drums the co-creation outweighs the AI-only approach, this is the opposite for formal structure, lyrics and voice synthesis. Team 2023_20 was the only team reporting a failed use of AI for creating harmony and voice synthesis with AI.

The teams’ own writings on their song concepts, their described creation process, their evaluation of diversity and ethical issues within said process, their thoughts on ownership of the song, and their overall evaluation of their human-AI co-creation process and the outcome of said process can be found in the dataset and can be used for further analysis.

4.3 Methodology and Validation

After reviewing the initial survey responses, we proceeded to create the data dictionary through a mixed-methods approach. The categories were created inductively by five researchers, iterating four times to reach final consensus. For each iteration of the data dictionary, two coders tested it on two sample entries to ensure that the categories were properly defined and applicable for the data.

We generated the dataset via consensus coding [41]. One researcher coded a selection of the data entries, collecting them into the dataset. A second coder then reviewed the initial coding, validating the coding by either

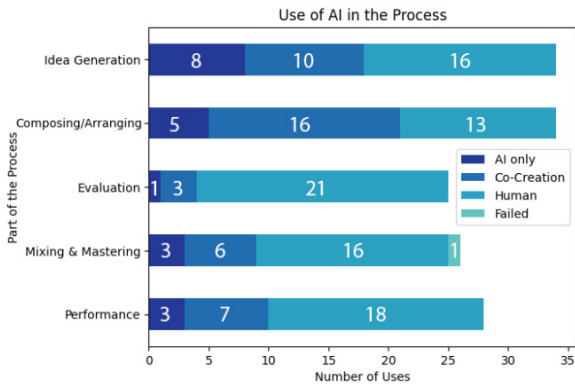

Figure 1. Overview of the Use of AI for the Compositional Process in HAISP: Idea Generation, Arrangement, Evaluation, Mixing & Mastering, Performance.

Figure 2. Overview of the Use of AI for the Elements of the Song in HAISP: Melody, Harmony, Bassline, Drums, Formal Structure, Lyrics and Voice.

citing a +1 for agreement with the coding choices or -1 for disagreement with the coding within the dataset, adding what they felt the coder was missing within their codes from the data. In the case of disagreement a third researcher helped decide on the final code as a tie-breaker.

4.4 Ethical Considerations

The study was approved by the university Institutional Review Board. When submitting to the contest, one question in the submission form asked directly and transparently for the team’s consent for their song and documentation to be used for research purposes. Teams gave consent by ticking a box in the form. While we erased all personal data from the dataset, song names are included due to their public availability on the AI Song Contest website.

5. USE CASE AND APPLICATIONS

Our dataset can be used to understand a variety of MIR tasks and work related to human-AI creative interactions, ranging from goals focused on research to practical creation of music. This section presents four possible use cases.

5.1 Use Case 1: More Insights on the AI Tools used in the Songwriting Process

HAISP lists not only all AI tools that teams used and indicated, but also contains the teams’ description of the process of utilizing said tools, with data showing which parts of the creative process (idea generation, composition, mixing/mastering, performance) AI was used on its own, in co-creation with the team, or even when co-creation with the AI system failed. Additionally, it reports the teams’ level of expertise and location. This provides not only valuable insights for tool developers and inspiration or guidance on using AI for other artists but also helps to answer research questions such as “How does the utilization of AI tools in music creation vary across different professional affiliations and stages of the creative process?”

5.2 Use Case 2: Understanding Attitudes and Impact of AI on the Creative Process

Within our dataset, there is reference to how creators use AI within their process, as well as their perceptions around the capabilities and limitations of AI. Additionally, creators share their perceptions of the final creation resulting from their collaboration with AI, providing valuable insights into the impact of AI on artistic expression and creative outcomes.

In their work *Beyond Diverse Datasets* [36], Huang et al. pose questions such as “What is valuable to those communities [that MIR investigates] and what is valuable to the community contributing to MIR?” and “How do musical communities wish for their practices to interact with emerging technologies (if at all), and what do they consider as potential misuses of their traditions?”. Our dataset offers a unique opportunity to start exploring these questions, drawing from the diverse perspectives of creators from various cultural, educational, and experiential backgrounds. By analyzing the reflections and experiences of creators documented in the dataset, researchers can gain insights into how different musical communities perceive and interact with AI technologies in their creative practices.

5.3 Use Case 3: Gaining Insight into Users’ Understanding of Ethics Around H-AI Co-Creation

Ethical considerations and questions about the validity of data were found frequently in the responses of AISC participants. Working with AI tools during the creation process can trigger questions around control [42], ownership of the final output [43], and freedom of personal expression [44]. Additionally, many participants spoke on the issue of AI systems and tools used during their process potentially being trained on datasets that violate the intellectual property rights of the original artists.

By examining how creators navigate ethical considerations in their process, researchers can uncover how AI tools are adopted and used within different musical traditions. This deeper understanding can inform discussions around the ethical implications of AI in music creation and

contribute to the development of responsible approaches to AI-driven creativity. One research question that this data can provide insight on is “What are the ethical considerations and challenges faced by creators when utilizing AI tools in their creative process, and how do these considerations impact their creative workflows?”

5.4 Use Case 4: Execution of Creative Possibilities

Our dataset can be used to understand the ways in which AI tools can expand the range of creative possibilities in songwriting and music creation. By leveraging this dataset, researchers can analyze how AI models have allowed users to generate innovative methods to address creative challenges, potentially expanding beyond the field of music creation into other creative fields.

One research question that can be explored with this dataset is “How do AI tools, particularly those leveraging big data and machine learning techniques, expand the creative possibilities in songwriting and music creation, and what novel approaches to executing creative problems do they enable?”. Specifically, one can explore the utilization of big data and machine learning techniques to address challenges such as data processing, limited musical ability, and idea generation. For example, AI-powered algorithms can analyze vast amounts of musical data to identify patterns and trends, providing inspiration for melody creation, chord progressions, and rhythmic structures. Additionally, machine learning techniques can assist in data processing tasks focused on mechanisms of creation, enabling creators to focus more on the higher level of creation process in music composition [45].

Extending the scope of research beyond music creation into other creative fields, researchers can use HAISP to examine how AI algorithms are applied to address creative challenges and gain insight into the broader implications of AI for fostering creativity and innovation.

6. COMPARISON WITH OTHER DATASETS

There are extensive datasets of AI-based music tools that focus on the methods of the respective AI systems [7] or reviews of AI-based music tools that focus on the metadata of the publication [1]. Another way to approach the topic of AI-supported creative processes is analyzing interfaces of AI-supported tools for creative endeavors [37]. In the MIR community, datasets are common, especially quantitative datasets and training datasets. Apart from [2], who analyzed the creation process of the first AISC teams, there have been no datasets consisting of qualitative data of the human-AI co-creation process released in MIR venues. The HAISP dataset presented in this paper, is a qualitative dataset of a substantial amount of curated user data, including a subjective description and evaluation of the process, practices, and ethical issues around the creative process with AI. Due to the international character of the AISC – with teams from over 20 countries in the 2023 edition alone – these descriptions come from individuals with diverse cultural backgrounds and musical traditions, which

is shown in their reflections and experiences.

The limited amount of data makes HAISP unsuitable for making general and widely applicable statements about human-AI interaction in songwriting. Rather, we see HAISP as a dataset that can be used to extend existing research in various academic disciplines, as it gives very detailed and rich insights that are well-suited to complement quantitative research insights. Therefore, we made HAISP publicly available and encourage researchers from different fields to work with the data, bringing in their respective perspectives and methods in order to foster an interdisciplinary dialogue on human-AI co-creation.

7. CONCLUSION

In conclusion, the Human-AI Songwriting Processes dataset stands as a potentially significant resource for the exploration of human-AI collaboration and creativity in music composition. Curated from submissions to the AI Song Contest, this dataset offers a view of the dynamics underlying AI-supported songwriting processes. It provides valuable insights into how creators from diverse backgrounds integrate AI tools into their creative workflows, reflecting on the capabilities, limitations, and ethical considerations inherent in human-AI collaboration. Furthermore, the adoption of the HAISP dataset has the potential to advance interdisciplinary inquiry, inspire further research, and contribute to ongoing discourse surrounding human-AI collaboration and creativity. By fostering critical inquiry and facilitating informed discourse, this dataset contributes to our understanding of technology’s role in creativity and innovation in the digital age. Future work on the Human-AI Songwriting Processes dataset will involve expanding the dataset to include information from participants in the AI Song Contest prior to 2023, enriching the dataset with a broader range of submissions and perspectives. Additionally, there are plans to conduct further analysis on the dataset, including analysis to explore the descriptive terminology used for AI tools and systems. In closing, the HAISP dataset holds promise for advancing our understanding of human-AI collaboration in music composition. Through its insights and reflections, it encourages continued exploration of the dynamic relationship between human creativity and machine intelligence.

8. ACKNOWLEDGMENTS

We thank all organizers and former co-organizers of the AI Song Contest, Anna Huang, Rujing Stacey Huang and Vincent Koops for their contribution in organizing this event. We also thank Aarushi Buddhavarapu for their contribution to the coding on this project.

ABSTRACT

Cue points indicate possible temporal boundaries in a transition between two pieces of music in DJ mixing and constitute a crucial element in autonomous DJ systems as well as for live mixing. In this work, we present a novel method for automatic cue point estimation, interpreted as a computer vision object detection task. Our proposed system is based on a pre-trained object detection transformer which we fine-tune on our novel cue point dataset. Our provided dataset contains 21k manually annotated cue points from human experts as well as metronome information for nearly 5k individual tracks, making this dataset 35x larger than the previously available cue point dataset. Unlike previous methods, our approach does not require low-level musical information analysis, while demonstrating increased precision in retrieving cue point positions. Moreover, our proposed method demonstrates high adherence to phrasing, a type of high-level music structure commonly emphasized in electronic dance music. The code, model checkpoints, and dataset are made publicly available.¹

1. INTRODUCTION

The skills required by a “Disc Jockey” (DJ) are diverse. To record and play live DJ mixes, DJs need to prepare and know their tracks well. An integral part of the track preparation phase is the placement of cue points. Coined by scratch DJs who placed stickers on vinyl records to indicate important sections, the functionality of cue points remains unchanged in the digital setting. A cue point may serve as an annotation for musical highlights, suitable mixing boundaries, or the general track structure which consists of musical phrases. Furthermore, digital cue points allow DJs to quickly loop a track segment or skip back and forward during a live performance, altering the track structure on the spot. Unfortunately, placing cue points and track preparation is often a cumbersome and time-consuming process. Similarly to other music information retrieval (MIR) tasks, such as onset detection or beat tracking, cue point placement is not straightforward, despite

¹ <https://github.com/ETH-DISCO/cue-detr>

the prominent structural regularity in electronic dance music (EDM) [1]. For instance, the presence of a prelude shifts the track structure, creating irregularity, and similarly, tracks with arbitrary number of additional bars or tempo variations create a significant challenge which needs to be addressed. We therefore ask the question whether cue point estimation can be automated with a learned approach, imitating human cue point placements by training a model on a manually annotated dataset.

This work addresses the placement of cue points, one of the first tasks during the preparation phase of a DJ mix. With this goal in mind we present CUE-DETR, a fine-tuned DETR image object detection model trained for cue point estimation on EDM tracks. We show CUE-DETR outperforms previous approaches without requiring detailed and meticulously curated rule sets, which leverage underlying low-level audio information.

Our contributions can be summarized as follows:

- We propose CUE-DETR, an object detection model capable of predicting cue points in EDM tracks. Compared to previous methods, our model achieves higher precision and shows significantly closer alignment with manually placed cue points.
- We make our EDM-CUE dataset publicly available, which is 35x larger than the previously available cue point dataset [2]. EDM-CUE contains the metadata for 4,710 EDM tracks, which includes tempo, beat, downbeat, and 21k manually placed cue point annotations provided by human experts.
- To increase evaluation objectivity, we introduce additional phrase aligned points to evaluate prediction accuracy. Moreover, we open-source the code and model checkpoints to further the research of DJ-related MIR tasks.

2. RELATED WORK

Recent years have seen emerging interests in building automated DJ systems where most approaches try to recreate a fully automated DJ pipeline [3–9]. Such systems aim to create seamless transitions between two tracks, each focusing on a different subset of challenges in the DJ’s task pipeline. Cue points are predominantly addressed in the context of finding suitable mix positions in automatic mixing systems [3, 6, 7, 10]. Music structure analysis forms the basis for most cue detection algorithms, as DJ mixes tend to adhere to the underlying high-level track structures [11].

High-novelty regions found through self-similarity [12], for instance, allow the determination of suitable mix sections based on the high-level music structure [6, 13, 14]. Furthering the structural knowledge of a track, crowd-sourced scrubbing data from streaming services uncovers additional structural context, as listeners tend to skip forward to the most prominent section of a track [10]. Applying learning-based concepts for the direct search of musical highlights [7] reveals useful information about the musical structure in a similar manner.

Generally, the accuracy of algorithmically chosen cue points varies depending on the granularity and completeness of the rule set implemented in conjunction with the structural analysis [13]. Adding further rules into the set, for instance, introduces a trade-off between the number of correctly estimated cue point positions and the correctness of each estimated cue point [14]. The main focal point of the open-source DJ system Automix [14] is a rule-based cue point estimation algorithm, including a validation dataset containing 145 tracks [2]. Automix implements four empirically chosen rules describing possible locations of “switch points,” a subset of cue points, on top of structural analysis. Furthermore, the implementation of Automix depends on underlying MIR tasks, such as beat tracking.

DJ mix reverse-engineering [15, 16] is a related task to cue point estimation, as it addresses the lack of available and ready-to-use datasets [17]. Such “unmixing” methods extract latent mixing information from recorded DJ mixes, whose retrieval typically relies on manual annotations, such as mix-in and mix-out points or volume gain curves. The use of pure DJ mix reverse-engineering for cue point estimation is limited as no novel cue points can be retrieved from existing DJ mixes.

In the context of lower-level MIR tasks, convolutional neural networks (CNNs) have been studied, for example, in onset detection [18] or beat tracking [19]. Furthermore, CNNs have proven helpful in musical structural analysis and boundary estimation [20]. Using an attention mechanism in conjunction with a CNN can help alleviating the challenges posed by the sequential nature of music. Nevertheless, adding an attention mechanism does not solve the main concern posed by the large amounts of data required for training. Another possible solution is to instead use a large pre-trained model and to then fine-tune the model on task-specific datasets. The Audio Spectrogram Transformer [21], for instance, demonstrates the possibility to transfer a pre-trained ViT model [22] from the image domain to the audio domain. Transformer architectures are often designed to apply the attention mechanism together with a pre-trained CNN backbone, leveraging the feature space previously learned by the CNN [23, 24].

3. METHODOLOGY

3.1 Dataset

We created EDM-CUE, a dataset containing music meta-data from four private collections of professional DJs.

Figure 1. Top: Distribution of cue point positions in EDM-CUE. Bottom: Distribution of distances between two subsequent cue points in EDM-CUE. The inter-cue distances indicate that 16 bars is the most represented phrasing length in our dataset.

Each of the four DJs uses the library management tool rekordbox² from which we collect the track name, artist name, tempo, beat grid, and cue points for each contained track. Cue points are given by their absolute position in seconds. The beat grid represents a visual metronome, which can be calculated from its stored values: the tempo and grid offset return the beat positions. Applying the time signature in combination with the initial beat number reveals the downbeat. Since we aggregate tracks from four individual collections, all duplicate tracks need to be merged. We summarize the tempo and grid offset to their respective mean values for all duplicate track entries. In order to merge duplicate cue points, we group all cue points based on their distance to neighboring points. Cue points within a distance of a quarter beat of one another form a group. The merged cue point value corresponds to the group center position. All dataset tracks are based on a 4/4 time signature and show constant tempo over time, outlier tracks were excluded during collection. We then pair the information of each track with the track ID found on Deezer³ to provide an additional reference.

Our dataset contains 4,710 EDM tracks consisting of around 380 hours of music. The tempo-range lies between 95 and 190 bpm, and track duration ranges from 1 minute 37 seconds to 10 minutes with an average of 4 minutes and 50 seconds. In total, the dataset contains 21,461 cue point annotations with an average count of 4.6 cue points per track. All tracks used to train the model are compressed to 128 kbps MP3 at 44.1 kHz.

3.2 Phrasing

Although cue points frequently align with high-level structural boundaries and tend to strongly coincide with phrase boundaries [11], the placement of cue points is a subjective task with no clear definition; therefore, annotations collected from DJs may not contain all plausible cue points. We first examine the distribution of our training data for

²<https://rekordbox.com>

³<https://www.deezer.com>

Figure 2. Calculation of phrase boundaries b_i using cue points c_i . Phrase boundaries, highlighted in blue, serve as additional points to evaluate prediction accuracy. Example a) represents a track with regular phrasing whereas b) shows a track with an irregular phrase between cue points c_0 and c_1 . The computed phrase boundaries b_i include the cue points.

cue point positions quantized to bars. Our training cue points exhibit a periodicity with high occurrences of cue points on multiples of 8 and 16 bars, as illustrated in Figure 1. When also taking the inter-cue spacing between neighboring cue points into account, we observe that a majority of our training tracks adhere to phrase lengths of 16 bars, followed by 8 bars. Due to the strong regularity, we will refer to sections with phrase lengths other than 8 or 16 bars as “irregular.” Furthermore, analyzing the cue points in EDM-CUE we find DJs often place cue points at the start of such irregular sections.

Since regular and clearly defined phrasing is common in EDM [1], we generalize our collected ground-truth data by estimating phrase boundaries B . Phrase boundaries serve as an approximation of the track structure which we use to further validate model accuracy. Using track duration t , phrase length l , and an ordered, ground-truth cue point set C , we find B . The non-empty set C must include cue points c_i which mark the start point of irregular phrase boundaries. Traversing the section preceding the first cue point $c_0 = b_0$ in increments of l yields the first entries of B . When the iteration reaches a negative value, the remaining track section from c_0 is traversed in the opposite direction until $b_i \geq t$. A new boundary b_i is added to B if the iteration step did not skip or reach any c_i . Otherwise, the next cue c_i is added to B as b_i . The two simplified examples in Figure 2 show resulting boundaries.

3.3 Model

Our proposed cue estimation system is based on DETR [23], a pre-trained object detection transformer. For each track in the dataset, we generate Mel spectrograms using 128 Mel bands at a sampling rate of 22,050 Hz. Our window length measures 2,048 samples, and the hop length is 512 samples.

The input of the model consists of 128×355 pixel spectrogram segments to fit the expected input image format for DETR while also maximizing the duration of the depicted audio to approximately 11 seconds per image. In the following, we refer to a complete track spectrogram as S . The training spectrogram segments S_T and inference spectrogram segments S_I denote the input images of the model. The model returns positional encodings for the pre-

dicted bounding boxes alongside the accompanying confidence scores and class labels represented by logits. The data pipeline is illustrated in Figure 3.

3.4 Preprocessing

We differentiate between preprocessing for training and inference, as the model is required to process complete spectrograms during inference, whereas for training, the model only requires image segments depicting cue points. A training image segment S_T is cut from S around a cue point p found in S . Using a random integer offset $o \in [0, 355)$, image S_T is defined as the segment with left side $p - o$ and right side $p - o + 355$. If image S_T partly lies outside of spectrogram S , the additional space in S_T is zero-padded. The inclusion of image offset o acts as a simple data augmentation strategy. For the training annotations, each cue point in an image S_T is encapsulated by a bounding box. The aforementioned box occupies the entire height of S_T and is centered around the cue point. In the event that the box extends beyond the image, it is cropped to align with the image borders. Due to this cropping strategy, all training tracks are split into training and validation sets and are indexed by their respective cue annotations.

To make predictions over the span of a full track, during inference, the complete spectrogram needs to be shown to the model. We employ a sliding window cropping strategy on spectrogram S with an overlap of 0.75 in order to generate inference image segments S_I . Similarly to training, the left side of spectrogram S is zero-padded with an arbitrary offset $o \in [89, 266]$ prior to cropping. Applying the zero-padding approaches the uniform distribution of cue point positions seen in the training data, thus increasing the chance to detect cue points at the very start of a spectrogram. As the final step, the resulting image sequence is normalized.

3.5 Postprocessing

We implement additional postprocessing for inference only since additional processing of the basic DETR output is not necessary during training. The model outputs contain the logits and positional encodings mapping to the predicted bounding box coordinates over images S_I . Applying a softmax function to the logits yields the class labels and confidence scores for each prediction, cue points are retrieved from the respective positional encodings. The positional box representation is converted to pixel coordinates in corner format to find the center point on the x -axis. The resulting point is mapped back to the absolute coordinates of track spectrogram S using the left edge of image segment S_I . Once all conversion results for spectrogram S have been accumulated, the confidence scores are sorted by their associated position, resulting in peaks where the confidence is highest. We implement a peak selection strategy using radius r ; final cue point candidates are selected in descending order based on their predicted confidence score. Candidates within radius r of a previously selected candidate are ignored. We use a confidence

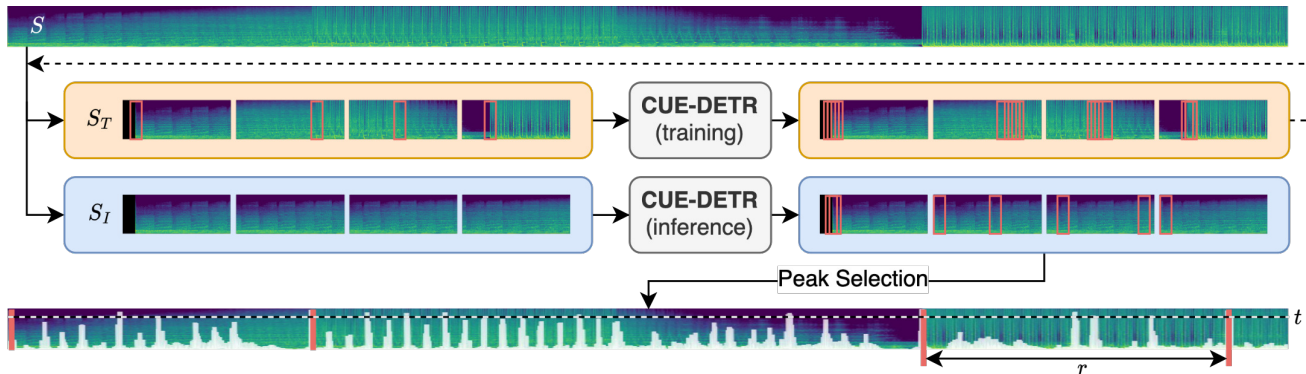

Figure 3. Pipeline of the proposed CUE-DETR architecture. During training, an input Mel spectrogram S is segmented into training images S_T . Each S_T consists of a spectrogram segment containing a cue point which is represented as a bounding box. Inference images S_I move across S using a sliding window. The predicted bounding boxes are converted to their center x -coordinate. The highest scoring positions are selected greedily among all candidates with minimum confidence $t = 0.9$. A selected position excludes all other candidates within a radius r . The bottom spectrogram shows the predicted positions as peaks based on the confidence value.

score threshold of 0.9 as the lower bound for selected candidates. Figure 4 shows three example spectrograms with sorted confidence scores. The highest peaks in the curve representation of confidence scores coincide with ground-truth cue points or phrase boundaries, however with noticeable additional high scoring positions. The additional high peaks are predominantly present at 4 bar intervals. As discussed in Section 3.2, we found ground-truth cue points align best with 16-bar phrases. We found that enforcing a minimum spacing r of 16 or 8 bars between consecutively predicted cue points improves the outcome of the final predictions with respect to precision.

4. EVALUATION

The final evaluation is conducted on 101 tracks which were excluded from the training and validation split. This test set contains 607 ground-truth cue point annotations.

4.1 Experiment Setup

We initialize CUE-DETR with pre-trained weights from DETR.⁴ The backbone is initialized with the ResNet-50 weights, and we set the backbone learning rate to 10^{-6} . For the transformer, we choose a learning rate of 10^{-5} , and set the weight decay to 10^{-4} . The bounding box width w is set to 21 pixels and the postprocessing radius r is fixed at 16 and 8 bars, referenced as r_{16} and r_8 , respectively. We train the model using AdamW [25] and schedule a learning rate reduction by factor 10 when the validation loss does not improve for 10 epochs. The final model is trained for 50 epochs on one NVIDIA TITAN Xp GPU with a batch size of 192.

While we experimented with training CUE-DETR using randomly initialized transformer weights, we found using pre-trained weights provided significantly better results. Even though the pre-trained transformer weights were trained on COCO 2017 [23, 26], a distinctly different

data distribution compared to Mel spectrograms, we corroborate previous findings of visual feature space transfer learning [21, 27].

We compare our model with two other methods, namely “Mixed In Key 10” (MIK), a commercial DJ software,⁵ and Automix [14], an open-source research project. We analyze all tracks directly without manual interference in MIK, as the program simultaneously estimates the beat grid to which it snaps generated cue points. From Automix, we used the cue point generation method directly.

4.2 Evaluation Metrics

We investigate the predicted cue points with respect to the manually annotated cue points and phrase alignment separately. In the following, we address the manually annotated cue point ground-truth set by *cues-only* and use the phrase length, measured in bars, to reference phrase alignment. Similarly to Automix, we assess the predictions using a tolerance window around the ground-truth cue points to estimate the hit rate of the predictions. We evaluate the models on two different tolerance windows T_1 and $T_{1/2}$ which measure one beat and one half-beat, respectively. On average, one half-beat in our test data measures approximately 172 milliseconds, which is comparable to the standard 150 milliseconds tolerance in beat tracking [28]. The values for precision, recall, the F_1 -score and Average Precision (AP) scores are retrieved from the hit rate. Lastly, we measure the cosine similarity between the sets of the predicted and actual cue point positions.

4.3 Ablations

As cue points have no clearly defined object boundaries, we further investigate the influence of the spectrogram context around a cue point included in a bounding box. We report the impact of the bounding box width w for the quality of predictions in Table 1 using AP. We report AP for cues-only as AP_C and report AP for phrase alignment

⁴ <https://huggingface.co/facebook/detr-resnet-50>

⁵ <https://mixedinkey.com>

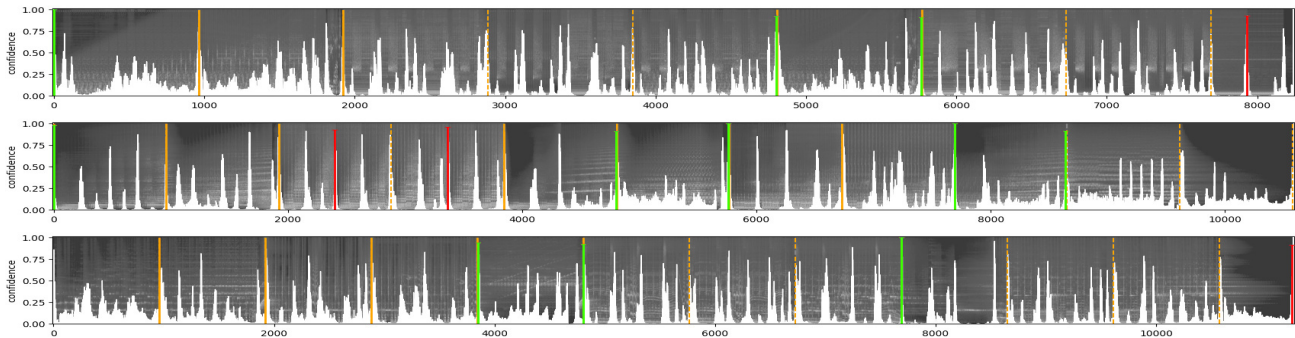

Figure 4. Predicted and ground-truth cue point positions shown over three Mel spectrograms of different random tracks from the evaluation split of EDM-CUE. The confidence score for each position is illustrated as the white curve. Magenta lines indicate correct model predictions, red lines indicate wrong model predictions. For reference, solid orange lines represent ground-truth positions and dashed orange lines illustrate 16-bar phrase boundaries.

Table 1. Ablation of the bounding box width w used during training of CUE-DETR. The Average Precision (AP) scores are reported as AP_C for cues-only ground-truth, AP_{16} and AP_8 indicate phrase alignment. The best results per scenario are bold and larger values are better.

	w	T_1 (one beat)			$T_{1/2}$ (half beat)		
		AP_C	AP_{16}	AP_8	AP_C	AP_{16}	AP_8
r_{16}	7	0.41	0.51	0.52	0.34	0.37	0.37
	15	0.41	0.57	0.60	0.36	0.42	0.42
	21	0.41	0.57	0.60	0.38	0.47	0.48
r_8	7	0.32	0.42	0.45	0.23	0.26	0.27
	15	0.32	0.49	0.53	0.25	0.33	0.34
	21	0.32	0.50	0.54	0.28	0.38	0.41

as AP_{16} and AP_8 . We trained three models with identical initialization parameters except for w which we set to $w_7 = 7$, $w_{15} = 15$, and $w_{21} = 21$ pixels, respectively.

Looking at the results for T_1 , the box width shows no impact on AP_C . The larger peak radius r_{16} increases AP_C for all models. Furthermore, AP increases from AP_C to AP_{16} for all models, most notably by 0.18 from 0.32 to 0.5 for w_{21} with r_8 . From AP_{16} to AP_8 we report an additional increase in AP. Using a larger w improves AP for the phrase alignment cases. The overall best AP score measures 0.6 for w_{15} and w_{21} with radius r_{16} . This radius produces identical results for w_{15} and w_{21} . The results for $T_{1/2}$ exhibit similar patterns, with the exception of w_{21} reporting improved AP over w_{15} on all accounts. Overall, the model with w_7 performs the least favorable, followed by w_{15} , which in turn is outperformed by w_{21} .

4.4 Results

The evaluation of the mean precision, recall, and the F_1 -score is summarized in Table 2. For all methods, the precision increases from the cues-only to the 16-bars and 8-bars ground-truth sets. Our r_{16} -model achieves the highest precision in all cases. The precision increases most notably for tolerance T_1 from the cues-only to phrase alignment

Figure 5. Distribution of ground-truth cue point positions in blue and predicted cue point positions in orange quantized to bars. The cosine similarity between the predicted cue point positions and ground-truth is 0.425 (Automix), 0.371 (MIK), and 0.851 (CUE-DETR).

ground-truth sets. More precisely, our r_8 -model shows an increase in precision by 0.31 from cues-only to 8-bar phrasing. The change from 16 to 8-bars is not as prevalent. Automix shows an improvement in precision from 0.14 to 0.24 and 0.3 over the three ground-truth sets. MIK shows little improvement over the different scenarios and produces more stable precision values. Using the tighter tolerance $T_{1/2}$, all precision values fall in proportion to each other. For recall, the difference of values between the two tolerances is similar to what is observed for precision. With the added phrasing boundaries, all methods show a reduction in recall, opposite to precision. The most significant drop in recall is observed from 16 to 8-bars. Our r_8 -model reports the highest recall on all accounts. The changes in the F_1 -score are less pronounced for all methods as the values remain nearly stable for cues-only and 16-bar phrase alignment. The best reported F_1 -score is associated with our r_8 -model over 16-bar phrasing at 0.46.

For further insight, we look at the distribution of the predicted results in Figure 5. Automix favors cue posi-

Table 2. Comparison of precision, recall, and the F_1 -score of Automix, Mixed In Key (MIK), and our method. Higher values correspond to better results. The upper rows show the evaluation using tolerance T_1 and the lower rows using $T_{1/2}$. From left to right, the results are given for the manually placed cue point only, the computed 16-bar phrasing and the computed 8-bar phrasing. We observe that CUE-DETR outperforms previous methods on precision, recall, and F_1 -score.

		<i>cues-only</i>			<i>16-bars</i>			<i>8-bars</i>		
		Precision	Recall	F_1	Precision	Recall	F_1	Precision	Recall	F_1
T_1	Automix	0.14	0.12	0.13	0.24	0.11	0.15	0.30	0.07	0.11
	MIK 10	0.20	0.25	0.22	0.21	0.13	0.16	0.25	0.08	0.12
	CUE-DETR (r_{16})	0.38	0.35	0.36	0.62	0.27	0.38	0.69	0.16	0.26
	CUE-DETR (r_8)	0.32	0.49	0.39	0.53	0.41	0.46	0.63	0.26	0.36
$T_{1/2}$	Automix	0.11	0.10	0.10	0.20	0.09	0.13	0.24	0.06	0.10
	MIK 10	0.14	0.19	0.16	0.15	0.09	0.12	0.18	0.06	0.09
	CUE-DETR (r_{16})	0.27	0.25	0.26	0.43	0.19	0.27	0.48	0.11	0.18
	CUE-DETR (r_8)	0.22	0.34	0.27	0.37	0.28	0.32	0.43	0.17	0.25

tions around the first three phrases with high alignment to ground-truth. The second cluster is predicted at the start of phrases 6 to 8 with an increased tendency for early predictions. MIK on the other hand exhibits more evenly distributed cue placements over the first 7 phrases. However, an increased number of predictions lie in between phrases where no ground-truth points lie. We observe that both Automix and MIK tend not to predict possible cue points in the second half of tracks. CUE-DETR predicts cue points with the highest adherence to ground-truth. Despite a few additional predictions similar to MIK, positions with the highest accumulation of cue points are covered by our predictions in a similar pattern. The cosine similarity of our quantized predictions reports the highest score of 0.851. In comparison, Automix scores 0.425 whereas MIK reaches 0.371.

4.5 Discussion

CUE-DETR shows strong adherence to ground-truth compared to other methods. Our method suggests good phrase alignment based on the distribution of our predicted cue point positions, as well as the increase in precision from cues-only to 16 bar phrases. A slight increase in precision is expected for all methods, however, a significant increase is only associated with strong phrase alignment due to the decrease in false positive predictions. The higher number of possible ground-truth positions decreases recall in return. If our method successfully detects irregular sections, the phrasing algorithm from Section 3.2 can be applied in postprocessing, which could further increase the precision while keeping the recall score high.

Despite using a metronome-agnostic approach, for which we fixed the distances r to the length of a phrase in terms of the dataset median tempo, the chosen values for r yield results with higher precision compared to the other methods. We assume the relatively homogeneous nature of our dataset minimized the impact of different tempos in the test data. For more diverse styles of music, including the tempo and beat grid information, similar to MIK, might be beneficial. On the other hand, it might be possible to train a model on beat and cue detection simultaneously.

The beat detection could then be used during postprocessing to identify the tempo, making the need for additional ground-truth beat grid or tempo information redundant.

One key limitation remains in the availability of training data, despite building our own dataset. Since we only had access to data with high similarity in style, we would like to investigate the performance of our method over a broader domain of electronic music in the future. Furthermore, our dataset annotations were provided by DJs who specialize in club DJing. Therefore, annotations from other types of DJs, such as scratch DJs or mobile DJs, would likely result in a largely different cue point distribution. We believe one main difference would lie in more cue points distributed around vocals or pickups instead of the first downbeat of phrases.

5. CONCLUSION

In this work we introduced CUE-DETR, an object detection model fine-tuned on Mel spectrograms capable of estimating cue points in EDM tracks. Candidate cue points produced by CUE-DETR demonstrate high adherence to the underlying music structure and exhibit a higher resemblance to manually placed cue points compared to previous approaches. Furthermore, we created EDM-CUE, a dataset containing 21k manually annotated cue points from four professional DJs. EDM-CUE also contains tempo, beat, and downbeat annotations for almost 5k EDM tracks. Our implementation includes a postprocessing step to filter the model predictions for the best positions, including a conversion of the results to timestamps. For the evaluation, we presented a complementary phrasing-based evaluation method, which is useful to assess cue point predictions in a more objective manner.

Furthermore, we demonstrated that CUE-DETR is capable of detecting large structural boundaries in music, despite only seeing small excerpts of the entire track. Our findings further acknowledge the potential of transformer-based architectures for the detection of time-based events in music.

rob@metabrainz.org

ABSTRACT

The ListenBrainz listens dataset is a continually evolving repository of music listening history events submitted by all ListenBrainz users. Currently totalling over 800 million entries, each datum within the dataset encapsulates a timestamp, a pseudonymous user identifier, track metadata, and optionally MusicBrainz identifiers facilitating seamless linkage to external resources and datasets. This paper discusses the process of raw data acquisition, the subsequent steps of data synthesis and cleaning, the comprehensive contents of the refined dataset, and the diverse potential applications of this invaluable resource. Although not the largest dataset in terms of music listening events (yet), its distinctiveness lies in its perpetual evolution, with users contributing data daily. This paper underscores the significance of the ListenBrainz listens dataset as a significant asset for researchers and practitioners alike, offering insights into music consumption patterns, user preferences, and avenues for further exploration in the fields of music information retrieval and recommendation systems.

Keywords: novel datasets, digital archives, metadata, linked data

1. INTRODUCTION

The advent of digital music streaming has led to an explosion of data on user listening habits. As the most prevalent form of music consumption today, with streaming accounting for 84% of total U.S. music revenue in 2023¹, this data holds immense potential for understanding trends, developing recommendation systems, and personalizing the user experience. However, most of this data is locked within commercial platforms and inaccessible to researchers or the public [1]. This lack of transparency hinders open-source development and independent research efforts in the music information retrieval field. AI-driven music recommendation systems, personalized playlists, and even music generation algorithms rely heavily on vast datasets of user

behavior to function effectively [2]. Open access to music consumption habits datasets is crucial in ensuring that these algorithms are developed and trained in a manner that is fair, transparent, unbiased, and representative of diverse musical tastes.

This paper introduces the ListenBrainz listens dataset, explores its contents, and potential applications. We will discuss the unique characteristics that distinguish it from other music datasets and highlight its significance as a valuable resource for researchers, practitioners, and music enthusiasts alike. Our goal is to provide the research community with a valuable resource for analyzing evolving music consumption patterns, exploring user preferences, and advancing open-source music information retrieval systems.

2. RELATED WORK

A few public music listening history datasets exist, most built upon data extracted from the social music platform Last.fm. These include the Last.fm Dataset-360K [5]; the Last.fm Dataset-1K [5], the LFM-1B dataset [6] and the LFM-2B dataset [7]. The LFM-1B dataset² and the LFM-2B dataset³ are not available anymore due to licensing issues.

All of these datasets were superseded by the introduction of the Music Listening History Dataset (MLHD) in 2017. MLHD stands out as one of the largest and most comprehensive publicly available datasets of music listening histories even today. It contains over 27 billion timestamped listening events from 583,000 users, enriched with demographic information and MusicBrainz identifiers for linking with external resources [3]. MLHD has been extensively used in research on music recommendation, user behavior analysis, and temporal trends in music consumption. To our knowledge, no newer datasets of comparable size and scope surpassing MLHD have been released since, highlighting the continued relevance and value of this resource. However, it is no longer possible to update MLHD with new data from Last.fm as the API endpoints originally used to curate the dataset have now been taken down [8].

The Music Streaming Sessions Dataset (MSSD), unveiled by Spotify, takes a unique approach by centering on listening sessions rather than individual track plays. It encompasses 160 million sessions, each providing in-

Feature	MLHD [3]	MSSD [4]	ListenBrainz
Source	Last.fm Scrobbles	Spotify Streaming Logs	ListenBrainz User Submissions
Size	27 Billion Listening Events	160 Million Listening Sessions	800+ Million (and growing) Listening Events
Scope	Individual Track Plays	Listening Sessions (upto 20 tracks)	Individual Track Plays
Content	Timestamp, Basic Track Metadata, Limited MBIDs, User Demographics	Timestamp, User Actions, Track Metadata, Audio Features, Playlist Snapshots	Timestamp, Extended Track Metadata, Comprehensive MBIDs Links
Updates	Static (Last Updated 2017)	Static (Last Updated 2019)	Dynamic (Continuously Updated)
Strengths	Large size, Comprehensive user demographics, MBIDs for linking	Focus on listening sessions, Includes audio features, Counterfactual evaluation subset	Continuously updated, User-controlled data, Diverse data sources (streaming, local files), Extended Metadata Coverage, MBIDs for linking

Table 1: Comparison of the important music listening datasets

sights into user actions within the session, audio features of the tracks, and corresponding track metadata [4]. While MSSD offers valuable data for analyzing the dynamics of listening sessions, its scope is more confined compared to MLHD. MSSD encompasses a smaller user base and covers a shorter time frame. As of today, the MSSD dataset is not available for download publicly ⁴.

A common limitation shared by all the mentioned datasets, including both MLHD and MSSD, is their static nature. They represent snapshots of data frozen at a particular moment in time, lacking updates since their initial release. This inherent static nature raises concerns about their ability to accurately reflect contemporary music consumption patterns and trends. Furthermore, these datasets are missing data on music released after their creation, potentially restricting their usefulness for research inquiries focused on recent musical trends and user preferences. Additionally, the track metadata provided in MLHD and MSSD is limited to basic information such as artist, track, and album names. In contrast, ListenBrainz allows users to submit any additional metadata they deem relevant alongside their listening events, providing a richer and more comprehensive dataset for analysis.

Table 1 offers a concise overview of the key characteristics and differences between the Music Listening History Dataset, the Music Streaming Sessions Dataset, and the ListenBrainz Listens Dataset.

3. BACKGROUND

3.1 Music Listening History

Music listening histories serve as extensive timelines of an individual’s music consumption, offering valuable insights into their preferences, habits, and evolving tastes. Aggregating these histories across different timeframes uncovers

broader patterns and trends in listening behavior [9] [10]. The open availability of such data holds immense potential for advancing music information retrieval research, enhancing recommendation systems, and fostering a deeper understanding of the relationship between individuals and music.

3.2 Data Donation

Data donation is a method of data collection which typically involves users proactively sharing their digital trace data, often by requesting and exporting their data from online platforms, with researchers [11]. Data donations are commonly used in the field of communications, especial social media, research [12]. The usefulness of data donations in music research being increasingly recognized as exemplified by the Fair Muse project [13].

3.3 The ListenBrainz Project

The ListenBrainz listens dataset has been developed as a part of the broader open source project, ListenBrainz ⁵. The project is maintained by the MetaBrainz Foundation, a non-profit organization dedicated to promoting open data initiatives in the music domain. The organization is renowned for its over two-decade-long stewardship of the comprehensive free and open source MusicBrainz database ⁶. All ListenBrainz data is generously licensed under the CC0 license, granting unrestricted use and creating a collaborative environment for research and development.

4. THE LISTENBRAINZ LISTENS DATASET

4.1 Data Collection

The ListenBrainz dataset is entirely crowdsourced, with users actively contributing their listening histories. Lis-

⁴ MSSD Dataset download page <https://www.aicrowd.com/challenges/spotify-sequential-skip-prediction-challenge>

⁵ <https://listenbrainz.org/>

⁶ History and details of the MetaBrainz Foundation Inc. and the MusicBrainz project can be found at <https://metabrainz.org/about>

	Traditional Data Donation	ListenBrainz
Data Acquisition	Users request data from platform and donate to researchers.	Data submitted directly to ListenBrainz (automatically or manually).
Temporality	One-time or infrequent bulk data donations.	Continuous, regular data contribution.
User Effort	Active user involvement required in export and donation	Minimizes user effort after initial setup.
Data Scope	Limited to a single platform or service.	Aggregates data from multiple sources.
User Control	Limited control post data donation.	Offers ongoing user control (editing, deletion, or contribution cessation).
Data Utilization	Often for specific research projects with limited broader application.	Continuously growing, multi-purpose dataset for diverse research and the music community.

Table 2: Data Collection: Traditional Data Donation vs. ListenBrainz Approach

tenBrainz’s data collection approach shares its ethos with traditional data donation approaches. Both involve voluntary participation and aim to provide transparency regarding data usage.

However, the traditional data donation approach has some limitations. The donated data is retrospective and represents a one-time export. Repeated donations require users to navigate potentially complex processes which discourage participation [12]. To overcome these limitations, ListenBrainz provides multiple ways for users to setup automatic submission of listening events from their music streaming platforms and local music players on a continuous basis. Table 2 sums up the differences between the traditional and ListenBrainz approach.

Users can submit their data through various methods.

1. APIs and local media players: ListenBrainz provides a free and open API⁷ allowing manual submission of listening histories and facilitates the development of plugins for music players, automating the process for seamless and reliable data collection⁸. There is a Last.fm compatible API available as well which allows existing Last.fm clients to readily integrate with ListenBrainz⁹.
2. Streaming services integration: ListenBrainz integrates with popular streaming services like Spotify, enabling users to effortlessly link their accounts and contribute their streaming listening history.
3. Mobile applications and browser extensions: Various mobile applications can be used to submit listen events from mobile devices. Browser Extensions like WebScrobber¹⁰ provide convenient tools for submitting listening data from web-based music platforms.
4. Import of streaming services data exports: ListenBrainz supports conventional data donation methods, allowing users to upload data packages from streaming platforms like Spotify’s extended stream-

ing data export.

It is important to note that ListenBrainz empowers users with complete control over their data. They can edit, delete, or export their listening history as desired, ensuring transparency and user agency.

Listing 1: A listen event in the ListenBrainz dataset

4.2 Data Cleaning and Synthesis

ListenBrainz ensures data quality through a robust cleaning and synthesis process. Every listening event requires a UTC epoch timestamp, a user identifier assigned by ListenBrainz, track name, and artist name. The *additional_info* field permits users to submit free-form JSON data. This flexibility empowers users to contribute any relevant information they deem valuable, fostering a richer understanding of music listening behaviors. Commonly used additional metadata fields include release name, MusicBrainz identifiers, track position, duration, and music service or media player used. A MBID is a 36 character

⁷ ListenBrainz API documentation is available at <https://listenbrainz.readthedocs.io/en/latest/users/api-usage.html>

¹⁰ WebScrobber <https://web-scrobber.com/>

Universally Unique Identifier that is permanently assigned to each entity in the MusicBrainz database. The range of MusicBrainz identifiers (MBIDs) supported by the ListenBrainz dataset is broader than MLHD [3] and hence, opens doors to a wealth of additional information. For example, a release MBID allows access to detailed label data and cover art from the MusicBrainz ecosystem. Listing 1 shows an example of a listen history event in the ListenBrainz dataset.

To prevent duplicates, ListenBrainz employs a real-time deduplication system based on the unique combination of user ID, timestamp, and a MessyBrainz identifier (MSID). MSIDs are random UUIDs assigned to the hash of the track, artist, and release names, serving as a robust method for identifying unique listening events.

While submitting MusicBrainz identifiers (MBIDs) alongside listening events greatly enhances the dataset’s connectivity and analytical potential, it’s not always a straightforward task for users. Local music collections often lack MBIDs in their ID3 tags, necessitating additional efforts to improve metadata quality. ListenBrainz encourages users to utilize tools like MusicBrainz Picard¹¹ to tag their collections effectively. Tagging collections becomes impractical when users engage with music through streaming services, where control over metadata submission is limited. To address this challenge, ListenBrainz employs a sophisticated background service known as the MBID mapper. This service automatically searches and associates relevant MBIDs with listening events based on the available metadata, enriching the dataset’s interconnectedness which is very helpful in downstream analysis. The inner workings of the MBID mapper involve complex algorithms and matching techniques beyond the scope of this paper. The MBIDs linked by the mapper are stored separately from user-submitted identifiers, empowering users of the dataset to choose whether or not to incorporate them into their analyses.

4.3 Dataset Format and Updates

The ListenBrainz dataset is available in two formats: ListenBrainz full export Dumps and ListenBrainz Spark Dumps. The ListenBrainz full export dumps contain the entire data submitted to ListenBrainz split in monthly chunks. Monthly data is organized into JSON lines files within yearly directories, providing comprehensive information for each listening event. The ListenBrainz spark dumps consist of chronologically ordered parquet files offering a subset of relevant fields optimized for batch processing and analysis.

The entire dataset is updated every 15 days, while incremental dumps capturing the listening events of the last 24 hours are produced daily. This ensures researchers and developers have access to both the comprehensive historical record and the most recent trends in music consumption.

5. DATASET ANALYSIS

As of today, the ListenBrainz listens dataset boasts a substantial collection of 876 million listening events contributed by approximately 28,000 users. Impressively, 764 million of these entries have been successfully linked with MusicBrainz identifiers, allowing for deeper analysis and connections with external music information resources. The dataset encompasses a diverse musical landscape, representing 900 thousand artists, 2.07 million albums, and a staggering 12.1 million recordings. Table 3 provides a summary of these key figures and a comparison with the corresponding figures of the MLHD dataset.

	MLHD [3]	ListenBrainz
Users	583 K	28,419
Listens (All)	27 B	876 M
Listens (with MBIDs)	-	764 M
Recordings	7 M	12.1 M
Albums	900 K	2.07 M
Artists	555 K	900 K

Table 3: Comparison of the size of the MLHD and ListenBrainz dataset

While the number of users and listening events in ListenBrainz is currently smaller compared to MLHD, it excels in its coverage of musical content, with several times the number of unique recordings, albums, and artists represented. This richness shows the potential of ListenBrainz for exploring a wider range of musical tastes and preferences.

The additional metadata recorded by ListenBrainz introduces several innovative features not present in the MLHD dataset. Specifically, 11% of listening events in ListenBrainz include track number information, while 12% of entries offer track duration data, which facilitates the analysis of listening session lengths and potential skipping behaviors. Additionally, 68% of listening events record the submission client. Although more than half of these clients are from Last.fm imports and Spotify, the remaining entries encompass a diverse array of user setups, including self-hosted music servers such as Navidrome and Funkwhale, as well as popular applications like Plex, PanoScrobbler, and WebScrobbler. This additional metadata enables new research opportunities to explore platform-specific listening behaviors and the influence of various music access modes on consumption patterns.

The temporal span of the ListenBrainz dataset is noteworthy, encompassing listening events dating back to 2005 and extending to the present year, 2024. Figure 2 illustrates the distribution of listening events across different years. Notably, the ability to submit past listening data to ListenBrainz suggests that the representation of earlier years may continue to grow over time. The lower number of events for 2024 is expected, given that only a portion of the year has elapsed.

Figure 1 shows the global coverage of the ListenBrainz

¹¹ MusicBrainz Picard <https://picard.musicbrainz.org/>

Figure 1: Artist Origins: Logarithm of number of listens of artists originating from a country

Figure 2: Temporal distribution of listening events

dataset, the artists in the dataset originate from a wide array of countries and regions. Although there is a noticeable concentration of artists originating from the United States, as evidenced by the darker shading, the dataset encompasses a diverse representation of artists from across the world particularly prominent in Europe, parts of South America, and Australia. This exploration also acts as an example of how MBIDs in the ListenBrainz dataset can be used to obtain useful information from the MusicBrainz database, in this case the country of an artist’s origin.

Figure 3 displays another temporal aspect of the dataset, the distribution of listening events based on the release year of the music. The graph reveals a clear trend towards a preference for newer music, with a significant surge in listening events observed from the 1990s onwards. This pattern aligns with the increasing availability and accessibility of digital music during this period. Nevertheless, the presence of listening events for music spanning several decades, dating back to the 1960s and earlier, emphasizes the assorted range of musical interests within the ListenBrainz community and the enduring appeal of older music.

6. USE CASES

The dataset is actively by the ListenBrainz project itself internally to power collaborative filtering algorithms that generate personalized recommendations, playlists, and engaging user reports. By combining these collaborative filtering techniques with content-based recommendations derived from MusicBrainz’s genre and folksonomy data, ListenBrainz creates a multifaceted and tailored music discovery experience for its users¹². In a further commitment to open-source music recommendation development, the ListenBrainz team has created the Troi recommendation toolkit¹³. This standalone toolkit adopts an API-first philosophy, enabling the construction of diverse and engaging playlists by utilising ListenBrainz data alongside other compatible datasets. Similarly, the Calliope project is an external initiative that leverages the ListenBrainz dataset to curate playlists and aid research and development in the field of open-source music recommendation systems¹⁴.

Beyond its applications in understanding general music preferences and trends, the listens data in ListenBrainz has proven valuable in exploring the impact of music recommendation diversity on listeners’ long-term attitudes and engagement [14]. Researchers have leveraged listens data available in ListenBrainz to develop and evaluate sequential music recommendation systems that utilize the powerful BERT transformer model [15].

Like MLHD, ListenBrainz is built upon a foundation of user-generated listening histories, making it conceptually similar and offering comparable data for analysis. Although the user base and overall size differ, the core data structure allows for the application of similar research methodologies and comparisons between findings. Addi-

Figure 3: Listening events by original release year of albums

tionally, music sessions can be extracted from individual listening events of the ListenBrainz dataset to reproduce and extend studies initially conducted on the session-based MSSD dataset. Consequently, we are certain that this dataset holds immense potential for reproducing and validating previously conducted studies on similar datasets.

ListenBrainz also presents itself as a significant advancement in music consumption research tools. Instead of developing custom data collection and processing tools for data donations, researchers can leverage ListenBrainz. Researchers are relieved from the technical burdens and logistical complexities of data collection, allowing them to dedicate their time and resources to the core aspects of their studies and analytical inquiries. The ListenBrainz platform provides participants with insights into their listening behavior which can potentially increasing study engagement as well. In return, the listening events submitted by the participants enrich the overall listens dataset.

7. LIMITATIONS

The dataset utilizes UTC timestamps which prevents its usage in temporal analyses involving time zones, such as the diurnal music preferences explored by Park et. al [10]. Future iterations of the dataset aim to incorporate timestamps aligned with users' respective time zones, further enhancing its analytical capabilities.

The dataset can only as diverse as the individuals who choose to share their listening histories, potentially creating limitations in representing the full spectrum of music consumption across various cultures, genres, and communities. For instance, Figure 1 reveals a geographic bias in ListenBrainz's user demographics, with a disproportionate number of users located in the Anglosphere. Efforts are underway to integrate demographic data, such as user region and gender, to provide additional context to detect and eliminate such biases.

An inherent challenge within music listening datasets, including ListenBrainz, is the difficulty in discerning

whether a listening event reflects a user's genuine music preference or merely their exposure to a track due to algorithmic recommendations or shuffle mechanisms within music streaming services. This ambiguity makes it difficult to determine if a specific listening event represents an active choice by the user or a passive encounter with a suggested track.

Further, growing concerns surrounding online privacy may lead users to be hesitant in sharing their personal data, including seemingly benign information like music listening habits, impacting the growth of the dataset. Individuals are becoming increasingly aware of data collection practices and harbor reservations about potential privacy risks and the possible misuse of their information [16].

8. CONCLUSION

In conclusion, the ListenBrainz listens dataset provides a rich and dynamic resource for understanding the complexities of music consumption. Its comprehensive collection of user listening histories, accurate to the second, offers valuable insights into individual preferences and general trends. The inclusion of MusicBrainz identifiers further enhances its utility, enabling seamless integration with external music databases and facilitating in-depth analyses.

To reiterate, the ListenBrainz listens dataset addresses a significant gap in the field by providing a continuously updated resource that can represent rapidly changing music preferences. As the ListenBrainz project is run by a non-profit entity devoid of vested corporate interests, we believe that it will emerge as an indispensable resource for future research endeavors. By embracing openness, user agency, and continuous growth, ListenBrainz listens dataset paves the way for a deeper understanding of how we engage with music.

ABSTRACT

Recent advances in generative models that iteratively synthesize audio clips sparked great success in text-to-audio synthesis (TTA), but at the cost of slow synthesis speed and heavy computation. Although there have been attempts to accelerate the iterative procedure, high-quality TTA systems remain inefficient due to the hundreds of iterations required in the inference phase and large amount of model parameters. To address these challenges, we propose SpecMaskGIT, a light-weight, efficient yet effective TTA model based on the masked generative modeling of spectrograms. First, SpecMaskGIT synthesizes a realistic 10s audio clip in less than 16 iterations, an order of magnitude less than previous iterative TTA methods. As a discrete model, SpecMaskGIT outperforms larger VQ-Diffusion and auto-regressive models in a TTA benchmark, while being real-time with only 4 CPU cores or even 30× faster with a GPU. Next, built upon a latent space of Mel-spectrograms, SpecMaskGIT has a wider range of applications (*e.g.*, zero-shot bandwidth extension) than similar methods built on latent wave domains. Moreover, we interpret SpecMaskGIT as a generative extension to previous discriminative audio masked Transformers, and shed light on its audio representation learning potential. We hope that our work will inspire the exploration of masked audio modeling toward further diverse scenarios.

1. INTRODUCTION

Text-to-audio synthesis (TTA) allows users to synthesize realistic audio and sound event signals by natural language prompts. TTA can assist the sound design and editing in the music, movie, and game industries, accelerating creators’ workflow [1]. Therefore, TTA has earned increasing attention in the research community.

Recent advances in deep generative models, especially iterative methods such as diffusion [2–5] and auto-

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

Figure 1. Audio synthesis performance and number of synthesis iterations of different methods. The size of circle represents the model size. SpecMaskGIT achieves good quality with only 16 iterations and a small model size.

Figure 2. Real-time factor of SpecMaskGIT on different Xeon CPU cores with standard Python implementation.

regressive models [6–8], have brought significant success to the sound quality and controllability in TTA tasks, but at the cost of slow synthesis speed. Since the synthesis speed of iterative methods is dominated by the number of iterations required at inference, techniques have been introduced to reduce iterations, *e.g.*, higher compression rate of raw audio signals [6] or more efficient diffusion samplers [4, 9]. Nevertheless, these iterative methods remain slow in synthesis speed and demanding for computing resources, as they typically require hundreds of iterations to synthesize a short audio clip. Moreover, the runtime of a single iteration increases due to the huge model size.

To further improve inference efficiency, Garcia *et al.* introduced the MaskGIT [10] synthesis strategy from computer vision to the audio domain and proposed VampNet [11]. Although VampNet can inpaint a 10-second clip with 24 iterations, 6 seconds are needed on GPU [11], which is still heavy for non-GPU environments. Moreover, VampNet is not compatible with text prompts or TTA tasks. Concurrent to our work, MAGNeT extended VampNet to text-conditional audio synthesis [12]. However, the method is less efficient as it requires 180 iterations, which is heav-

ier than some diffusion models that only require 100 iterations [4, 9, 13, 14]. Since both VampNet and MAGNeT work in a wave-domain latent space, it is difficult to conduct frequency-domain inpainting tasks such as bandwidth extension (BWE) in a zero-shot manner. Besides the aforementioned limitations, the audio representation learning potential of a masked generative Transformer has not been investigated yet.

As a summary, an audio synthesis method that is compatible with text prompts, highly efficient in synthesis speed, and flexible for various downstream tasks is yet to be explored. To this end, we propose SpecMaskGIT, an efficient and flexible TTA model based on the masked generative modeling of audio spectrograms. Our contributions lie in the following aspects:

- **Efficient and effective TTA.** SpecMaskGIT synthesizes a realistic 10-second audio clip in less than 16 iterations, which is one order of magnitude smaller than previous iterative methods (Fig. 1. As a discrete generative model, SpecMaskGIT outperforms larger VQ-Diffusion (Diff-Sound [2]) and auto-regressive (AudioGen-base [6]) models in a TTA benchmark, while being real-time with 4 CPU cores (Fig. 2) or even $30\times$ faster on a GPU.
- **Flexibility in downstream tasks.** SpecMaskGIT is interpreted and implemented as a generative extension to previous discriminative audio masked Transformers [15–18]. The masked spectrogram modeling principle and architecture design similar to Audio Masked Auto-encoder (MAE) [16–18] is believed to have contributed to the representation learning potential of SpecMaskGIT. Unlike prior art about finetuning MAE-like architectures for BWE [18, 19], SpecMaskGIT enables BWE in a zero-shot manner.

We hope this efficient, effective and flexible framework paves the way to the exploration of masked audio modeling toward further diverse scenarios [20].¹

2. RELATED WORKS

Synthesizing audio signals in raw waveform is challenging and computationally demanding [21]. Therefore, the mainstream approach to audio synthesis is to first generate audio in a compressed latent space, and then restore waveforms from latent representations. Auto-regressive models such as Jukebox [22], AudioGen [6] and MusicGen [23] use vector-quantized (VQ) variational auto-encoders (VAE) [24] to tokenize raw waveforms into a discrete latent space. While AudioGen and MusicGen use a higher compression rate than Jukebox, 500 iterations are required to synthesize a 10-second clip, slowing generation down.

Advances in audio representation learning such as Audio MAE ([16–18]) indicate that Mel-spectrogram is an effective compression of raw audio signals, as it emphasizes acoustic features of sound events while maintaining sufficient details to reconstruct raw waveforms. Inspired by the above success of representation learning, several methods used discrete [2] or continuous [3, 4, 9, 13, 14] diffusion

Figure 3. SpecVQGAN encodes/decodes non-overlapping 16-by-16 time-mel patches into/from discrete tokens.

models upon the latent Mel-spectrogram space created by a VAE or SpecVQGAN [25]. These diffusion models require up to 200 iterations for high-fidelity synthesis, which is still challenging for low-resource platforms and interactive use cases. While distilling a diffusion model can effectively reduce the required iterations [26–28], we limit our discussion to non-distilled methods for a fair comparison. For Mel-based synthesis methods, waveforms are reconstructed from Mel-spectrogram with a neural vocoder, such as HiFiGAN [29] or BigVSAN [30].

In pursuit of higher synthesis efficiency, VampNet [11] and the concurrent MAGNeT [12] adopted the parallel iterative synthesis strategy from MaskGIT [10]. Originally proposed for class-conditional image synthesis tasks, MaskGIT uses a Transformer with bi-directional attention - instead of the uni-directional counterpart of auto-regressive methods - to reduce the required number of iterations. Although VampNet and MAGNeT reduced the number of iterations compared to their auto-regressive counterparts, VampNet does not support text prompts, while MAGNeT takes 180 iterations, which is even heavier than some diffusion models that only require 100 iterations [4, 9, 13, 14]. Moreover, it is difficult for methods built upon wave-domain latent spaces to address frequency domain tasks such as BWE, limiting their applications.

3. SPECMASKGIT

The efficiency, effectiveness and flexibility of SpecMaskGIT is due to a combination of efforts, including among other, the high compression rate in the tokenizer, the small model size, and the fast synthesis algorithm.

3.1 Spectrogram Tokenizer and Vocoder

A modified SpecVQGAN [25] is trained to tokenize non-overlapping 16-by-16 time-mel patches into discrete tokens, and recover the tokens back to Mel-spectrogram as in Fig. 3. Reconstructed Mel-spectrograms are then transformed to waveforms by a pre-trained vocoder. On top of the $3.2\times$ compression offered by the wave-to-mel transform in our configuration, SpecVQGAN further offers $256\times$ compression of the spectrogram, resulting in a total of over $800\times$ compression of the raw waveform, effectively reducing the number of tokens to synthesize.

We utilize the standard Mel transform widely used in vocoders [29–32] for optimal Mel computation, as hyperparameters of Mel transform have an impact on tokenizers’ performance [9]. To stabilize the training, we keep the spectrogram normalization in the original SpecVQGAN, which clips Mel bins lower than -80 dB or louder than 20 dB, and then maps the spectrogram into the $[-1.0, 1.0]$ range. Our modified SpecVQGAN is shown competitive in reconstruction quality in Sec. 5.1.

¹ Demo: <https://zzaudio.github.io/SpecMaskGIT>

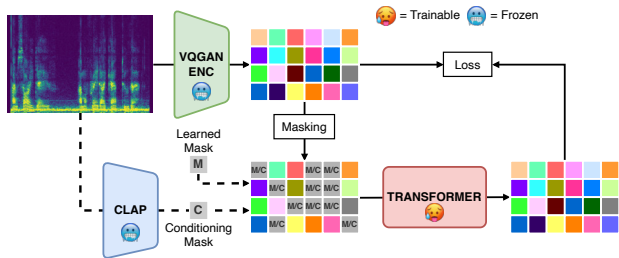

Figure 4. Self-supervised training of SpecMaskGIT. The Transformer is trained to reconstruct SpecVQGAN token sequences - randomly masked with varying ratios - unconditionally via a learned mask token ("M"); or conditioned on a semantic token from the CLAP encoder ("C").

3.2 Masked Generative Modeling of Spectrograms

We train a masked generative Transformer upon the discrete latent space of the pretrained SpecVQGAN as in Fig. 4. First, the pretrained CLAP encoder [33] maps the input audio to a semantic embedding aligned with its corresponding text descriptions. Meanwhile, the input audio is tokenized by SpecVQGAN. Finally, similar to representation learning such as Audio MAE [16–18], a bi-directional Transformer is trained to reconstruct Mel-spectrogram token sequences from a randomly masked input.

There are two major differences from Audio MAE. First, the masking ratio is *not* a fixed value but sampled on-the-fly from a truncated Gaussian distribution that is centered at 55% [34] and ranges from 0% to 100% [10]. As a result, although in each training step SpecMaskGIT behaves similarly to Audio MAE, it learns the training data distribution from various masking ratios, hence gaining the ability to iteratively refine audio tokens by gradually decreasing the masking ratio across multiple iterations, which is explained in Sec. 3.4. Second, while Audio MAE works on raw Mel-spectrogram, optimizing the mask reconstruction by mean square error; SpecMaskGIT works in a discrete latent space, which means the reconstruction of a masked position evolves to retrieval of the correct code from the SpecVQGAN codebook, *i.e.*, a multi-class single-label classification procedure. Therefore, the loss function becomes the cross entropy (CE) loss with label smoothing equal to 0.1. Following Audio MAE, visible positions in the input are not considered in the loss calculation:

$$\text{Loss} = \text{CE}(\text{prediction}[\text{mask}], \text{label}[\text{mask}]). \quad (1)$$

3.3 Text Conditioning via Sequential Modeling

Similarly to [4], we train SpecMaskGIT without audio-text pairs by using a pretrained CLAP model [33], for which audio and text embeddings are aligned in a shared latent space. Leveraging such alignment, after training with the audio branch of CLAP (see Fig. 4), we can directly condition our pretrained model with the text branch as shown in Fig. 5. We use a publicly available CLAP checkpoint ("630k-audioset-best.pt" [33]) for better reproducibility.

Although the above design is inspired by AudioLDM [4], SpecMaskGIT is different in the way CLAP embeddings are injected. Besides the FiLM mechanism ([35]) used in AudioLDM, prior works inject text conditions via

cross-attention [2, 3, 9, 13, 14], even for methods based on sequential modeling such as AudioGen [6] and MAG-NeT [12], which inevitably involves efforts to modify basic DNN modules. We believe that reusing modules, such as the Vision Transformer (ViT) [36], across different tasks is beneficial for efficient development, so we choose to achieve text-conditional audio synthesis by pure sequential modeling, *i.e.*, prepending the CLAP embedding to the input sequence to the Transformer. Note that the CLAP embedding is mapped to the same dimension as the Transformer by a linear layer in advance. As a result, SpecMaskGIT can be implemented with the same ViT used in Audio MAE [16–18], thus we view SpecMaskGIT as a generative extension to previous discriminative masked spectrogram modeling methods. We hypothesize the masked modeling and ViT implementation similar to Audio MAE has contributed to the representation learning potential of SpecMaskGIT, as is shown in Sec. 5.2.

While the common practice in [10, 16–18] is to use a learnable but input-independent token to indicate which parts in the sequence are masked ("M" in Fig. 4), the mask reconstruction task is challenging as the input-independent mask offers no hint for a better reconstruction. To further guide the mask reconstruction procedure, we propose to directly use the input-dependent CLAP embedding as a conditional mask ("C" in Fig. 4), which offers semantic hints like "a dog barking sound" to the model, and is found beneficial to TTA performance in Sec. 5.1.

3.4 Iterative Synthesis with Classifier-free Guidance

We follow the parallel iterative synthesis strategy proposed in MaskGIT [10] in general, but additionally employ classifier-free guidance (CFG) [37] to improve the synthesis quality. This iterative algorithm allows SpecMaskGIT to synthesize multiple high-quality tokens at each iteration, reducing the number of iterations to a value one order of magnitude smaller than previous TTA methods.

To enable CFG, we replace the CLAP embedding with the learned mask token on a random 10% of training steps. At inference phase, both the conditional (ℓ_c) and unconditional (ℓ_u) logits for each masked token are computed. The final logits ℓ_g are made by a linear combination of the two logits based on t , the guidance scale:

$$\ell_g = \ell_u + t(\ell_c - \ell_u). \quad (2)$$

Intuitively, CFG balances between diversity and audio-text alignment. Inspired by [38], we introduce a linear scheduler to the guidance scale t , which linearly increases t from 0.0 to an assigned value through the synthesis iterations. This allows the result of early iterations to be more diverse (unconditional) with low guidance, but increases the influence of the conditioning for late iterations, and is proved beneficial to synthesis quality in Sec. 5.1.

The parallel iterative synthesis of SpecMaskGIT shown in Fig. 5 is explained as follows:

1. Estimating. For each masked position, the Transformer estimates the probability of each code in the SpecVQGAN codebook to be the correct one, *i.e.*, the categorical distribution in the SpecVQGAN latent space.

Figure 5. The iterative text-to-audio synthesis in SpecMaskGIT.

Figure 6. Zero-shot time inpainting and bandwidth extension for general audio data via SpecMaskGIT.

2. Unmasking. Given the categorical distribution over the codebook for each masked position, a code is randomly sampled. This step is different from the deterministic unmasking in Audio MAE.

3. Scheduling. Although SpecMaskGIT can unmask all positions at once, the quality of the synthesized audio is low. To iteratively refine the synthesis, we need to re-mask the result to a masking ratio that is lower than the current iteration. We follow the common practice in [10–12, 34] to use a cosine scheduler to decide the masking ratio at each iteration. The cosine scheduler re-masks a larger portion of the synthesized tokens for early iterations, which is intuitive as the quality in earlier iterations is lower.

4. Top-*k* sampling. Given the masking ratio for the next iteration, we know *k* tokens are going to be re-masked. The log-likelihood of unmasked tokens is used to decide the *k* worst tokens. Since it is observed that a deterministic top-*k* retrieval leads to the synthesis of monotonous images in [39], we follow [11, 34] and add Gumbel noise to the log-likelihood, making the top-*k* sampling stochastic:

$$\text{confidence} = \log(p) + t_{\text{gumbel}} \cdot n_{\text{gumbel}}, \tag{3}$$

where *p* is the probability of each unmasked token calculated from the CFG logits in Eq. 2, *n_{gumbel}* is the Gumbel noise, and *t_{gumbel}* is the noise temperature. Following [34], we linearly anneal *t_{gumbel}* by a coefficient defined as *iter/num_iter*, with “*iter*” index of the current iteration and “*num_iter*” the total number of scheduled iterations.

5. Repeating. Repeat all steps until the cosine scheduler reduces the masking ratio to 0.

For TTA, SpecMaskGIT starts the above iterative procedure from a fully masked sequence as in Fig. 5. Nevertheless, the iterative algorithm is also valid when the masking ratio of an input sequence is lower than 100%, which automatically enables zero-shot inpainting in both time and frequency domain as is shown in Fig. 6. It is worth noticing that since VampNet [11] and MAGNeT [12] employ a wave-domain tokenizer, frequency inpainting or bandwidth extension (BWE) are difficult.

4. EXPERIMENTS

We pretrained the SpecVQGAN [25] and two vocoders (HiFiGAN [29] & BigVSAN [32]) on AudioSet (AS) un-

balanced and balanced subset [40] for 1.5M steps. The AS we collected contains around 1.8 million 10-second audio segments of diverse sound sources and recording environments. AS has been widely used in general audio representation learning [16–18]. We followed the “VGGSound” configuration in the original SpecVQGAN repository [25] without using LPAPS loss as suggested in the repository itself. Our SpecVQGAN has around 75M parameters, and a codebook of 1024 codes, each of which is represented by a 256-dim embedding. As mentioned in Sec. 3.1, the standard Mel-spectrogram transform from vocoders [29, 30] is utilized, which transforms a 10-second audio clip at sampling rate 22.05kHz into 848 frames with 80 Mel bins. The Mel-spectrogram is further tokenized into 265 tokens.

SpecMaskGIT employs the ViT implementation widely used in previous audio masked Transformers [15, 16, 18, 41]. To be consistent with the image MaskGIT [10], 24 Transformer blocks are used, in which the attention dimension is 768 with 8 heads and the feedforward dimension is 3072, resulting in around 170M parameters. We trained SpecMaskGIT on AS for 500k steps with a batch size of 112. When training the model on AudioCaps (AC) [42], we train for 250k steps with a batch size of 48, as AC only contains 50k 10-second audio clips. To stably train SpecMaskGIT, we follow the common practice in [16–18] to employ a linear warmup and then a cosine annealing of the learning rate (LR). We warmup 16k steps for AS and 5k steps for AC. The base LR is set to 1e-3, and the LR equates to the base LR times the batch size divided by 256 [17, 34]. The iterative synthesis algorithm is based on the open-source implementation of [34].

To evaluate the **TTA synthesis** quality of SpecMaskGIT, we benchmark on the AudioCaps (AC) test set with the text prompts released by [4] for fair comparison. To investigate the flexibility of SpecMaskGIT in downstream tasks, we use the checkpoint trained on AS for 500k steps in the following tasks: **Zero-shot time inpainting.** We manually mask out the 25th to 35th Mel-spec frames (around 1.9s) of AC test set, and employ SpecMaskGIT to inpaint the lost regions in a zero-shot manner, *i.e.*, no task-specific finetuning. **Zero-shot audio bandwidth extension.** The top 16 Mel-spec bins (*i.e.*, components beyond 4.3kHz) of AC test set are masked, which creates

a $2.5\times$ BWE task. For all tasks above, we compute the Fréchet Audio Distance (FAD) using [43] since FAD is widely adopted to evaluate TTA [4, 9, 13, 14], time inpainting [4] and BWE [44] tasks. To investigate the representation learning potential of SpecMaskGIT, we further linear probe the model for the multi-label (genre, instrument and mood) **music tagging** task in MagnaTagATune (MTAT) [45] - a dataset widely used to evaluate music tagging models [46–49] - with ROC-AUC and mAP as metrics [46]. We use a single linear layer with batch normalization and 0.1 dropout as the probe.

5. RESULTS

5.1 Text-to-audio Synthesis

We report FAD scores of SpecMaskGIT in Tab. 1 together with other discrete models. Our model is first trained on AS for 500k steps and then finetuned on AC train set for 250k steps. The CFG scale is set to 3.0 empirically. SpecMaskGIT outperforms DiffSound (VQ-Diffusion), MAGNeT-small (similar to SpecMaskGIT but in latent wave domain), as well as AudioGen-base (auto-regressive) in terms of FAD with one order of magnitude fewer iterations. The FAD score is achieved training without any audio-text pairs, which proves the effectiveness of such self-supervised approach for discrete models. We also find the proposed conditional mask described in Sec. 3.3 to improve FAD score without additional parameters or computations. Both CFG and its linear scheduler contribute to improve the FAD.

Given the small number of iterations and model size, SpecMaskGIT can synthesize realistic 10-second audio clips in real-time with only 4 cores of a Xeon CPU (Fig. 2), or $30\times$ faster than real-time on an RTX-A6000 GPU, making it attractive for interactive applications and low-resource environments.

When compared to state-of-the-art (SOTA) continuous diffusion models in Tab. 2, SpecMaskGIT could not achieve a comparable FAD score, but we emphasize that the proposed method offers good performance with high efficiency, *i.e.*, smaller model size and fewer iterations, which can be clearly seen in Fig. 1. Overall, continuous methods are advantageous in terms of FAD with respect to discrete methods. We leave the further improvement of our discrete generative model as future work.

Ablation study: Gumbel noise and iterations number. We use HiFiGAN in all ablation studies. As mentioned in Sec. 3.4, Gumbel noise is essential to the top- k sam-

Table 2. Benchmarking on AudioCaps test set. Dis.: discrete methods. Con.: continuous methods.

pling during iterative synthesis. Fig. 7 shows that a temperature of 1.5 is optimal. SpecMaskGIT achieves good quality (FAD = 3.4) with only 8 iterations, and reaches its best (FAD = 2.8) with 16. More iterations do not improve performance, which is consistent with MaskGIT [10].

Figure 7. Left: FAD vs. Gumbel temperature. Right: FAD vs. Number of iterations.

Ablation study: Audio reconstruction quality. We evaluate the reconstruction FAD (rFAD) scores of two vocoders and SpecVQGAN in Tab. 3 with previous methods reported in [9]. Even with a similar architecture, rFAD of DiffSound and SpecMaskGIT can vary a lot due to different Mel computation and vocoder. Our pipeline achieves SOTA level rFAD scores for Mel-spectrogram methods while maintaining the highest compression rate (*i.e.*, the lowest latent rate) which helped SpecMaskGIT to outperform methods such as DiffSound and Make-an-audio by a large margin, yet with higher efficiency. We further analyze the rFAD of vocoders using ground truth input Mel-spectrograms, and find a significant performance gap between HiFiGAN and BigVSAN, which is not observed when vocoders are combined with SpecVQGAN. This indicates that SpecVQGAN is the bottleneck for reconstruction quality and asks for future improvements.

Ablation study: Bias in AudioCaps benchmark. The dataset gap between AC and other larger, more diverse datasets is investigated. It is observed in [4] that finetuning (FT) a TTA model on AC improves the TTA perfor-

mance in terms of FAD, though the model is pretrained on a larger dataset. We reproduced this phenomenon with SpecMaskGIT as shown in Tab. 5. We also observed that training on the small-scale AC alone brought better FAD score than the model trained with larger datasets in Tab. 6, which is consistent with [13, 14].

We hypothesize that there is a data distribution gap between AC and other datasets, such that when a model fully fits other datasets, the distribution of its synthesis deviates from AC, resulting in worse FAD. Therefore, we continued to train SpecMaskGIT on AS until 800k steps, and depict the “FAD vs. training step” curves on both the valid and test set of AC to verify our hypothesis. It is clear in Fig. 8 that SpecMaskGIT learns to synthesize audio in the early stage and keeps improving the FAD on AC. As the training goes on, SpecMaskGIT just fits toward AS, which worsens the FAD on AC.

Figure 8. FAD vs. AudioSet training steps.

Inspired by audio classification tasks in which early stop is applied to prevent the model from overfitting to the train set, we propose to apply early stop to the SpecMaskGIT model trained solely on AS, and report the competitive FAD score with other methods that are without AC finetuning or AC-alone training in Tab. 7. We believe that a more comprehensive and less biased benchmark would contribute to future advances in TTA research.

5.2 Downstream Inpainting, BWE and Tagging Tasks

Results of the time inpainting and audio BWE tasks are shown in Tab. 8. We utilize the pipeline in Fig. 6 unconditionally, with Gumbel temperature 1.5 and 16 iterations. SpecMaskGIT significantly improves the input signals in terms of FAD, validating its zero-shot ability in

Table 7. Benchmarking on AudioCaps test set without AC finetuning or AC-alone training.

Ground truth	0.0	0.0

such tasks. BWE performance can be further improved by applying low-frequency replacement (LFR) [51, 52]. Unlike prior arts that finetune MAE-like architectures for BWE [18, 19], SpecMaskGIT achieves it zero-shot. In Tab. 4, the potential of SpecMaskGIT in representation learning is confirmed by the music tagging performance on the MTAT dataset. As a TTA model, SpecMaskGIT outperforms classification-specialized models such as CLMR, MusiCNN, MULE, and MERT (the MAE-like model in wave domain). SpecMaskGIT achieves an ROC-AUC comparable to Jukebox, which contains 5B parameters. We hypothesize the tagging capability comes from the masked spectrogram modeling and ViT implementation similar to Audio MAE, as explained in Sec. 3. We leave the in-depth investigation of SpecMaskGIT in downstream tasks as future work.

6. CONCLUSION

Generative models that iteratively synthesize audio clips sparked great success to text-to-audio synthesis (TTA). However, due to the hundreds of iterations required for inference and the large amount of model parameters, high-quality TTA systems remain inefficient. To address the challenges, we propose SpecMaskGIT, a light-weight, efficient yet effective TTA model based on masked generative modeling of spectrograms. SpecMaskGIT synthesizes realistic audio clips in less than 16 iterations, an order of magnitude less than previous iterative TTA methods. It also outperforms larger discrete models in a TTA benchmark, while being real-time with 4 CPU cores and 30× faster with a GPU. Compared to similar methods, SpecMaskGIT is more flexible for downstream tasks such as zero-shot bandwidth extension. Moreover, we interpret SpecMaskGIT as a generative extension to Audio MAE and shed light on its audio representation learning potential. We hope our work inspires the exploration of masked audio modeling toward further diverse scenarios.

7. ETHICAL STATEMENT

SpecMaskGIT is supposed to assist creators in the sound design and editing workflow. Our method presents a huge advancement in the efficiency of TTA technology, which makes TTA accessible to a broader range of users, including creators who do not have GPUs. Despite of the technical advances, there is concern for the potential reflection of training data biases. The model may not be able to maintain a consistent sound quality or audio-text alignment when prompted by text descriptions or audio clips that are rarely presented in the training data. We also pointed out that the benchmark widely used to evaluate TTA models in the research community is biased, and hope our findings here can contribute to a less biased benchmark in the future. The challenge in dataset bias emphasizes the importance for in-depth consideration and collaboration with stakeholders across various communities.

ABSTRACT

Audio-based generative models for music have seen great strides recently, but so far have not managed to produce full-length music tracks with coherent musical structure from text prompts. We show that by training a generative model on long temporal contexts it is possible to produce long-form music of up to 4m 45s. Our model consists of a diffusion-transformer operating on a highly downsampled continuous latent representation (latent rate of 21.5 Hz). It obtains state-of-the-art generations according to metrics on audio quality and prompt alignment, and subjective tests reveal that it produces full-length music with coherent structure.

1. INTRODUCTION

Generation of musical audio using deep learning has been a very active area of research in the last decade. Initially, efforts were primarily directed towards the unconditional generation of musical audio [1, 2]. Subsequently, attention shifted towards conditioning models directly on musical metadata [3]. Recent work has focused on adding natural language control via text conditioning [4–7], and then improving these architectures in terms of computational complexity [8–11], quality [12–15] or controlability [16–19].

Existing text-conditioned models have generally been trained on relatively short segments of music, commonly of 10–30s in length [4–7] but in some cases up to 90s [14]. These segments are usually cropped from longer compositions. Although it is possible to generate longer pieces using (e.g., autoregressive [8]) models trained from short segments of music, the resulting music shows only local coherence and does not address long-term musical structure (see Table 4, MusicGen-large-stereo results). Furthermore, the analysis of a dataset of metadata from 600k popular music tracks¹ (Figure 1) confirms that the majority of songs are much longer than the lengths addressed by previous works. Therefore, if we want to produce a model

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

Figure 1: Cumulative histogram showing the proportion of music that is less than a particular length, for a representative sample of popular music¹. Dotted lines: proportion associated with the max generation length of our model (285s) and of previous models (90s). The vertical axis is warped with a power law for greater readability.

that can understand and produce natural musical structure, it is likely necessary to train and generate on a longer time window. We identify 285s (4m 45s) as a target length, as it is short enough to be within reach of current deep learning architectures, can fit into the VRAM of modern GPUs, and covers a high percentage of popular music.

In previous works [4, 20] it has been hypothesized that “semantic tokens enable long-term structural coherence, while modeling the acoustic tokens conditioned on the semantic tokens enables high-quality audio synthesis” [20]. Semantic tokens are time-varying embeddings derived from text embeddings, aiming to capture the overall characteristics and evolution of music at a high level. This intermediate representation is practical because it operates at low temporal resolution. Semantic tokens are then employed to predict acoustic embeddings, which are later utilized for waveform reconstruction.² Semantic tokens are commonly used in autoregressive modeling to provide guidance on what and when to stop generating [4, 20].

Another line of work [14] implicitly assumes that conditioning on semantic tokens is unnecessary for long-form music structure to emerge. Instead, it assumes that structure can emerge by training end-to-end without semantic tokens. This involves generating the entire music piece at once (full-context generation), rather than generating audio autoregressively guided by semantic tokens [4, 20]. This approach has the potential to simplify the pipeline from four stages² to three (text→text-embedding→acoustic-token→waveform) or even one (text→waveform). While the single-stage approach represents the closest approxi-

² [4, 20] are typically conformed by four stages (denoted here as →): text→text-embedding→semantic-token→acoustic-token→waveform.

Figure 3: Architecture of the autoencoder.

mation to end-to-end learning, its may be challenging to implement due to the VRAM limitations of current GPUs. Our model consists of three stages able to generate an entire music piece of 4m 45s at once without semantic tokens.

Most music generation works rely on autoencoders to condense the long waveforms into compact latent representations (acoustic tokens or embeddings). Prominent examples utilize residual-vector-quantizers to provide discrete acoustic tokens [21–23] for autoregressive or masked token modeling [8–10, 16]. Another prominent line of work focuses on variational autoencoders to provide a continuous and normalized acoustic embedding [5, 7, 12, 14] for latent diffusion modelling. Our work relies on latent diffusion modeling to generate music from text prompts. Yet, and differently from prior works operating with latent rates of 40Hz to 150Hz [14, 23, 24], our autoencoder relies on a highly downsampled latent operating at 21.5Hz (Table 5). We argue that maintaining perceptual quality at low latent rates can be essential for training generative models on long temporal contexts, enabling the creation of long-form music without the need to rely on semantic tokens.

In our work we scale a generative model to operate over the 285s (4m 45s) time interval. This is achieved by using a highly compressed continuous latent, and a generative model relying on latent diffusion (Sections 2 and 3). The resulting model obtains state-of-the-art results in terms of audio quality and text-prompt coherence (Section 4.1), and is also capable of generating long-form music with coherent structure (Sections 4.2 and 4.4) in 13s on a GPU.

Code to reproduce our model ³ and demos ⁴ are online.

2. LATENT DIFFUSION ARCHITECTURE

Our model generates variable-length (up to 4m 45s) stereo music at 44.1kHz from text prompts. It comprises three main components: an autoencoder that compresses waveforms into a manageable sequence length, a contrastive text-audio embedding model based on CLAP [25, 26] for text conditioning, and a transformer-based diffusion model that operates in the latent space of the autoencoder. Check their exact parametrizations online in our code repository.³

2.1 Autoencoder

We employ an autoencoder structure that operates on raw waveforms (Figure 3). The encoder section processes these waveforms by a series of convolutional blocks, each of which performs downsampling and channel expansion via strided convolutions. Before each downsampling block, we employ a series of ResNet-like layers using dilated convolutions and Snake [27] activation functions for further processing. All convolutions are parameterized in a weight-normalised form. The decoder is almost identical to the encoder structure, but employs transposed strided convolutions for upsampling and channel contraction at the start of each upsampling block. The encoder and decoder structures are similar to that of DAC [23], but with the addition of a trainable β parameter in the Snake activation, which controls the magnitude of the periodicity in the activation. We also remove the $\tanh()$ activation used in DAC at the output of the decoder, as we found it introduced harmonic distortion into the signal. The bottleneck of the autoencoder is parameterized as a variational autoencoder.

We train it using a variety of objectives. First, the reconstruction loss, consisting of a perceptually weighted multi-resolution STFT [28] that deals with stereo audio as follows: the STFT loss is applied to the mid-side (M/S) representation of the stereo audio, as well as the left and right (L/R) channels separately. The L/R component is weighted by 0.5 compared to the M/S one, and exists to mitigate potential ambiguity around L/R placement. Second, an adversarial loss term with feature matching, utilizing 5 con-

volitional discriminators [22] with hyperparameters consistent with previous work [14], but with channel count scaled to give ≈ 4 times the parameter count. And third, the KL divergence loss term that is weighted by $\times 10^{-4}$.

2.2 Diffusion-transformer (DiT)

Instead of the widely used convolutional U-Net structure [5–7, 12], we employ a diffusion-transformer (DiT). This approach has seen notable success in other modalities [29], and has recently been applied to musical audio [30]. The used transformer (Figure 2) follows a standard structure with stacked blocks consisting of serially connected attention layers and gated multi-layer perceptrons (MLPs), with skip connections around each. We employ layer normalization at the input to both the attention layer and the MLP. The key and query inputs to the attention layer have rotary positional embedding [31] applied to the lower half of the embedding. Each transformer block also contains a cross-attention layer to incorporate conditioning. Linear mappings are used at the input and output of the transformer to translate from the autoencoder latent dimension to the embedding dimension of the transformer. We utilize efficient block-wise attention [32] and gradient checkpointing [33] to reduce the computational and memory impact of applying a transformer architecture over longer sequences. These techniques are crucial to viable training of model with this context length.

The DiT is conditioned by 3 signals: *text* enabling natural language control, *timing* enabling variable-length generation, and *timestep* signaling the current timestep of the diffusion process. Text CLAP embeddings are included via cross-attention. Timing conditioning [3, 14] is calculated using sinusoidal embeddings [34] and also included via cross-attention. Timing conditioning is also prepended before the transformer, along with a sinusoidal embedding describing the current timestep of the diffusion process.

2.3 Variable-length music generation

Given that the nature of long-form music entails varying lengths, our model also allows for variable-length music generation. We achieve this by generating content within a specified window length (e.g., 3m 10s or 4m 45s) and relying on the timing condition to fill the signal up to the length specified by the user. The model is trained to fill the rest of the signal with silence. To present variable-length audio outputs shorter than the window length to end-users, one can easily trim the appended silence. We adopt this strategy, as it has shown its effectiveness in previous work [14].

2.4 CLAP text encoder

We rely on a contrastive model trained from text-audio pairs, following the structure of CLAP [26]. It consists

of a HTSAT-based [35] audio encoder with fusion and a RoBERTa-based [36] text encoder, both trained from scratch on our dataset with a language-audio contrastive loss. Following previous work [14], we use as text features the next-to-last hidden layer of the CLAP text encoder.

3. TRAINING SETUP

Training the model is a multi-stage process and was conducted on a cluster of NVIDIA A100 GPUs. Firstly, the autoencoder and CLAP model are trained. The CLAP model required approximately 3k GPU hours⁵ and the autoencoder 16k GPU hours⁴. Secondly, the diffusion model is trained. To reach our target length of 4m 45s, we first pre-train the model for 70k GPU hours⁴ on sequences corresponding to a maximum of 3m 10s of music. We then take the resulting model and fine-tune it on sequences of up to 4m 45s for a further 15k GPU hours⁴. Hence, the diffusion model is first pre-trained to generate 3m 10s music (referred to as the *pre-trained* model), and then fine-tuned to generate 4m 45s music (the *fully-trained* model).

All models are trained with the AdamW optimiser, with a base learning rate of $1e - 5$ and a scheduler including exponential ramp-up and decay. We maintain an exponential moving average of the weights for improved inference. Weight decay, with a coefficient of 0.001, is also used. Parameter counts for the networks are given in Table 1, and the exact hyperparameters we used are detailed online³.

The DiT is trained to predict a noise increment from noised ground-truth latents, following the v-objective [37]. We sample from our model using DPM-Solver++ [38] (100 steps), with classifier-free guidance [39] (scale of 7.0).

3.1 Training data and prompt preparation

Our dataset consists of 806,284 files (19,500h) containing music (66% or 94%)⁶, sound effects (25% or 5%)⁵, and instrument stems (9% or 1%)⁵. This audio is paired with text metadata that includes natural-language descriptions of the audio file’s contents, as well as metadata such as BPM, genre, moods, and instruments for music tracks. All of our dataset (audio and metadata) is available online⁷ for consultation. This data is used to train all three components of the system from scratch: the CLAP text encoder, the autoencoder and the DiT. The 285s (4m 45s) target temporal context encompasses over 90% of the dataset.

During the training of the CLAP text encoder and the DiT, we generate text prompts from the metadata by concatenating a random subset of the metadata as a string. This allows for specific properties to be specified during inference, while not requiring these properties to be present at all times. For half of the samples, we include the metadata-type (e.g., Instruments or Moods) and join them with a delimiting character (e.g., Instruments: Guitar, Drums, Bass Guitar|Moods: Uplifting, Energetic). For the other half, we do not include the metadata-type and join the

⁵ GPU hours represent one hour of computation on a single GPU. The training process was distributed across multiple GPUs for efficiency.

⁶ Percentages: number of files or GBs of content, respectively.

⁷ <https://www.audiosparx.com/>

properties with a comma (e.g., Guitar, Drums, Bass Guitar, Uplifting, Energetic). For metadata-types with a list of values, we shuffle the list. Hence, we perform a variety of random transformations of the resulting string, including two variants of delimiting character (“;” and “|”), shuffling orders and transforming between upper and lower case.

4. EXPERIMENTS

4.1 Quantitative evaluation

We evaluate a corpus of generated music using previously established metrics [14], as implemented in *stable-audio-metrics*.⁸ Those include the Fréchet distance on OpenL3 embeddings [40], KL-divergence on PaSST tags [41], and distance in LAION-CLAP space [26, 42]⁹.

We set MusicGen-large-stereo (MusicGen) [8] as baseline, since it is the only publicly available model able to generate music at this length in stereo. This autoregressive model can generate long-form music of variable length due to its sequential (one-sample-at-a-time generation) sampling. However, note that MusicGen is not conditioned on semantic tokens that ensure long-term structural coherence, and it was not trained to generate such long contexts.

The prompts and ground-truth audio used for the quantitative study are from the Song Descriptor Dataset [43]. We select this benchmark, with 2m long music, because other benchmarks contain shorter music segments [4] and are inappropriate for long-form music evaluation. As vocal generation is not our focus and MusicGen is not trained for this task either, we opted to ensure a fair evaluation against MusicGen by curating a subset of 586 prompts that exclude vocals.¹⁰ This subset, referred to as the Song Descriptor Dataset (no-singing), serves as our benchmark for comparison. We assess 2m generations to remain consistent with the ground-truth and also evaluate our models at their maximum generation length—which is 3m 10s for the pre-trained model or 4m 45s for the fully-trained one (Tables 2 and 3, respectively). For each model and length we study, we generate one render per prompt in our benchmark. This results in 586 generations per experiment.

Our model is first pre-trained to generate 3m 10s music (pre-trained model) and then fine-tuned to generate 4m 45s music (fully-trained model). Tables 2 and 3 show the quantitative results for both models and inference times. Comparing metrics between the pre-trained model and the fully-trained one shows no degradation, confirming the viability of extending context length via this mechanism. The proposed model scores better than MusicGen at all lengths while being significantly faster.

4.2 Qualitative evaluation

We evaluate the corpus of generated music qualitatively, with a listening test developed with webMUSHRA [44].

Mixed in with our generated music are generations from MusicGen and also ground-truth samples from the Song Descriptor Dataset (no-singing). Generations of our fully-trained model are included at both 4m 45s and 2m long, whilst ground-truth is only available at 2m. We selected two samples from each use case that were competitive for both models. For MusicGen it was difficult to find coherently structured music, possibly because it is not trained for long-form music generation. For our model, we found some outstanding generations that we selected for the test. Test material is available on our demo page.

Test subjects were asked to rate examples on a number of qualities including audio quality, text alignment, musical structure, musicality, and stereo correctness. We report mean opinion scores (MOS) in the following scale: *bad* (1), *poor* (2), *fair* (3), *good* (4), *excellent* (5). We observed that assessing stereo correctness posed a significant challenge for many users. To address this, we streamlined the evaluation by seeking for a binary response, correct or not, and report percentages of stereo correctness. All 26 test subjects used studio monitors or headphones, and self-identified as music producers or music researchers. In order to reduce test time and maximise subject engagement, we split the test into two parts. Each participant can choose one of the parts, or both, depending on their available time.

Results in Table 4 indicate that the generations from our system are comparable to the ground-truth in most aspects, and superior to the existing baseline. Our model obtains *good* (4) MOS scores across the board and stereo correctness scores higher than 95%, except for 2m long generations where its musical structure is *fair* (3). Differently from our quantitative results in Table 3, qualitative metrics show that 2m long generations are slightly worse than the 4m 45s generations (specially musical structure). We hypothesize that this could be due to the relative scarcity of full-structured music at this length in our dataset, since most music at this length might be repetitive loops. These results confirm that semantic tokens are not strictly essential for generating music with structure, as it can emerge through training with long contexts. Note, however, that the temporal context must be sufficiently long to obtain structured music generation. It was not until we scaled to longer temporal contexts (4m 45s), that we observed music with *good* structure, reflecting the inherent nature of the data. It is also noteworthy that the perceptual evaluation of structure yields to a wide diversity of responses, as indicated by the high standard deviations in Table 4. This highlights the challenge of evaluating subjective musical aspects. Finally, MusicGen achieves a stereo correctness rate of approximately 60%. This may be attributed to its tendency to generate mixes where instruments typically panned in the center (such as bass or kick) are instead panned to one side, creating an unnaturally wide mix that was identified as incorrect by the music producers and researchers participating in our test.

4.3 Autoencoder evaluation

We evaluate the audio reconstruction quality of our autoencoder in isolation, as it provides a quality ceiling for our system. We achieve this by comparing ground-truth and reconstructed audio via a number of established audio quality metrics [22, 23]: STFT distance, MEL distance and SI-SDR (as in AuraLoss library [28], with its default parameters). The reconstructed audio is obtained by encoding-decoding the ground-truth audio from the Song Describer Dataset (all the dataset, 706 tracks) through the autoencoder. As a comparison, we calculate the same metrics on a number of publicly available neural audio codecs in-

cluding Encodec [22], DAC [23] and AudioGen [24]. Encodec and DAC are selected because are widely used for generative music modeling [4, 8, 10]. We select the Encodec 32kHz variant because our MusicGen baseline relies on it, and DAC 44.1kHz because its alternatives operate at 24kHz and 16kHz. Further, since our autoencoder relies on a continuous latent, we also compare against AudioGen, a state-of-the-art autoencoder with a continuous latent. Notably, AudioGen presents both continuous and discrete options, and we report both for completeness. All neural audio codecs are stereo, except DAC 44.1kHz and Encodec 32 kHz. In those cases, we independently project left and right channels and reconstruct from those.

The results in Table 5 show that the proposed autoencoder is comparable or marginally worse in raw reconstruction quality with respect to the other available baselines, whilst targeting a significantly larger amount (2x-5x) of temporal downsampling, and hence a lower latent rate. Our results are not strictly comparable against discrete neural audio codecs, but are included as a reference. For a qualitative assessment of our autoencoder’s reconstruction quality, listen to some examples on our demo site.

4.4 Musical structure analysis

We explore the plausibility of the generated structures by visualizing the binary self-similarity matrices (SSMs) [45] of randomly chosen generated music against real music of the same genre. Real music is from the Free Music Archive (FMA) [46]. Similarly to real music, our model’s generations can build structure with intricate shifts, including repetition of motives that were introduced at the first section. Red marks in Figure 4 show late sections that are similar to early sections. In MusicGen examples, early sections rarely repeat (e.g., see diagonal lines in Figure 4c) or music gets stuck in a middle/ending section loop (repetitive/loop sections are marked in blue in Figure 4). Note that our model’s middle sections can also be repetitive, while still maintaining an intro/outro. We omit MusicGen’s second row because most of its SSMs exhibit a similar behaviour.

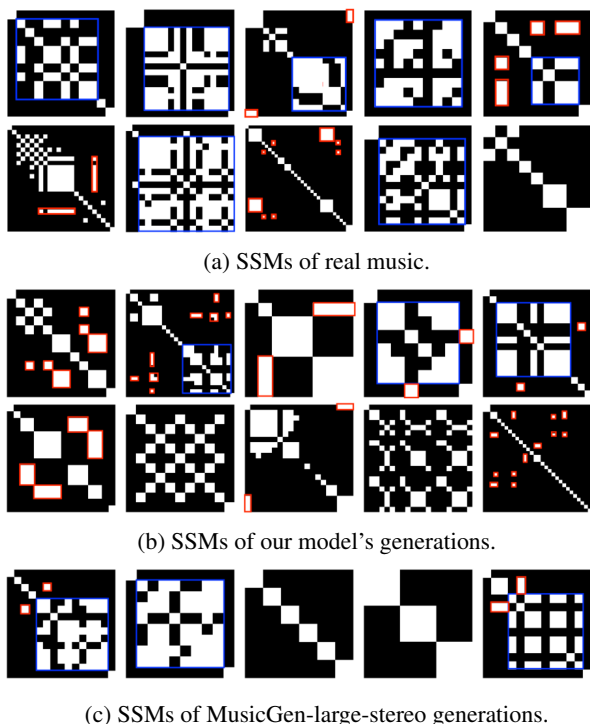

Figure 4: Each column shows the SSMs of different genres (left to right): rock, pop, jazz, hip-hop, and classical.

4.5 Memorization analysis

Recent works [47, 48] examined the potential of generative models to memorize training data, especially for repeated elements in the training set. Further, musicLM [4] conducted a memorization analysis to address concerns on the

potential misappropriation of creative content. Adhering to principles of responsible model development, we also run a comprehensive study on memorization [4, 47, 48].

Considering the increased probability of memorizing repeated music within the dataset, we start by studying if our training set contains repeated data. We embed all our training data using the LAION-CLAP⁸ audio encoder to select audios that are close in this space based on a manually set threshold. The threshold is set such that the selected audios correspond to exact replicas. With this process, we identify 5566 repeated audios in our training set.

We compare our model’s generations against the training set in LAION-CLAP⁸ space. Generations are from 5566 prompts within the repeated training data (in-distribution), and 586 prompts from the Song Descriptor Dataset (no-singing, out-of-distribution). We then identify the top-50 generated music that is closest to the training data and listen. We extensively listened to potential memorization candidates, and could not find memorization. We even selected additional outstanding generations, and could not find memorization. The most interesting memorization candidates, together with their closest training data, are online for listening on our demo page.

4.6 Additional creative capabilities

Besides text-conditioned long-form music generation, our model exhibits capabilities in other applications. While we do not conduct a thorough evaluation of these, we briefly describe those and showcase examples on our demo page.

Audio-to-audio — With diffusion models is possible to perform some degree of style-transfer by initializing the noise with audio during sampling [15, 49]. This capability can be used to modify the aesthetics of an existing recording based on a given text prompt, whilst maintaining the reference audio’s structure (e.g., a beatbox recording could be style-transferred to produce realistic-sounding drums). As a result, our model can be influenced by not only text prompts but also audio inputs, enhancing its controllability and expressiveness. We noted that when initialized with voice recordings (such as beatbox or onomatopoeias), there is a sensation of control akin to an instrument. Examples of audio-to-audio are on our demo page.

Vocal music — The training dataset contains a subset of music with vocals. Our focus is on the generation of instrumental music, so we do not provide any conditioning based on lyrics. As a result, when the model is prompted for vocals, the model’s generations contains vocal-like melodies without intelligible words. Whilst not a substitute for intelligible vocals, these sounds have an artistic and textural value of their own. Examples are given on our demo page.

Short-form audio generation — The training set does not exclusively contain long-form music. It also contains shorter sounds like sound effects or instrument samples. As a consequence, our model is also capable of producing such sounds when prompted appropriately. Examples of short-form audio generations are also on our demo page.

5. CONCLUSIONS

We presented an approach to building a text-conditioned music generation model, operating at long enough context lengths to encompass full musical tracks. To achieve this we train an autoencoder which compresses significantly more in the temporal dimension than previous work. We model full musical tracks represented in the latent space of this autoencoder via a diffusion approach, utilizing a diffusion-transformer. We evaluate the trained model via qualitative and quantitative tests, and show that it is able to produce coherent music with state-of-the-art results over the target temporal context of 4m45s.

6. ETHICS STATEMENT

Our technology represents an advancement towards aiding humans in music production tasks, facilitating the creation of variable-length, long-form stereo music based on textual input. This advancement greatly enhances the creative repertoire available to artists and content creators. However, despite its numerous advantages, it also brings inherent risks. A key concern lies in the potential reflection of biases inherent in the training data. Additionally, the nuanced context embedded within music emphasizes the necessity for careful consideration and collaboration with stakeholders. In light of these concerns, we are dedicated to ongoing research and collaboration with those stakeholders, including artists and data providers, to navigate this new terrain responsibly. Adhering to best practices in responsible model development, we conducted an exhaustive study on memorization. Employing our methodology, we found no instances of memorization.

COMPOSER’S ASSISTANT 2: INTERACTIVE MULTI-TRACK MIDI INFILLING WITH FINE-GRAINED USER CONTROL

Martin E. Malandro
Sam Houston State University
malandro@shsu.edu

ABSTRACT

We introduce Composer’s Assistant 2, a system for interactive human-computer composition in the REAPER digital audio workstation. Our work upgrades the Composer’s Assistant system (which performs multi-track infilling of symbolic music at the track-measure level) with a wide range of new controls to give users fine-grained control over the system’s outputs. Controls introduced in this work include two types of rhythmic conditioning controls, horizontal and vertical note onset density controls, several types of pitch controls, and a rhythmic interest control. We train a T5-like transformer model to implement these controls and to serve as the backbone of our system. With these controls, we achieve a dramatic improvement in objective metrics over the original system. We also study how well our model understands the meaning of our controls, and we conduct a listening study that does not find a significant difference between real music and music composed in a co-creative fashion with our system. We release our complete system, consisting of source code, pretrained models, and REAPER scripts.

1. INTRODUCTION

Composers using generative systems to help them create music desire the ability to steer the systems towards outputs reflective of their style and intent [1]. A study of the challenges that composers faced in the 2020 AI Song Writing Contest found that the systems used in that contest were not easily steerable, and called for new systems and interfaces that are more decomposable, steerable, and adaptive [2]. A 2023 user study of the MMM [3,4] multi-track MIDI infilling model, integrated into a digital audio workstation (DAW) with an interface containing only a temperature parameter, found that users desired additional steering control over the outputs of the model [5]. Another multi-track MIDI infilling model, Composer’s Assistant [6], was adopted by a team of composers to help recreate the lost music of the opera *Andromeda* [7]. Those composers expressed difficulty using the model to create melodies that fit the lyrics they already had, since lyrics

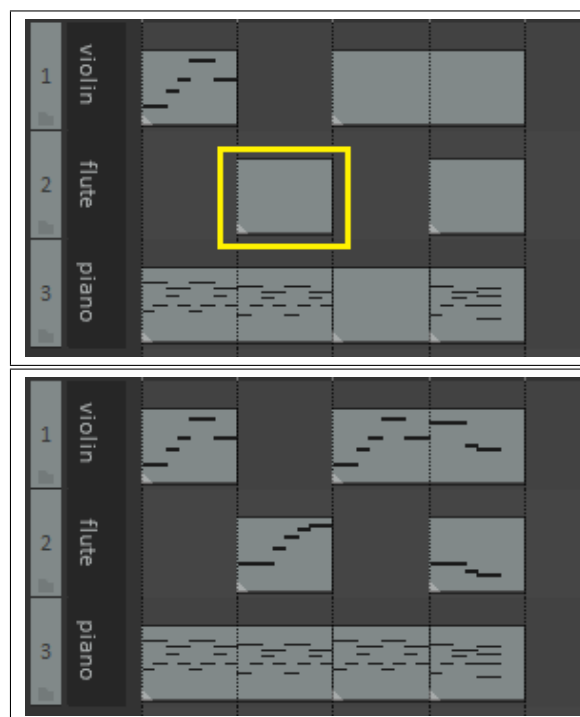

Figure 1. A 4-measure prompt in REAPER, followed by a model output. Users place empty MIDI items in REAPER to tell the model in which measures to write notes, and track names to tell the model what instrument is on each track. A track-measure in the prompt is boxed.

tend to have a natural rhythm to them and that model does not offer rhythmic control over its outputs [8].

Composer’s Assistant (hereafter, “CA”) is a DAW-integrated multi-track MIDI infilling model. The *multi-track infilling problem* is the following: Given a slice of measures from a multi-track song, where the notes have been deleted from some of the track-measures (a *track-measure* is a measure within a track), fill in the notes for the deleted track-measures using the notes that remain as the context—see Figure 1. A model trained to complete this task without any further instruction might write parts that are musically coherent but different from what the user had in mind. For instance, a composer who generates a guitar track to accompany a drum track and bass track might receive a busy, high-pitched solo, a medium-speed, medium-pitched solo, a strummed rhythmic part, or any number of other types of outputs that may not match the composer’s intent for the track. It would be useful for the user to have

the ability to condition the output on parameters such as rhythm (or, if a specific rhythm is not provided, horizontal note density instead), vertical note density, and pitch range.

In this work, we build upon CA to train a new model that offers a wide range of user controls. This work was guided by conversations with several composers who have used CA for co-creative composition, and represents an effort to remedy perceived shortcomings of that system. New controls introduced to the CA system in this work include two types of rhythmic conditioning, horizontal and vertical density controls, pitch step and leap propensity controls, several types of pitch range controls, and a rhythmic interest control. We also include a control that instructs the model not to generate octave-shifted copies of music that exists in the prompt. All of our controls are designed with a DAW-integrated interface in mind. We study the power of our controls via objective metrics, we study the extent to which the model has learned the meaning of our controls, and we conduct a listening study to evaluate music created in a co-creative fashion with our model. We release our complete, DAW-integrated system and our source code.¹

2. PREVIOUS WORK

A wide range of generative music models predate this work, including MusicVAE [9], Piano Transformer [10], Coconet [11], and many others [12–19]. FIGARO [20] explored symbolic music generation with fine-grained user control, and Music SketchNet [21] explored single-track monophonic infilling with pitch and rhythm controls.

Previous DAW-integrated models include DeepBach [22], the Piano Inpainting Application [23], and Magenta Studio [24]. Cococo [25] is a DAW-like interface to Coconet, supporting 4 tracks and arbitrary user-driven infilling/part rewriting, similar to DeepBach. NONOTO [26] is a model-agnostic interface for symbolic music infilling.

Prior multi-track infilling models include MMM [3, 4], MusIAC [27], and CA [6], all of which are transformer models. The 8-bar web demo of MMM can handle up to 6 tracks, and is limited to a 4/4 time signature. MMM has two DAW-integrated versions; however, at the time of this writing they are not publicly available. MusIAC limits inputs to 3 tracks (melody, bass, and accompaniment), 16 bars, and a collection of four time signatures. CA can handle an arbitrary collection of tracks and time signatures, provided that the time signatures contain no more than 8 quarter notes per bar. CA is integrated into the REAPER DAW, and the underlying model runs locally on the user’s machine. Each of these models offers its own set of user controls for infilling: CA offers polyphony controls, MMM offers note density and polyphony controls, and MusIAC offers five controls including note density.

In most previous works, note density is computed simply by dividing the number of notes by the number of time steps. This means that a slow part with many thick chords can have the same density as a fast monophonic part, making it difficult for a user to steer the model towards the de-

Figure 2. A prompt with 1D rhythmic conditioning in REAPER, followed by a model output. Users draw the rhythms they want in the selected MIDI items, and the model chooses pitches for these rhythms that fit with the rest of the prompt. Unselected MIDI items are included in the prompt to the encoder, and remain unchanged.

sired rhythmic speed with a density control. Additionally, most prior works have density control sliders (with values ranging from, e.g., 1–10) whose quantiles were defined by the training data. While this approach is attractive from a training perspective, it is difficult to navigate from a user perspective—e.g., what does a density of 7/10 mean?

In this work, we take a different approach to note density, first by factoring note density into horizontal (rhythmic) and vertical densities, and second by adopting musically meaningful quantiles for these measurements. We note that MuseMorphose [28] also decomposed note density into horizontal and vertical densities, albeit with a different definition of vertical density (in their work, “polyphony score”) than ours. We also develop a wide range of additional steering controls, including a user option for explicit rhythmic control. With this option, the user can supply rhythms in their model prompts, and the model chooses only the pitches—see Figure 2. To our knowledge, the controls we implement in this paper comprise the most comprehensive and user-friendly set of steering controls for multi-track MIDI infilling to date.

3. MEASUREMENTS FOR USER CONTROLS

In this section we describe the measurements underlying the user controls implemented in this work. Recall that music in MIDI format is time-quantized to a uniform grid of some number of *ticks* per quarter note.

¹ <https://github.com/m-malandro/composers-assistant-REAPER>

Figure 3. Six examples of rhythmic interest levels. Points mark note onsets in a 4/4 measure.

3.1 Horizontal Measurements

Horizontal note onset density. We define the *horizontal note onset density* of a collection of measures from a track to be the number of ticks with a note onset divided by the total number of ticks. In interval notation, we quantize horizontal note onset densities to the following six bins: Less than half notes; [Half notes, Quarter notes]; [Quarter notes, Eighth notes]; [Eighth notes, 16th notes]; [16th notes, 4.5 onsets per quarter note]; ≥ 4.5 onsets per quarter note.

Rhythmic interest. Given a slice of measures from a track, let v denote the binary rhythm vector of those measures. Let $\hat{v} = v - \bar{v}$ denote v , re-centered at 0. We compute dot products of \hat{v} with its nontrivial shifts and record the highest of their absolute values as a measure of rhythmic uniformity. Rhythmic uniformity is scaled by $1/||\hat{v}||^2$ and subtracted from 1 to yield *rhythmic interest*, which we divide into Low (< 0.14), Medium (≥ 0.14 and < 0.4), and High (≥ 0.4) bins. These quantiles were hand-selected by looking at many examples. See Figure 3 for examples.

3.2 Vertical Measurements

Vertical note onset density. We define the *vertical note onset density* of a collection of track-measures from a track to be the number of notes divided by the number of ticks containing an onset. In interval notation, we quantize vertical note onset densities into the following five bins: 1 note per onset; (1 note per onset, 2 notes per onset]; (2 notes per onset, 3 notes per onset]; (3 notes per onset, 4 notes per onset]; > 4 notes per onset.

Average number of pitch classes per note onset. This measure is the same as vertical note onset density, but with pitches replaced with pitch classes. It is $(\sum_t \# \text{pitch classes at } t) / \# \text{ticks containing an onset}$. We use the same bins as vertical note onset density: 1 pitch class per onset; (1 pitch class per onset, 2 pitch classes per onset]; (2 pitch classes per onset, 3 pitch classes per onset]; (3 pitch classes per onset, 4 pitch classes per onset]; > 4 pitch classes per onset.

3.3 Pitch Measurements

Pitch step and leap propensity. Given two consecutive notes, a *step* is a difference in pitch of 1–2 semitones, while a *leap* is a difference of more than 2 semitones. Pitch repetitions are neither steps nor leaps. We generalize to chords as follows: Given a chord C_1 followed by a chord C_2 , define the chord distance $d(C_1, C_2)$ to be the average of the

minimum pitch movements needed to get from the notes in C_1 to the notes in C_2 :

$$d(C_1, C_2) = \frac{1}{|C_1|} \sum_{n_1 \in C_1} \min_{n_2 \in C_2} |\text{pitch}(n_1) - \text{pitch}(n_2)|.$$

Going from a chord C_1 to a chord C_2 , we have a *repetition* when $d(C_1, C_2) = 0$, a *step* when $0 < d(C_1, C_2) \leq 2$, and a *leap* when $d(C_1, C_2) > 2$. Given a slice of measures from a track containing n chords, we count the number of steps and leaps and divide by $n - 1$ to obtain the *pitch step propensity* and *pitch leap propensity* for the slice. We quantize pitch step and leap propensities into the following seven bins: [0, 0.01), [0.01, 0.2), [0.2, 0.4), [0.4, 0.6), [0.6, 0.8), [0.8, 0.99), [0.99, 1.0).

Note onset chromagrams. When prompted to generate new tracks to accompany an arrangement already containing several tracks, we observed that the CA model would often generate a copy (possibly shifted by some number of octaves) of one of the tracks in the prompt. While this is often “correct,” it is not particularly useful for co-creative composition—if that is what the composer wanted, they could easily create this themselves. To create a control that tells the model to write genuinely new parts, for each track-measure in a song, we record whether that track-measure has the same note onset chromagram as another track-measure in its measure. (Given a track-measure T , the set of ordered pairs $\{(\text{pitch}(n) \pmod{12}, \text{onset tick}(n)) : n \text{ is a note whose onset is in } T\}$ is the note onset chromagram of T .)

3.4 Other Measurements

Pitch range. The *pitch range* of a collection of track measures is simply a record of their lowest and highest pitch.

Rhythmic information. We define the *1D rhythmic information* of a collection of measures from a track to be the set of note onset ticks and corresponding note durations after flattening all notes to the same pitch. If multiple notes share an onset, we record only the longest of their durations. The *2D rhythmic information* of a collection of measures from a track is the same, but with the number of note onsets and number of pitch classes at each onset also recorded.

4. CONTROLS AND MODEL

We use the MIDI-like token-based language from [6] to tokenize music. This language supports masking of arbitrary subsets of track-measures from any slice of measures from a song. We add additional tokens to the language to serve as control tokens for the measurements introduced in Section 3. For each of the measurements that are quantized into bins in Sections 3.1–3.3, for each bin, we create a separate control token. We also create a control token to indicate when a track-measure has a different note onset chromagram from all other track-measures in its measure—we call this token the different-note-onset-chromagram (DNOC) token. We also create pitch range

controls and explicit rhythmic controls. For pitch range control, we create four control tokens: high (strict), low (strict), high (loose), and low (loose), and we follow such a token by a pitch token to indicate the value of the measurement. With strict pitch range controls, which can be supplied on a per-track or per-track-measure basis, the model is expected to generate at least one pitch at each extreme. With loose pitch range conditioning, the model is expected to generate at least one note within 7 semitones of each extreme and not extend beyond the extremes. The idea is that a user could supply a loose pitch range for, e.g., a vocal melody, whose bounds are given by the range of the vocalist. For rhythmic conditioning, we create masked pitch tokens, which are included with rhythmic tokens (describing note onset position and note duration) in prompts. For 1D rhythmic conditioning, we include a single masked pitch token at each tick containing any number of note onsets. For 2D rhythmic conditioning, we include masked pitch tokens describing both the number of note onsets and the number of pitch classes at each onset.

As in [6], we train a T5-like [29] encoder-decoder transformer [30] model. Our main model (which we refer to as our *large* model) is 512-dimensional, with 16 encoder layers and 16 decoder layers. This model has about $3.5\times$ the number of parameters of the CA model, which is 384-dimensional, with 10 encoder layers and 10 decoder layers. To examine the effect of model scaling on performance, we also train a *small* model having the same dimension and number of layers as the CA model. For inference, we use nucleus sampling [31] with a threshold of $p = 0.85$.

During training, we mask a random subset of track-measures from a slice of measures within a song, and we ask our model to generate the tokens for the masked track-measures. All unmasked track-measures within the slice are included in the prompt provided to the encoder. In each example, we include a random subset of our control tokens in our prompts. Control tokens operating on the track level are appended to the prompt, while control tokens operating on the track-measure level are inserted into the prompt in place of the masked tokens that the model is asked to generate. For training, values for control tokens are computed using only the masked track-measures. For inference, this allows a user to specify attributes for track-measures to be filled that differ arbitrarily from the attributes of the unmasked track-measures in the prompt. During inference in the DAW, we apply only the control tokens supplied by the user.

We quantize music to a mixed grid that accommodates 32nd notes and 16th note triplets. This grid has 24 ticks per quarter note, of which 12 are valid locations for note onsets. To train our models, we use the CA training dataset (a dataset of public-domain and permissively-licensed MIDI files). As in [32], we take the “e” folder of the Lakh MIDI dataset (LMD) [33, 34] to be our validation set.

5. EVALUATION

In [6], CA generally outperformed MMM [3, 4] on objective and subjective measures. However, whether this

Table 1. Objective infilling summary statistics. All cells are percentages of the form mean^s, where s is a letter. Different letters within a metric and column indicate significant location differences ($p < 0.01$) in the samples for those table entries according to a Wilcoxon signed rank test with Holm-Bonferroni correction.

was due to training approach, training dataset, model size, and/or other factors is unclear. To make a direct comparison between our work and previous work, we adopt CA as our baseline for comparison on objective metrics.

5.1 Objective Evaluation

We take the “f” folder of the LMD to be our test set. From each file, we select random 8-measure slices and attempt to prepare three test examples:

- Random infilling: Each track-measure in the slice is masked with probability 0.5.
- Track infilling: One track from the slice, containing note onsets in at least 7 measures, is masked completely.
- Last-bar infilling: Every track-measure in the last measure of the slice is masked.

We take 5000 examples of each type of infilling to be our test set. For each example, we take the masked notes to be the ground truth, and after evaluating the example with our models we compute precision and recall as in [6]. The F_1 score for an example is the harmonic mean of its precision and recall: $F_1 = (2 \cdot \text{precision} \cdot \text{recall}) / (\text{precision} + \text{recall})$. We also compute the pitch class histogram entropy difference and the groove similarity (as defined in [35]) between the ground truth and the output for each example.

We evaluate our test examples with our models, providing user controls describing the information in the masked track-measures to the maximum extent possible. In particular, we provide 2D rhythmic conditioning, pitch step and leap propensity, pitch range per track-measure, and the DNOC token (wherever applicable) to our models. Results are averaged and presented in Table 1. For examples evaluated by CA, we provide all of the control information available to that model—in particular, mono/poly switches at the track-measure level. We note that supplying rhythmic conditioning and pitch range information for track-measures containing only one pitch is equivalent to unmasking those track-measures. Therefore, to make a fair comparison between our models and CA, we unmask those track-measures in our prompts to CA and we give that model “credit” for those track-measures as if it had generated them itself. (14.46% of the track-measures from our test set fall into this category.) We see a dramatic increase in performance of our models relative to CA. As expected, our large model outperforms our small model (except for groove similarity for the random infilling task), but the differences in performance between our models are small. Note that the groove similarity score for our models is not 100%, indicating that our models sometimes (albeit rarely) fail to follow exactly the rhythms in their prompts.

Next, we examine the effect of each control introduced in this paper by repeating our test examples, but with only limited control information supplied to the model. For each control introduced in this paper, we examine the F_1 scores obtained by supplying only that control to the model. We also examine what happens when we supply a growing collection of controls, roughly in order of how much effort is required for a user to supply such controls in practice—specifically, we supply, in order: vertical controls, horizontal controls, our DNOC control, pitch/step leap controls, pitch range (per track), 1D rhythmic conditioning, 2D rhythmic conditioning, and finally pitch range (per track-measure). The resulting large table of F_1 scores is omitted, but the primary observation is that pitch range and rhythmic conditioning controls have the largest positive effect on the F_1 scores of model outputs. Model size has only a minor effect. Horizontal, vertical, pitch step/leap propensity, and DNOC controls also have only minor effects on F_1 scores. This raises the questions of whether the model understands the meaning of these controls and whether these controls are useful for co-creative composition, which we address in the next two sections.

5.2 Model Understanding of Control Tokens

Our model can generate music from scratch by prompting it with prompts containing no notes. To examine the understanding our model has of our control tokens, we use an empty prompting strategy: We prompt the model to generate some number of bars of single-track music from scratch, with no control tokens, and then we repeat the empty prompt with a single control token added. We use this approach to examine our horizontal, vertical, pitch step, pitch leap, and DNOC control tokens. For each con-

Figure 4. Horizontal density distributions.

Figure 5. The observed probability of success for each control token in our empty prompting test.

trol token we generate 5000 examples, and we examine the resulting distributions. (For the DNOC control, we use a 1-bar example where a viola and cello play an ostinato one octave apart, and prompt the model to write a violin part to accompany them.)

A plot of our horizontal note onset density distributions is given in Figure 4. Plots of other distributions are similar.

For each control token, we also compare the observed probability of obtaining an output described by that token when the token is supplied versus when it is not supplied, finding that all 34 tokens mentioned above indeed push our model towards outputs having the characteristics they are intended to encode. Probabilities of success vary, however—see Figure 5. Our DNOC token performs well, with a success rate of 90.5%, as compared to unconditioned outputs having a different note onset chromagram 14.2% of the time. Our model has also done a good job of learning the concepts of horizontal density, high and

low rhythmic interest, high and low vertical density, monophonic versus polyphonic generation, and high and low step and leap propensity. However, when supplied with the appropriate control token, our model has trouble generating parts with medium rhythmic interest (with a 42% chance of success, versus 35.2% for unconditioned outputs), and with more than 4 pitch classes per onset (with a 8.92% chance of success, versus 0.04% for unconditioned outputs).

Additionally, our model has not learned the precise boundaries for our bins. For instance, when asking the model to generate a part with a horizontal density in the interval [Quarter notes, Eighth notes), we observed that our model would often generate a straight eighth note pattern. When allowing for a tolerance of up to one bin away, though, all of our control tokens have a success rate of over 50%, and 26/34 of them have a success rate of over 80%.

Our model learned the meaning of each of these control tokens solely via natural training data. In future work, it may be possible to achieve better control token understanding performance by training on synthetic examples and/or by changing the boundaries of the bins.

5.3 Subjective Evaluation

We used our model in an iterative, co-creative fashion to create 12 snippets of music, each about 16 bars long. To create these snippets, we started with 6 pieces of real music and deleted one or more tracks in the music. We then used our model interactively to fill these deleted tracks. Specifically, each time the model generated music, we kept the generated track-measures we liked, and continued using the model to fill the remaining track-measures until done. We carried out this process under two sets of rules:

- CA-: We did not use rhythmic conditioning, and did not hand-edit the notes in any outputs.
- CA+: We were allowed to use every control available, including rhythmic conditioning, and we were allowed to make small hand edits to outputs. This is the approach closest to how the model would be used in practice.

In both cases we were allowed as many generations as we wanted. We recorded the creation of these examples, which took about 2 hours in total.² Volunteers were asked to score as many of these 18 snippets of music as they wished, according to perceived **R**hythmic correctness, **P**itch correctness, **M**emorability, and **O**verall, each on a scale of 0 to 4. Volunteers were not told which pieces of music were real and which were composed with our system. 28 individuals volunteered and ranked an average of 10.4 snippets along each of our 4 axes. Aggregated results are presented in Figure 6. Each bar in this figure represents 94–99 data points.

We compare real music to music composed with our two approaches CA- and CA+ with paired *t*-tests, using data from whenever a volunteer ranked both. Each of these

Figure 6. Subjective evaluation of our model.

Metric	Real	Metric	Real
R	CA-	M	CA-
	0.693	CA+	0.052
P	CA-	O	CA-
	0.887		CA+
M	CA-	CA-	0.039
	0.791	CA+	0.099
O	CA-		
	0.211		

Table 2. Uncorrected *p*-values from paired *t*-tests in our subjective comparisons.

8 tests involved 93–96 pairs of values. See Table 2. After Holm-Bonferroni correction, we do not find a significant ($p < 0.05$) difference between real music and music composed with either approach in any of these 8 tests. We know that our model is competent at avoiding rhythmic and pitch errors, so we are not surprised by our R and P results. However, we had some difficulty creating a proper drum part in one example with the CA- approach, and we expected to find at least one significant M or O difference. We suspect that there are subjective quality differences, at least between real music and the music we created with the CA- approach, that are not large enough for this study to detect reliably. Nevertheless, we believe that this indicates that music co-created with our model has the potential to be on par with human-composed music. We also believe that results of similar studies would vary greatly depending on the skill of the composer using the system. We invite the reader to listen to our samples³ and to try our system.

6. CONCLUSION

We have introduced a wide range of steering controls for multi-track MIDI infilling, and we have trained a transformer model to implement these controls. We have created an interface for our controls, and we have integrated our model and controls into the REAPER digital audio workstation for co-creative symbolic music composition. Our work in this paper comprises Composer’s Assistant 2, and we have released our complete system and source code.⁴

7. ETHICS STATEMENT

There are currently unresolved ethical and legal questions regarding the inclusion of copyrighted data in training sets for generative models. While we suspect it would be possible to obtain better objective (and possibly subjective) results by training a model on a larger and more varied dataset (e.g., the Lakh MIDI dataset [33, 34]), we chose to train our models only on copyright-free and permissively licensed files, primarily for the following two reasons:

First, we want our model outputs to be usable by composers. While there is a possibility that our models may output copyrighted musical information (even if such information was not present in the training dataset), we believe that training only on copyright-free and permissively-licensed musical data minimizes this possibility.

Second, for many composers, we view the models that we have released not as the models that the composers would actually use in their work, but rather as starting points for customization and personalization. Many composers we have spoken to have said that models that write “generic” music are not useful to them. Instead, they want generative systems that can suggest ideas in their own style. Due to our training set, the models we have released are most proficient at infilling classical, choral, and folk music. However, informal experiments suggest that our models can be finetuned on a relatively small number of MIDI files to write in the style of those files, and hence the style limitations of our released models may not matter. The code we have released supports finetuning by end users. While this can benefit composers who wish to use our system, there is also the risk that our models may be finetuned by users to impersonate the styles of others.
