ABSTRACT

Replicating analog device circuits through neural audio effect modeling has garnered increasing interest in recent years. Existing work has predominantly focused on a one-to-one emulation strategy, modeling specific devices individually. In this paper, we tackle the less-explored scenario of one-to-many emulation, utilizing conditioning mechanisms to emulate multiple guitar amplifiers through a single neural model. For condition representation, we use contrastive learning to build a tone embedding encoder that extracts style-related features of various amplifiers, leveraging a dataset of comprehensive amplifier settings. Targeting zero-shot application scenarios, we also examine various strategies for tone embedding representation, evaluating referenced tone embedding against two retrieval-based embedding methods for amplifiers unseen in the training time. Our findings showcase the efficacy and potential of the proposed methods in achieving versatile one-to-many amplifier modeling, contributing a foundational step towards zero-shot audio modeling applications.

1. INTRODUCTION

Neural audio effect modeling, the task of simulating analog circuitry and digital audio effects using neural networks, has garnered significant interest driven by advances in deep learning [1–9]. Various network architectures have been proposed for emulating different effect pedals and guitar amplifiers (amps). Through modeling nonlinearities, harmonic distortions, and transient responses inherent to analog circuitry, neural models offer an alternative to their physical counterparts. Such models enable widespread applications in automatic mixing [10–12], audio style transfer [13, 14] and beyond, contributing to new music production and sound design workflows.

Real-world audio effect pedals or amplifiers are known for their rich acoustic diversity, leading to different “tones.”

Figure 1: A one-to-one approach cannot emulate an unseen audio effect. In contrast, the proposed one-to-many approach can achieve zero-shot modeling by using a tone embedding encoder that turns a reference audio example of that effect into a conditioning input at inference time.

There are multiple types of pedals (e.g., compression, EQ, distortion, reverb, modulation), possessing different characteristics. Even pedals of the same effect type can sound fairly differently due to different implementations. A user can further adjust the device parameters via tuning the associated knobs (e.g., a gain knob) to shape the tone. Moreover, it is common to interconnect effect pedals in various orders and forms to constitute an “effect chain,” collectively creating a unique tone. A guitar amplifier can also be viewed as an effect chain as there are pre-amp, tone stack, power amp, and cabinet components arranged in specific order that vary across brands and underlying circuitries. The rich diversity of tones represents a central challenge for neural audio effect modeling.

While exciting progress is being made, to simplify the task, most prior research has concentrated on the *one-to-one* mapping setting, building a neural model for emulating the behavior of only *one* device (i.e., a pedal or an amp) at a time [15, 16]. Some models make further simplification and model only a certain parameter setting (a.k.a., “snapshot”) of a device and do not take any condition signals [3, 4, 6], while others incorporate device parameters as conditions for a “full” modeling of the device [2, 17].

Little work, if any, has been done to tackle the more challenging task of building a single universal model that can emulate multiple devices at once. This is harder as different devices are built from varying combinations and configurations of analog circuits, leading to distinct sonic characteristics. We posit that a transition to such a *one-to-many* setting is beneficial. On one hand, it holds the key towards neural audio effect modeling with broader versatility, better reflecting the complexity seen in the real world.

On the other hand, doing so may empower the single model to learn the similarities and distinctions among different audio effects, building up a “tone space” that permits interpolation and extrapolation of *seen* tones (i.e., tones made available to the model during training time) to approximate an *unseen* tone or to create a *new* tone.¹

We are in particular interested in the case of emulating unseen tones in this paper. Specifically, we envision a *zero-shot* scenario where we have a model that can take a reference audio signal in the style of an unseen tone as the input condition, and learn to *clone* the tone on-the-fly during the inference time, with no (i.e., “zero”) model re-training. See Figure 1 for an illustration.

In this paper, we set forth to tackle one-to-many neural modeling of multiple guitar amps by a single model. Our training data contains pairs of clean (dry) signal and the corresponding wet signal rendered by an amp, out of $N = 9$ possible guitar amps featuring low-gain and high-gain ones. Instead of building N models, one for each amp, our one-to-many model can take a condition signal indicating the specific amp tone of interest and convert a given clean signal into the corresponding wet signal at inference time. The attempt to build such an end-to-end one-to-many model represents the first contribution of this work.

While a straightforward approach to condition the generation process is via using a look-up table (LUT) to indicate the target amplifier, the LUT approach cannot deal with unseen amplifiers. Targeting zero-shot applications, we use contrastive learning [18] to build a *tone embedding encoder* to capture tone- (or style-) related information of a referenced audio, and then use the resulting tone embedding as the condition for generation, as illustrated in Figure 2. We show via experiments that, for seen guitar amps, the tone embedding seems information richer than the LUT embedding, leading to more effective one-to-many modeling. Moreover, the tone embedding approach also works well for zero-shot learning of unseen amps, as we can turn arbitrary referenced audio of that amp into a condition to clone its style. In our evaluation, we use not only two additional guitar amps not seen during training time, but also self-recorded audio signals of guitar playing to validate the model’s effectiveness in real-world conditions. The idea to realize zero-shot tone transfer in our one-to-many model stands as the second contribution of our work.

We invite readers to visit our demo website for audio samples demonstrating the result of our model.²

2. BACKGROUND

The process of applying effects to an audio signal in the real world can be described by $\mathbf{y} = f(\mathbf{x}, \phi)$, where $\mathbf{x} \in \mathbb{R}^{C \times T}$ denotes the input signal with C channels and T samples, $\mathbf{y} \in \mathbb{R}^{C' \times T}$ the processed output, and $\phi \in \mathbb{R}^M$ the control signal with M distinct control parameters. The function f encapsulates the accumulative transformation

Figure 2: Diagram of the audio processing workflow. A clean signal \mathbf{x} is input into the generator \mathcal{G} , which uses the tone embedding from the tone embedding encoder to produce the wet signal \mathbf{y} . The encoder \mathcal{E} generates the tone embedding ϕ by analyzing a reference wet signal \mathbf{z} .

exerted by the devices involved in the effect chain connecting the input and the output. Neural audio effect modeling aims to replicate this implicit function f using either a single neural network [4, 11] (i.e., the “end-to-end” approach) or a cascade of modularized networks [10, 14]. The latter approach is feasible only when the devices involved in the transformation is known beforehand, not applicable to the envisioned zero-shot scenario. Therefore, we focus on the the end-to-end approach in this work.

Common *backbone* models for end-to-end audio effect modeling include convolution neural network (CNN)-based [1, 3, 6, 17], recurrent neural network (RNN)-based [2, 5], and hybrid models [4, 11]. As mentioned in Section 1, existing models mostly model one device at a time, sometimes even neglecting the control parameters ϕ . For those models that consider control parameters, a “condition representation” to represent the control signal and a “conditioning mechanism” to condition the generation process by the control signal is needed.

For the *condition representation*, the common approach in the field of neural audio effect modeling is via quantizing the device parameters and then using a one-hot encoding or look-up table (LUT) to indicate the specific parameter setting of interest. Such *ID-based* embeddings has also been used in other one-to-many audio modeling tasks, such as singing voice conversion (SVC) [19–21]. Importantly, the LUT embeddings are learned at training time and then fixed at inference time, thereby failing to accommodate unseen conditions. This is not a problem for modeling the parameters of a device, because there will not be unseen parameters for a known device. However, it is an issue in our one-to-many setting, as we are not able to exhaustively include all the possible devices at training time.

For the *conditioning mechanism*, a common approach is via “concatenation,” expanding ϕ over time to get $\phi^+ \in \mathbb{R}^{M \times T}$ and concatenating it with the input \mathbf{x} channel-wisely, forming a new input $\mathbf{x}^+ \in \mathbb{R}^{(C+M) \times T}$ to the model. Concatenation has been used by both CNN- [1] and RNN-based models [2]. Another common approach is via “feature-wise linear modulation” (FiLM) [22], which has usually been adopted by CNN-based models [7, 17].

¹ We note that, the idea of using “devices” to define tones is less applicable in the neighboring automatic mixing tasks [11, 12].

² <https://ss12f32v.github.io/Guitar-Zero-Shot/>

FiLM injects conditions to the model by using $\phi \in \mathbb{R}^M$ as the input to predict different scaling γ_l^c and shifting β_l^c coefficients through a few linear (dense) layers, and then performing element-wise affine transformation of the intermediate feature maps of each layer of the backbone model, i.e., $\text{FiLM}(\mathbf{F}_l^c, \gamma_l^c, \beta_l^c) = \gamma_l^c \mathbf{F}_l^c + \beta_l^c$, for each layer l and each c -th channel of the corresponding feature map.

Our work differs from the prior work in the following three aspects. First, we tackle multi-device modeling, conditioning our network by “devices” rather than “parameters” of a single device. Second, we adopt the idea of *content-based* embeddings developed in SVC [23–27] to compute the condition representation instead of the ID-based embeddings, so as to deal with unseen devices. This is specifically done via the proposed tone embedding encoder, whose details are introduced in Section 3.1. Finally, we report experiments on zero-shot tone transfer.

3. MULTI-TONE AMPLIFIER MODELING

Our goal is to develop a conditional generator, denoted as $\mathcal{G}(\mathbf{x}, \phi)$, that can replicate the effect of an amplifier’s audio effect chain f , guided by a tone embedding ϕ . The objective of the generator \mathcal{G} is to produce an output \mathbf{y} from the input \mathbf{x} , where \mathbf{x} and \mathbf{y} are temporally aligned and share the same musical content, but exhibit different tones (i.e., clean tone vs. a target amp tone). In our work, the tone embedding ϕ is a learnable representation of various tones. Specifically, as depicted in Figure 2, we employ a tone embedding encoder, denoted as \mathcal{E} , to derive the tone embedding ϕ from a reference audio signal \mathbf{z} , with $\phi = \mathcal{E}(\mathbf{z})$. It is important to note that the reference signal \mathbf{z} and the target \mathbf{y} *must* match in tone, but their musical content *can* be different. More details on this in Section 3.3.

3.1 Tone Embedding Encoder

Our goal is to train an encoder \mathcal{E} that can extract tone- (or style-) related features from a given wet guitar audio signal, while neglecting content-related information. Namely, this entails style/content disentanglement. We propose to employ the self-supervised contrastive learning framework of SimCLR [18], which was originally for images [28, 29], to train such an audio encoder. Specifically, our idea is to treat pairs of audio clips with *different* playing contents but the *same* tone as the “positive” pairs, and otherwise the “negative” pairs. Any audio clip would go through the same audio encoder to get an embedding representation of that clip, and the learning objective of SimCLR is to train the encoder such that the embeddings of clips from a positive pair are close to each other, while embeddings of clips from a negative pair are separated apart. By virtue of the way positive and negative data pairs is constructed, the encoder learns to project clips of the same tone to similar places in the embedding space, regardless of the underlying musical content.³

³ The use of contrastive learning for representation learning has been widely done in the musical audio domain before, for tasks such as music classification [30–33] and automatic mixing [12]. What’s different here is the application of contrastive learning to the domain of guitar amp tones

Figure 3: Diagram of a layer of the generator \mathcal{G} , which uses gated convolutional neural network (GCN) [6] as the backbone and FiLM [22] for conditioning; \mathbf{h}_l denotes the output of the previous layer and \mathbf{h}_{l+1} the current layer.

It is easier to train the encoder if we have a collection of realistic wet guitar signals featuring different combinations of contents and tones. Such a dataset, however, is hard to come by. Guitar signals collected in the wild need to be transcribed and labeled to get content- and style-related information. Alternatively, we may use software simulation to convert a set of clean signals into different wet signals, but the tones supported by open-source tools such as Pedalboard [34, 35] are limited in diversity. Through a joint work with Positive Grid, a leading guitar amp and effect modeling company, we have the advantage of accessing high-quality and diverse data. The training data for the encoder \mathcal{E} is from using a larger number of clean guitar signals as input to the company’s commercial software to render wet signals with a great diversity of tones using different combinations of amplifiers and effect pedals.

3.2 Conditional Generator

Paying more attention on the condition representation part (i.e., ϕ and \mathcal{E}), we use existing methods for the model backbone and the conditioning mechanism for our conditional generator \mathcal{G} . Specifically, we adapt the gated convolutional neural network (GCN) [6] as our model backbone, for its demonstrated efficacy in neural audio effect modeling. For the conditioning mechanism, we use FiLM [22]. As shown in Figure 3, each layer of GCN passes the output of the previous layer \mathbf{h}_l through a 1D convolution with a progressively increasing dilation factor, followed by sigmoid and tanh for gated activation. The resulting feature map is then modulated by the FiLM module, before being processed by a 1x1 conv1d and then added with the output of the previous layer with a residual link. The same tone embedding ϕ is used in all the L layers of GCN, but each layer l has its own learnable parameters. The outputs from all layers are finally concatenated and processed through a final 1x1

(which has not been attempted before, to our best knowledge), and the way we prepare positive/negative pairs for tone representation learning.

conv1d mixing layer to generate the output signal \mathbf{y} .⁴

The tone embedding encoder \mathcal{E} is trained with a large set of wet signals rendered with different combinations of amps and effect pedals, while the generator \mathcal{G} is trained separately with a smaller set of paired data of clean and wet signals rendered with different amps (not using effect pedals). The encoder \mathcal{E} is trained beforehand and then fixed (i.e., parameters frozen) while training the generator \mathcal{G} .

The training data of \mathcal{G} is also from Positive Grid, containing 30 minutes of clean input data (for \mathbf{x}) rendered with 9 different guitar amplifiers (for \mathbf{y}). For performance evaluation, we divide the clean signals into training, validation, and test sets with an 80/10/10 ratio. According to the company’s taxonomy, there are 3 types of amps:

- *High-gain* tones are perceived as highly distorted. We have Mesa Boogie Mark IV (amp1), PRS Archon 100 (amp2), and Soldano SLO-100 (amp3).
- *Low-gain* tones are often recognized as an overdrive sound. Our data contains Fender Tweed Deluxe (amp4), Vox AC30 (amp5), and Matchless DC30 (amp6).
- *Crunch* tones exhibit a mid-range gain level, in between low- and high-gain. Our data contains Vox AC30 Handwired Overdriven (amp7), Friedman BE100 (amp8), and Overdriven Marshall JTM45 (amp9).

3.3 Source of the Reference Audio Signal

While training \mathcal{G} , for each data pair $\{\mathbf{x}, \mathbf{y}\}$, the encoder \mathcal{E} takes a reference signal \mathbf{z} providing information of the tone of \mathbf{y} . Therefore, \mathbf{y} and \mathbf{z} must match in tone. However, interestingly, \mathbf{y} and \mathbf{z} can be different in content.

The naïve **paired reference** method of simply setting $\mathbf{z} = \mathbf{y}$ demands the reference signal and target output, and accordingly the input \mathbf{x} , to play the same content. This is fine at training time, but is too restrictive and not practical at inference time, especially for zero-shot scenarios. Following the idea of using “target-unaligned audio” of a prior work [8], we instead employ an **unpaired reference** method, selecting a signal \mathbf{z} *at random* from the training set as long as it is rendered with the same amp tone as \mathbf{y} .

Besides zero-shot capability, the proposed unpaired reference method may further encourage style/content disentanglement, because here ϕ only provides information concerning the tone of the target, not its content.

3.4 Zero-shot Tone Transfer

At inference time, the proposed model \mathcal{G} holds the potential to clone the tone of a reference signal \mathbf{z}^* for even unseen tones and unseen reference signals, via using $\mathcal{E}(\mathbf{z}^*)$ as the condition ϕ^* . This might be feasible as the encoder \mathcal{E} has actually been trained on a great diversity of tones besides the limited number of N tones used to train \mathcal{G} .

⁴ Unlike [6], we pad zeros at the start of the signal but not in the intermediate feature maps, for otherwise there would be unwanted impulse-like sounds. This means each layer ends up being shorter in our case. To keep the output size consistent across layers, we crop the residual part of each layer following the causal principle.

Besides using $\phi^* = \mathcal{E}(\mathbf{z}^*)$, we consider the following two *retrieval-based* alternatives to get ϕ^* , referred to as “nearest-embedding” and “mean-embedding” respectively.

- $\phi^* = \arg \max_{\phi \in \Phi} \text{sim}(\mathcal{E}(\mathbf{z}^*), \phi)$, where $\phi = \mathcal{E}(\mathbf{z})$ denotes the embedding for a reference signal *seen* and sampled from the training set, $\text{sim}(\cdot, \cdot)$ the cosine similarity between two vectors, and Φ the collection of embeddings for such seen reference signals from the training set to be compared against the query $\mathcal{E}(\mathbf{z}^*)$. Namely, this method picks the known reference signal \mathbf{z} whose embedding is closest to that of the unseen reference \mathbf{z}^* as the surrogate to condition the generation process. We set the size of the candidate set $|\Phi| = 3,600$ in our implementation.
- $\phi^* = \arg \max_{\phi \in \{\psi_1, \psi_2 \dots, \psi_N\}} \text{sim}(\mathcal{E}(\mathbf{z}^*), \phi)$, where ψ_n stands for the average of the embeddings associated with the n -th amp tone (out of the N seen amp tones) from the aforementioned candidate set Φ . This can be viewed as an LUT-like approach because we use one mean embedding to represent each amp tone for retrieval.

3.5 Implementation Details

The encoder \mathcal{E} is developed by Positive Grid using in-house data and implementation. It is an audio encoder that processes mel-spectrograms of guitar signals, trained with a batch size of 200 short audio clips sampled at 16kHz, along with data augmentation techniques such as adding noise and random cropping.

For the generator \mathcal{G} , we followed [14] and applied -12 dBFS peak normalization to the training data to balance the sound levels of different amplifiers and ensure headroom for distortion. We randomly paired a 3.5-second monaural clean input sampled at 44.1kHz with an amp output from the 9 amplifiers as the training examples. We trained the generator \mathcal{G} on an NVIDIA RTX 3090 GPU (with 24 GB memory), using the Adam optimizer [36] with a learning rate of $1e-3$ and a batch size of 12. While both the input and output of \mathcal{G} are time-domain waveforms, we used complex-valued spectral loss as the training objective, with an STFT window length of 2,048 and a hop length of 512, for this loss function led to better result in our pilot study.

For the architecture of \mathcal{G} , we configured the GCN with $L = 12$ conv1D layers, each with 16 channels, followed by a final 1×1 conv1d layer combining the outputs of all the preceding layers to a monaural waveform. For conditioning, we firstly projected each 512-dim tone embedding produced by \mathcal{E} to a 128-dim vector, then applied a series of 10 linear layers at each GCN layer to predict the scaling and shifting coefficients γ_l^c and β_l^c for FiLM. The total number of trainable parameters of \mathcal{G} is around 120k, and the model training of \mathcal{G} converged in 1/2 days.

4. EXPERIMENTAL RESULTS

4.1 Tone Embedding Visualization

We examine the tone embedding space of the 9 target amps first, using t-SNE [37] for dimension reduction and visual-

		GCN	FiLM-GCN			Concat-GCN	
		one-to-one	LUT	ToneEmb (paired)	ToneEmb (unpaired)	LUT	ToneEmb (paired)
high-gain	Amp1	0.0420	0.1441	0.1189	0.0777	0.1593	0.1523
	Amp2	0.0268	0.1951	0.0670	0.1189	0.1741	0.1208
	Amp3	0.0527	0.1659	0.1254	0.1143	0.1777	0.1304
low-gain	Amp4	0.0087	0.0698	0.0230	0.0275	0.0618	0.0775
	Amp5	0.0004	0.0813	0.0167	0.0138	0.0334	0.0166
	Amp6	0.0014	0.0947	0.0169	0.0121	0.0779	0.0275
crunch	Amp7	0.0393	0.1022	0.0860	0.0885	0.0733	0.0988
	Amp8	0.0124	0.1583	0.0760	0.0604	0.1562	0.0775
	Amp9	0.0035	0.1593	0.0375	0.0290	0.1211	0.0407

Table 1: Efficacy of various models in modeling 9 guitar amplifiers, measured in complex STFT loss on the test data. The leftmost column shows the result of the baseline *one-to-one* GCN approach, building one model per amp. The others are *one-to-many*, building a single model for all the 9 amps, using FiLM (middle three) or concatenation (last two) as the conditioning mechanism. For conditioning representation, we evaluate LUT and the proposed tone embedding (‘ToneEmb’) with either paired or unpaired reference (cf. Section 3.3). Best results of one-to-many models are highlighted.

Figure 4: A t-SNE visualization of the tone embeddings from the wet signals of the $N = 9$ amps. Each point represents a tone embedding extracted from a wet signal, with color and shape indicating the category of the amp tone. We see 2 big cross-amp clusters and 9 small clusters for each amp, suggesting the ability of the encoder \mathcal{E} to distinguish between different tones based on their embeddings.

ization. Figure 4 shows that the embeddings of the wet signals of the same amp, while differing in musical content, indeed cluster together in the projected 2-D space, demonstrating the efficacy of our encoder \mathcal{E} in capturing tone-related information. Moreover, we see two big clusters, which somehow separate high-gain amps (amps 1–3) from low-gain amps (amps 4–6). There are also overlaps, suggesting some similarity among the amps. Amp 7 is closer to high-gain, while amps 8 and 9 closer to low-gain.

4.2 Efficacy of One-to-many Neural Amp Modeling

Next, we evaluate the efficacy of modeling the 9 target amps, comparing different approaches (one-to-one versus one-to-many), conditioning mechanisms (FiLM or the simpler concatenation), and condition representation (the pro-

posed tone embedding, ‘ToneEmb’ for short, or LUT). We implement all models using GCN as the backbone.

Result shown in Table 1 leads to several observations. From the leftmost column, we see low-gain amps seem easier to model than crunch amps, while high-gain amps are the most challenging (i.e., with higher testing losses). Signals from a high-gain amp are highly-distorted, with more high-frequency components that may be harder to be modeled. Similar trends can be seen from other columns.

The middle columns show the result of the one-to-many GCN with FiLM conditioning (‘FiLM-GCN’). Firstly, we see the losses are in general higher than those of the one-to-one non-conditional baseline. This is expected, as we treat the result of the one-to-one model as a performance upperbound, for one-to-one modeling is inherently easier. Among the three variants of FiLM-GCN, ToneEmb with unpaired reference leads to the best result for most amps, reducing greatly the performance gap between the one-to-one approach and the variant with the straightforward LUT-based conditioning representation. While LUT only learns N unique embeddings ϕ , one for each amp, ToneEmb is much more versatile as it computes a unique embedding for each reference wet signal. It seems that the ToneEmb embeddings are thereby information richer, benefiting multi-amp modeling.

For ToneEmb, we initially expect that the advantage of ‘unpaired reference’ over ‘paired reference’ is on zero-shot learning of unseen amps. For seen amps, paired reference simply uses the target wet signal \mathbf{y} as the reference signal \mathbf{z} , providing direct and potentially stronger condition signals. To our surprise, while both ‘ToneEmb (paired)’ and ‘ToneEmb (unpaired)’ greatly outperform the LUT approach, the unpaired approach slightly outperforms the paired approach for most amps. This may be due to the stronger incentive of style/content disentanglement induced by unpaired referencing, as discussed in Section 3.3, but more empirical studies (which we leave as future work) are needed to confirm this.

	non-retrieval	retrieval-based	
	$(\phi^* = \mathcal{E}(z^*))$	nearest	mean
unseen high gain	0.2511	0.2560	0.2593
unseen low gain	0.0338	0.0274	0.0404

Table 2: Efficacy of using different methods for FiLM-GCN (cf. Section 3.4) for zero-shot modeling of two unseen amps, measured again in complex STFT loss.

Finally, Table 1 shows that the ablated version of using concatenation as the conditioning mechanism leads to worse results most of the time. We hence use FiLM-GCN trained with unpaired referencing in experiments below.

4.3 Zero-shot Learning on Unseen Amplifiers

To investigate the potential of the proposed methodology on zero-shot learning, we create wet signals using two “unseen” amplifiers—*High Gain EL34 V2* (high gain) and *Dumble ODS 50* (low gain)—using the clean signals from the test set, and use them as the reference signals z^* for FiLM-GCN, to see whether it can learn the tones zero-shot. Namely, both the content and style are unseen at training time. Here, we evaluate the non-retrieval-based method of using $\phi^* = \mathcal{E}(z^*)$ and the two retrieval-based methods introduced in Section 3.4.

Table 2 shows that the non-retrieval-based method slightly outperforms the other two for the unseen high-gain amp, while nearest-embedding performs the best for the unseen low-gain amp. More importantly, comparing the losses tabulated in Tables 1 and 2, we see that the loss for the unseen low-gain amp is not greatly larger than the loss for the seen low-gain amps, only 1–2 times larger. The loss of the unseen high-gain amp is a bit high, but is only about 2 times larger than those of the seen high-gain amps. We take this as a positive indication of the efficacy of the proposed model in dealing with unseen tones.

Table 2 also shows that mean-embedding performs the worst, adding support of using more versatile embeddings for conditioning. In this regard, the non-retrieval-based method is actually more flexible than nearest-retrieval, as it can compute the reference embedding ϕ^* on-the-fly without referring to a pre-computed presumably large collection of embeddings. Future work can be done to study its effectiveness with more amps (i.e., larger N).

4.4 Case Study on Zero-shot Amp Tone Transfer

To further study the zero-shot scenario, we present finally a case study employing a self-recorded (by one of the authors) guitar solo audio signal with content and tone both unseen at the training time. This recording was captured using a Boss GT-1000 effects processor with a default factory preset based on a high-gain Marshall amplifier setting. The effect chain included not only this unseen amp but also an equalizer (EQ) with a high-cut filter at 10kHz.

The visualization of the spectrograms shown in Figure 5 suggests that the generated result possesses characteris-

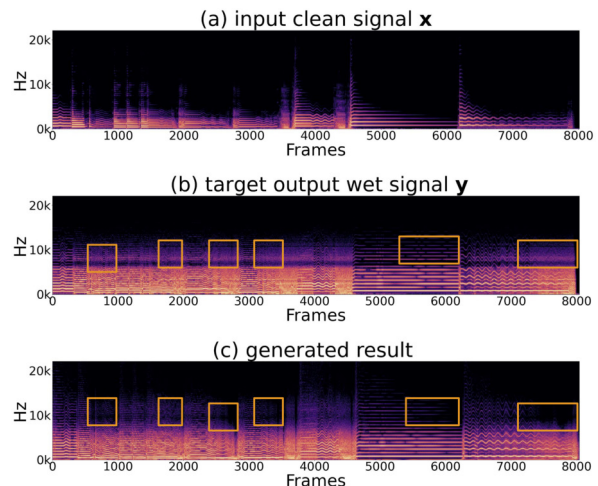

Figure 5: Spectrograms of the input clean signal, target wet signal, and the generated result of the proposed one-to-many FiLM-GCN model, in the zero-shot case study reported in Section 4.4. The orange squares show that our model still struggles to model high-frequency components.

tics similar to those of the target wet signal, but there are notable difference in the high-frequency area. Since we do not consider EQ as a modeling target, our model cannot produce filter-based effects on the signal, resulting in additional harmonics in the spectrum. Furthermore, the sustain of each note is not perfectly reproduced, as the harmonics in the highlighted orange squares are not sequentially connected compared to the case of the target, indicating a struggle to model the high-frequency content accurately.

Despite these limitations, our model can still generate reasonable harmonics according to the input. For the quick string-bending content around frames 6,000 to 7,000, the generated harmonics are correctly damped. Our tone embedding encoder recognizes that the tone of the reference signal is closer to high-gain, empowering the generator to process the input accordingly. We provide audio samples in the supplementary material, including a multi-track recording and a remixed audio created by rendering multiple track separately using our model.

5. CONCLUSION

In this paper, we have presented an end-to-end one-to-many methodology that uses conditions from a tone embedding encoder to emulate multiple guitar amps through a single model, providing empirical evidences of its potential for zero-shot amp modeling. Moving forward, several avenues for future work emerge. First, for more comprehensive audio effect modeling, we can apply our methodology with various configurations of audio effect chains. Second, we can further improve the model’s effectiveness on one-to-many modeling by incorporating more advanced architectures and conditioning mechanisms, such as hypernetwork-based conditioning [9, 38]. Finally, for more effective zero-shot tone transfer, we can train the model on a wider range of amplifier types, which might also pave the way for universal amplifier modeling.

6. ACKNOWLEDGEMENTS

We thank Positive Grid for assistance with the datasets, guitar effect plugins, and for sharing the tone embedding model mentioned in Section 3.1. This work is also partially supported by a grant from the National Science and Technology Council of Taiwan (NSTC 112-2222-E-002-005-MY2).

MEL-ROFORMER FOR VOCAL SEPARATION AND VOCAL MELODY TRANSCRIPTION

Ju-Chiang Wang Wei-Tsung Lu Jitong Chen

ByteDance, San Jose, CA, USA

ju-chiang.wang@bytedance.com

ABSTRACT

Developing a versatile deep neural network to model music audio is crucial in MIR. This task is challenging due to the intricate spectral variations inherent in music signals, which convey melody, harmonics, and timbres of diverse instruments. In this paper, we introduce Mel-RoFormer, a spectrogram-based model featuring two key designs: a novel Mel-band Projection module at the front-end to enhance the model’s capability to capture informative features across multiple frequency bands, and interleaved RoPE Transformers to explicitly model the frequency and time dimensions as two separate sequences. We apply Mel-RoFormer to tackle two essential MIR tasks: vocal separation and vocal melody transcription, aimed at isolating singing voices from audio mixtures and transcribing their lead melodies, respectively. Despite their shared focus on singing signals, these tasks possess distinct optimization objectives. Instead of training a unified model, we adopt a two-step approach. Initially, we train a vocal separation model, which subsequently serves as a foundation model for fine-tuning for vocal melody transcription. Through extensive experiments conducted on benchmark datasets, we showcase that our models achieve state-of-the-art performance in both vocal separation and melody transcription tasks, underscoring the efficacy and versatility of Mel-RoFormer in modeling complex music audio signals.

1. INTRODUCTION

Modeling musical audio signals with deep neural networks (DNNs) for MIR tasks has emerged as a vibrant and promising area of research [1–5]. Most of such DNN models are built upon the spectrogram, a fundamental frequency-time representation of audio signals. Traditional approaches typically treat the spectrogram as a sequence of spectra over time, with the frequency axis representing the feature dimension. However, recent advancements have encompassed explicit modeling of the frequency dimension as a sequence in their architecture designs [5–9], recognizing its rich semantic information in music audio

signals, including melody, harmonics, and instrument timbres. These architectures have showcased state-of-the-art performance in various MIR tasks such as vocal melody extraction [5], section segmentation [10], instrument transcription [8], and music source separation [11], leveraging the model’s ability to discern spectral patterns effectively.

The Transformer architecture [12] has demonstrated remarkable efficacy not only in Natural Language Processing but also in various MIR tasks, where it excels at modeling sequences to predict high-level musical semantics such as tags, beats, chords, sections, and notes [5, 8–10, 13–15]. However, its potential to accurately predict low-level audio signals remained uncertain. Lu et al. proposed a novel architecture, called BS-RoFormer [11], to tackle the task of music source separation (MSS), which aims to separate audio recordings into musically distinct sources such as vocals, bass, and drums [16, 17]. Inspired by the Band-Split RNN (BSRNN) model [7], BS-RoFormer adopts the interleaved sequence modeling, treating time and frequency dimensions as two separate sequences. Notably, it replaces Recurrent Neural Networks (RNNs) with Transformer encoders, demonstrating exceptional performance. This was evident in its first-place ranking and substantial margin of performance gain over the runner-up in the Music Separation track of the Sound Demixing Challenge 2023 (SDX’23) [18].

Another key attribute contributing to the success of BS-RoFormer is the band-split module at the front-end. Traditional Transformer-based models typically rely on a Convolutional Neural Network (CNN) front-end to extract features from the spectrogram for the succeeding Transformer blocks (e.g., [5, 13, 19]). However, CNNs are not inherently designed to model two spectral events that are far apart in frequency, which could limit the model to characterize detailed spectral patterns. In contrast, the band-split module divides the frequency dimension into a number of subbands and employs multi-layer perceptrons (MLPs) to directly project the raw subband spectrograms into a sequence of band-wise features for the succeeding Transformer to model it along the frequency axis. From another perspective, the band-split mechanism can be seen as a set of learnable band-pass filters, underscoring the importance of designing an effective band-division scheme.

In this paper, we introduce *Mel-RoFormer*, which is a successor of BS-RoFormer with an enhanced band-division scheme that leverages the Mel-scale [20] to improve the model’s generalization ability. The Mel-scale is

engineered to mimic the non-linear perception of sound by the human ear, exhibiting higher discrimination at lower frequencies and reduced discrimination at higher frequencies. It has a long history as a reference for designing acoustic features [21] such as MFCC and mel-spectrogram in audio signal processing. We develop the Mel-band mapping based on the Mel-scale, resulting in a band-division that generates overlapping subbands in frequency. In contrast, the band-split scheme in BS-RoFormer is defined empirically and produces non-overlapping subbands.

Mel-RoFormer is applied to address two fundamental MIR tasks: vocal separation and vocal melody transcription, which involve isolating singing voices from audio mixtures and transcribing their lead melodies, respectively. Mel-RoFormer demonstrates superior performance compared to BS-RoFormer and other MSS models in experiments. For vocal melody transcription, we propose a two-step approach instead of training a unified model. We first pretrain a vocal separation model and then fine-tune it for vocal melody transcription. The resulting model achieves state-of-the-art performance across all metrics and exhibits strong robustness in detecting note offsets, which is considered to be the most challenging aspect of the task [22].

Readers can refer to the open-sourced implementation¹ and configurations² for Mel-RoFormer and its variants.

2. RELATED WORK

To address the capabilities of DNN models that pay attention to modeling the frequency dimension for MIR tasks, SpecTNT is one of early successful attempts. Central to SpecTNT’s architecture is the TNT block, where two Transformer encoders are strategically arranged to model along both frequency and time axes. A novel concept introduced by SpecTNT is the Frequency Class Token (FCT), which serves to bridge of the two Transformers, enabling the interchangeability of embeddings across both axes within the TNT block. However, SpecTNT relies on CNNs at the front-end, and the FCT is obtained through aggregating features from the frequency sequence, potentially leading to information loss. Nonetheless, SpecTNT has showcased remarkable performance across various MIR tasks such as beat tracking [14], chord recognition [5], structure segmentation [10], and vocal melody estimation [5]. Its successor, Perceiver TF [8], is designed to enhance efficiency while demonstrating outstanding performance in multitrack instrument/vocal transcription tasks.

Moving on to MSS, a key MIR task that has significantly benefited from DNNs, approaches typically span frequency-domain and time-domain methodologies. The benchmark MUSDB18 dataset [23] offers 4-stem sources including vocals, bass, drums, and others, adhering to the definition established by the 2015 Signal Separation Evaluation Campaign (SiSEC) [24]. Frequency-domain approaches rely on spectrogram-based representations as input, leveraging models such as fully connected neural net-

works [25], CNNs [26–28], and RNNs [29] to achieve separation. Conversely, time-domain approaches such as Wave-U-Net [30], ConvTasNet [31], and Demucs [32] construct their DNNs directly on waveform inputs. Recently, Hybrid Transformer Demucs (HTDemucs) [33] has proposed a novel approach, utilizing a cross-domain Transformer to amalgamate both frequency- and time-domain models, showcasing promising potential in this field. However, none of the mentioned approaches employ Transformers to model the inter-context of frequency and time as two separate sequences.

The output of vocal melody transcription is a sequence of non-overlapping notes, each comprising onset and offset times along with a pitch key, assuming the melody is monophonic. Due to limited training data availability, only a few studies have focused on transcribing note-level outputs from polyphonic music audio, underscoring the significance of pre-training [34] or semi-supervised [35] techniques. Recently, Wang et al. released a human-annotated dataset comprising 500 Chinese songs [36], along with a baseline CNN-based model. Donahue et al. [34] propose leveraging pre-trained representations from Jukebox [37] to enhance melody transcription, primarily focusing on lead instruments such as synthesizers, guitars, piano, and vocals. They curate a dataset of 50 hours of melody transcriptions sourced from crowdsourced annotations. However, clarity regarding the quality and identification of vocal melody annotations within songs remains lacking. In [35], a teacher-student training scheme is introduced to leverage pseudo labels derived from fundamental frequency (F0) estimations of vocals. On the other hand, [38] presents a system that necessitates a vocal separation as a front-end. In our approach, we employ vocal separation as a pre-trained model for fine-tuning a specialized model, which can be more efficient and task-optimal.

3. MODEL

Figure 1 illustrates the diagram of Mel-RoFormer, consisting of three major modules: Mel-band Projection, RoFormer blocks, and Embedding Projection. Subsequent subsections will delve into the Mel-band Projection and Embedding Projection modules, while readers can find further details on the RoFormer blocks in [11], where they are referred to as “RoPE Transformer blocks.”

Mel-RoFormer takes the input of a complex spectrogram X with dimensions $(C \times F \times T)$, where C , F , and T denote the number of channels, frequency bins, and time steps, respectively. This frequency-time representation X is typically obtained via a short-time Fourier transform (STFT), encompassing both real and imaginary parts. In stereo mode, C is defined as $2 \times 2 = 4$, reflecting the presence of two channels for real and imaginary spectrograms. The output of Mel-RoFormer is denoted by Y , with dimensions $(Z \times T)$, where Z and T represent the number of output features and time steps, respectively. One can treat Y as the feature matrix over time. Depending on the downstream tasks, appropriate values for Z can be set, and Y can be rearranged accordingly, as detailed in Section 4.

Figure 1. The diagram of Mel-RoFormer, which consists of three major modules: Mel-band Projection, RoFormer Blocks, and Embedding Projection. The input is a Complex Spectrogram, and the output is an Embedding tensor, which can be rearranged into the desired shape.

Figure 2. Illustration of Mel filter-bank with 7 bands. In this example, the length of frequency bins is 1024. Here, the frequency bins from 1 to 46 are encompassed by the 0-th Mel-band (i.e. \mathcal{F}_0), those from 24 to 77 are encompassed by the 1-th Mel-band (i.e. \mathcal{F}_1), and so forth.

3.1 Mel-band Projection Module

The Mel-band Projection module comprises a frequency-to-Mel-band mapping and a set of K multi-layer perceptrons (MLPs). Each subband of X is denoted as X_k with dimensions $(C \times |\mathcal{F}_k| \times T)$, where $\mathcal{F}_k \in \{0, 1, \dots, F-1\}$ represents the indices of frequency bins for the k -th subband, and F is the length of frequency bins.

The frequency-to-Mel-band mapping, represented as $\{\mathcal{F}_k\}_{k=0}^{K-1}$, stems from the Mel filter-bank, as depicted in Fig. 2, where triangular-shaped filters are centered at different Mel frequencies on the Mel-scale. The indices of non-zero values of a filter correspond to the frequency bins of the respective Mel-band. Mathematically, the Mel-scale follows a quasi-logarithmic function of acoustic frequency, ensuring that perceptually similar pitch intervals (e.g., octaves) possess equal width across the entire audible range. The width of a Mel-band (i.e., $|\mathcal{F}_k|$) is twice the distance between its center and the center of the preceding Mel-band. Consequently, the latter half of a Mel-band overlaps with its subsequent Mel-band, and so forth, until reaching the final Mel-band. In contrast, due to the band-split design in BS-RoFormer [11], the frequency ranges of different subbands do not overlap. The Mel-band Map depicted in Fig. 1 exemplifies the frequency-to-Mel-band mapping, illustrating a binary relationship between 1024 frequency bins and 7 Mel-bands.

The input X_k is rearranged into a shape of $(C|\mathcal{F}_k| \times T)$ for the MLP layer. The k -th MLP, denoted as Λ_k , com-

prises an RMSNorm layer [39] followed by a linear layer. The linear layer transforms from $C|\mathcal{F}_k|$ dimensions to D dimensions, where D is the number of latent features. The resulting outputs $\{\Lambda_k(X_k)\}_{k=0}^{K-1}$ are stacked to form a shape of $(D \times K \times T)$, serving as input to the subsequent RoFormer blocks. The Mel-band Projection module can be conceptualized as a learnable Mel filter-bank, with the MLP layer functioning as the mechanism to learn the filters. This grants the model greater flexibility in determining the optimal shapes for different filters, without being confined to predefined filter designs such as triangle-shaped ones (see Fig. 2).

3.2 RoFormer Blocks

The RoFormer blocks consist of a stack of L interleaved RoPE Transformer encoders [40]. The interleaved sequence modeling processes the data across time (T) and subband (K) dimensions alternately. In BS-RoFormer [11], the authors observed that Rotary Position Encoding (RoPE) played a crucial role in enhancing Transformer performance compared to using traditional absolute position encoding. It is suggested that RoPE aids in preserving the positional information within the sequence, making it invariant to repetitive processes of rearrangement.

Specifically, the data is first rearranged into a time-indexed shape of $(DK \times T)$, allowing modeling across time. Subsequently, it is rearranged into a band-indexed shape of $(DT \times K)$, facilitating modeling across subbands. The former step treats the data as a time sequence, while the latter treats it as a subband sequence. By repeating this process, information from different time steps and subbands becomes interchangeable, thereby enhancing the model’s ability to generalize.

3.3 Embedding Projection Module

The Embedding Projection module plays a crucial role in generating suitable embeddings necessary for various downstream tasks. It has been observed that utilizing MLPs can lead to more effective mask estimation compared to using plain linear layers in source separation tasks [41]. Our preliminary investigation also suggests that removing this module can result in unstable training.

This module comprises K individual MLPs, denoted as Φ_k , each containing an RMSNorm layer, a linear layer followed by a Tanh activation, and another linear layer followed by a gated linear unit (GLU) layer [42]. The first linear layer transforms from D to $4D$ dimensions, while the subsequent linear layer with GLU transforms from $4D$ to a desired length Z_k . Here, Z_k specifies the number of output features for Φ_k based on its specific purpose, as elaborated in Section 4. All the MLP outputs are concatenated along the feature dimension, resulting in a final output shape of $(Z \times T)$, where $Z = \sum_k Z_k$.

4. DOWNSTREAM TASKS

This section details the application of Mel-RoFormer tailored for vocal separation and vocal melody transcription.

4.1 Vocal Separation

For vocal separation, the Embedding Projection estimates the mask for the complex spectrogram. Each MLP Φ_k is designed to align its output shape with that of the corresponding input Mel-band complex spectrogram, with Z_k set as $C|\mathcal{F}_k|$. The output Y is rearranged into

$$[\hat{\Phi}_0, \hat{\Phi}_1, \dots, \hat{\Phi}_{(K-1)}], \quad (1)$$

with dimensions $(C \times \hat{Z} \times T)$, where $\hat{\Phi}_k$ with a shape of $(|\mathcal{F}_k| \times T)$ is the output corresponding to the k -th Mel-band, and $\hat{Z} = \sum_k |\mathcal{F}_k|$. Because adjacent Mel-bands overlap, the estimated mask values of the overlapping frequency bins are averaged:

$$\hat{M}[c, f, t] = \frac{1}{S_f} \sum_k \hat{\Phi}_k[c, f, t], \quad (2)$$

where \hat{M} represents the estimated mask, c , f , and t are the indices of channel, frequency bin, and time step, respectively, and S_f is the count of the overlapping frequency bins. The estimated mask \hat{M} has the same shape $(C \times F \times T)$ as that of the input X , encompassing both the real and imaginary parts of the complex spectrogram.

We utilize complex Ideal Ratio Masks (cIRMs) [43] as our optimization goal for the vocal separation model. The estimated mask \hat{M} derived from Embedding Projection can serve as the cIRMs. The separated complex spectrogram \hat{Y} is obtained by element-wise multiplication of the cIRM with the input complex spectrogram: $\hat{Y} = \hat{M} \odot X$. Subsequently, an inverse STFT (iSTFT) is applied to \hat{Y} to reconstruct the separated signal \hat{y} in the time-domain.

Let ψ denote the target time-domain signal, and $\Psi^{(w,r)}$ denote the corresponding complex Spectrogram using a window size w and time-resolution r for STFT. We employ the mean absolute error (MAE) loss to train the cIRMs \hat{M} . Specifically, the objective loss encompasses both the time-domain MAE and the multi-resolution complex spectrogram MAE [44]:

$$\mathcal{L} = \|\psi - \hat{y}\| + \sum_{w \in W, r \in R} \|\Psi^{(w,r)} - \hat{Y}^{(w,r)}\|, \quad (3)$$

where the configurations for multi-resolution STFTs cover 5 window sizes with $W = \{4096, 2048, 1024, 512, 256\}$, and 2 resolutions with $R = \{100, 300\}$ frames per second.

4.2 Vocal Melody Transcription

Instead of starting training from scratch, we utilize a pre-trained vocal separation Mel-RoFormer and fine-tune it for vocal melody transcription. Given that the Embedding Projection module in the pre-trained vocal separation model functions as a mask estimator, it might inherently possess biases towards signal-level semantics. Therefore, we opt to replace the pre-trained Embedding Projection with a newly initialized one, with a modification specifically on the output dimension. To ensure equal contribution from each Mel-band to the feature dimension, we set a uniform value of 64 for all Z_k 's. The resulting embeddings take the shape of $(64K \times T)$, with a $64K$ -dimensional feature vector for each time step.

We adopt the "onsets and frames" approach [45], employing two frame-wise predictors: an onset predictor and a frame predictor, both of which receive embeddings from Mel-RoFormer. The onset predictor identifies the onset event of a pitched note, while the frame predictor determines the continuation of a pitched note. This design facilitates a post-processing method where the initiation of a new note is determined only if the onset predictor indicates the start of a pitch, and simultaneously, the frame predictor confirms the presence of an onset for that pitch within the succeeding frames. The onset and frame predictors operate at a time-resolution of 50 frames per second. In cases where the Mel-RoFormer embeddings do not match this time-resolution, we employ 1-D adaptive average pooling over the time dimension.

We employ an MLP layer for the onset predictor, consisting of a linear layer followed by a Rectified Linear Unit (ReLU), dropout with a rate of 0.5, and another linear layer. The linear layer has 512 hidden channels, and the output dimension is set to 60, representing 60 supported pitches. For the frame predictor, a single linear layer is utilized, outputting 61 pitch classes, with one indicating non-pitch. Binary cross-entropy losses of the two predictors are summed as the final loss to train the entire model. The thresholds for the onset and frame predictors are set at 0.45 and 0.25, respectively.

5. EXPERIMENT

Our experiments cover vocal separation and vocal melody transcription. In the vocal separation evaluation, we train and test two types of models: the first on 44.1kHz stereo audio recordings, and the second on 24kHz mono audio recordings. Next, we utilize the model trained on 24kHz mono audio recordings as the pre-trained model for fine-tuning in the vocal melody transcription evaluation.

5.1 Datasets

Table 1 overviews the datasets used in this study. We use four public datasets for evaluation. The data splitting ad-

Dataset	Task	Songs	Split
MUSDB18HQ [23]	sepa	150	train 100, test 50
MoisesDB [46]	sepa	240	train 200, val 40
MIR-ST500 [36]	trans	500	train 330, val 37, test 98
POP909 [47]	trans	909	train 750, val 50, test 109
In-House	sepa	1533	train 1433, val 100

Table 1. Summary of the datasets used in this study. Abbreviations: ‘sepa’: vocal separation, ‘trans’: vocal melody transcription, ‘val’: validation.

heres to the official guidelines of each dataset, except for POP909, where songs with IDs ranging from 801 to 909 are reserved for testing. The ‘Split’ column of Table 1 indicates the numbers of songs allocated for training, validation, and testing. All data for separation tasks are stereo recordings with a sampling rate of 44.1kHz, and stem-level recordings are pre-mixed into four stems: vocals, bass, drums, and other. The audio of transcription data was re-sampled to mono with a 24kHz sampling rate to follow the conventional setting [38]. Although access to some songs in MIR-ST500 was restricted, our test set, comprising 98 songs, closely resembles the original setting of 100 songs.

5.2 Configuration for Vocal Separation

To obtain the frequency-to-Mel-band mapping, we employ the Mel filter-bank implementation in librosa [48], which emulates the behavior of the function in MATLAB Auditory Toolbox [49]. By using `librosa.filters.mel`, we acquire the mapping matrix comprising a triangle filter for each Mel-band. Subsequently, we binarize this matrix by setting all non-zero values to 1, thereby discarding the triangle filters. This process yields the Mel-band Map depicted in Figure 1.

We follow the method outlined in [11] for performing random remixing data augmentation. This strategy involves cross-dataset stem-level combination, resulting in a significantly larger number of examples than the original size of the datasets combined.

Tree evaluation scenarios are considered: ① *musdb18-only*: train a 44.1kHz stereo model only on the MUSDB18-HQ training set; ② *all-data*: all additional data, including MUSDB18HQ, MoisesDB, and In-House, are used to train a 44.1kHz stereo model; ③ *musdb18+moisesdb*: MUSDB18HQ and MoisesDB are resampled to train a 24kHz mono model, serving as the pre-trained model for fine-tuning for the melody transcription task.

Our main baseline is BS-RoFormer [11]. For scenarios ① and ②, we set the parameters as follows: $T=800$ (8-second chunk), $K=60$, $D=384$, $L=12$, and a window size of 2048 and a hop size of 441 for STFT. In scenario ③, two models are trained: *24k-small* and *24k-large*. The small model uses $T=300$ (6-second chunk), $K=32$, $D=128$, $L=12$; while the large model uses $T=300$ (6-second chunk), $K=32$, $D=256$, $L=24$. Both models adopt a window size of 1024 and a hop size of 480 for STFT. All the separation models use the “overlap & average” de-framing method [11] with a hop of half a chunk. These

Model	Vocals	# Param
HDemucs [52] [†]	8.04	-
Sparse HT Demucs [33] [†]	9.37	-

TFC-TDF-UNet-V3 [53] [†]	9.59	-
BS-RoFormer ①	11.49	93.4M
Mel-RoFormer ①	12.08	105M
BS-RoFormer ② [†]	12.82	93.4M
Mel-RoFormer ② [†]	13.29	105M

Tested with resampled 24kHz mono audio

BS-RoFormer (24k-small) ③	10.56	8.0M
Mel-RoFormer (24k-small) ③	11.01	9.1M
BS-RoFormer (24k-large) ③	12.19	48.4M
Mel-RoFormer (24k-large) ③	12.69	50.7M

Symbol † indicates models trained with extra data. Symbols ①, ②, and ③ indicate the three evaluation scenarios.

Table 2. Result (in SDR) on MUSDB18HQ test set.

above mentioned settings remain consistent between Mel-RoFormer and BS-RoFormer.

For training, we utilize the AdamW optimizer [50] with a learning rate (LR) of 0.0005. The LR is reduced by 10% every 40k steps. To optimize GPU memory usage, we employ flash-attention [51] and mixed precision. Specifically, the STFT and iSTFT modules use FP32, while all other components use FP16. Regarding hardware configurations, we employ different setups for each scenario. In scenario ①, 8 Nvidia A-100-80GB GPUs with `batch_size=64` are used, and the training stopped at 400K steps (~40 days). For scenario ②, 16 Nvidia A100-80GB GPUs with `batch_size=128` are utilized, and the training halted at 1M steps (~93 days). In scenario ③, 16 Nvidia V100-32GB GPUs with `batch_size=96` are used, and the training stopped at 500K steps (~31 days).

The reason to use a large number of training steps is driven by the continuous improvement observed in the model’s performance, coupled with the absence of overfitting. This can be attributed to two main factors: the effect of the random remixing augmentation and the inherent capability of the model itself. These factors contribute to the model’s ability to continuously learn and adapt to the training data, resulting in sustained performance improvements without encountering overfitting issues.

5.3 Result for Vocal Separation

Table 2 presents the results, with the signal-to-distortion ratio (SDR) values [54] computed by `museval` [55] as the evaluation metric. The median SDR across the median SDRs over all 1-second chunks of each test song is reported, following prior conventions. Several representative existing models are included for comparison.

From the result, we see that Mel-RoFormer achieve state-of-the-art performance. It is evident that Mel-band Projection significantly enhances vocal separation performance, leading to a consistent improvement over BS-

RoFormer, with an average gain of 0.5 dB across all scenarios. This showcases the effectiveness of the Mel-band mapping scheme in capturing human voices. Qualitative analysis indicates that Mel-RoFormer produces smoother vocal sounds with more consistent loudness. On the other hand, the 24kHz mono model also performs admirably, which bodes well for downstream tasks like vocal melody transcription, as they do not necessitate high-quality audio with high sampling rates. Furthermore, the smaller model with 9.1M parameters achieves over 11 dB, demonstrating its potential for resource-constrained environments.

5.4 Configuration for Vocal Melody Transcription

Three evaluation scenarios are studied: ④ trained on MIR-ST500; ⑤ trained on POP909, and ① trained on a combination of MIR-ST500 and POP909. With $T=300$ and $K=32$ for Mel-RoFormer, the resulting embedding matrix for the onset and frame predictors has a shape of (2048×300) , representing a 6-second input with a frame rate of 50Hz. We also consider a variant that is trained from scratch without a pre-trained model.

For fine-tuning, we use the AdamW optimizer with a LR of 0.001 for the onset and frame predictors and 0.0001 for the Mel-RoFormer module. The LR is reduced by 10% with a patience of 15 epochs, where an epoch comprises 100 steps. The best model is selected based on validation performance for testing.

For baselines, we implement SpecTNT [5] and MERT [15]. SpecTNT features 5-layer TNT blocks and is trained with the random mixing augmentation method outlined in [8]. For MERT, we use the pre-trained weights of “MERT-

v1-330M,” where the model accepts 5-second input with a 24kHz audio sampling rate and produces embeddings with a shape of (1024×375) . All mentioned models are trained or fine-tuned using 8 Nvidia V100-32GB GPUs.

Evaluation metrics include the F-measures of Correct Onset (COn), Correct Onset and Pitch (COnP), and Correct Onset, Pitch, and Offset (COnPOff). These metrics are computed using `mir_eval` [57], with a pitch tolerance of 50 cents and a time tolerance of 50 ms. For POP909, we adjust the time tolerance to 80ms due to the less precise nature of note onsets and offsets in its labeling method [47].

5.5 Result for Vocal Melody Transcription

Tables 3 and 4 display the results on MIR-ST500 and POP909, respectively, featuring a comparison with various existing models. It is worth noting that fine-tuning a pre-trained model typically converges in fewer than 15K steps, while training from scratch requires significantly more steps (e.g., 50k steps) and yields significantly inferior performance compared to fine-tuned models.

Several key observations emerge from the results. Firstly, our proposed model (Mel-RoF-large and Mel-RoF-small) achieves state-of-the-art performance across all metrics on both MIR-ST500 and POP909, showcasing its effectiveness. Particularly noteworthy is the substantial performance improvement in COnPOff over the baselines (e.g., a 7.5 percentage point increase in Mel-RoF-large compared to SpecTNT), highlighting the robustness of Mel-RoFormer in accurately determining full notes, including onset, pitch, and offset. This can be attributed to its capability to extract clean singing voices, thereby minimizing the influence of irrelevant instruments. Comparing our models to MERT underscores the superiority of Mel-RoFormer, owing to its architectural design and pre-training with a relevant task. This emphasizes the importance of explicitly modeling frequency with Transformers and suggests that the separation task can be a valuable objective when training a foundation model.

Cross-comparing MIR-ST500 and POP909, we note that annotations are relatively more consistent in MIR-ST500. In contrast, POP909 exhibits errors primarily at note offsets, along with global time shifts in several songs. Consequently, we accept a larger time tolerance of 80 ms in the evaluation scenario. Particularly, in scenario ①, training with combined datasets improves test performance on POP909 but degrades that of MIR-ST500, consistent with our observations about labeling quality.

6. CONCLUSION

We have presented the Mel-RoFormer model, which integrates the Mel-band Projection scheme to enhance its ability to model musical signals effectively. Our experiments have shown highly promising results in vocal separation and vocal melody transcription. These findings suggest the potential of Mel-RoFormer as a foundation model for various other MIR tasks, including chord recognition and multi-instrument transcription [58].

ABSTRACT

The field of Optical Music Recognition (OMR) focuses on models capable of reading music scores from document images. Despite its growing popularity, OMR is still confined to settings where the target scores are similar in both musical context and visual presentation to the data used for training the model. The common scenario, therefore, involves manually annotating data for each specific case, a process that is not only labor-intensive but also raises concerns regarding practicality. We present a methodology based on training a neural model with synthetic images, thus reducing the difficulty of obtaining labeled data. As sheet music renderings depict regular visual characteristics compared to scores from real collections, we propose an unsupervised neural adaptation approach consisting of loss functions that promote alignment between the features learned by the model and those of the target collection while preventing the model from converging to undesirable solutions. This unsupervised adaptation bypasses the need for extensive retraining, requiring only the unlabeled target images. Our experiments, focused on music written in Mensural notation, demonstrate that the methodology is successful and that synthetic-to-real adaptation is indeed a promising way to create practical OMR systems with little human effort.

1. INTRODUCTION

Encoding and transcribing sheet music by hand is a complex and error-prone task that often requires individuals with specialized knowledge of the music notation at hand. An alternative to this manual digitization is the utilization of advanced artificial intelligence technologies, which enable the automated interpretation of musical documents. This technology is known as Optical Music Recognition (OMR) [1].

OMR has been a subject of research for several years [2], experiencing slow progress initially [3]. However, the recent adoption of advanced machine learning techniques, notably Deep Learning, has catalyzed significant improvements in the field [4]. Current OMR systems, albeit not fully perfected, present a more efficient and accurate alternative to manual transcription efforts [5].

In the context of machine learning, existing literature reports models that achieve satisfactory levels of accuracy when processing collections that share graphic characteristics with the training corpus [6–9]. This situation poses challenges for applying OMR technology to new collections, as it is not always feasible, practical, or resource-efficient to dedicate efforts towards annotating a segment of the target collection for training purposes.

This work explores the potential of creating OMR models to address diverse music collections by leveraging synthetic data for training. Given the vast availability of symbolic music data and score engraving tools, generating synthetic data for training presents itself as a viable and promising approach. However, the significant graphical disparities between renderings and real music collections suggest that a straightforward application of such synthetic data might not suffice. To address this issue, we consider the strategy proposed by Alfaro-Contreras & Calvo-Zaragoza [10], aimed at adapting pre-trained transcription models—in our case, initially trained on synthetic data to accommodate real-world music collections. Some previous works on OMR also implement domain adaptation but in other related tasks such as layout analysis [11] or music-object detection [12].

Our experimentation focuses on early monophonic music written in Mensural notation, as there exists a significant number of collections in this notation, each with specific characteristics. This abundance enables us to conduct a thorough examination, aiming to derive conclusions that are broadly applicable and representative. We will use the same synthetic data (and model) to independently adapt to five different Mensural collections. Our experiments indicate that our approach enables consistent synthetic-to-real adaptation, leading to notable improvements in many settings compared to the baseline. While there is still potential for better adaptation, our method represents a significant step towards developing practical OMR models that do not rely on corpus-specific labeled data.

2. BACKGROUND

The traditional OMR pipeline comprises four stages [13]: (i) *image pre-processing*, which includes tasks such as binarization, distortion correction, or staff separation; (ii) *music symbol detection*, which involves steps such as staff-line removal, connected-component search, and classification; (iii) *notation assembly*, which relates the individual identified components to reconstruct the musical notation; and (iv) *encoding*, which exports the recognized notation to a specific language for storage and further computational processing.

With the rise of Deep Learning, the so-called *end-to-end* formulation has emerged as an alternative to OMR. This approach, which has been dominating the state of the art in other applications such as text or speech recognition [14, 15], is currently considered the reference model in OMR. The related literature includes many successful solutions of this type [16–18], often with some prior pre-processing such as staff segmentation [19, 20].

However, as introduced above, there is still no computational approach for creating a universal OMR system; *i.e.*, one that is capable of dealing with any kind of collection. Instead, in this work, we take a more practical strategy that leverages synthetic data and domain adaptation. Synthetic data, generated through score engraving tools, provides a seemingly infinite resource for training machine learning models without the necessity for laborious manual annotation.

Nevertheless, the utilization of synthetic data presents a critical challenge: while synthetic scores are generated under precise, controlled conditions, real-world music scores exhibit a wide variety of visual characteristics. This variance results in a significant domain gap, where models trained exclusively on synthetic data struggle to generalize. Domain Adaptation (DA) becomes essential to reduce performance degradation by fine-tuning a pre-trained model with unlabeled data from the target domain [21]. While DA has been applied to some stages of the legacy OMR workflow [12, 22], its application to end-to-end approaches remains unexplored. Our contribution is the introduction of an unsupervised synthetic-to-real DA method that employs a specific set of loss functions to adapt pre-trained models using only target staff images.

3. METHODOLOGY

The methodology followed in this work is illustrated in Figure 1. First, a general OMR model is trained in a supervised way using synthetic data. Then, before processing a real collection, for which images but no annotations are available, we apply an unsupervised adaptation approach that modifies the pre-trained model. Then, the adapted model is used to perform OMR on the targeted collection.

The following sections describe the operation of the OMR model and the unsupervised adaptation approach.

Figure 1: Overview of the unsupervised synthetic-to-real Optical Music Recognition methodology followed in this work.

3.1 Optical Music Recognition model

Our OMR model works at the staff level, assuming that a certain layout analysis has already detected the different staves of the score, as in recent literature [6, 7, 9, 23]. Then, the goal of the model is to retrieve the sequence of music-notation symbols that appear in a given staff.

The state of the art for the aforementioned formulation is to train a Convolutional Recurrent Neural Network (CRNN), using the so-called Connectionist Temporal Classification (CTC) [9, 23]. The convolutional part learns discriminative features from images, while the recurrent block models these features in terms of music-symbol sequences. CTC allows training without explicit information about the location of the symbols in the image [24], which enables an end-to-end learning framework from just pairs of staff images and corresponding transcripts.

Given a staff image \mathbf{x} , the output of the CRNN is a stochastic sequence $\pi_{\mathbf{x}} = (\pi_{x_1}, \dots, \pi_{x_K})$, $\pi_{x_i} \in [0, 1]^{\Sigma}$, where K is the number of frames (columns) processed by the recurrent block and Σ represents the vocabulary of music-notation symbols.¹ $\pi_{x_i}^{\sigma}$ represents the probability of observing music-notation symbol σ in the i -th frame of the input ($\sum_{\sigma \in \Sigma} \pi_{x_i}^{\sigma} = 1$). The whole sequence $\pi_{\mathbf{x}}$ is often referred to as the *posteriorgram* of \mathbf{x} .

For performing OMR, the posteriorgram is converted into an actual sequence of music-notation symbols by following a *greedy policy* based on retrieving the most probable symbol per frame and applying some direct operations to remove repeated symbols and “blank” tokens.

3.2 Unsupervised adaptation

The model explained in the previous section has demonstrated its goodness in scenarios where the training data belongs to the same collection to be processed. However, this is not interesting in most practical cases, especially when the model is trained with synthetic data, as it barely generalizes to real collections. In this section, we explain the considered approach to adapt a pre-trained model to a (real) target collection using only its images.

Specifically, given a mini-batch $b = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N)$ of target staff images, we fine-tune the pre-trained model with the following loss:

¹ The number of frames is usually less than the number of columns of the original image because the convolutional block typically includes pooling operations.

$$\mathcal{L} = \alpha \cdot \mathcal{L}_a(b) + \beta \cdot \mathcal{L}_r(b) \quad (1)$$

The loss involves two terms, weighted by parameters α and β (to be tuned empirically), respectively: i) one that modifies the model’s weights to perform adaptation to a real collection (\mathcal{L}_a), and ii) a regularization term that prevents meaningless convergence for OMR (\mathcal{L}_r). These are formally introduced in the following sections.

For this adaptation stage, we are not allowed to use the synthetic training corpus, despite being available in our particular case. This is because we are interested in the case for which the original training set is not accessible.

3.2.1 Adaptation term

The first mechanism aims to reduce the discrepancy between the pre-trained model and the target collection by aligning extracted features. Specifically, we approximate the distribution of the pre-trained model as a Gaussian distribution $\mathcal{N}_S(\mu_S, \sigma_S^2)$, using the Batch Normalization (BN) statistics stored in the corresponding layers.² During training, BN normalizes layer outputs within each mini-batch, ensuring zero-mean and unit-variance. Exponentially weighted averages of these mean and variance vectors, represented as μ_S and σ_S^2 , respectively, are stored during training so that they can be used in the prediction phase to perform standardization.

To reduce distribution discrepancies between the pre-trained and the target collection, we fine-tune the layers preceding BN by forcing their extracted features to have mean and variance vectors similar to those of the source data. Specifically, when given batch b , we compute the mean μ_b and variance σ_b^2 . The target batch feature distribution is subsequently approximated as $\mathcal{N}_b(\mu_b, \sigma_b^2)$. We then employ the feature-averaged Kullback-Leibler (KL) divergence to align the target batch feature distribution with the pre-trained feature distribution:

$$\mathcal{L}_a(b) = \mathcal{D}_{\text{KL}}(\mathcal{N}_b || \mathcal{N}_S) \quad (2)$$

This is described in the context of a single BN layer, but it can be applied to many of them by calculating the loss for each and then adding them up.

3.2.2 Regularization

The previous mechanism can lead to an informational collapse, where the model consistently extracts the same features, regardless of the input image, to match the expected distribution. This would lead to eventually predicting the same music-notation symbol in all frames, which is useless for OMR.

Furthermore, we want to encourage predictions that exhibit music-symbol diversity. This can be induced by maximizing entropy within each frame’s predictions across the batch with the following loss:³

² Assuming BN layers for this purpose is a soft constraint since most of the considered CRNN architectures for OMR include these.

³ Note that the equation is negating the entropy so that the loss is performing *maximization* during gradient descent.

$$-\sum_{k=1}^K \sum_{\sigma \in \Sigma} \mathcal{H}(\pi_{\mathbf{b}_k}^\sigma) = \sum_{k=1}^K \sum_{\pi \in \Sigma'_S} \sum_{i=1}^{|\mathbf{b}|} \left(\pi_{x_{i_k}}^\sigma \log \pi_{x_{i_k}}^\sigma \right) \quad (3)$$

Specifically, this term penalizes that the same frame in different samples of the batch provides an identical probability distribution over the vocabulary Σ .

Unfortunately, minimizing Eq. 3 might lead to probabilities for a specific frame to be uniformly distributed. In other words, this encourages the model to predict that all music-notation symbols are equiprobable in each frame. However, these distributions should ideally resemble a one-hot distribution, linking each image frame to a single symbol from Σ . To mitigate this, we must further regularize the model to encourage the predictions to behave as one-hot vectors by minimizing the entropy of each frame’s output:

$$\sum_{i=1}^{|\mathbf{b}|} \sum_{k=1}^K \mathcal{H}(\pi_{x_{i_k}}) = -\sum_{i=1}^{|\mathbf{b}|} \sum_{k=1}^K \sum_{\sigma \in \Sigma} \left(\pi_{x_{i_k}}^\sigma \log \pi_{x_{i_k}}^\sigma \right) \quad (4)$$

Therefore, the regularization term of our unsupervised adaptation process becomes:

$$\mathcal{L}_r(b) = \sum_{i=1}^{|\mathbf{b}|} \sum_{k=1}^K \mathcal{H}(\pi_{x_{i_k}}) - \sum_{k=1}^K \sum_{\sigma \in \Sigma} \mathcal{H}(\pi_{\mathbf{b}_k}^\sigma) \quad (5)$$

where predictions are encouraged to behave like the output of an OMR process, while preventing all predictions from providing the same symbol.

4. DATA

This section covers data handling and preparation, encompassing synthetic data generation to pre-train the model, the considered real datasets for the adaptation experiments, and the encoding of the output vocabulary of the OMR.

4.1 Synthetic data generation

We have considered a modified version of the Printed Images of Mensural Staves (PRIMENS) dataset [9]. The PRIMENS dataset is a synthetic corpus designed to emulate low-quality scans of printed mensural sources. It was obtained by transforming compositions by composers such as Agricola, Frye, and Ockeghem, which are accessible through the Josquin Research Project (JRP)⁴. The original JRP files consist of transcriptions in Common Western Modern notation encoded using `**kern` format. To obtain a Mensural notation dataset, Martínez-Sevilla et al. converted the original files to `**mens` format [25]. Given the polyphonic nature of these compositions, they isolated individual monophonic excerpts by segmenting them into randomly chosen measures spanning from 3 to 18. The

⁴ <https://josquin.stanford.edu/>. Last accessed April 12th, 2024.

authors also modified the original clefs accordingly to increase variability and thus expand the dataset size.

The images were generated using the digital engraver Verovio [26], with random values applied to all available options within permitted ranges. Subsequently, these images were also distorted to mimic genuine printed image scans by employing a random sequence of graphical filters through GraphicsMagick Image Processing System. Furthermore, this simulation of real images was further enhanced by blending randomly damaged old paper textures with distorted images. Figure 2a shows a staff example of the PRIMENS dataset.

When analyzing the music-symbol distribution of the original PRIMENS dataset, we found that it lacked bar lines and custodes, two common elements in Mensural corpora. To standardize the vocabulary, we randomly introduced bar lines with a probability of 10% per monophonic excerpt. Custodes were added at the end of each staff, positioned at the most repeated pitch of that region to ensure meaningful vertical staff alignment.

4.2 Real datasets

We have considered five corpora of Mensural music, both handwritten and typeset:

- CAPITAN corpus [27]: a set of 97 manuscript pages dated from the 17th century of liturgical music. An example of a particular staff from this corpus is depicted in Figure 2b.
- Il Lauro Secco (SEILS) corpus [28]: a collection of 151 typeset pages corresponding to an anthology of Italian madrigals of the 16th century. Figure 2c shows a staff example of this set.
- GUATEMALA corpus [29]: a collection of 385 handwritten pages from a polyphonic choir book, part of a larger collection held at the “Archivo Histórico Arquidiocesano de Guatemala”. An example of a particular staff from this corpus is depicted in Figure 2d.
- MOTTECTA corpus [9]: a set of 297 printed pages from a collection of the “Biblioteca Digital Hispánica” dated from the 17th century. Figure 2e shows a staff example of this set.
- MAGNIFICAT corpus [5]: a set of 127 typeset pages corresponding to a Spanish choir book of the 16th century. See Figure 2f for a sample of this corpus.

4.3 Output encoding

OMR primarily deals with image signals, leading OMR systems to prioritize learning graphic concepts over musical ones. This explains why, when training end-to-end OMR models, an internal representation referred to as “agnostic” is used instead of a semantic representation where music symbols are encoded based on their musical significance [28, 30]. This agnostic representation categorizes elements within a collection of musical symbols according

Figure 2: Staff samples of the synthetic data (a) used to train the initial OMR model, which is then adapted to the five Mensural corpora (b-f).

to their form, representing event duration, and their height or vertical position on the staff, denoting pitch. In essence, each symbol is denoted as the 2-tuple $z_i = \langle f_i, h_i \rangle : f_i \in \Sigma_F, h_i \in \Sigma_H$, where Σ_F and Σ_H represent the spaces for the different form and height labels, respectively. This approach effectively describes all symbols, including rests that symbolize silence and can be positioned at various vertical locations.

The concise structure of the agnostic representation not only facilitates faster convergence of OMR models but also enables non-experts to annotate music data, making the subsequent conversion to a semantic representation automatable [31]. However, holistic OMR models do not leverage this dual dimensionality. Instead, they treat each combination of form and height as a single category— $|\Sigma| = |\Sigma_F| \times |\Sigma_H|$. Recent works [8, 23] have shown that splitting the symbols in z_i into their two components and retrieving them sequentially—first, the form and then, the height—leads better recognition rates. Note that the cardinality of the set of symbols in this *split-sequence encoding* is $|\Sigma| = |\Sigma_F| + |\Sigma_H|$, much lower than that of the *standard encoding*, at the expense of doubling the length of the sequence to be predicted. Figure 3 shows a staff sample and its encoding representations in standard and split-sequence encoding.

In this work, we consider both the standard encoding and the split-sequence encoding representations. When using the latter encoding, we adhere to the 2D-greedy decoding method proposed in [8]. This method adjusts the standard CTC greedy decoding to ensure that the output predictions conform to the form-height pattern of the split-

Figure 3: Staff sample and its encoding representations in standard (above) and split-sequence (below) encoding. Note that L_n and S_n respectively denote the line or space of the staff on which the symbol may be placed, which refers to its height property.

sequence encoding representation.

Note that when using the split-sequence encoding representation, we transition from a cardinality of $\Sigma_F \times \Sigma_H$ to one of $\Sigma_F + \Sigma_H$. This implies fewer different symbols and subsequently enables a greater overlap of vocabularies between the source and target collections. This feature makes it particularly suitable for our synthetic-to-real scenario.

Table 1 provides a summary of the characteristics of each label space for the considered corpora. As for data partitioning, we adhere to the same training, validation, and test splits as outlined in the referenced works.

Table 1: Overview of the corpora used in this work: number of staves, vocabulary size for each label space considered (form and height separately for the split-sequence encoding, and a single token combining these two pieces of information for the standard encoding), and engraving style.

	Staves	Vocabulary			Engraving style
		Form	Height	Combined	
PRIMENS	42 136	37	34	386	Synthetic
CAPITAN	828	62	16	372	Handwritten
SEILS	1 136	37	17	205	Typeset
GUATEMALA	3 263	52	17	315	Handwritten
MOTTECTA	1 847	38	15	228	Typeset
MAGNIFICAT	1 340	42	19	220	Typeset

5. EXPERIMENTAL SET UP

This section describes the evaluation protocol and the implementation details.

5.1 Evaluation metric

We consider the Symbol Error Rate (SER) for assessing the performance of the presented recognition scheme, as in previous works [6–9]. This metric is computed as the average number of elementary editing operations (insertions, deletions, or substitutions) required to match the sequence predicted by the model with that in the ground truth, normalized by the length of the latter. In mathematical terms, this is expressed as:

$$\text{SER} (\%) = \frac{\sum_{i=1}^{|\mathcal{S}|} \text{ED}(\hat{\mathbf{z}}_i, \mathbf{z}_i)}{\sum_{i=1}^{|\mathcal{S}|} |\mathbf{z}_i|} \quad (6)$$

where $\mathcal{S} \subset \mathcal{X} \times \mathcal{Z}$ is a set of test data, $\text{ED} : \mathcal{Z} \times \mathcal{Z} \rightarrow \mathbb{N}_0$ denotes the string edit distance [32], and $\hat{\mathbf{z}}_i$ and \mathbf{z}_i respectively represent the estimated and target sequences. For comparative purposes, we convert all predicted and ground-truth sequences to split-sequence before computing the metric.

5.2 Implementation details

The CRNN scheme is based on that used typically for OMR [7, 9, 27]. Specifically, we used four convolutional layers that applied 64 filters of size 5×5 , 64 filters of size 5×5 , 128 filters of size 3×3 , and 128 filters of size 3×3 , respectively. We considered a Leaky ReLU activation with a negative slope of $\alpha = 0.2$ and max-pooling stages of size and striding factors of 2×1 (except the first convolutional layer, which is 2×2). The produced feature maps were fed into two Bidirectional Long Short-Time Memory layers with 256 hidden units each and a dropout value of 50%, followed by a fully-connected network with $|\Sigma'|$ units that provide a probability for each possible music-notation token.

The evaluation pipeline consisted of two stages: (i) training the source model, and (ii) adapting it to the target dataset using the AMD method. For (i), we used the ADAM optimizer with a batch size of 16 elements and a fixed learning rate of 10^{-3} . We stopped the training using an early stopping strategy with a patience of 20 epochs, retaining the weights that minimize the SER metric in the validation partition. In (ii) we maintained the batch size of 16, the learning rate was selected through a random search ranging from 10^{-3} to 3×10^{-4} , and a maximum of 50 training-adaptation epochs was considered as we fine-tuned an already trained model.

Regarding data pre-processing, we replicated the exact experimental conditions outlined in the aforementioned reference works. Specifically, we resized each staff image to a height of 64 pixels, preserving the aspect ratio (individual samples may vary in width), and converted them to grayscale without any additional pre-processing steps. Additionally, following the approach outlined in the aforementioned works, we incorporated a data augmentation step during the training of the source models.

6. RESULTS

This section presents the results obtained from applying the experimental scheme to the different presented corpora. Specifically, Table 2 depicts the performance of the PRIMENS model before and after adaptation for each real target Mensural corpus in terms of the SER metric.⁵

The most important remark is that the considered synthetic-to-real adaptation framework improves the performance of the synthetic-only scenario across all datasets. The approach does not solve the adaptation challenge completely (the reference value is still far in most cases), but it allows taking the model to more usable levels without

⁵ Code at: <https://github.com/OMR-PRAIG-UA-ES/ISMIR-2024-SYNTHETIC2REAL-OMR>.

Table 2: Results in terms of the SER (%) metric for each real Mensural corpus before and after the unsupervised adaptation of the OMR model trained with the synthetic PRIMENS dataset. For completeness, we also include the in-collection performance, where the real corpus is used for both training and testing. These performances are shaded in gray, serving as an upper-bound reference. Final row reports the relative improvement ($\downarrow\Delta$ %) when adaptation is performed.

	Target corpus									
	CAPITAN		SEILS		GUATEMALA		MOTTECTA		MAGNIFICAT	
	Standard	Split-sequence	Standard	Split-sequence	Standard	Split-sequence	Standard	Split-sequence	Standard	Split-sequence
In-collection (reference)	6.7	6.2	1.8	1.7	1.6	1.6	3.3	2.9	1.5	1.5
Before adaptation	45.9	43.1	23.9	21.3	46.9	53.4	25.8	29.2	12.8	12.8
After adaptation	32.9	32.9	19.3	18.5	21.4	18.1	17.1	16.4	9.1	10.6
Relative improvement	$\downarrow 28\%$	$\downarrow 23\%$	$\downarrow 19\%$	$\downarrow 14\%$	$\downarrow 54\%$	$\downarrow 66\%$	$\downarrow 34\%$	$\downarrow 44\%$	$\downarrow 29\%$	$\downarrow 17\%$

the need to initially annotate data. This is quite useful, for example, in the context of OMR plus post-correction.

The degree of relative improvement varies depending on the specific dataset, ranging from 66% to 14%. In this sense, it is difficult to draw a correlation between the different factors and the degree of improvement. However, it is worth highlighting that the scenarios with a greater margin (for example, GUATEMALA and CAPITAN) lead to a greater absolute improvement. This may indicate that there is a glass ceiling to the performance that can be obtained by training with a synthetic corpus, since in the cases where the result is already relatively successful (e.g. MAGNIFICAT) the improvement is rather limited.

Concerning the output encoding, the split-sequence encoding generally yields better SER figures in the in-collection scenario. However, the differences are marginal in the other two scenarios. Therefore, this does not represent a relevant factor for adaptation.

To provide more insights into the adaptation process, we explored the “relevant” parts of the image that the different OMR models consider to predict the symbols. Gradient-weighted Class Activation Mapping (Grad-CAM) [33] is an interpretability method that uses the gradients of any target prediction to produce a coarse localization map highlighting the important regions in the image for such predictions. Figure 4 shows the activation map over the same test image for the three different scenarios considered: (a) in-collection, (b) before adaptation, and (c) after adaptation. Specifically, we display here the case of processing the real collection GUATEMALA. We can observe how the initially misplaced pixel activations in scenario (b) are corrected to the actual music symbols after adaptation in scenario (c), showing a high degree of similarity to the activation map of the in-collection model of scenario (a).

7. CONCLUSIONS

Existing end-to-end OMR approaches have exhibited remarkable performance in transcribing collections that share graphic characteristics with the training corpus. However, when this condition is not met, allocating resources to manually annotate training data to maintain performance levels becomes impractical and resource-intensive. Our work proposes a possible solution to this challenge. Firstly, we train an initial OMR model with synthetic scores. By doing so, we eliminate the need for hu-

Figure 4: Activation maps over the same GUATEMALA test image using an OMR model trained with (a) GUATEMALA scores, (b) PRIMENS scores, and (c) PRIMENS scores but adapted to GUATEMALA images.

man manual annotation of training data. Subsequently, we tailor this model to the specific characteristics of the target corpus through unsupervised adaptation, using only unlabeled images from the target corpus. This adaptation process employs a loss function to align the learned features of the model with those of the target collection while ensuring the model does not converge to undesirable solutions. Our experiments across five distinct Mensural datasets validate the effectiveness of our synthetic-to-real adaptation as a viable approach to developing universal OMR systems with little human effort. However, there remains room for improvement. Future research avenues may explore leveraging self-labeled samples obtained through the adapted model to further enhance its performance and robustness or exploring few-shot scenarios.

ABSTRACT

We propose a novel symbolic music representation and Generative Adversarial Network (GAN) framework specially designed for symbolic multitrack music generation. The main theme of symbolic music generation primarily encompasses the preprocessing of music data and the implementation of a deep learning framework. Current techniques dedicated to symbolic music generation generally encounter two significant challenges: training data’s lack of information about chords and scales and the requirement of specially designed model architecture adapted to the unique format of symbolic music representation. In this paper, we solve the above problems by introducing new symbolic music representation with MusicLang chord analysis model. We propose our MMT-BERT architecture adapting to the representation. To build a robust multitrack music generator, we fine-tune a pre-trained MusicBERT model to serve as the discriminator, and incorporate relativistic standard loss. This approach, supported by the in-depth understanding of symbolic music encoded within MusicBERT, fortifies the consonance and humanity of music generated by our method. Experimental results demonstrate the effectiveness of our approach which strictly follows the state-of-the-art methods.

1. INTRODUCTION

Music plays an indispensable role in our daily lives, and there is a significant demand for creating new musical contents. Automatic music generation is one of the most intriguing tasks in bringing new music experiences to consumers [1]. The earliest studies in the 1950s focused on a combination of music theory and Markov-chains-based probabilistic models, and realized randomly creating music parts and combining them into a synthesis [2]. Contemporary studies have achieved higher quality and faster music generation by utilizing advanced neural networks

such as Generative Adversarial Networks (GANs), Transformer, and diffusion models [3–5]. Despite significant advancements, previous methods continue to suffer from challenges such as insufficient data extraction and unstable training trajectories. Consequently, there is room for new approaches for more effective music representations and more robust deep learning architectures.

In particular, chords are crucial for conveying emotional and humanistic expressions in music, yet few methods take chords into account in symbolic music representation. Consequently, previous methods are deprived of indispensable information about chords and scales. This lack results in the generation of music that exhibits a diminished degree of humanity. Therefore, previous methods for music generation face limitations in their ability to produce human-like and high quality expressions [6]. A feasible solution to overcome this difficulty is the integration of a chord analysis model [7]. Chord analysis model aids in the extraction of chord data from raw audio, fostering a novel representation method that encompasses chord information [8–11]. With the aid of state-of-the-art chord analysis models, we can generate more harmonious and structured music with more regular chord progressions by automatically extracting and encoding chords from raw audio files. Therefore, it is expected that adopting chord analysis models in creating new symbolic representations of music will enable the generation of music that is closer to human composition.

Another problem arises from the ever-changing format of symbolic music representation, which makes designing the model’s architecture that fits symbolic music generation to be another challenge. GANs are widely applied in the symbolic music generation field because the addition of a discriminator obviously strengthens the fidelity of the overall generative model [12–17]. The performance of GANs is deeply influenced by the architecture of the generator and discriminator. Previous studies have demonstrated the effectiveness of transformer-based generators [6, 7, 18–23]. Whereas, the architecture of the discriminator has been extensively discussed in recent years. Some methods [12, 14, 16, 17] involve constructing a discriminator based on CNN or Transformer, while others [15] utilize pre-trained models adapted to their tasks. Compared to hand-crafted discriminators, using pre-trained models often achieves a fairly good result

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

because pre-trained models are already trained on large and diverse datasets. Therefore, the application of pre-trained models will allow the GAN to leverage their learning and knowledge, ensuring the training efficiency and stability.

However, there are few choices of pre-trained models designed for symbolic music representation that can be used as the discriminator considering the input format and length limitation. We solve this problem by applying BERT-based scores, which are well correlated with human ranking and can jointly measure quality and diversity [24,25]. Since BERT is trained using a self-supervised loss on bidirectional contexts of all attention layers, it can effectively extract representations [26–28]. Muhamed *et al.* employ a pre-trained Span-BERT model and achieve considerable results on harmonic choices and overall music quality, showing that pre-trained BERT-based models outperform CNN-based discriminator [15]. Hence, employing a pre-trained model as a discriminator can amplify the overall performance of the GAN model.

In this paper, we propose a novel symbolic music generation method using the chord-aware symbolic music representation and MusicBERT-based discriminator. In terms of symbolic musical expression, we introduce the novel symbolic music representation with chord information derived from MusicLang¹, one of the state-of-the-art chord analysis models. By employing symbolic music representation with chord information, our model can achieve the generation of more human-like music that considers chord progressions. For the model architecture, we employ the Multitrack Music Transformer (MMT) [6] as the generator and fine-tune the MusicBERT [29], a symbolic music understanding model pre-trained in large-scale dataset, as the discriminator. Leveraging the superior comprehension capabilities of MusicBERT, we can improve GAN’s performance, thereby facilitating the creation of higher-quality music. Furthermore, we introduce relativistic standard loss to further optimize the stability and consistency of the training process [30]. The use of Relativistic Standard GAN (RS-GAN) has realized great results in the field of image generation. It enables models to account for the fact that half of the data in a mini-batch is fake, leading to more accurate estimations of data realism [14, 31]. Building upon the innovations mentioned above, our model is capable of retrieving substantial information about chords and scales, acquiring knowledge in music theory, and autonomously generating multitrack music of superior quality and enriched with human-like characteristics.

The contributions of this paper are summarized as follows.

- We propose a modified MMT style symbolic music representation including chord and scale information.
- We develop MMT-BERT, an optimized GAN architecture utilizing MMT and MusicBERT, with relativistic standard loss to enhance the stability of the training process and achieve better results.

2. RELATED WORKS

2.1 Symbolic Music Representation

To enable computers to properly understand music, research on symbolic music representation has been conducted for many years [32]. Musical Instrument Digital Interface (MIDI) is the most commonly used format for symbolic music representation, containing performance data and control information for musical notes. In the music processing community, many researchers symbolize music with MIDI-like events [33].

Huang *et al.* have proposed REvamped MIDI-derived events (REMI), which adds note duration and bar events, enabling models to generate music with subtle rhythmic repetition [7]. However, the REMI representation often encounters a challenge that the sequence is too long. Building upon the REMI framework, Hsiao *et al.* have proposed Compound Word Transformer (CP) [18]. CP modifies REMI’s approach by transforming one-dimensional sequence tokens into compound words sequence using specific rules. Although this modification significantly shortens the average token sequence length and simplifies the model’s ability to capture musical nuances, CP is hard to generate multitrack music [6]. Dong *et al.* have proposed their multitrack music representation, which represents music with a sequence of sextuple tokens, along with a Transformer-XL-based generation method Multitrack Music Transformer (MMT). This approach utilizes a decoder-only Transformer architecture, adept at processing multi-dimensional inputs and outputs. MMT leverages the advantages of the Transformer to enable the generation of longer multitrack music compositions than previous music generation methods. However, MMT’s representation scheme lacks chord event inclusion, an essential element in musical compositions. In contrast, our symbolic music representation technique builds on the foundation laid by MMT by integrating chord information, enabling our model to produce more harmonically rich compositions.

2.2 Generative Adversarial Network-based Music Generation

Previous studies have employed various GANs to realize symbolic music generation [12, 13, 17]. In early states, Dong *et al.* have proposed MuseGAN, a CNN-based GAN architecture, managing to generate multitrack music pieces [16]. However, CNN-based GANs often suffer from problems such as limited local perception, fixed-size inputs, etc. Muhamed *et al.* solved this problem by introducing their Transformer-GANs model, using a Transformer-

Event type t_j	Quintuple token $\mathbf{x}_i^{t_j}$
start-of-song	(0, 0, 0, 0, 0)
instrument	(0, 0, 0, 0, instrument)
start-of-score	(0, 0, 0, 0, 0)
note	(beat, position, pitch, duration, instrument)
chord	(beat, degree, root, mode, extension)
end-of-song	(0, 0, 0, 0, 0)

Table 2. The elements of the quintuple token $\mathbf{x}_i^{t_j}$ for each event type t_j .

XL-based generator and pre-trained Span-BERT as the discriminator [15]. Transformer-XL introduces the notion of recurrence into the deep self-attention network, enabling the reuse of hidden states from previous segments as memory for the current segment, allowing for the modeling of long-range dependencies. For the discriminator, Span-BERT is utilized to extract sequence embeddings followed by a pooling and linear layer. The bidirectional transformer has a comparable capacity to the transformer-based generator and uses the self-attention mechanism to capture meaningful aspects of the input music sequence. Their research validates the efficacy of employing a Transformer-XL-based generator in conjunction with a BERT-based discriminator [34]. Building on this concept, we developed the MMT-BERT model by utilizing MMT as the generator and Music-BERT as the discriminator.

3. METHODOLOGY

3.1 Proposed Symbolic Music Representation

In our approach, we introduce a novel symbolic music representation that incorporates chords. Table 1 shows differences between the conventional approaches and the proposed symbolic music representation. While most conventional representations omit details about chords, we focus on chord information-aware representation to facilitate the process of generating music that more closely resembles humans. First, we extract music data including chords and notes from MIDI files based on MuspyToolkit [35] and MusicLang. During the extraction process, we recognize a chord once per bar, i.e., every four beats. We exclude songs with a time signature other than 4/4, limit the number of chords in a bar to one, and ignore chord changes within a bar since MusicLang only detects chord changes once per bar. Each time MusicLang detects a chord change, it extracts the scale degree, tonality root, tonality mode, chord octave and extension note of the chord. After extracting chord and note information, we encode a piece of music into a sequence of quintuple tokens $\mathbf{X} = (\mathbf{x}_0, \dots, \mathbf{x}_{N-1})$, where \mathbf{x}_i and N denote the i -th quintuple token and the total number of quintuple tokens, respectively. Here, t represents the following event type: {start-of-song, instrument, start-of-score, note, chord, end-of-song}. The meanings of each event type are shown as follows:

- **Start-of-song:** The beginning of the music piece
- **Instrument:** An instrument used in the music piece

Quintuple tokens	Meaning
$\mathbf{x}_0^{\text{start-of-song}}$: (0, 0, 0, 0, 0)	Start of song
$\mathbf{x}_1^{\text{instrument}}$: (0, 0, 0, 0, 6)	Instrument : harpsichord
$\mathbf{x}_2^{\text{instrument}}$: (0, 0, 0, 0, 40)	Instrument : violin
$\mathbf{x}_3^{\text{instrument}}$: (0, 0, 0, 0, 42)	Instrument : cello
$\mathbf{x}_4^{\text{start-of-score}}$: (0, 0, 0, 0, 0)	Start of score
$\mathbf{x}_5^{\text{chord}}$: (1, 1, 7, 2, 9)	Chord: beat=1, degree=1, root=G, mode=minor, extension=9th
$\mathbf{x}_6^{\text{note}}$: (1, 1, 46, 6, 6)	Note : beat=1, position=1, pitch=A2, duration=6, instrument=harpsichord bar 1
$\mathbf{x}_{12}^{\text{chord}}$: (5, 1, 7, 2, 6)	Chord: beat=5, degree=1, root=G, mode=minor, extension=6th
$\mathbf{x}_{13}^{\text{note}}$: (5, 7, 48, 5, 42)	Note : beat=5, position=7, pitch=G2, duration=5, instrument=cello bar 2
$\mathbf{x}_{N-1}^{\text{end-of-song}}$: (0, 0, 0, 0, 0)	End of song

Figure 1. An example of the proposed representation. Compared to the conventional representation, the proposed representation incorporates an additional chord event (highlighted by red blocks) per bar, thereby aiding the model in understanding the relationship between the notes and chords.

- **Start-of-score:** The beginning of a sequence of musical events, including notes and chords
- **Note:** A note characterized by beat, position, pitch, duration, and instrument
- **Chord:** A chord characterized by beat, scale degree, root note, mode, and extension note
- **End-of-song:** The end of the music piece

The meaning of each element in the quintuple token \mathbf{x}_i^t varies depending on the event type t . The correspondence between the event type t and the meanings of the quintuple token \mathbf{x}_i^t is shown in Table 2. Additionally, it is noted that we apply different embeddings for the different features sharing the same axis. A schematic diagram of the proposed representation is illustrated in Figure 1. In this way, we can obtain a symbolic music representation that incorporates chords that is suitable for input into the aforementioned MMT-BERT architecture.

3.2 MMT-BERT Architecture

The fundamental structure of our MMT-BERT architecture is based on a GAN architecture, employing MMT as the generator and MusicBERT as the discriminator. The overview diagram of MMT-BERT is illustrated in Figure 2. The primary concept of GAN is minimizing the loss to enhance the generator’s ability to deceive the discriminator by producing fake music indistinguishable from real music, while simultaneously maximizing the discriminator’s accuracy in distinguishing between real and fake music. Details of the generator and discriminator will be discussed later.

3.2.1 Generator

As the generator, we employ MMT [6], a Transformer-XL-based model that consists solely of decoders. In MMT, elements in the quintuple token \mathbf{x}_i are individually embedded first, and then concatenated, followed by the addition of

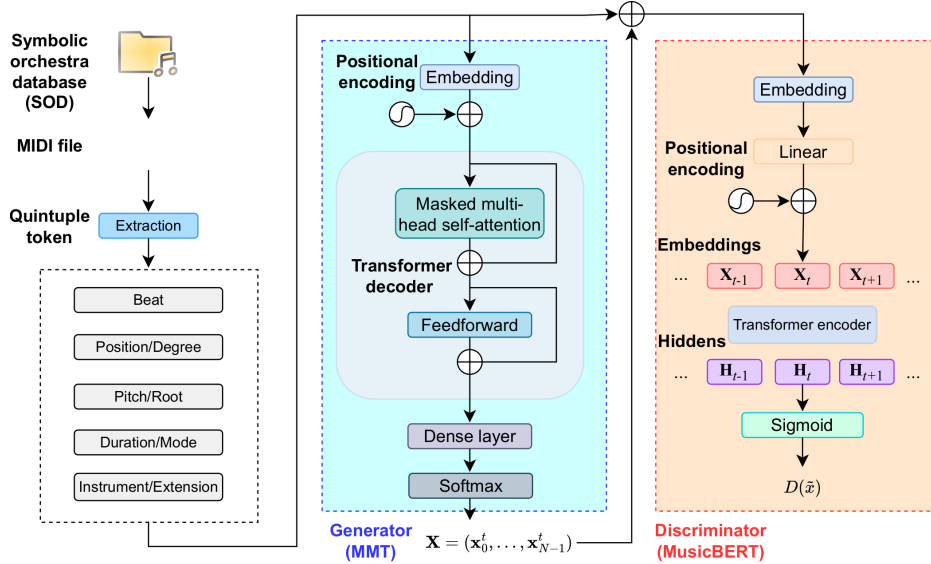

Figure 2. The diagram of the MMT-BERT. The generator is built upon Transformer-XL architecture, and the discriminator is built upon MusicBERT. A MIDI file from the dataset is firstly encoded into a sequence of quintuple tokens before fed into the model. Embeddings of the 6 elements are concatenated by a linear layer and converted into a single vector. Then they are fed into the encoder and decoder layers with the addition of position embeddings.

positional embeddings. Subsequently, this combined input is passed through transformer decoder blocks, which are composed of a masked multi-head self-attention layer and a feedforward layer. The output from the decoder blocks is then processed by a dense layer and a softmax layer, resulting in the generation of new music samples. MMT proves advantageous due to its capability to handle multi-dimensional input and output spaces, aligning perfectly with the requirements of symbolic music representation. Significantly, MMT can retain hidden states from previous segments, thereby eliminating the need for recalculating from scratch with each new segment. These retained states function as a memory aid for the current segment, establishing a recurrent connection between segments.

The application of MMT as the generator allows for instrument-controllable multitrack music generation with extended duration and higher training speed. Such a key feature facilitates the modeling of extensive long-range dependencies.

3.2.2 Discriminator

As the discriminator, we adopted MusicBERT [29], a large-scale Transformer model developed for symbolic music understanding. MusicBERT consists of a Transformer encoder and utilizes a masked language modeling approach where certain tokens in the input music sequence are masked and then predicted by the model output. The original proposed encoding method, called OctupleMIDI process transforms a symbolic music piece into a sequence of octuple tokens, each containing eight basic elements related to a musical note. In order to make MusicBERT act as a discriminator adapted to the proposed representation mentioned in Sec. 3.1, we refine the input and output format of MusicBERT. Quintuple tokens are converted into a single vector through the concatenation of embeddings and

a linear layer. The resulting vector is combined with position embeddings and provided as input to the Transformer encoder. To predict each of the five tokens within the quintuple, separate softmax layers are added to map the hidden states of the Transformer encoder to the vocabulary sizes of the different element types. MusicBERT’s proficiency in comprehending symbolic music as the discriminator integrates with MMT’s generation process, thereby aiding in the stability of the training process and faster convergence.

3.2.3 Relativistic Standard Loss

Inspired by RS-GAN [31], one of the state-of-the-art methods in GANs, we adopt the relativistic standard loss as our objective function. Applying relativistic standard loss prevents the network from becoming overconfident, leading to slower and more careful decisions, allowing the generator more room to adjust its weights and improve the training process [30]. The probability that the given fake data is more realistic than a randomly sampled real data is defined as follows:

$$D(\tilde{x}) = \text{sigmoid}(C(f) - C(r)), \quad (1)$$

where $C(\cdot)$ denotes a non-transformed layer, and \tilde{x} denotes real/fake data pairs $\tilde{x} = (r, f)$. Hence, the loss function of the generator G and the discriminator D are defined as follows:

$$L_G = \mathbb{E}_{(r,f) \sim p(r,f)} [\log(\text{sigmoid}(C(r) - C(f)))] - \sum_i r_i \log f_i, \quad (2)$$

$$L_D = \mathbb{E}_{(r,f) \sim p(r,f)} [\log(\text{sigmoid}(C(f) - C(r)))] \quad (3)$$

where r_i and f_i denote ground truth logits and generated music logits, respectively. It is noted that we add cross entropy to the loss function of generator in order to accelerate

the convergence process of the loss function. By training both the generator and discriminator with the relativistic standard loss to emulate human-like musical compositions, our MMT-BERT model can generate high quality music pieces that incorporate sophisticated chord information.

4. EXPERIMENT

4.1 Experiment Setup

In the experiment, we utilize the Symbolic Orchestral Database (SOD) [36], which comprises 5,864 music pieces encoded as MIDI files along with associated metadata. The dataset is partitioned into training, testing, and validation sets, receiving 80%, 10%, and 10% of the data, respectively. We set a temporal resolution of 12 time steps per quarter note for detailed timing accuracy. The Transformer-XL generator is composed of six decoder layers with 512 dimensions and eight self-attention heads, and the MusicBERT discriminator consists of one encoder layer with two self-attention heads. The maximum length for symbolic music sequences is set at 1024, with a maximum of 256 beats. To optimize the models, we employ the Adagrad optimizer to mitigate issues of gradient explosion and vanishing [37]. Additionally, to enhance the robustness of the data, we augment it by randomly transposing all pitches by $s \sim U(-5, 6)$ ($s \in \mathbb{Z}$) semitones and assign a starting beat. Here, U denotes a uniform distribution.

As comparative methods, we employ three state-of-the-art music generation models: MMM [21], FIGARO [23], and MMT [6]. We validate the performance of our MMT-BERT model by conducting quantitative evaluations using existing metrics and subjective experiments to assess the human-like qualities of the generated music pieces.

4.2 Quantitative Evaluation

Following [6], we evaluate the generated music pieces using four metrics: pitch class entropy similarity (PCES), scale consistency similarity (SCS), groove consistency similarity (GCS), and average length (AL). We consider higher values of PCES, SCS, and GCS as indicators of superior quality, while a higher AL denotes a greater capability to produce long-duration music pieces.

In preparation for calculating PCES, the pitch class entropy (PCE) is defined as follows:

$$\text{PCE} = - \sum_{i=0}^{11} h_i \log_2(h_i), \quad (4)$$

where h_i denotes the number of occurrences of each note name in the 12-dimensional pitch class histogram. As the PCE values increase, the tonality of the generated music pieces exhibits greater instability. However, it is important to recognize that more stable tonality does not necessarily imply higher quality. Subsequently, we calculate PCES between generated music samples and human compositions as follows:

$$\text{PCES} = 1 - \frac{|\text{PCE}_{\text{gen}} - \text{PCE}_{\text{tr}}|}{\text{PCE}_{\text{tr}}}, \quad (5)$$

where PCE_{gen} and PCE_{tr} denotes the PCE value of generated music samples and human compositions, respectively. Moreover, noticing that PCE is intrinsically linked to the volume of data, we truncate the generated musical pieces to the preceding k seconds and calculate their PCES.

The scale consistency (SC) is derived by calculating the proportion of tones that conform to a conventional scale and presenting the value for the most closely aligned scale [38]. SC serves as an indicator of the model’s proficiency in generating musical segments that demonstrate cognizance of chords and scales within the current bar. The SCS between generated music samples and human compositions is defined as follows:

$$\text{SCS} = 1 - \frac{|\text{SC}_{\text{gen}} - \text{SC}_{\text{tr}}|}{\text{SC}_{\text{tr}}}, \quad (6)$$

where SC_{gen} and SC_{tr} denote the SC values of generated music samples and human compositions, respectively.

To calculate GCS, we first define a groove pattern \mathbf{g} as a 64-dimensional binary vector. The groove consistency (GC) between two grooving patterns ($\mathbf{g}^a, \mathbf{g}^b$) is defined as follows:

$$\text{GC} = 1 - \frac{1}{Q} \sum_{i=0}^{Q-1} \text{XOR}(g_i^a, g_i^b), \quad (7)$$

where $\text{XOR}(\cdot, \cdot)$ denotes the exclusive OR operation, and g_i denotes a position in a bar at which there is at least a note onset. Q is the dimensionality of \mathbf{g}^a and \mathbf{g}^b . GC is a measure of music’s rhythmicity. The value of GC stands for the steadiness in rhythm of the generated music pieces. The GCS between generated music samples and human compositions is defined as follows:

$$\text{GCS} = 1 - \frac{|\text{GC}_{\text{gen}} - \text{GC}_{\text{tr}}|}{\text{GC}_{\text{tr}}}, \quad (8)$$

where GC_{gen} and GC_{tr} denote the GC values of generated music samples and human compositions, respectively.

AL denotes the mean duration of the generated music pieces, which collectively illustrates the model’s ability to generate musical sequences with significant length.

The results of the quantitative evaluation are shown in Table 3. To facilitate a fair comparison by standardizing the lengths of music pieces, PCES is assessed over a 15-second span due to the limitations of MMM and FIGARO in producing extended compositions. Experimental results show that MMT-BERT achieves higher performance in PCES, SCS, and GCS compared to the other methods, demonstrating its effectiveness in generating high quality music pieces. This achievement is attributed to its chord awareness and the symbolic music understanding facilitated by MusicBERT. MMT-BERT’s AL is marginally less than that of MMT, and this results from integrating chord events that are not converted to audio during the decoding phase. However, MMT-BERT’s AL significantly surpasses that of MMM and FIGARO, confirming its capability to generate longer compositions. Additionally, the AL of all the music pieces in the SOD we used, which also serve as

Table 4. Subjective evaluation results. Each metric is rated on a five-point scale, with the average score being calculated.

the ground truth, is 99.88 seconds. Evaluation results show that MMT-BERT can produce music of higher quality than MMT, and of longer duration than MMM and FIGARO.

4.3 Impacts of Chord Event and Discriminator

MMT-BERT aims to generate more harmonious, more human-like music pieces through the addition of chord events and adversarial generative learning by employing MusicBERT as its discriminator. To evaluate aspects related to richness and humanness, we have conducted subjective experiment and ablation study.

In the subjective experiment, we asked 18 music amateurs as the following five questions and requested that they rated each on a five-point scale.

- **Richness (R):** Does the music piece have diversity and interestingness?
- **Humanness (H):** Does the music piece sound like it was composed by an expressive human musician?
- **Correctness (C):** Does the music piece contain perceived mistakes in composition or performance?
- **Structureness (S):** Does the music piece exhibit structural patterns such as repeating themes or the development of musical ideas?
- **Overall (O):** What is the general score of the music piece?

As mentioned in Sec. 4.2, FIGARO and MMM employ a music representation that considers percussive sounds and typically generates much shorter pieces. Therefore, the nature of the music pieces generated by these models, FIGARO and MMM, differs significantly from that of MMT-BERT and MMT due to their use of percussive sounds and shorter compositions. To fairly evaluate the human-like quality of the generated music pieces, we compared MMT-BERT with MMT, a state-of-the-art approach whose generated compositions have lengths and musical styles that are

relatively similar to those of MMT-BERT. Additionally, to ensure clarity in subjective evaluation, we included the results for MMM and FIGARO. The results of the subjective evaluation are shown in Table 4. Table 4 indicates that MMT-BERT scores are particularly high in both richness and humanness compared to MMT. This suggests that the application of chord events and MusicBERT contribute to the generation of music pieces that more closely resemble human compositions. On the other hand, regarding correctness, our method did not specifically aim to enhance this metric, which may cause the gap in this value. For the same reason, our method exceeds MMT by a small margin in structureness mainly because of uncertainty. Although there is no clear advantage between MMT and MMT-BERT in correctness and structureness, our method still outperforms MMT in richness and humanness. The overall score also proves the superiority of MMT-BERT, which indicates that chord events and MusicBERT enhance the ability to create music similar to that produced by humans.

The results of the ablation study are shown in Table 3 along with the quantitative evaluation results. It is evident that the addition of chord events improves PCES and SCS. MusicBERT also contributes to the enhancement of PCES and GCS.

5. CONCLUSION

In this paper, we have proposed the chord-aware symbolic music generation approach, named MMT-BERT. By extracting chord information from raw audio files, we have devised a chord-aware symbolic music representation. We also developed a novel RS-GAN architecture based on MMT and MusicBERT. Both experimental evaluations validate the efficacy of our method in producing music pieces of superior quality, enhanced human likeness, and considerable length. In future works, we plan to explore methods that refine musical structure and incorporate information from various musical modalities.

ABSTRACT

Current version identification (VI) datasets often lack sufficient size and musical diversity to train robust neural networks (NNs). Additionally, their non-representative clique size distributions prevent realistic system evaluations. To address these challenges, we explore the untapped potential of the rich editorial metadata in the Discogs music database and create a large dataset of musical versions containing about 1,900,000 versions across 348,000 cliques. Utilizing a high-precision search algorithm, we map this dataset to official music uploads on YouTube, resulting in a dataset of approximately 493,000 versions across 98,000 cliques. This dataset offers over nine times the number of cliques and over four times the number of versions than existing datasets. We demonstrate the utility of our dataset by training a baseline NN without extensive model complexities or data augmentations, which achieves competitive results on the SHS100K and Da-TACOS datasets. Our dataset, along with the tools used for its creation, the extracted audio features, and a trained model, are all publicly available online.

1. INTRODUCTION

Artists continue to cover, remix, and reinterpret musical works, creating a rich tapestry of musical versions that celebrate the originals. This proliferation presents a complex challenge: how to accurately identify different versions of a musical work within vast digital catalogs. Version identification (VI) addresses this problem using audio processing methods to find versions of query tracks in music catalogs [1–3]. VI has thus emerged as a crucial solution with significant implications across multiple applications including music discovery, musicological research, and copyright enforcement. From both the artists’ and copyright holders’ perspectives, VI has substantial importance as it offers a tool for financial compensation to many music industry stakeholders.

Recently, multiple datasets, all derived from scraping

the SecondHandSongs¹ website, were proposed for developing VI systems [4–7]. These datasets have facilitated the development of various systems based on convolutional neural networks (CNNs) [5–12]. However, their limited sizes have restricted the feasibility of employing larger architectures, such as transformers, which are increasingly utilized in other music information retrieval (MIR) tasks [13, 14]. Additionally, existing datasets such as Da-TACOS [5] and SHS100K [4] lack comprehensive metadata, such as genre, style, and release year, which can be useful for detailed performance evaluation and sophisticated training approaches. Furthermore, they fall short in presenting sufficient challenges regarding the distribution of clique sizes, genres, styles, and track durations.

This study introduces a significantly larger and more challenging VI dataset. Rather than relying on SecondHandSongs, we use public editorial metadata from the Discogs² database, which has not been explored in the field previously. Discogs is collaboratively maintained by music enthusiasts and professionals who submit detailed metadata about music releases, including artist details, release information, and extensive credit descriptions. These descriptions not only list track artists and writers but also provide aliases, name variations, and artist relationships, offering a rich framework for identifying versions.

Using this metadata, we propose a methodology for identifying a large dataset of versions and mapping this dataset to various music audio collections. The resulting dataset is the largest open-source VI dataset to date. Our contributions can be summarized as follows:

1. A metadata-only dataset, Discogs-VI, containing over 1,900,000 versions of around 348,000 works.
2. A subset of this dataset, Discogs-VI-YT, containing about 493,000 versions of around 98,000 works matched to YouTube URLs of official music uploads. It contains over nine times as many works and over four times as many versions as other datasets.
3. A larger and more challenging test set that contains other publicly available test sets.
4. A pre-trained baseline model, Discogs-VINet.

The dataset³, together with the tools for its creation, the extracted audio features, and the model trained on this data⁴, are publicly available online.

Discogs-VI-YT	Discogs	98,785	493,049	658	5	2	1.5	1.0	✓	Rich metadata, features (full track)
Discogs-VI	Discogs	348,796	1,911,611	1,837	6	2	-	-	-	Rich metadata

Table 1. Overview of publicly-available VI datasets. Da-TACOS refers to the benchmark subset, for which the 2,000 noise works are not reported as they do not form cliques. SHS refers to the SecondHandSongs website. MCS: maximum clique size; ACS: average clique size; mCS: median clique size; A-URL: average YouTube URLs per version; m-URL: median YouTube URLs per version; OV: use of official YouTube videos only. “-” denotes that the property is not applicable.

2. IDENTIFYING VERSIONS ON DISCOGS

Discogs database metadata has been previously used in other MIR tasks [17–19]. In this section, we describe the proposed methodology to identify versions and cliques using its metadata. The complete Discogs data is shared as monthly data dumps under a Public Domain license, making it easy to access. In our study, we used the July 2024 data dump.

Numerous metadata fields are provided for releases, tracks, and artists, some of which are relevant for VI. We use the track title, track artists, featuring track artists, release artists, track writer artists, and release writer artists metadata. The artist metadata contains unique artist IDs and provides information regarding group memberships, artist aliases, and artist name variations, which we use extensively. In addition, we include genre, style, record label, release format, release date, master release, and release country metadata that can be potentially useful.

2.1 Version finding from metadata

We use two critical pieces of information to establish the version relationship between two tracks: the track title and the track writer artists, indicated by the “Written-By” metadata field. Specifically, we consider two tracks with the same title and a shared writer artist as versions. This is a sufficient but not necessary condition since two tracks with different names can also be versions. Nonetheless, this condition facilitates finding a significant amount of cliques and versions from the database with high precision.

The search for cliques operates on a set of tracks from the database whose track titles are normalized by applying string processing. This includes transliterating Latin characters by removing diacritics, removing leading articles, replacing “&” with “and”, eliminating any text within parentheses, and removing punctuation marks. These steps aim to mitigate potential differences in metadata between different releases and eliminate mix or edit indicators enclosed in parentheses, e.g., “(Radio Edit)”, thus facilitating the process of identifying cliques. Later, such differences are considered for differentiating between versions.

Using the normalized track titles, we partition the set of tracks into disjoint subsets using exact string matching. Then, we further partition these subsets by the common

track writer relation to distinguish different cliques with the same title. To do so, we compile a set of writer artist IDs for every track. Given that an artist on Discogs may represent a group with several members, we extend our collection to contain all associated members and incorporate each artist’s known aliases and name variations. As a result of the two-step partitioning, tracks that have the same normalized title and share a track writer are joined in the same cliques. We opted for the shared writer approach because not all writers are consistently included in credits on some releases.

Once the cliques are formed, we identify different versions by the track or release artists. In cases where track artists metadata is available, it is used; otherwise, the release artists metadata is used. If there are featuring track artists, they are also included. Therefore, a set of tracks belonging to the same clique and performed by the same set of artists is defined as a version. After identifying the versions, we discard the cliques with only one version.

In previous VI datasets, versions are not treated as sets of tracks as in our dataset. This difference arises because Discogs often lists multiple releases for essentially the same version of a track, which may vary only by the year or country of the release. Without direct access to these releases, it is impossible to confirm their differences in advance. Therefore, we treat such tracks as identical versions. Remarkably, our dataset comprehensively includes a variety of version types as systematized in [20], including live versions, remixes, and radio edits, which add valuable diversity and potential utility.

The resulting dataset, Discogs-VI, contains numerous cliques and versions. Statistics about the dataset in comparison to other datasets are provided in Table 1.

2.2 Limitations

Due to the complex processes of composing, performing, and releasing music, along with issues related to incomplete or inaccurate metadata, there are potential issues related to our approach.

Title variability: Versions can have different names, e.g. “Moon Over Naples” is the original version of both “Spanish Eyes” and “Blue Spanish Eyes”. Due to having different names, our algorithm falsely places these versions into different cliques. To address this issue, comple-

mentary data from SecondHandSongs or a large language model with music history knowledge can be used.

Rule-based text matching: Even for a single language, capturing all syntactic variations with simple rules is difficult. Yet, the database contains many languages with different syntaxes. A music named-entity recognition model may help to resolve this issue.

Metadata ambiguity: “You’re My Everything” is credited to “Miles Davis” in some releases while to “Miles Davis and John Coltrane”, and to “The Miles Davis Quintet” in others. These credential differences often arise from practical or legal reasons associated with publishing music. However, we can not know beforehand if they are different versions using only metadata. To reduce duplicate versions, we treat them as the same version.

3. VERSION SEARCH IN YOUTUBE

Owing to its detailed metadata, Discogs-VI can be mapped to music audio catalogs or other metadata sources. For our research purposes, we use YouTube. To match the Discogs metadata of a version to the YouTube metadata of a video, we design a rule-based algorithm.

In the matching process, we only accept videos provided by an official distributor, which can be the artists themselves or third parties such as record labels. This approach is adopted because we expect the official uploads to have more accurate metadata and be more persistent on the platform over time. Consequently, our dataset is the only VI dataset containing official uploads exclusively. In addition, due to this selectivity, our algorithm demonstrates high retrieval accuracy.

Discogs provides YouTube URL annotations for some of the releases associated with versions. However, these annotations are not on the track level and they are rarely provided. For a unified approach, we instead query YouTube for all versions. The queries are created using the Discogs version metadata in the format “artist1, artist2 - track title”, and if featuring artist information is available, we concatenate “(featuring artist3)”. We then store the top five results for each query and apply our metadata-matching algorithm to all stored results, which allows alternative URLs for certain versions.

As a result, we successfully matched 34% of the versions of Discogs-VI to a YouTube URL. Between these matched versions, we were able to download 98% successfully, corresponding to 33% of the total versions. We then discarded the versions that were not downloaded and the cliques without at least two downloaded versions to create the Discogs-VI-YT dataset. It contains 26% of the versions and 28% of the cliques of Discogs-VI.

3.1 Metadata matching algorithm

From Discogs metadata, our algorithm utilizes the track title, track artists, or, if unavailable, the release artists, along with any featuring artists. From YouTube, it uses the video’s category, uploader, artist, description, duration, and title. We process the strings similarly to the method de-

scribed in Section 2.1, except that the punctuation marks and possible texts within parentheses are not deleted to identify different versions.

The algorithm initially checks if the video metadata contains the “Music” category and if the video is an official YouTube upload. We consider a video official under the following conditions: an artist or a label provided the video, which is indicated in the video description; the video uploader is an artist topic channel auto-generated by YouTube; or the Discogs artist name is the same as the video uploader’s. Videos with a duration longer than 20 minutes are discarded to deal with the potential but unlikely issue of tracks sharing their titles with their albums or EPs, which could lead to full-release audio downloads.

If a video metadata passes these controls, we use the title and artist information to decide a match. If two titles are equal, we use the artist information. If the titles do not match exactly, we apply some heuristics to strip the video title from any additional information related to remastering, HD, lyrics, etc., and re-attempt the match. We then compare all possible permutations to deal with video titles in the “artist1, artist2 - track title (featuring artist3)” format, using exact string matching. This approach makes the dataset less noisy at the cost of losing potential matches.

3.2 Limitations

Since search results and the availability of YouTube videos can be affected by geolocation, re-creating the dataset may yield differences.⁵ Moreover, some URLs may become unavailable in the future.⁶ To mitigate this issue, we provide multiple YouTube URLs per version when possible. Therefore, even if the main URL becomes inactive, numerous versions can still be recovered from alternative URLs. Furthermore, since we only include official uploads, the probability of a video disappearing should be lower than in other datasets. These features have not been considered in previous datasets that share YouTube URLs [4, 21].

Another limitation of our methodology is that less than 8% of versions are matched to the same YouTube URLs. Analysis showed that almost all of these versions are members of the same cliques. For the cliques that exhibit this issue, we manually kept one of the duplicate versions.

4. DATASET ANALYSIS

Following the methodologies described in Section 2 and Section 3, we created the Discogs-VI and Discogs-VI-YT datasets, respectively. Table 1 reports their sizes. The large amount of detailed metadata in Discogs-VI shows great potential: combined with an industrial-scale music audio catalog, it can create new possibilities for VI system development. Moreover, Discogs-VI-YT contains more clique and version audio than all the others combined, promising to boost model performance and generalization capability.

The range of clique sizes in our dataset is unparalleled by others in the field. The presence of cliques with many

⁵ We conducted YouTube queries from Barcelona, Spain.

⁶ The URLs were accessed between March 2023 and July 2024.

versions is beneficial for metric learning, as it provides numerous examples within each clique [22]. The average, median, and maximum clique sizes in the dataset indicate that the distribution has a long tail, with the weight concentrated on small clique sizes. Unlike other datasets, this distribution is highly representative of real use cases.

Figure 1 reports the genre distribution of Discogs-VI-YT, demonstrating significant coverage over 13 genres. The distribution of styles, which is included in the project repository, covers 512 styles from Mambo to Tech House. Importantly, such genre metadata opens new possibilities for developing and evaluating VI systems. Previous studies have not delved into genre and style analyses, leaving their effect on performance underexplored. Given that our dataset contains relatively reliable genre and style annotations⁷ such analysis is now possible [17].

Figure 1. Discogs-VI-YT version genre distribution.

Table 2 compares the total number of artists of several VI datasets. Da-TACOS and SHS100K datasets provide only one artist per version while Discogs-VI offers multiple. For a consistent comparison, we count one artist per Discogs-VI version and do not include the group members. In addition, Da-TACOS noise works are not considered. The number of versions and artists comparisons between SHS100K and Discogs-VI-YT implies that our dataset contains more versions per artist on average.

Dataset	Artists
Da-TACOS	6,375
SHS100K	34,170
Discogs-VI-YT	67,345
Discogs-VI	239,949

Table 2. Number of track artist comparison between selected datasets. One artist per version is reported.

Figure 2 reports the audio duration distribution of Discogs-VI-YT, reflecting a comprehensive music collection. We observed that the long-duration tracks are mostly live versions and jazz or electronic music tracks, which can be notoriously long. Having long tracks increases the difficulty of training VI systems due to requiring effective time aggregation techniques or small embedding dimensions.

4.1 Development and test splits

We split the Discogs-VI-YT dataset into training, validation, and test sets. To increase the compatibility with other

⁷ Discogs genre and style annotations are release-level, however, they serve as a reasonable approximation for individual tracks.

Figure 2. Discogs-VI-YT audio duration distribution.

datasets, the cliques in Discogs-VI that intersect with the Da-TACOS benchmark and SHS100K-Test sets are ensured to be part of our test set. We excluded CoversDataset from this consideration due to its lack of metadata.

To determine the intersection between our dataset and the Da-TACOS benchmark set, we conducted a thorough comparison of track titles and track writers using artist names, aliases, and name variations. We successfully identified 935 out of the 1,000 (93%) Da-TACOS cliques and 1,412 out of the 2,000 (71%) “noise” tracks. Given the detailed artist metadata we employed, it is unlikely that the unidentified works are included in our training set. Moreover, since Da-TACOS selects its “noise” tracks from those lacking alternate versions and our Discogs-VI consists exclusively of tracks with at least two versions, these tracks are also unlikely to be included in our training set. Regarding the SHS100K-Test set, we identified 1,555 out of the 1,692 cliques (90%). The union of the identified cliques from both datasets is reserved for our test set.

We aimed for a 90-10% development-test split; therefore, we sampled new cliques to add to the reserved cliques. While sampling the additional cliques, we did not exclude the SHS100K-Train set to use our dataset without restrictions. The reserved cliques from the Da-TACOS benchmark and SHS100K-Test sets had large enough sizes in our dataset. Moreover, similar to [7], we believe that having small-sized cliques in the test set simulates real use cases better. Therefore, we randomly sampled the additional cliques from sizes two to six. The remaining cliques were assigned to the development set and were further partitioned into training and validation sets following a 90-10% split. Figure 3 shows the clique size distribution of our splits, and Table 3 compares the split sizes of different datasets.

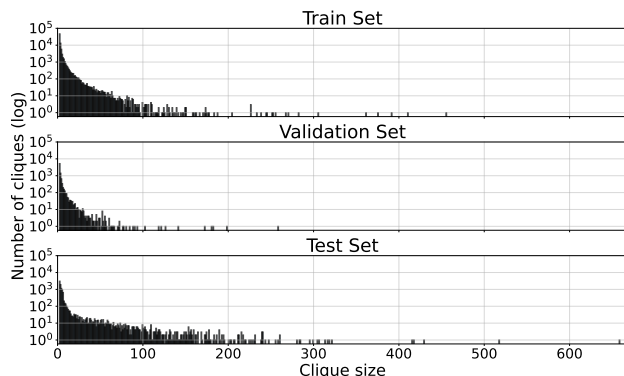

Figure 3. Discogs-VI-YT splits clique size distributions.

Dataset	Split	Cliques	Versions	MCS	ACS	mCS
Da-TACOS	Benchmark	1,000	13,000	13	13	13
	Noise	2,000	2,000	-	-	-
SHS100K	Test	1,692	10,547	162	6	5
	Validation	1,842	10,884	17	6	6
	Train	5,324	87,091	359	16	12
Discogs-VI-YT	Test	9,878	116,197	658	12	3
	Validation	8,890	37,081	258	4	2
	Train	80,017	339,771	455	4	2

Table 3. Dataset partition sizes. MCS: maximum clique size; ACS: average clique size; mCS: median clique size

4.2 Audio representations

We computed the following audio representations commonly used in VI systems: chroma, HPCP [2], and CQT [23]. They are available under request for non-commercial scientific research purposes.

5. BASELINE MODEL

To demonstrate the utility of Discogs-VI-YT we search for a baseline model that uses computationally inexpensive input representations and is feasible for training on a consumer-grade GPU.

TPP-Net [8] and its successor CQT-Net [10] rely on the classification loss for training. Due to the large number of cliques in Discogs-VI-YT, these models are difficult to train on this dataset without modifications. ByteCover [11], ByteCover2 [12], and LyraC-Net [24] are also difficult to train as they employ the classification loss with additional losses and feature complex architectures having significantly more parameters. Additionally, the code and pre-trained weights for these three models are not publicly available. We do not consider ByteCover3 [25] and CoverHunter [26] as they do not target full-track inputs. MOVE [9] and Re-MOVE [3] are not considered due to their reliance on computationally expensive input representations. Ultimately, we selected CQT-Net, primarily due to its adaptability for use with Discogs-VI-YT.

5.1 CQT-Net

The original model is trained with the classification task, where clique IDs of the SHS100K dataset are used as class labels. A multi-length training strategy that presents the model with three different segments from each version is used to reduce possible biases toward input duration. Additionally, tempo change and spectral masking data augmentation techniques are used. During retrieval, the classification head is discarded and the remaining network is used for extracting version embeddings, whose similarity is computed with cosine similarity.

5.2 Discogs-VINet

Training CQT-Net with classification loss is challenging due to the large number of cliques in Discogs-VI-YT. Therefore, we utilize the triplet loss, similar to previous

research [6, 9]. To this end, we remove the classification head from the architecture and change the affine projection layer to a linear projection with 512-dimensional outputs. Additionally, we include an L_2 normalization layer to ensure that embeddings lie on the unit hypersphere. The resulting model contains 5.2 million parameters.

At each training iteration, a mini-batch is created by randomly sampling 48 distinct cliques and two random versions per clique. With this configuration, each sample can only have one positive; hence, the positive mining strategy is equivalent to offline random sampling. For mining negatives, we use online hard-negative mining.

We extract the CQT input representations before training with CQT-Net’s setting. However, we store them with 16-bit precision due to the large storage requirement of our dataset. Unlike CQT-Net’s multi-length training strategy, we use fixed-length inputs where consecutive CQT frames of about 185 seconds are taken randomly. Then the features are mean downsampled with a factor of 20, following the authors. To demonstrate the benefits of using our large dataset, we do not use any data augmentation method during training, such as tempo and key modifications, spectral masking techniques, or audio degradation methods used in previous VI research.

We train Discogs-VINet for 50 epochs, which takes about 25 hours using a single Nvidia RTX2080. We use the AdamW optimizer, setting the initial learning rate to $1e-3$ and adjusting via exponential decay. The triplet loss margin is set to 0.1.

During training, we use our validation set to monitor performance. Every five epochs, we simulate the VI task and save the best model in terms of mean average precision (MAP). However, we evaluate the model at the end of the training on Discogs-VI-YT, Da-TACOS, and SHS100K datasets using MAP and the mean rank of the first relevant item (MR1) metrics.

5.3 Evaluation on Discogs-VI-YT

Due to potential overlaps between the training sets of publicly available VI models and the Discogs-VI-YT test set, we could not benchmark the publicly available models. For instance, as discussed in Section 4.1, there can be shared tracks with the SHS100K-Train set. Similarly, the Da-TACOS training set, which is not publicly available, may share tracks with our test set, rendering comparisons with models trained on this dataset unreliable. Additionally, as discussed in Section 5, training numerous models on Discogs-VI-YT were not possible. We acknowledge these limitations and suggest that benchmarking models is a critical area for future research.

Despite these challenges, we present the scores obtained by Discogs-VINet. Our model obtains a MAP score of 0.443 and an MR1 score of 614.1 on the Discogs-VI-YT test set, which establishes the baseline scores on this dataset. The contrast between the MR1 and MAP values can be attributed to the realistic clique size distribution. As shown in Figure 3, the test set contains numerous cliques with size two. When a query is made with a ver-

Training data	Model	d	Da-TACOS		SHS100K-Test		SHS100K-Test**	
			MAP \uparrow	MR1 \downarrow	MAP \uparrow	MR1 \downarrow	MAP \uparrow	MR1 \downarrow
Da-TACOS	MOVE [9]	4,000	0.495	48 [†]	\times	\times	\times	\times
	MOVE [9]	16,000	0.507	46 [†]	\times	\times	\times	\times

	CQT-Net [10]	300	\times	\times	0.655	55	\times	\times
	ByteCover [11]	2,048	\times	\times	0.836	47	\times	\times
	ByteCover2 [12]	128	\times	\times	0.839	46	\times	\times
	ByteCover2 [12]	1,536	\times	\times	0.863	39	\times	\times
SHS100K-Train*	ByteCover [11]	2,048	0.714	23	\times	\times	\times	\times
	ByteCover2 [12]	128	0.718	23	\times	\times	\times	\times
	ByteCover2 [12]	1,536	0.791	19	\times	\times	\times	\times
SHS100K-Train**	LyraC-Net [24]	1,024	\times	\times	\times	\times	0.765	48
Private	LyraC-Net [24]	1,024	0.813	15	\times	\times	0.884	33
Discogs-VI-YT	Discogs-VINet	512	0.607	24	\times	\times	0.660	61

Table 4. Performance comparison on the Da-TACOS benchmark and SHS100K-Test sets. * denotes that the Da-TACOS benchmark set tracks were removed, ** denotes that the corresponding authors of that model downloaded the available URLs (therefore LyraC-Net [24] and Discogs-VINet are not evaluated on the same data), d denotes the embedding dimension, \times denotes that the result was not available, and [†] denotes the corrected calculations described in Section 5.4.

sion from these cliques, retrieving the only other version in high rankings contributes significantly to the MAP metric.

5.4 Evaluation on Da-TACOS and SHS100K

We tested Discogs-VINet on the Da-TACOS benchmark and SHS100K-Test sets. From the SHS100K-Test set, we could download 8,489 versions (80% of the total). As discussed in Section 4.1, we perform an extensive analysis to ensure that our training set has a minimal intersection with the evaluated sets.

The results are presented in Table 4, relying on results reported in the literature except for MOVE and Re-MOVE, for which we recomputed the results due to a metric calculation problem we discovered. In the public Da-TACOS evaluation script, "noise" works are wrongly boosting the MR1 score instead of being excluded. We corrected this issue, tested the official MOVE and Re-MOVE models, and listed the updated MR1 values.

In Table 4, Discogs-VINet outperforms both MOVE and Re-MOVE on the Da-TACOS benchmark set, which is a significant improvement given the simplicity of our input representation and lack of data augmentations. Unlike such, Discogs-VINet does not depend on pre-trained models for input representation. As a result, it exhibits significantly faster embedding extraction, similar to those reported in [12].

On the SHS100K-Test set, even though we used a slightly smaller subset due to some URLs becoming unavailable, we could not improve over other considered models, except for the TTP-Net and CQT-Net. In particular, CQT-Net, which we modified for our baseline, performed similarly. We posit that these differences may stem from the absence of data augmentation techniques in our methodology or from the classification loss possibly structuring the latent space more effectively than the triplet loss

we implemented. Nonetheless, further experiments are required.

ByteCover, ByteCover2, and LyraC-Net outperform Discogs-VINet by a significant margin. This performance difference can be attributed to several factors: the combined use of classification and triplet losses, as reported in the literature [27], the advantages obtained by training larger architectures, or the absence of data augmentations in our model. However, it is important to note that independent studies have raised concerns about the reproducibility of the published results associated with the ByteCover approach [24, 28].

6. CONCLUSION

We presented a new methodology to create a VI dataset from a previously unused metadata source, Discogs. Using this metadata, we identified a large number of cliques and versions to create the Discogs-VI dataset and matched a large portion of the versions with official YouTube URLs to create its Discogs-VI-YT subset. Our datasets surpass existing datasets by far in size and provide unprecedented metadata detailing genre, style, and artist relationships.

To demonstrate the utility of Discogs-VI-YT, we trained a baseline model, Discogs-VINet, on the training set and evaluated the model performance on the test set, establishing baseline results. Additionally, we assessed Discogs-VINet’s performance on the Da-TACOS benchmark and SHS100K-Test sets, where it demonstrated competitive performance. Notably, our model achieved these results without relying on any data augmentation techniques, multiple training losses, or complex architectural designs.

We leave training large models, using the metadata relations for training and evaluation, and investigating the role of data augmentations as future work.

ABSTRACT

The meteoric surge of AI-generated music has prompted significant concerns among artists and publishers alike. Some fear that the adoption of AI is poised to result in massive job destruction; others sense it will jeopardize and eventually upend all legal frameworks of intellectual property. AI, however, is not the first instance where humanity has confronted the prospect of machines emulating musical creativity. Already in the Baroque, various modes of musical artificiality were explored, ranging from automata and organ stops mimicking human performance and natural sounds, up to devices for mechanized composition (e.g., Athanasius Kircher, Johann Philip Kirnberger, C.P.E. Bach, Antonio Calegari and Diederich Nickolaus Winkel). Valuable insights emerge from the reconsideration—and digital implementation—of these curiosities through the lens of present-day generative models. It can be argued that the very notion of ‘artificiality’ has presented humanity with long-standing philosophical dilemmas, in addressing the debate on the role of art as a substitute of (divine) nature. By digitally implementing and formalizing some pioneering instances of algorithmically-generated music we wish to illustrate how mechanical devices have played a role in human art and entertainment prior to our digital era.

1. INTRODUCTION

The rise of AI-generated music has sparked considerable concern among both artists and publishers. Some worry that the integration of AI technology may lead to widespread job displacement, while others foresee potential threats to existing legal structures governing intellectual property rights. The very notion of ‘artificiality’ has a decidedly negative ring to most people, evoking feelings of distrust, inauthenticity, and deviations from the ‘natural’ or ‘genuine.’ This can be attributed to the Platonic tradition. In *The Republic* (c. 375 BCE), Book X, Plato famously criticised the act of imitation (*mimesis*) in art and poetry as the ‘copy of a copy,’ merely satisfying the inferior senses and base pleasures, and lacking connections

with truth, virtue, or other higher ideas. The imitator, Plato contended, was a person who “has neither knowledge nor right opinion about whether the things they make are fine or bad.” [1, p. 1206]

But art is of course ‘artificial’ by its very nature, as a cultural expression, and vice versa: all artificiality requires art. Like ‘artifact’ and ‘artifice,’ ‘artificiality’ combines the Latin noun *ars* with the verb *facere* into one expression which means ‘doing art.’ ‘Art,’ consequently, can be understood as something so well-made (or ‘artful’) that it can substitute for the real or natural, which it is inseparably paired with. Artificiality, in this sense, does not need to possess any pejorative connotation; it simply amounts to ‘art’ or ‘artistry’ itself. As man-made contraption, an artifice demands art, being the craftsmanship or ‘science’ required to entice the beholder or listener through its mimicry. The past teaches us important lessons in this regard.

Artificiality, or “Nature’s Changeling,” [2, p. 51] as Margaret Cavendish termed it in *The Blazing World* (1666), has long fascinated humanity for providing an illusion of divine creation. The idea of building an alternative reality, which can be controlled by its human creators, has appealed to artists, scholars, and musicians through the ages. In particular in the long Baroque (c. 1550–1800) ‘artificial’ even denoted anything that was ‘artful.’ When, for example, the English diarist John Evelyn (1620–1706) visited the royal park of Brussels, on 8 October 1641, he marveled at “*artificial* cascades, rocks, grots” and a “grot of more neat and costly materials, full of noble statues, and entertaining us with *artificial* music.” [3, p. 37] In 1635, the French literary critic Jean Chapelain (1595–1674) contended that:

imitation in all poems, must be so perfect that *no difference appears between the thing imitated and that which imitates* [emphasis added], for the principal effect of the latter consists in proposing to the mind, in order to purge it of its unbridled passions, the objects as true and present”. [4, p. 115]

The Italian painter and architect Federico Zuccaro (1539–1609), furthermore, distinguished three types of design: natural (implying the imitation of nature), artificial (being a stylized distortion of nature), and fantastic-artificial (producing images of an entirely imaginary and unusual kind). [5] In sum, the Baroque revelled in artifi-

Historical notions and current challenges of musical artificiality”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

ciality, hailing the *trompe l'œil*, masquerade, automaton, and other sorts of mimicry as pinnacles of art.¹ [6, p. 10]

The Baroque did not perceive anything deceptive per se about artificiality, as long as not the mimicry itself—the relationship between artifice and nature—and the methods to obtain it were denied. Thus, François Hédelin, abbé d'Aubignac (1604–1676), argued in *La Pratique du théâtre* (1657) that spectators in the theatre knew all too well they were tricked when being “shown a new heaven, a new Earth, and an infinity of wonders that we believe to be present, at the very time we are quite sure we are being deceived.”² Conscious of the fact they were beholding painted canvases, handled by mechanical equipment, they relished the thought of artists producing such wonders. In a similar vein, Francis Bacon (1561–1626) included “all manner of feats of juggling, false apparitions, impostures, and illusions” in Salomon’s house, the utopian research institute evoked in *New Atlantis* (publ. posth., 1627):

[a]nd surely you will easily believe that we, that have so many things truly natural which induce admiration, could in a world of particulars deceive the senses, if we would disguise those things and labour to make them seem more miraculous. *But we do hate all impostures, and lies*; [emphasis added] insomuch as we have severely forbidden it to all our fellows, under pain of ignominy and fines, that they do not show any natural work or thing, adorned or swelling; but only pure as it is, and without all affectation of strangeness. [7, p. 40]

Consequently, the Baroque accepted and even actively endorsed methods of replicating nature as expressions of supreme craftsmanship, but it demanded that the mechanics of those “miraculous” devices be fully acknowledged and revealed.

It was only in the nineteenth century, as ‘authority’ and ‘originality’ emerged as core values of a “new code of artistic morality,” [8, p. 319] that a shift occurred in the understanding of art. This transformation altered the perception of the artwork from a handcrafted, artisanal product—an ‘artifice’—into a cerebral, isolated, and unique expression of genius. To replicate something came to be seen as an act of unoriginality, forgery, or plagiarism, [9] while technologies for mechanical reproduction (including photography, audio recording, and cinematography) were held responsible for the destruction of art’s ‘aura.’ [10] Plato returned with a vengeance.

In what follows, we will revisit the Baroque, and more particularly the devices for mechanised music composi-

¹ German Bazin argued that “Perhaps the most surprising feature of Baroque art,” the art historian and former Louvre curator Germain Bazin argued, is how the artists “who in thought and deed created new worlds could indulge in childish games of make-believe. One might pretend to be Apollo, Rinaldo, the Grand Turk, or even Confucius, but never simply oneself...”

² “on nous montre un nouveau Ciel, une nouvelle Terre, & une infinité de merveilles que nous croyons avoir présentes, dans le temps même que nous sommes bien assurés qu’on nous trompe.”

tion through which it explored artificiality in music. In discussing and digitally implementing a select number of these curiosities, our intention is not necessarily to engage in history for the sake of history itself, but rather to gain *transhistorical* insights into the workings and ethics of generative models in music composition.

By digitally implementing and formalizing some pioneering instances of algorithmically-generated music we wish to illustrate how mechanical devices have played a role in human art and entertainment prior to our digital era.

2. A SELECTED HISTORY OF GENERATIVE MODELS IN MUSIC

Whenever mechanical music is mentioned, one naturally thinks of our latest inventions, of the most highly perfected products of a technical, industrial age. [11]

The opening of 1934 article by Hugo Leichtentritt on mechanical musical instruments is an instructive example of how humanity has regularly confronted itself with cultural changes caused by technological progress, such as the early 20th century media revolution of radio broadcasting, movies and musical recordings. [12] Breakthrough technologies, such as the printing press, musical automata and clockworks, and audio recordings have always transformed artistic practice into new, unforeseen modes of expression. For instance, musical styles such as hip-hop, electronic dance music and *musical collages* such as Luciano Berio’s *Sinfonia* (1968), [13] laid their foundation on the possibility to repeat, transform, assemble and interact with pre-recorded material.

In a similar fashion, watching automata playing music in action, ingeniously designed using programmed cylinders and cogwheels mechanisms, [14] must have been an unimaginable experience for our forerunners, only comparable to our modern wonder for AI tools. These devices were able to entertain their public with musical pieces composed on the spot without any apparent human intervention.

We can even reassess Henry Purcell’s famous “Wonderous Machine” bass aria from *Ode for St Cecilia’s Day* Z. 328, reinterpreting the lyrics through the lens of an impatient Baroque musician (in this case a lute player) confronting themselves with the infinite possibilities of indefatigable mechanical devices:

*Wondrous machine!
To thee the warbling lute,
though used to conquest,
must be forced to yield,
with thee unable to dispute.*

The voice and instrumental accompaniment’s patters seem to emulate the *perpetuum mobile* of mechanically driven musical instruments, the like of which are described in later treatises like Engramelle’s *La Tonotechnie ou l’art de noter les cylindres* (1775) or ambitious implementations such as Diederich Nikolaus Winkel *Componium* (1821), a

Figure 2. Opening ground bass, accompaniment of the two oboes and singing voice dotted diminutions of respectively measures 1-2, 3-4 and 15-16.

mechanical device able to play an almost endless amount of variations on a pre-programmed piece of music. [15]

But how to translate a highly complex activity, such as music, into an algorithmic procedure? The act of music-making, either planned by a composer or made *ex tempore* by an improviser, arises from selecting musical gestures from an associative knowledge base stored in the musician's long-term memory. [16] For centuries, musicians have built such repositories, organising the vast palette of musical gestures, or schemata, through various systems of classification. [17] Tables, decision trees and voice-leading matrices have helped musicians to create a repertoire of melodic, harmonic and rhythmic patterns reflecting their contemporary musical style and performance practice.

Archetypical musical schemata were represented by rules, such as Thomas Campion's procedure for four-voice harmonisation of a given bass line. [18, p. 1-8] Moreover, Pietro Cerone encyclopaedic work *El melopeo y maestro*, [19] provided an endless series of musical tables and examples, similar in fashion to our modern "training sets" for AI models, that musicians internalised in their long term-memory, ready to be used during improvisation or composition of new pieces. [20]

Figure 3. Voice-leading rules four four-voice harmonisation of a given bass melody. The procedure is based on the bass movements and relative consonances between the upper and lower voices.

Several treatises, like Giovanni Battista Chiodino's *Arte Pratica Latina et Volgare di far contrapunto a mente, et a penna* (1610), focussed on contrapuntal patterns that could be used by musicians to harmonise a given melody or bassline, while others, like Francesco Rognoni *Selva de varii passaggi* (1620), provided the students with complex rhythmic patterns for ornamenting melodic lines and cadential formulas not very dissimilar to 20th-century collections like Nicolas Slominsky's *Thesaurus of Scales and Melodic Patterns* (1947) or Jerry Coker's *Patterns for Jazz* (1970).

Of particular interest for our discussion is the 'Arca Musarithmica', a computational device designed by the German polymath Athanasius Kircher (1602–1680) and described in the second volume of his *Musurgia Universalis* (1650). [21] Kircher's compositional tool generates four-voice homophonic and polyphonic harmonisations (respectively named *contrapunctus simplex* and *floridus*) on the basis of a given set of verses and a musical scale, according to the contemporary Renaissance theory of authentic and plagal modes. The machine was designed to generate hymns for Jesuit missionaries working in religious communities outside Europe: thanks to Kircher algorithm, the priests could easily generate music from a liturgical text in the native language of their communities and compose the music according to the "affect" of the verses. [22] As if anticipating Purcell's "Wonderous Machine," the author describes the algorithm as "wondrous music" (*musurgiae mirificae*), referring to the device's capacity to instill wonder (*meraviglia*) in listeners and composers (or operators) alike. ³ To the best of our knowledge, Kircher is one of the first to use an abstract representation of the four-voice counterpoint: he assigned numerals to the scale's relative degrees and provided tables of rhythmic patterns that

³ A recent digital implementation of the *arca* has been made by Andrew A. Cashner of University of Rochester. The code is publically available on GitHub at <https://github.com/andrewacashner/kircher> while a web-based application can be found at <https://arca1650.info>

Figure 4. An earlier example of the use of dice and randomness in musical composition is Pietro Cerone *Enigma de la suerte, ò de los dados* appearing in his *El melopeo y maestro* (1613), pag. 1124. [31]

could be independently assembled with each other. A more "serialistic" approach can be found in the Anonymous treatise *Ludus Melothedicus* (1758), where the author created a series of numerical tables, where each number corresponded to a chromatic pitch and a given duration.

A detailed analysis of Kircher's voice-leading patterns reveals that these four-voice harmonies conform to typical 16th century musical schemata and chord progressions. Many of these progressions are based on counterpoint rules encoded in other treatises, like the one of Thomas Campion, the musical examples of Vicente Lusitano *Introductione facilissima, et novissima, ...* (1553), [23] Thomas Morley *A Plain and Easy Introduction to Practical Music* (1597) [24] and Tomás de Santa María *Libro llamado arte de tañer fantasía* (1565) [25]. [26]

Furthermore, the idea of encoding contrapuntal structures in a series of mathematical operations has found several resonances in the works of C.P.E. Bach *Einfall einen doppelten Contrapunct in der Octave von 6 Tacten zu machen* (1757), [27] the stylistic analysis of "Palestrina style" counterpoint of Serge Taneiev *Convertible Counterpoint in the Strict Style* (first publication, 1909) [28] and in the theories of melody, harmony and rhythm of 18th century mathematician Leonard Euler. [29]

A step ahead of pure deterministic rules, was the introduction of randomness in the compositional process, reducing the musician's agency on the generated artifact. The development of combinatorics, with its first application to music theory can be found in the early 17th century works of Kircher and Marin Mersenne, musicians explored the possibility of generating music from a series of exemplars through a randomized process, usually implemented by appending musical fragments according to numerical tables and dice rolling. To the best of our knowledge, the first published "dice game" (*würfelspiel* in German) is Johann Philipp Kirnberger *Der allezeit fertige polonoisen- und menüettencomponist* (1757), providing random tables to generate popular dance music (a polonaise and a menuet) for two violins and harpsichord accompaniment. [30]

In the coming decades, many other musicians imitated

Figure 5. Ingestion of lyrics into the generated music in Calegari's *Gioco Pitagorico Musicale*.

Kirnberger's curious experiment to generate music in an algorithmic fashion, leaving the user's agency to pure chance. The best known of these "dice games" is probably *Anleitung so viel Walzer oder Schleifer mit zwei Würfeln zu componiren*, attributed to W.A. Mozart and published by Nikolaus Simrock around 1790. Its fame is so great that a digital implementation of the compositional device had already been developed by David Caplin in 1955. [32,33]

Of particular interest is Antonio Calegari's *Gioco Pitagorico Musicale* (1801), which provides a framework for including lyrics to the generated airs and duets. In the title the author states clearly that the game is designed "for people without any knowledge of music",⁴ willing to amuse themselves at home with a seamless infinite combination of songs in the then current operatic style. [34]

A similar statement, made in the introduction of Andrea Mangeruva's *Nuovo Metodo per Comporre Migliaja di Walser* (1839), where the author designed a complicated randomised procedure based on modular arithmetic, encourages the use of the book for domestic music-making and amusement but warns the reader about the "seriousness" of his device: according to Mangeruva a "mechanical musician" (*un musico meccanico*) cannot aspire to "true music" (*la vera musica*), making an analogy between rules and procedures of prosody with the art of poetry. [35, p. 4] Unfortunately, Mangeruva's treatise is nothing more than a plagiarism of a 1811 French publication *Barême musical, ou l'Art de composer la musique sans en connaître les principes* attributed to Italian composer Gioseffo Catrufo. [30]

Many of these publications address a specific facet of music-making, namely amusement and entertainment. Is not by chance that these "dice games" were mainly used to generate popular music, in the form of songs and dances. Furthermore, we have noticed how many publishers have attributed their publications to famous composers, such in the case of the *Gioco Filharmonico*, attributed to Joseph Haydn by Luigi Marescalchi in 1793. Misattributions, rearrangement and even unauthorized reprints have been surprisingly common in the genre, as previously stated in the

⁴ "Col quale potrà Ognuno, anco senza sapere di Musica, formarsi una Serie quasi infinita di piccole Ariette"

Figure 6. Musical table from Andrea Mangeruva *Nuovo Metodo*.

instance of Mangeruva's "borrowing" from *Barème musical*.

Concerning the algorithms, they are mostly based on a series of basic musical variations of a piece, like a menuet or countrydance, composed beforehand by the author. Afterwards, a series of puzzles, enigmas, and randomizations are used as expedients to deceive the user, keeping the illusion that the procedure must be of some kind of magic. In several manuscript sources of early "dice games" the term *cabala* is often used,⁵ alluding to the duality between modern science, in the nascent theory of probability, and proto-scientific disciplines like alchemy and astrology. [36]

3. DIGITAL IMPLEMENTATIONS

A series of digital implementations of the treatises described in our paper are publically available on our GitHub repository.⁶ Alongside the Python code, we are providing the digital images of the discussed treatises and a small dataset of musical examples in LilyPond⁷, MIDI and PDF format, both from the generated music as for the input exemplars. The transcriptions of each musical fragment could be used as ground truth for Optical Music Recognition tasks involving the transcription of individual measures, both for printed as for handwritten music. [37] Furthermore, this unique musical corpus might be used in future research as baselines for evaluating generative models emulating 18th century Western classical music. A detailed list of pre-digital generative models for music can be found on the aforementioned *Artyfyshall Byrd* GitHub.

4. CONCLUSIONS

The present article wishes to present the current discussion on Artificial Intelligence and music from an historical perspective. The desire to artificially emulate nature

⁵ Several 18th century musical dice games refer explicitly to the Jewish kabbalah in their title and content, such as Johann P. Kirnberger *Cabala per componendi minuetti*, Bernardo Ottani *Tavola per la Cabala* and the anonymous *Musicalische Cabala* preserved in the National Library of France. For a detailed list of treatise visit our GitHub repository.

is a fascinating feature of human beings, and can find its roots in history, as well as in myths like Pygmalion, described in Ovid's *Metamorphoses* (c. 8 CE), Book X. [38, p. 128-148] With the technological developments of the Modern Period we have increasingly refined our craft to a point where the differences between the 'artificial' and the 'natural', between the 'authentic' and the 'forged', are almost impossible to discern. [39] On the other hand, the challenges afforded by technology and its artificial devices encourage us to reconsider the meaning of creativity and the role of art in our culture. [40] New technologies pose a "challenge to the imagination" for composers and performers, [41] extending the boundaries of human's creative effort. This statement is still valuable to our modern "wondrous" times, where the dreams of Leonard Euler [42] and Ada Lovelace⁸ [14] to mathematically encode every facet of music so that a machine could generate new pieces have become a tangible reality. Studing what it meant for our forerunnes to interact with the wonders of *musurgiae mirificae* can help us frame the current issue from a historical, dialectical perspective.

5. ACKNOWLEDGMENTS

We are particulary grateful to the library staff of the Conservatory of Venice Benedetto Marcello (Paolo da Col and Silvia Urbani) for the digital images of Mangeruva and Calegari treatises. We are also thankful to the Abjad developers for providing a useful Python library compatible with the Lilypond music encoding syntax [43].

ABSTRACT

Automatic singing skill evaluation (ASSE) systems are predominantly designed for solo singing, and the scenario of singing with accompaniment is largely unaddressed. In this paper, we propose an end-to-end ASSE system that effectively processes both solo singing and singing with accompaniment using data augmentation, where a comparative study is conducted on four different data augmentation approaches. Additionally, we incorporate bi-directional cross-attention (BiCA) for feature fusion which, compared to simple concatenation, can better exploit the inter-relationships between different features. Results on the 10KSinging dataset show that data augmentation and BiCA boost performance individually. When combined, they contribute to further improvements, with a Pearson correlation coefficient of 0.769 for solo singing and 0.709 for singing with accompaniment. This represents relative improvements of 36.8% and 26.2% compared to the baseline model score of 0.562, respectively.

1. INTRODUCTION

In recent years, the widespread use of digital media has changed the way users interact with music, giving rise to new applications like streaming services and online karaoke platforms [1, 2]. As numerous singing content is published daily by these applications, it becomes very expensive and practically unscalable to retrieve high-quality content manually. One such scenario is the discovery of vocal talent in the vast online platforms, where automatic singing skill evaluation (ASSE) systems can be used to examine and rate all the singing content, so that the top-tier can be distributed for more views, subscribers, and ultimately more profits.

Despite the potential commercial values, ASSE is a difficult task that encompasses both subjective preferences and multi-dimensional objective features (e.g., intonation accuracy, rhythm accuracy, range, and dynamics) that professional judges also consider when evaluating vocal performances [3]. Over the years, different ASSE systems have been proposed. Depending on whether a reference melody is taken as the ground truth, these ASSE systems can be classified as reference-dependent [4–9] or reference-independent approaches [10–18]. Recent research on ASSE has been mainly focused on reference-independent deep learning-based approaches, where CNN-based architectures are often used to extract useful patterns from input spectrograms [11, 14, 15, 17, 18]. Other features including pitch histograms [11, 14, 15, 17] and singer timbre embeddings [17, 18] are also used, and these features are usually fused via concatenation. Although this is a simple way of feature fusion, the more advanced techniques that could uncover deeper relationships between these features are still unexplored in ASSE.

Another limitation of the current ASSE research stems from the lack of open-source datasets and high-quality annotations. For example, among the three recent datasets: neither the Smule DAMP dataset [14] nor the YJ-16K dataset [18] is open-sourced, and although Lyra-SA [19] is available after filling out an application form¹, the authors claimed that singing skill annotations are still immature and therefore not sufficiently curated for research purposes yet. Other ASSE datasets including self-made recordings [9, 20] or collections from singing platforms [7, 12] are also non-public. The lack of publicly available datasets is one of the major impediments that significantly hinder the advancement of ASSE research.

Finally, most ASSE systems require solo singing as input, leaving the scenario of singing with accompaniment largely unexplored [7–9, 11, 12, 14, 15]. On the other hand, [17] proposed an ASSE system that can process singing with accompaniment, but it is achieved by employing a singing voice separation tool [21] as a pre-processing step to remove the accompaniment, which not only results in a more complicated and computationally expensive system, also the model input is still essentially solo

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

¹ Available at: <https://lyracobar.y.qq.com/singvoicedataset.html>

singing. In this paper, we propose a new ASSE system capable of processing both solo singing and singing with accompaniment in an end-to-end manner, thereby eliminating the need for a singing voice separation tool. This is achieved through data augmentation during training, where we present the same singing clip in three distinct versions: solo singing, singing with its original accompaniment, and singing remixed with a different accompaniment. For the remixed version, we explore and compare four different approaches, which will be detailed in Section 2.2.2. Furthermore, we explore feature fusion techniques beyond simple concatenation, since such methods can better integrate and amalgamate diverse data sources with greater efficacy [22, 23]. In particular, we adopt a Bi-directional Cross-Attention (BiCA) mechanism during feature fusion, given its effectiveness in capturing the reciprocal knowledge exchange between the source and target features in both directions [24]. The contributions of this paper are:

- We propose an ASSE system that processes both solo singing and singing with accompaniment. The system functions in an efficient end-to-end manner, thereby eliminating the need for a singing voice separation tool required by the baseline model [17].
- We adopt a BiCA mechanism during feature fusion, which better exploits the inter-relationships between different features and facilitates their reciprocal knowledge exchange, compared to simple feature concatenation (see Section 2.2.1).
- We explore data augmentation for ASSE and compare four different approaches: the existing Shuffle-And-Remix [25], the proposed Same-Song Remix, the proposed Key-Match Remix, and All Remix that combines the data augmented from the above three methods (see Section 2.2.2).
- Results show that BiCA and data augmentation boost performance individually (see Section 3.4). The combination of both results in further improvements, with a Pearson correlation coefficient of 0.769 for solo singing and 0.709 for singing with accompaniment on the 10KSinging dataset. This represents relative improvements of 36.8% and 26.2% compared to the baseline score of 0.562 [17], respectively.

2. METHODOLOGY

2.1 The Baseline Model

In the ASSE literature, singing skills can be presented as a ranking [11], a category [8, 9, 12, 18] (e.g., awesome, mediocre, or inferior), or a numerical score [14, 15, 17, 20] (e.g., 60 out of 100). We consider numerical scores for singing skills since they can be mapped into discrete categories or sorted as a ranking, which can be used in different scenarios. Within this range, the existing literature on ASSE is quite limited, and we consider [17] the baseline

model for our study, due to its superior performances to the recent ASSE system [14].

The pipeline of the baseline model is shown in Fig. 1(a): it begins by extracting solo singing from the input using an existing singing voice separation tool [21], then the Constant-Q Transform (CQT) is computed and processed by a Convolutional Recurrent Neural Network (CRNN) with an attention mechanism. Following this, the 200-dimensional output from the CRNN and attention is fused with the 120-dimensional pitch histogram² and the 512-dimensional X-vector³ using concatenation. Finally, the combined features are subsequently fed into a streamlined pair of dense layers to output the predicted singing rating.⁴

Compared to [14], three improvements were made in [17]: (1) the attention mechanism was added to the CRNN structure to further explore the useful, long-term relationships in the feature space; (2) X-vector [26] was added as additional features to depict the singing voice timbre, representing the control, resonance, and power that can be essential in singing skill evaluations; (3) the network structure was also finetuned to accommodate the first two improvements, where an extra dense layer was added to optimize the performance. Furthermore, they presented the 10KSinging dataset, which includes the singing skill ratings for 9,756 songs from 93 Chinese male singers and 97 Chinese female singers, and it was further divided into training, validation, and testing sets with 8,000, 756, and 1,000 songs, respectively. Each song from 10KSinging has two versions: the original singing with accompaniment version and the solo singing version, where the accompaniment of the latter was removed using a singing voice separation tool [21]. They used both versions to train their proposed ASSE model and found the solo singing version achieved better performances. Therefore, they considered singing voice separation an integral part of the pipeline, extracting solo singing as the input to their ASSE model shown in Fig. 1(a). As a result, a 62.4% relative improvement was achieved on Pearson correlation coefficient compared to [14] (0.562 VS. 0.346) on the 10KSinging dataset, serving as a solid baseline in this paper.

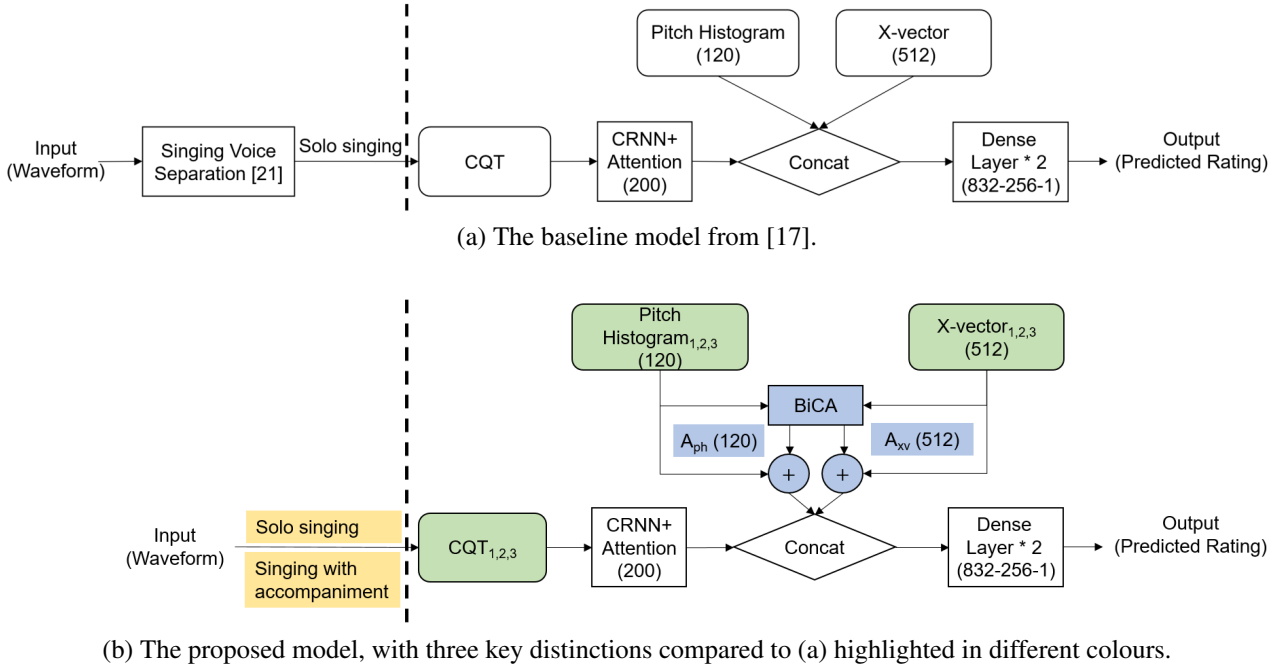

2.2 The proposed Model

Our proposed ASSE model is shown in Fig. 1(b), which highlights the three improvements compared to the baseline model Fig. 1(a) in different colours. The yellow part indicates that the proposed model can process both solo singing and singing with accompaniment, while the baseline model requires singing voice separation to extract solo singing from the input; the blue part represents the use of bi-directional cross-attention between the pitch histogram

² Originally proposed in [14], pitch histogram is a global representation of pitch distribution for music, where all octave-equivalent pitches are folded, resulting a range of 12 pitch classes. The distance between two adjacent pitch classes is represented with 10 bins.

³ According to [26], X-vector distinguishes different kinds of voice timbre. It has been applied to areas including speaker/emotion recognition [27], and singer identification [28].

⁴ The reader can refer to [14] for more specifics regarding the CRNN structure and the pitch histogram generation, and [17] for details on the attention mechanism integrated into the CRNN and X-vector extraction.

(b) The proposed model, with three key distinctions compared to (a) highlighted in different colours.

Figure 1. Illustration of the baseline model (a) and the proposed model (b). The diagram on the right of the dashed line indicates the architecture of the two ASSE systems, where (a) requires singing voice separation as pre-processing [21] to extract solo singing while (b) can process both solo singing and singing with accompaniment (yellow) in a more efficient, end-to-end manner. The proposed model features Bi-directional Cross-Attention (BiCA, blue) and data augmentation (green) using the three distinct training sets of 10KSinging, namely: subindex 1 as singing with accompaniment, subindex 2 as solo singing, and subindex 3 as singing and accompaniment remix discussed in Section 2.2.2. The number in parentheses represents the number of dimensions, while A_{ph} and A_{xv} denote the attention output for the pitch histogram and X-vector, respectively. Both A_{ph} and A_{xv} enter a sum operation with their respective input feature via residual connections.

and X-vector features (see Section 2.2.1); the green part represents data augmentation, where three distinct sets of 10KSinging: singing with accompaniment, solo singing, and singing and accompaniment remix are used during the training process (see Section 2.2.2).

2.2.1 Bi-directional Cross-Attention

As discussed above, the baseline model [17] includes a self-attention mechanism in CRNN to capture the long-term relationships from the input CQT spectral representation. This is based on the scaled dot-product attention layer proposed by Vaswani et al [29]:

$$\begin{aligned} \text{Attn}(Q, K, V) &= \text{softmax}\left(\frac{Q \times K^T}{\sqrt{D}}\right) \times V \\ &= \text{softmax}(S) \times V, \end{aligned}$$

where Q , K , V , S , and D denote the query, key, value, similarity matrix, and dimension of the attention layer, respectively.

In addition to the self-attention mechanism adopted by the baseline model, we further improve our approach by applying cross-attention to the remaining two features: pitch histogram and X-vector, since there can be correlations between singers' pitch accuracy and timbre quality that are beneficial for ASSE. In the cross-attention mechanism, the query Q_t is derived from the target t , with the key

K_s and the value V_s derived from the source s . The attention output $\text{Attn}_t(Q_t, K_s, V_s)$ is then added to the target t via a residual connection, leaving the source s unmodified. This means if we aim to apply cross-attention to both pitch histogram and X-vector features, we need to do it twice: one using pitch histogram as target (t), X-vector as source (s) and vice versa for the other one. To reduce the excessive computational demands in this case, we adopted Bi-directional Cross-Attention (BiCA) [24] that contains a reciprocal attention mechanism, where a shared query-key (QK) matrix [30] is applied to update both the target t and the source s in parallel. Concretely, the similarity matrices of S_t and S_s in BiCA can be calculated as:

$$S_t = \frac{(QK)_t \times (QK)_s^T}{\sqrt{D}} = S_s^T,$$

where $(QK)_t$ and $(QK)_s$ are the shared query-key matrices projected from t and s , respectively. As a result, the attention features of t and s can be respectively obtained by multiplying the corresponding similarity matrix with the value matrix projected from both t and s :

$$\text{Attn}_t = \text{softmax}(S_t) \times V_s; \quad \text{Attn}_s = \text{softmax}(S_s) \times V_t$$

Finally, we perform a residual connection in both t and s to add the corresponding attention features Attn_t and Attn_s . Overall, we enhance the learning of inter-relationships between pitch histogram and X-vector by

implementing the cross-attention mechanism, specifically BiCA⁵ to our approach illustrated in Fig. 1(b). This way, our proposed model is capable of maintaining the effectiveness of cross-attention while being computationally efficient [24].

2.2.2 Data Augmentation for ASSE

As discussed in Section 1, the lack of data can hinder the research and development of ASSE models, and we aim to mitigate this problem by adopting data augmentation. For this purpose, we use the 10KSinging dataset from [17], which contains 9,756 songs in two versions: singing with accompaniment and solo singing. It is further divided into training, validation, and testing sets with 8,000, 756, and 1,000 songs, respectively. We combine the two versions (singing with accompaniment and solo singing) of the training sets and develop a third one called “singing and accompaniment remix”, with an additional 8,000 songs generated by remixing the solo singing with a different accompaniment to create more data. For this purpose, we compare three different remixing approaches:

- **Shuffle-And-Remix** [25]: this existing approach remixes each solo singing with a randomly selected accompaniment from another song. Note that with this approach, the singing and accompaniment may not be in the same musical key, and combining the two will introduce differences in musical key irrelevant to ASSE and may interfere with the training process. Therefore, we propose two new remixing techniques that ensure the same key between singing and accompaniment as follows.
- **Same-Song Remix**: instead of using a different song, we can shift the accompaniment track of the same song by a random duration between 5 to 15 seconds ahead or behind the singing track and remix both. This creates a unique alignment where the vocals and music are out of their original synchronization but still ensures both are in the same musical key.
- **Key-Match Remix**: we use the Madmom key detection algorithm [31] to iterate all the accompaniments and eliminate the ones that are in a different key than the solo singing. Among the remaining candidates, we randomly pick one accompaniment, and remix it with the solo singing.

As a result, we have an augmented training set of 24,000 songs in total, where singing with accompaniment, solo singing, and singing and accompaniment remix all contribute 8,000 songs, indicated respectively as subindex 1, 2, 3 in Fig. 1(b). Furthermore, we can extend the set of subindex 3 by combining the augmented data from all three remixing approaches above (8000×3 songs) and propose a fourth approach: **All Remix**, with 40,000 songs in total.

⁵ We use an open-source implementation of BiCA available at: <https://github.com/lucidrains/bidirectional-cross-attention>.

3. EXPERIMENTS

As indicated in [17], each song of the 10KSinging dataset is associated with an overall, normalized rating between 0 and 1, and the goal of our ASSE model is to predict a regressed value close to the ground truth rating. Although the work presented in this paper is not open-source for proprietary restrictions, most of the essential components are open-source as follows: the code base and the fundamental structure of CRNN, including the pitch histogram calculation can be found at Github⁶; the annotations for 10KSinging, the attention mechanism appended after CRNN, and the X-vector calculation can be found at [17], and we will respectively explain our experimental settings and relevant implementation details in Section 3.1 and Section 3.2 for the ease of reproducing our work.

3.1 Experimental Settings

We first investigate the effect of data augmentation in five settings: no data augmentation, Shuffle-And-Remix (SAR), Same-Song Remix (SSR), Key-Match Remix (KMR), and All Remix (ALL) proposed in Section 2.2.2. In each data augmentation setting, we can either use the baseline architecture (Fig. 1(a)) or adopt BiCA (Fig. 1(b)), resulting in a total of 10 experiments. In each experiment, we present the performance on the 1000-song test set from the two versions of 10KSinging: singing with accompaniment (“w/ acc”) and solo singing (“w/o acc”). As shown in Table 1, the first two experiments involve no data augmentation and each has two distinct ASSE models that are trained using the two versions of 10KSinging (“w/ acc” and “w/o acc”), same as [17].

For the remaining eight experiments involving data augmentation, each uses an augmented training set of 10KSinging, which contains songs from the following three sets: singing with accompaniment, solo singing, and singing and accompaniment remix introduced in Section 2.2.2. Unlike the first two experiments, each of the eight experiments has only one ASSE model, which is evaluated in both “w/ acc” and “w/o acc” test sets. Altogether, 12 models are trained in total to explore the effects of data augmentation and BiCA.

3.2 Implementation Details

We adopt the same parameters for generating CQT and pitch histograms as described in [17], namely 96-bin CQT and 120-bin pitch histogram. For training, we use Mean Squared Error (MSE) as the loss function, where the epoch with the lowest MSE on the validation set is chosen as the best-performing model, both in the “w/ acc” and “w/o acc” settings. We use the Adam optimizer and a learning rate of 0.0001. The number of epochs is set to 250 with a batch size of 4. All other parameters remained consistent with those outlined in [17], except for a few adjustments, which are detailed below.

⁶ Implementation can be found at: <https://github.com/AME430/Towards-Training-Explainable-Singing-Quality-Assessment-Network-with-Augmented-Data>.

Data Aug	BiCA	MSE(↓)		MAE(↓)		Bad P%(↓)		Pearson(↑)	
		w/o acc	w/ acc	w/o acc	w/ acc	w/o acc	w/ acc	w/o acc	w/ acc
No (8,000)	No [17]	0.0042	0.0046	0.0495	0.0524	10.1%	11.8%	0.562	0.497
No (8,000)	Yes	0.0038	0.0043	0.0459	0.0499	8.7%	10.5%	0.623	0.539
SAR (24,000)	No	0.0041	0.0044	0.0495	0.0519	9.3%	9.4%	0.561	0.522
SAR (24,000)	Yes	0.0031	0.0033	0.0386	0.0415	6.5%	7.3%	0.697	0.670
SSR (24,000)	No	0.0041	0.0044	0.0497	0.0515	9.6%	10.2%	0.555	0.514
SSR (24,000)	Yes	0.0029	0.0033	0.0385	0.0416	5.8%	7.0%	0.714	0.673
KMR (24,000)	No	0.0041	0.0044	0.0496	0.0521	8.9%	9.8%	0.562	0.517
KMR (24,000)	Yes	0.0028	0.0031	0.0375	0.0413	6.2%	6.9%	0.730	0.687
ALL (40,000)	No	0.0039	0.0040	0.0471	0.0478	9.4%	10.1%	0.593	0.576
ALL (40,000)	Yes	0.0025	0.0030	0.0351	0.0387	4.7%	6.1%	0.769	0.709

Table 1. The ASSE results of Mean Squared Error (MSE), Mean Absolute Error (MAE), Bad Case Proportion (Bad P%), and Pearson correlation coefficient (Pearson) on the singing with accompaniment test set (w/ acc, 1,000 songs) and the solo singing test set (w/o acc, 1,000 songs) from the 10KSinging dataset [17]. SAR, SSR, KMR, and ALL refer to the four different data augmentation methods introduced in Section 2.2.2: Shuffle-and-Remix, Same-Song Remix, Key-Match Remix, and All Remix, respectively, where the number in parenthesis indicates the number of songs used as training data. For experimental purposes, no data augmentation, SAR, SSR, KMR, and ALL is respectively applied to the model architecture without and with Bi-Directional Cross-Attention (BiCA, illustrated in Fig. 1(b)) to demonstrate the individual and reciprocal effects of data augmentation and BiCA. The downward and upward arrows on the evaluation metrics respectively represent the desirable lower or higher values for better performances. The best results are highlighted in bold, which concentrate on the ASSE model employing both All Remix data augmentation and BiCA (ALL-Yes), is therefore our proposed method in this paper.

We use the sigmoid activation function following the final dense layer to constrain the output range between 0 to 1. Also, the Exponential Linear Unit (ELU) activation function is introduced within the dense layer. These adjustments can facilitate the model’s ability to learn a more accurate distribution of the output score.

3.3 Evaluation Metrics

Although correlation coefficients are often used as the evaluation metric in ASSE [5, 13–15, 17, 32], we aim to incorporate additional metrics to demonstrate the performances of ASSE models more comprehensively. Overall, four evaluation metrics are considered:

- Mean squared error (MSE) (↓): same as the loss function introduced in Section 3.2.
- Mean absolute error (MAE) (↓): it shows how much the predicted rating deviates from the ground truth in the linear scale.
- Bad case proportion (↓): same as [17], the predicted rating will be considered a bad case if its MAE is no less than 0.1.
- Pearson correlation coefficient (↑): it demonstrates the degree of correlation between the predicted rating and the ground truth, within the range of $[-1, 1]$.

3.4 Results and Discussions

The results are shown in Table 1, where we use acronyms to represent each experiment. For example, No-No indi-

cates the experiment without data augmentation nor BiCA, and KMR-Yes indicates the experiment using both KMR augmentation and BiCA, etc.

3.4.1 Results on BiCA

We first investigate the effects of BiCA by comparing the models with and without BiCA under five different data augmentation settings (No-No VS. No-Yes; SAR-No VS. SAR-Yes; SSR-No VS. SSR-Yes; KMR-No VS. KMR-Yes; ALL-No VS. ALL-Yes), finding that using BiCA results in consistent performance improvements in all cases. This demonstrates that the employment of BiCA effectively helps the ASSE models capture useful inter-relationships between pitch histogram and X-vector and facilitate their reciprocal knowledge exchange, leading to better results. This is reasonable since there can be correlations between singers’ pitch accuracy and timbre quality that are beneficial for ASSE. For example, singers with excellent singing skills tend to have great pitch accuracy (indicated by pitch histogram) and timbre quality (indicated by X-vector), and vice versa for mediocre or inferior singers.

3.4.2 Results on Data Augmentation

We then compare the four data augmentation approaches: SAR, SSR, KMR, and ALL to no data augmentation. When using the baseline architecture (Fig. 1(a) without BiCA), results show overall marginal improvements in almost all cases (SAR-No VS. No-No; SSR-No VS. No-No; KMR-No VS. No-No; ALL-No VS. No-No). When

BiCA is applied, the improvement is much more apparent (SAR-Yes VS. No-Yes; SSR-Yes VS. No-Yes; KMR-Yes VS. No-Yes; ALL-Yes VS. No-Yes). These results demonstrate the effectiveness of data augmentation and its reciprocal advantage with BiCA. As discussed in Section 3.4.1, it seems that data augmentation provides more samples for BiCA to further exploit correlations between pitch histogram and X-vector, which can be beneficial for evaluating singing skills in ASSE.

Of particular interest, we notice that KMR achieves superior results among all three data augmentation approaches (KMR-Yes VS. SSR-Yes VS. SAR-Yes). This could be that KMR combines the advantages of SAR and SSR, where the former mixes the singing with a different accompaniment and the latter ensures the same key between singing and accompaniment, leading to better performances. Despite their differences, we can combine the augmented data from SAR, SSR, and KMR as All Remix (see Section 2.2.2) for even more training data, resulting in the best results overall (SAR-Yes VS. SSR-Yes VS. KMR-Yes VS. ALL-Yes).

3.4.3 Results on Solo Singing and Singing with Accompaniment

Additionally, we compare the performances presented in solo singing (w/o acc) and singing with accompaniment (w/ acc) scenarios. Results show that the ASSE models consistently perform better in solo singing, which is understandable considering singing with accompaniment contains irrelevant accompaniment information that can interfere with the training of ASSE models. Although we can follow [17] to add a singing voice separation step (see Fig. 1(a)) to remove accompaniment for better performances, we choose to keep the end-to-end nature of our ASSE system (see Fig. 1(b)) and consider the performance gap between solo singing and singing with accompaniment for our proposed ASSE model (ALL-Yes) non-essential, since both are performing better than the baseline No-No in the solo singing (w/o acc) condition.

3.4.4 Overall Results

Finally, once we combine data augmentation with BiCA, our proposed ALL-Yes model yields notably better results than the baseline [17] (No-No) across all metrics: reaching relative improvements of 40.5% on MSE (0.0025 VS. 0.0042, likewise for the following ones), 29.1% on MAE, 53.5% on Bad P %, and 36.8% on Pearson in solo singing (w/o acc); 34.8% on MSE (0.0030 VS. 0.0046, likewise for the following ones), 26.1% on MAE, 48.3% on Bad P %, and 42.7% on Pearson in singing with accompaniment (w/ acc) scenario.

As discussed in Section 3.1, there are two models under No-No, one trained for w/o acc and the other trained for w/ acc conditions. [17] then proposed the former in the paper due to its superior performance. However, it can only process solo singing data and requires a singing voice separation tool to remove accompaniment from the input. In comparison, our proposed ALL-Yes model can process

both solo training and singing with accompaniment inputs, and this is what we refer to as an end-to-end ASSE model, which does not require singing voice separation and also yields notably better performances, with Pearson correlation coefficients of 0.769 in w/o acc and 0.709 in w/ acc, compared to the baseline model of 0.562.

4. CONCLUSIONS

In this paper, we introduce a new ASSE system using data augmentation and compare four specific augmentation approaches: the existing Shuffle-And-Remix [25], the novel Same-Song Remix, Key-Match Remix, and All Remix we propose. Results show that our All Remix approach achieves the best performances, and our system can process both solo singing and singing with accompaniment in an end-to-end manner, thereby eliminating the need for a singing voice separation tool required by the baseline model [17]. We also introduce a Bi-directional Cross-Attention mechanism (BiCA) as a feature fusion method to ASSE for the first time, which discovers useful inter-relationships between pitch histogram and X-vector and results in consistent performance improvements in our experiments.

With the combination of BiCA and All Remix data augmentation approach, we not only achieve notable improvements in ASSE performances compared to the baseline [17], we also develop a versatile model capable of processing both solo and instrumentally accompanied vocal performances. To the best of our knowledge, such encompassing ASSE models have not been proposed in existing literature before.

5. FUTURE WORK

Looking ahead, we will continue this research by incorporating future open-source ASSE datasets proposed in the literature. Indeed, we could only make use of the 10K Singing dataset due to the lack of open-source datasets in this domain. Our future work also includes exploring alternative features that could potentially improve the performances of our ASSE models. For instance, we will consider large-scale music models that employ self-supervised learning, since features extracted by those models such as Jukebox [33] and MERT [34] have recently been proven effective and even established new SOTA performances in various music-related tasks. Therefore, these features will be incorporated into our model to exert their potential. Finally, since data augmentation combining solo singing with different versions of accompaniment results in consistent performance improvements, we will explore more data augmentation methods for solo singing by, for example, adding noise, adjusting gain, and applying high/low-pass filters that have been employed in other MIR-related tasks [35] for better performances.

ABSTRACT

This paper approaches the problem of separating the notes from a quantized symbolic music piece (e.g., a MIDI file) into multiple voices and staves. This is a fundamental part of the larger task of music score engraving (or score typesetting), which aims to produce readable musical scores for human performers. We focus on piano music and support homophonic voices, i.e., voices that can contain chords, and cross-staff voices, which are notably difficult tasks that have often been overlooked in previous research. We propose an end-to-end system based on graph neural networks that clusters notes that belong to the same chord and connects them with edges if they are part of a voice. Our results show clear and consistent improvements over a previous approach on two datasets of different styles. To aid the qualitative analysis of our results, we support the export in symbolic music formats and provide a direct visualization of our outputs graph over the musical score. All code and pre-trained models are available at https://github.com/CPJKU/piano_svsep.

1. INTRODUCTION

The musical score is an important tool for musicians due to its ability to convey musical information in a compact graphical form. Compared to other music representations that may be easier to define and process for machines, for example, MIDI files, the musical score is characterized by how efficiently trained musicians can read it.

An important factor that affects the readability of a musical score for instruments that can produce more than one note simultaneously, is the separation of notes into different *voices* (see Figure 1). This division may follow what a listener perceives as independent auditory streams [1], which can also be reflected in a clearer visual rendition of a musical score [2]. A similar point can be made for the division

into multiple staves (generally 2) for instruments with a large pitch range, such as piano, organ, harp, or marimba. We will consider in this paper piano music.

The term voice is frequently used to describe a sequence of musical notes that do not overlap, which we call a *monophonic voice*. However, this definition may be insufficient when considering polyphonic instruments. Voices could contain *chords*, which are groups of *synchronous notes* (i.e., notes with the same onset and offset) and are perceived as a single entity [3]. We name a voice that can contain chords a *homophonic voice*. Note that partially overlapping notes cannot be part of a homophonic voice.

Music encoded in MIDI (or similar) formats, even when containing quantized notes, time signature, or bar information, often does not contain voice and staff information. The same can be said for the output of music generation [4], transcription [5], or arranging [6] systems. Therefore, such music cannot be effectively converted into a musical score, to be efficiently read and played by human musicians.¹ The tasks of producing voice and staff information from unstructured symbolic music input are called *voice separation* (or voice segregation in some papers [3]) and *staff separation*, respectively.

Most of the existing approaches to voice separation have focused only on music with monophonic voices [7–12], which is not sufficient for our goal of engraving² piano music. The task of homophonic voice separation is much harder to solve: the presence of chords within voices makes the space of solutions grow much bigger; and the choice of the “true voice separation” can be ambiguous, with multiple valid alternatives among which experts may disagree.

The existing approaches to homophonic voice separation can be divided into two groups: the first [1, 3, 5, 13] use dynamic programming algorithms based on a set of heuristics, which makes for systems that are controllable and interpretable, but also hard to develop and tune. Such systems are often prone to fail on exceptions and corner cases that are present in musical pieces. The second group of approaches [14–17] applies deep learning models to predict a voice label for each note. Such an approach creates

* Equal contribution.

¹ Voice and staff separation are only two of the multiple elements, such as pitch spelling, rhythmic grouping, and tuplet creations, which need to be targeted by a score engraving system, but we will only focus on the former two in this paper.

² “score engraving” and “score typesetting” are used interchangeably.

Figure 1. Comparing different voice/staff assignments for two bars from C. Debussy’s *Estampes - Pagodes*. (top) original; voices can be inferred from the beam grouping and (horizontal lines connecting notes), rests, and stem sharing, and are colored for clarity. (bottom) hard-to-read rendition with voice and staff assigned according to heuristics we propose as a baseline.

two fundamental issues: i) the necessity of setting a maximum number of voice labels, and ii) a (highly) unbalanced ratio of occurrence of some voice labels. Moreover, all these approaches assume that a voice cannot move between the two staves, which is not true for complex piano pieces.

In this work, we propose a novel system for homophonic voice separation that can efficiently and effectively assign notes to voices and staves for polyphonic music engraving. Efficiency is ensured by a graph neural network (GNN) encoder, which can create input embeddings with a relatively small number of parameters. Effectiveness is targeted by approaching voice prediction not as a note labeling, but as an edge prediction problem [12], which solves the maximum voice number and the label imbalance problems presented above. Our system predicts staff and voice separately and does not make any assumption on the number of voices; therefore it can deal with cross-staff voices and complex corner cases. We avoid the problem of ground truth ambiguity since we focus specifically on voice separation for musical score engraving, therefore we can extract the (unique) ground truth directly from digitized musical scores.

We evaluate our system on two piano datasets of different difficulty levels, one containing popular, the other classical music. A comparison with a baseline and the approach of Shibata et al. [5] shows a consistent improvement in performance on both datasets. Finally, we develop a visualization tool to display the input and output of our system directly on the musical score, and discuss some predictions and comments on homophonic voice separation.

2. RELATED WORK

The most influential work for this paper is the monophonic voice separation system by Karystinaios et al. [12]. Similarly, we consider voice separation a edge prediction task and use a similar score-to-graph routine and the same GNN

encoder. Differently from that work, we consider homophonic voices and staves and, therefore, we extend the model formulation, the deep learning architecture, and the postprocessing routine to deal with this information.

Shibata et al. [5] developed a voice and staff separation technique applied after music transcription to quantized MIDI files. It works in two stages: first, an HMM separates the notes of the two hands (which will then be used as staff), and then a dynamic programming algorithm that maximizes the adherence to a set of heuristics is applied to separate voices in the two hands independently. We compare against this method since it is the most recent approach focusing specifically on homophonic voice separation.

There are some approaches based on neural networks [14–17], but they never perform this task in isolation, but rather in combination with other tasks such as symbolic music transcription, full scorification, and automatic arrangement. This means that they can only train on a much smaller dataset and a comparison would not be fair.

All the approaches mentioned before, except [12], perform voice separation as a label prediction task, which is problematic, as discussed in the introduction, due to the label imbalance and choice of the maximum number of voices. The former is particularly problematic for the neural network approaches.

3. METHODOLOGY

Our system inputs data in the form of a set of quantized notes (e.g., coming from a quantized MIDI or a digitized musical score), each characterized by pitch, onset, and offset. This information is modeled as a graph, which we call *input graph*, and then passed through a GNN model to predict an *output graph* containing information about voices, staves, and chord groupings. We remind the reader that in our ‘homophonic voice’ scenario, chords are groups of synchronous notes that belong to the same voice.

3.1 Input Graph

From the set of quantized notes representing a musical piece we create a directed heterogeneous graph [18] $G_{in} = (V, E_{in}, \mathcal{R}_{in})$ where each node $v \in V$ corresponds to one and only one note, and the edges $e \in E_{in}$ of type $r \in \mathcal{R}_{in}$ model temporal relations between notes [12]. \mathcal{R}_{in} includes 4 types of relations: onset, during, follow, and silence, corresponding, respectively, to two notes starting at the same time, a note starting while the other is sounding, a note starting when the other ends, and a note starting after a time when no note is sounding. We also create the inverse edges for during, follows, and silence relations. Each node corresponds to a vector of features: one of the 12 note pitch classes³ (C, C#, D, etc.), the octave in $[1, \dots, 7]$, the note duration, encoded as a float value $d \in [0, 1]$ computed as the ratio of the note and bar durations, passed through a tanh function to limit its value and boost resolution for shorter

³ We don’t consider tonal pitch classes [19] since they are not specified in MIDI files which we assume to be our input.

notes, as proposed in [12]. We don't consider grace notes in our system, and we remove them from the input notes.

3.2 Output Graph

The output graph $G_{out} = (V, E_{out}, \mathcal{R}_{out})$ has the same set V of nodes as the input graph, but a staff number in $\{0, 1\}$ is assigned to every node. There are two edge types in E_{out} : chord and voice, i.e. $\mathcal{R}_{out} = \{\text{"chord"}, \text{"voice"}\}$.

Voice edges [8, 12] are an alternative in the literature to the more straightforward approach of predicting a voice number for every note; the usage of voice edges has the advantage of enabling a system to work with a non-specified number of voices, and avoiding the label imbalance problem for high voice numbers. Voice edges are directed edges that connect consecutive notes (without considering rests) in the same voice. Formally, let $u_1, u_2 \in V$ be two notes in the same voice then $(u_1, \text{"voice"}, u_2) \in E_{out}$ if and only if $\text{offset}(u_1) \leq \text{onset}(u_2)$ and $\nexists u_3 \in V$ within the same voice such that $\text{offset}(u_1) \leq \text{onset}(u_3) < \text{onset}(u_2)$.

The previous definition also holds in our setting with homophonic voices. Let us extend the definition of *chord* (a set of synchronous notes) to include the limit case of a single note. Two chords are consecutive if any two notes, respectively, from the first and second chords are consecutive. In the case of two consecutive chords with m and n notes in the same voice, there will be $m * n$ voice edges.

Chord edges are undirected and connect all notes that belong to the same chord without self-loops, so for a n -note chord, there are $n(n - 1)$ edges. They serve to unambiguously identify which notes together form a single chord.

The same output graph can be created from an already properly engraved score. To obtain the graph we only need to draw the true voice edges between consecutive notes in the same voice within a bar and for chord edges we draw the chord ground truth between synchronous notes with the same voice number assignment. This graph can subsequently serve as the ground truth during training.

3.3 Problem Simplification

In this section, we apply some obvious musical constraints to reduce computation and memory usage in our pipeline, without impacting the results. Let us first focus on *chord edge* prediction. Given the simple constraint that all notes of a chord must start and end simultaneously, we can restrict the chord edge prediction process to only consider pairs of synchronous notes (same onset and offset values) as candidates. We do this by creating a set of *chord edge candidates* Λ_c which are calculated automatically and associated with our input graph. Only notes connected by such candidate edges will be considered in the chord prediction part of the model (see next section).

The same reasoning can be applied to the voice edges, by creating a set of *voice edge candidates* Λ_v such that $\forall u_1, u_2 \in V, (u_1, \text{"voice"}, u_2) \in \Lambda_v$ only when $\text{offset}(u_1) > \text{onset}(u_2)$. Another step can be taken towards reducing the number of candidates in the set Λ_v by incorporating some musical engraving considerations.

The separation of notes in multiple voices does not have to be consistent in the whole score, but only within each bar, to produce the intended visual representation. There are no graphical elements that show if two notes in different bars are or are not in the same voice⁴. Music engraving software does not force users to use consistent voices across bars. This can be often observed in digitized musical scores where music motives that belong to the same voice, are assigned different voices in different bars. Such observations have motivated projects such as the Symbolic Multitrack Contrapuntal Music Archive [20] that explicitly encode a "global" voice number.

Since cross-bar consistency is not necessary for our goal of engraving (and is often wrongly annotated in our data) we limit the *voice edge candidates* Λ_v to contain only pairs of notes that occur within the same bar. This design choice is also reflected in our evaluation, i.e. we do not evaluate how the voices propagate across bars, but only within each bar. Note that this process is different from processing each bar independently since our network (detailed in the next section) considers music content across bars.

3.4 Model

We design an end-to-end model (see Figure 2) that receives an input graph as described in Section 3.1 and produces an output graph as in Section 3.2. The model is organized as an encoder-decoder architecture.

The encoder receives an input graph created from a quantized MIDI score and passes it through three stacked Graph Convolutional Network (GCN) blocks to produce a node embedding for each note. We use the heterogeneous version of the Sage convolutional block [18] with a hidden size of 256; the update function for each node u is described by:

$$\begin{aligned} \mathbf{h}_{\mathcal{N}(u)}^{(l+1)} &= \sum (\{\mathbf{h}_v^l, \forall v \in \mathcal{N}(u)\}) \\ \mathbf{h}_u^{(l+1)} &= \sigma(\mathbf{W} \cdot \text{concat}(\mathbf{h}_u^l, \mathbf{h}_{\mathcal{N}(u)}^{l+1})) \end{aligned} \quad (1)$$

where $\mathcal{N}(u)$ are the neighbors of node u , σ is a non-linear activation function, \mathbf{W} is a learnable weight matrix.

The decoder consists of three parts that all use the same node embedding as input: i) a staff predictor; ii) a voice edge predictor; and iii) a chord clustering (i.e., a chord edge predictor). The *staff predictor* is a 2-layer Multi-Layer Perceptron (MLP) classifier that produces probabilities for each graph node (i.e., each note) to belong to the first or second staff. The *voice edge predictor* receives the embeddings of pairs of notes connected by edge candidates and produces a probability for each pair to be in the same voice. It works by concatenating the pairs of note embeddings and applying a 2-layer MLP. The final decoder part, *chord clustering*, receives the embeddings of pairs of notes connected by chord edge candidates (i.e., pairs of synchronous notes) and produces the probability for a pair to be merged into a chord. This is achieved by computing the cosine similarity between the elements of the pair. This process forces the

⁴ This may change for cross-bar beamings, but they are very rarely used in standard music notation (there are no occurrences in our datasets) and therefore we do not consider them in this work.

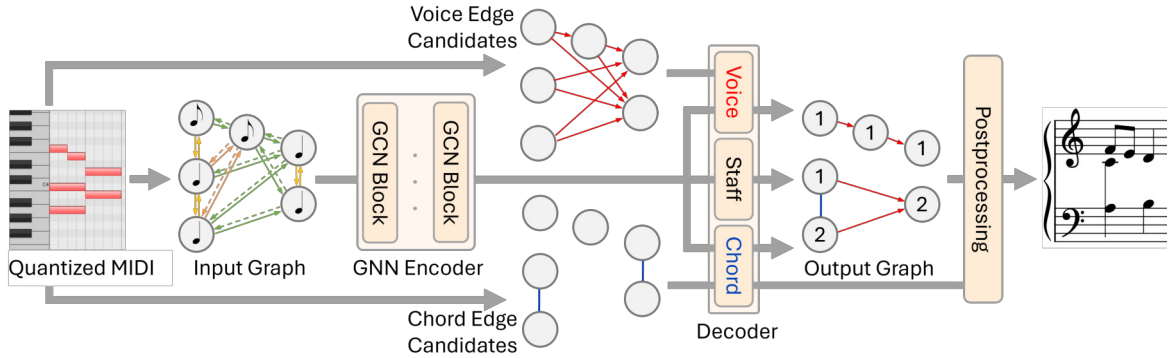

Figure 2. Our Architecture. For simplification, we display the output graph as having “hard” voice predictions, while these are probabilities over voice candidates.

node embeddings created by the decoder to be similar to each other for notes of the same chord, which helps the voice predictor produce consistent voice edge probabilities for notes of the same chord. We apply a threshold to pass from probabilities to decisions on which notes to cluster.

The complete model contains $\sim 3M$ parameters and we train it end-to-end with the (unweighted) sum of three *Binary Cross Entropy* loss functions, one for each task.

3.5 Postprocessing

A straightforward approach to deciding whether to connect two notes with a voice edge would be to threshold the predicted voice edge probabilities. However, even when using edge and chord candidates, we could still produce three kinds of invalid output: (1) multiple voices merging into one voice, (2) one voice splitting into multiple voices, and (3) notes in the same chord that are not in the same voice. To eliminate these issues, we add a postprocessing phase that accompanies our model and guarantees a valid output according to music engraving rules.

The first step, which we call *chord pooling*, merges all nodes that belong to the same chord to a single new “virtual node”. This is done by looking for the connected components considering only chord edges in the output graph, then *pooling* in a single node all original nodes in each connected component, creating a new node which has as incoming and outgoing voice edges all edges entering and exiting the original nodes, respectively. If multiple edges collapse in one edge (e.g. in the case of two consecutive chords in the same voice), the new edge has a probability that is the average of the corresponding edge probabilities.

After the first step, we are left with monophonic streams, which could still exhibit problems (1) and (2). We can solve this with the technique proposed in [12] for monophonic voices, i.e. by framing the voice assignment problem as a linear assignment problem [21] over the adjacency matrix obtained by the updated edge candidates Λ'_v . We follow the linear assignment step by unpooling or unmerging the nodes that were previously pooled, in this way, obtaining the original nodes again. During unpooling, the incoming edges and outgoing edges of the “virtual nodes” are reassigned to each original node, thus resolving problem (3).

Figure 3. Output graph postprocessing. We do not display the predicted staff labels.

The complete postprocessing method is depicted in Figure 3. It is worth noting that the staff labels are not considered during the postprocessing phase, and we copy them unchanged to the postprocessed output graph.

3.6 Evaluation

We evaluate the predicted voice assignments with the metric proposed by Hiramatsu et al. [15], which formalizes the metric of McLeod and Steedman [22]. This is a version of the F1-score for voice separation [8] which is adapted to work on homophonic voices, by reducing the importance of notes if they are part of a chord. This is important since chords create many voice edges (e.g., two 4-note chords in the same voice are connected by 16 edges), which could potentially overshadow the importance of edges in monophonic voices (or voices with fewer/smaller chords).

Formally, the homophonic voice F1-score $F1$ is calculated as:

$$P = \frac{\sum_{i < j} a_{ij} \hat{a}_{ij} / \hat{w}_i}{\sum_{i < j} \hat{a}_{ij} / \hat{w}_i}, \quad R = \frac{\sum_{i < j} a_{ij} \hat{a}_{ij} / w_i}{\sum_{i < j} a_{ij} / w_i} \quad (2)$$

$$F1 = \frac{2PR}{P + R}$$

where $i < j$, in the sum, considers all pair of notes i, j such that $\text{offset}(i) < \text{onset}(j)$; a_{ij} , \hat{a}_{ij} are equal to 1 or 0 if a voice edge exists or not in the ground truth and predictions, respectively; and w_i and \hat{w}_i are the number of notes that are chorded together with the note i in the ground truth and predictions, respectively. Unlike [15], we consider

only notes j in the same bar of i , for the reasons presented in Section 3.3. We evaluate the staff prediction part of our model with binary accuracy, and we assess chord prediction with the F1 score computed on the chord edges.

3.7 From Network Prediction to Readable Output

The computation of voice and staff numbers is sufficient for the system evaluation, but not for producing a usable tool, which we are interested in in this paper. The missing step, to be described in this section, is the integration of the network predictions into a readable musical score. To achieve this integration we need to undertake two essential steps: beam together notes within the same voice, and infill rests to "fill holes" within each voice.

For the first step, we proceed according to the rules of engraving [2]. We beam two consecutive notes (or chords) in the same voices if their duration is less than a quarter note (excluding ties) unless they belong to different beats. Following the music notation convention we consider the compound time signatures, i.e., $\frac{6}{x}, \frac{9}{x}, \frac{12}{x}$ to have, respectively, 2, 3, and 4 beats. When confronted with tied notes, the algorithm prioritizes producing notations with the fewest number of notes, an heuristic which promotes easier-to-read notation [23].

The second step consists of introducing rests so that each voice fills the entire bar and can be correctly displayed. Some rests could be set as invisible to improve the graphical output when their presence and duration are easy to assume from other score elements, but we display all of them for simplicity. As for the notes, we choose the rest types (with eventual dots) to minimize the number of rests in the score.

The two steps described above cover common cases and produce a complete score in MEI format [24]. However, the score export is still a prototype, since developing one that is robust against all corner cases is an extremely complex task, and is outside the scope of this paper. Since score output problems may obscure the output of our system, we also develop a graph visualization tool. Both the input and output graphs (including the candidate edges) can be displayed on top of the musical score in an interactive web-based interface based on Verovio [25]. Some examples of the output graph visualization are in Figure 4.

4. EXPERIMENTS

We train our model with the ADAM optimizer with a learning rate of 0.001 and a weight decay of $5 * 10^{-4}$ for 100 epochs. For a quantitative evaluation, we compare our results with those of a baseline algorithm and the method proposed by Shibata et al. [5], on two rather diverse datasets.

Our baseline algorithm assigns all notes under C4 (middle C) to the second staff and the rest to the first. Then it groups all synchronous notes (per staff) as chords. Finally, it uses the time and pitch distances between the candidate pairs of notes as weights to be minimized during the linear assignment process (the same as we use in our postprocessing) which creates the voice edges.

4.1 Datasets

We use two piano datasets of different styles and difficulties to evaluate our system under diverse conditions. The ability to handle complex corner cases should not reduce the performance on easier (and more common) pieces.

The *J-Pop* dataset contains pop piano scores introduced by [5]. Most of the scores consist of accompaniment chords on the lower staff and some simple melodic lines on the upper staff. The dataset contains 811 scores; we randomly sampled 159 (roughly 20%) of these for testing and used the rest for training and validation.

The *DCML Romantic Corpus* is more challenging. It was created by [26] and contains piano pieces from the 17th to 20th centuries with some virtuosic quality. It includes characteristics such as cross-staff beaming, a high number of voices, challenging voicing, etc. Similarly to the pop dataset we randomly sample 77 out of the 393 scores (approx. 20%) and use the rest for training and validation.

The *J-Pop* dataset is available in MusicXML format, while the *DCML Romantic Corpus* is in Musescore file format. We use Musescore to convert DCML files to MusicXML and load them with the Python library Partitura [27] to extract the note list.

4.2 Results

Our model aims to be generic across a variety of music, therefore we train a single model on the joined training set of pop and classical scores, not two individual ones. The rules that govern the handling of voices may be fundamentally different in the two datasets, but we assign to the model the task of handling these differences. This approach ensures better future scalability on bigger and more diverse datasets. We compute the metrics separately on the test part of our two datasets.

Table 1 reports results for three versions of our graph-based model: the complete model from Section 3, a variant without postprocessing, and a variant without chord prediction and postprocessing (our postprocessing technique cannot be run without the chord prediction task, since it pools nodes that belong to the same predicted chord). The method of Shibata requires the specification of the number of voices per staff. For compactness, we report only the results with one voice per staff (2 voices total); the results degrade by increasing the number of voices.

Our results show that even our system without pooling and without postprocessing obtains consistently better results than both Shibata et al. [5] and our baseline. Interestingly, the chord prediction task improves the Voice F1 results even when the post-processing is not used; this confirms the benefits of multi-task training, and of enforcing notes of the same chord to have similar representations in the hidden space, with cosine similarity, to predict coherent voice edges. However, we observe a reduction in staff accuracy, probably for the same reason, since the same hidden representation is also used to predict chords, making it harder (though not impossible) to split notes of the same chord in different staves. When the full system is used, there are further improvements in Voice F1.

Dataset	J-pop Dataset			DCML Romantic Corpus		
	Staff Acc	Chord F1	Voice F1	Staff Acc	Chord F1	Voice F1
Baseline	89.9	86.9	85.4	80.7	65.2	78.2
Shibata et al. [5]	92.8	-	92.2	88.5	-	84.9
GNN wo Chord wo Post	96.5 ± 0.1	-	95.2 ± 1.9	91.5 ± 0.1	-	87.2 ± 3.3
GNN wo Post	96.3 ± 0.1	94.9 ± 0.1	95.7 ± 0.4	91.0 ± 0.1	79.5 ± 0.4	88.9 ± 0.4
GNN	96.3 ± 0.1	94.9 ± 0.1	96.6 ± 0.1	91.0 ± 0.1	79.5 ± 0.4	89.9 ± 0.2

Table 1. Metrics for our the J-Pop and DCML test sets. “GNN” denotes our method, without postprocessing (“GNN wo Post”), and without both postprocessing and chord prediction parts (“GNN wo Chord wo Post”). All GNN model runs are repeated 5 times: ± refers to the standard deviation of results across runs.

We are also evaluate our system on the bar-level and study performances for music excerpts of varying difficulties. We compute the voice F1 score for each bar and average them based on the number of voices in the ground truth. We compare with Shibata et al. [5] with 1 & 2 voices per staff (vps). Table 2 shows the results for the DCML Romantic Corpus. Both our model and [5] perform best with 2 voices, the most common number in our dataset. Interestingly, Shibata et al. approach with 2 vps never outperforms vps 1, not even when the target number of voices is 3 or 4, a situation that vps 1 cannot handle. This can be explained by the fact that Shibata et al. parameters were tuned on a simpler dataset, and accepting more voices creates more errors than benefits. Setting vps > 2 consistently degraded the performances, probably also for similar reasons.

#Voices	#Bars	GNN	[5] 1vps	[5] 2vps
1	322	96.6	88.3	87.9
2	4576	94.1	89.3	88.1
3	2464	89.0	84.2	81.5
4	719	81.6	80.5	75.1
5	99	81.6	76.7	73.7
6	17	78.4	68.9	61.6

Table 2. Voice F1 score aggregated by bars with the same number of voices in the ground truth, on the DCML Corpus. Shibata et al. [5] is used with 1 and 2 voices per staff (vps).

4.3 Qualitative Analysis

Let us take a closer look into the predictions of our deep-learning approach (GNN) on the excerpt of Figure 4 produced by our visualization tool. Our approach captures correctly the cross-staff voice in the first two bars, while such a situation causes performance degradation for all other voice separation approaches that don’t support it. We observe some disagreements with the original score in Measure 3: our model predicts a single chord (instead of splitting across the staff) containing all the synchronous syncopated quarter notes, and also mispredicts the staff for the first D#4 note. A more in-depth study of why this happens is not trivial, as neural networks are not interpretable. This is a drawback compared to heuristic-based separation techniques.

Synchronous notes with the same pitch are problematic.

Figure 4. Comparison of voice and staff assignment between the original score (Ground Truth) and our method (GNN) on the first bars of C. Debussy’s Estampes-Pagodes. Voice edges are drawn in red and chord edges in blue.

Our system can predict different voices for these notes, while Shibata et al. always predict them as a chord in the same voice, and this reduces the performances for pieces that contain a lot of them, like Schumann Kinderszenen Op.15. For fairness, we should note that we should expect the output of a music transcription system to only contain one of these notes, instead of multiple like in our current input. An enhancement of our system would then be able to receive a single note as input, assign multiple voices to it (with multiple incoming and outgoing edges) and then split it into multiple notes. Another current limitation of our system is the missing support for grace notes, which in the actual version are ignored and removed from the input.

5. CONCLUSION AND FUTURE WORK

This paper presented a novel graph-based method for homophonic voice separation and staff prediction in symbolic piano music. Our experiments highlight our system’s effectiveness compared to previous approaches. Notably, we obtained consistent improvements over two datasets of different styles with a single model.

Future work will focus on integrating grace notes and the possibility of multiple voices converging on a single note. We aim to create a framework that produces complete engravings from quantized MIDI, including the prediction of clef changes, beams, pitch spelling, and key signatures.

huan.zhang@qmul.ac.uk

ABSTRACT

Our study investigates an approach for understanding musical performances through the lens of audio encoding models, focusing on the domain of solo Western classical piano music. Compared to composition-level attribute understanding such as key or genre, we identify a knowledge gap in performance-level music understanding, and address three critical tasks: expertise ranking, difficulty estimation, and piano technique detection, introducing a comprehensive Pianism-Labeling Dataset (PLD) for this purpose. We leverage pre-trained audio encoders, specifically Jukebox, Audio-MAE, MERT, and DAC, demonstrating varied capabilities in tackling downstream tasks, to explore whether domain-specific fine-tuning enhances capability in capturing performance nuances. Our best approach achieved 93.6% accuracy in expertise ranking, 33.7% in difficulty estimation, and 46.7% in technique detection, with Audio-MAE as the overall most effective encoder. Finally, we conducted a case study on Chopin Piano Competition data using trained models for expertise ranking, which highlights the challenge of accurately assessing top-tier performances.

1. INTRODUCTION

Traditional music understanding tasks focus on composition-level attributes: key, tempo, genre and instrumentation are widely explored [1–3]. These attributes are not only tagged individually via end-to-end approaches but have also been the focus of foundation models and various musical representations aimed at learning them in a unified manner [4, 5], facilitating cross-modal understanding [6, 7].

However, a large portion of human music activity is focused not on the composed songs or pieces themselves, but on the process of learning and performing them [8]. Despite its great importance to the vast community of students, teachers and musicians, the ability to understand performance nuances (challenging techniques, skill varieties, stylistic differences, difficulty grading, etc.) has not been grasped by machines. Sporadic experiments [9] of

these tasks are conducted, often on small-scale [10, 11] or proprietary [12–14] datasets. Performance understanding, in contrast to the more recognized composition-level music understanding, suffers from scarcity of data [15, 16], ambiguity of tasks [17], and the inherent complexity of modelling and representing expressive elements in performances [18, 19].

Meanwhile, unified representations and foundation models have advanced several fields by providing robust and versatile frameworks [6, 20], demonstrating their potential to overcome challenges related to data scarcity and task specificity. Building on this precedent and their applications to compositional-level understanding [21], we extend the capacities of pre-trained audio encoders such as MERT [22] and MULE [5] into the performance-understanding realm, investigating the shared knowledge between composition- and performance-level understanding: Do pre-trained audio encoders capture performance nuances? Can they categorize performance-related attributes? If not, how can we improve their performance?

This work is a first step in filling the gaps within the performance understanding realm. Applying domain-adaptation to pre-trained audio encoders, we work towards a *piano judge* that specializes in ranking performers’ skill level, determining the given repertoire’s difficulty and core techniques, thus pursuing a human piano teacher’s capability and paving the way to performance understanding in an educational context. Our contributions¹ include:

1. We benchmark three tasks in the realm of audio performance understanding: expertise ranking, difficulty estimation, and solo piano technique detection.
2. We leverage four audio representation learners (Jukebox, Audio-MAE, MERT, DAC) and compare their capabilities in tackling the downstream tasks.
3. We release the Pianism-Labeling Dataset (PLD) with detailed labeling curated for the three tasks, the first large-scale dataset (136 hrs in total) that aims to address performance understanding.
4. We fine-tune DAC [23] and AudioMAE [24] by domain-adaptation with solo piano, and compare their performances with pre-trained versions.
5. We conduct a case study on Chopin Piano Competition data (*ICPC-2015*), exploring how a trained expertise ranking model can be transferred to rank candidates in the most prestigious competition of the pianistic scene.

2. RELATED WORK

2.1 Performance and education focused understanding

The exploration of performance through recordings provides rich resources for music understanding. Automatic performance analysis (APA) [17] delves into dimensions from dynamics [25, 26] to timing [27, 28], forming the basis for tasks such as performer identification and automatic music performance assessment (MPA) [15]. The former seeks to attribute performances to their respective musicians based on stylistic and technical signatures [29, 30], and the latter aims to evaluate the quality and expression of performances. MPA approaches can be further divided by the level of proficiency. For novice players, the emphasis is on technical accuracy, ensuring correct notes and rhythm via score alignment [16, 31] or detecting conspicuous mistake regions [14] in a score-free context. Advanced performers are assessed by their expression and musicality, usually in the form of predicting rating scores on multiple dimensions [12, 32]. Recently, the release of feedback-based assessment data [33, 34] offers the possibility to conduct multimodal MPA in a more personalized manner.

On the other hand, the analysis of performances in an educational context emphasizes the identification of challenges and learning opportunities within the repertoire: expert-annotated difficulty level is predicted from symbolic scores [35] via a machine learning classification approach that merges musicologically-inspired score features. At a more granular level, we would like to identify instrument-specific techniques that demand practice. For example, techniques such as *acciaccatura* and *portamento* on Chinese bamboo flute can be identified from spectro-temporal patterns [36], but similar problems have yet to be explored on piano because of the homogeneity of piano sound. Other learning aid information such as fingering [9, 37] and bowing [38] can also be predicted. In this work, we focus on expertise, difficulty and technique estimation by extracting relevant information from performance audio. This work is the first of its kind in piano technique detection and expertise ranking, and the first to use an audio representation approach for difficulty estimation [9, 39].

2.2 Leveraging audio representations for downstream tasks

The surge of learning audio representations was originally motivated by generative models such as AudioLM [40] and MusicLM [41]. Jukebox [42] is a generative model trained on 1.2M songs. Subsequent work [4, 43] has shown that Jukebox’s representations can be effective features for task-specific linear classifiers. Jukebox embeddings have also been employed in multimodal learning [6] of music captioning and reasoning tasks. MERT [22] uses masked language modelling (MLM) style acoustic self-supervised pre-training. With a music teacher and an acoustic teacher, MERT demonstrates good performance in downstream music understanding tasks and extends its music understanding ability into question answering and captioning [44] by generating music representations to aid language models.

Audio-MAE [24] is a vanilla 12-layer transformer that learns to reconstruct randomly-masked spectrogram patches. The output feature map from the penultimate block of an Audio-MAE encoder has been used to encode fine-grained patterns in audio [45]. Different from previous approaches, Descript-Audio-Codec (DAC) [23] is a neural audio compression autoencoder that compresses high-dimensional signals into lower dimensional discrete tokens. DAC has been proven useful in a generative context [46], but there have been few attempts to explore it with downstream understanding tasks [47].

The four aforementioned audio representations are chosen for our investigation. Since they are constructed from different theoretical approaches (quantized codecs vs. continuous spectrograms) and trained on different data (general audio vs. music), this variety presents an opportunity to evaluate the extent to which the encoded information contributes to performance understanding.

3. METHODOLOGY

3.1 Downstream problem definitions

3.1.1 Expertise ranking

We formulate our assessment into a ranking problem: given audio performances p_1 and p_2 , which one has the higher expertise? We define three coarse levels of expertise (beginner, advanced and virtuoso), represented by integers 0, 1 and 2, respectively, and define a function Q which maps a performance to one of these levels. Instead of directly predicting the absolute expertise level Q , we learn a 2-way or 4-way ranking function between each pair of performances from different levels, R_2 or R_4 , as below:

$$R_2 = \begin{cases} 0 & Q(p_1) < Q(p_2) \\ 1 & Q(p_1) > Q(p_2) \end{cases} \quad R_4 = \begin{cases} 0 & Q(p_2) - Q(p_1) = 2 \\ 1 & Q(p_2) - Q(p_1) = 1 \\ 2 & Q(p_1) - Q(p_2) = 1 \\ 3 & Q(p_1) - Q(p_2) = 2 \end{cases} \quad (1)$$

The motivation is to teach the model a relative notion of expertise, instead of an absolute level or category of the performance quality. In real life and competition settings (as will be discussed in Sec 5.1.1), we are more interested in the comparative skill level among a set of candidates.

3.1.2 Difficulty estimation

Following the literature [9, 18, 35] on difficulty level prediction, we formulate the problem as a classification task with 9 difficulty classes, given the dataset described in Section 4.2, which has 9 levels of difficulty annotation. Given that the difficulty annotation is subjective and boundaries between levels are fuzzy, we also report the results of 3-class estimation by merging the level groups, as in [35].

3.1.3 Technique identification

Given a piece, a piano teacher can immediately identify the most challenging passage(s) that would require students hours of practice to master: intense octave runs, fast flowing scales, repeating notes that require finger iteration, etc.

Encoder	C	F (Hz)	Dim
Jukebox	2048	345	64
MERT	-	75	1024
Audio-MAE	-	51.2	768
DAC	9×1024	87	1024
Spectrogram	-	150	128

Table 1. Specifications of the audio encoders as well as the spectrogram baseline: C is the codebook size, F is the frame rate in Hz and Dim is the hidden dimension of the embedding (mel-bins for spectrogram).

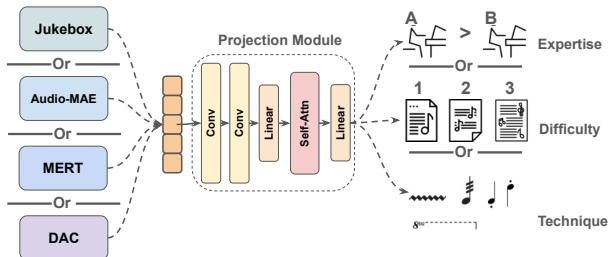

Figure 1. Overview of our tasks and experiment pipeline. For the expertise ranking, two audio embeddings are concatenated in the time dimension.

In the technique-specific dataset (Section 4.3), we include 7 common techniques and formulate a multi-label classification task for technique identification. Given that our labels are relatively sparse, we also experiment with the case of single-label prediction in which predicting any one of the multiple labels is considered correct.

3.2 Audio embeddings and encoder fine-tuning

An overview of the used audio embeddings is given in Table 1. For Jukebox, we employ the 345 Hz sample rate encoding, and for Audio-MAE, the 768-dimensional embedding is taken from the ViT-B Transformer encoder. Additionally, we considered a spectrogram baseline, as a low-level representation to compare with the trained embeddings. We use 128 mel bins, an FFT of 400 samples, and hop size of 160 samples, resulting in a spectrogram with frame rate of 150 Hz and 128 dimensions that feeds into the prediction head module like the trained embeddings.

We examine whether fine-tuning the two generic-audio-trained encoders DAC and Audio-MAE with domain-specific data results in a performance boost. The two encoders are fine-tuned using their original self-supervision objective on around 2k hours of solo piano recordings, from datasets of MAESTRO [48], ATEPP [49], SMD [50], Mazurkas² as well as the novel PLD data introduced in this work. For DAC, the fine-tuning lasts for 25k iterations while the Audio-MAE is fine-tuned for 64 epochs.

3.3 Experiments

For all encoders, we first compute 10-second segment audio embeddings (or spectrograms), and include a maximum of 5

²<http://www.charm.rhul.ac.uk/index.html>

	task type	classes	tracks	len. (s)
Expertise	Multi-class	2 or 4	1694	167.4
<i>ICPC-2015</i>	Multi-class	2	137	1827.0
Difficulty	Multi-class	3 or 9	737	269.8
Techniques	Multi-label	7	222	45.5

Table 2. Dataset statistics (number of classes, number of tracks and average duration) for each task.

minutes (30 segments) of audio as input with padding. The concatenated embedding of each audio track is of shape $(30, F \times 10, D)$ where F is the frame rate and D is the embedding dimension as shown in Table 1.

Given the audio embedding, we transform it through a prediction head module that consists of two 2D convolutional layers ($n_{kernel} = 7, n_{stride} = 5$), one linear layer to align different input dimensions, and one self-attention layer ($n_{heads} = 2, d = 128$), followed by a final linear layer that projects to the desired classes of each task. A full pipeline of the experiments is shown in Figure 1. As is standard practice [4, 43], we maintain a straightforward projection module design, aiming to minimize its influence on the probing performance.

Regarding each individual task, we run a grid search on the hyper-parameters for learning rate, weight decay, batch size, etc. The details for the final training parameters for each task are documented in the project page³. All fine-tuning and training are conducted on one NVIDIA A5000.

4. PIANISM-LABELING DATASET

The pianism-labeling dataset (PLD) includes audio and annotations for three notions that are centrally relevant to pianism and piano education: **expertise**, piece **technique** and **difficulty**, where dataset statistics are specified in Table 2. All of the labeling, metadata correspondence, as well as examples are available on the project page.

4.1 Expertise

We curated a collection of solo piano recordings from YouTube, each annotated with an expertise level. Their categorization was based on information gleaned from the YouTube channels’ descriptions, which provided insights into the background of the recordings. This categorization process was validated by two college-level piano students to ensure accuracy.

- **Beginner** (562): Amateur level, featuring mostly adult self-taught learners’ practice recordings.
- **Advanced** (570): Performances of music students and junior competition recordings.
- **Virtuoso** (562): Famous pianists’ recordings sourced from the ATEPP [49] dataset. To balance with the other groups, we randomly select a subset of 562 of the 11K recordings.

The repertoire of selected performances is mainly focused on the Western classical repertoire, with some rearranged folk and pop songs at the Beginner level. Indeed,

³<https://bit.ly/3SYzozY>

it is challenging to align the performed repertoire across levels since the complexity of played pieces increases with the expertise: e.g. Beginners’ pieces are shorter (av. 128.9 s) than Advanced (201.1 s) or Virtuoso (171.8 s) tracks.

In experiments, the three levels are first individually split into train and test subsets and then paired up randomly. Each recording only shows up once in the pairs to prevent leakage, which results in 2694 pairs in training.

4.1.1 ICPC-2015

In this task we aim to assess whether the learnt comparative ranking objective can be applied to the professional domain, the International Chopin Piano Competition, with data gathered from the 2015 edition (*ICPC-2015 dataset*)⁴. We employ only the preliminary round performances to ensure limits on the length and instrumentation (i.e. solo), and assume that the overall better players clearly demonstrate their skills in the preliminary round performance. Out of 160 candidates, 137 recordings are successfully retrieved.

We compile the data into ranking pairs similar to Section 4.1, by first assigning a score $S(c)$ for each candidate based on their progression into the following rounds. For every round that the candidate passes into, the score is incremented with 1 point. For candidates a, b with their respective scores $S(a), S(b)$, all preliminary round recordings are formed into pairs with ranking as in Eq. 1. As shown in Table 2, the preliminary round recordings have an average duration of 30 minutes. Thus, we obtain paired ranking results for each pair of 5-minute segments (30 segments in total) and use majority voting to obtain the final rank among two recordings.

4.2 Difficulty

We employ the *Can I Play It?* (CIPI) [35] dataset for our task of difficulty prediction. Given that the original dataset is sourced in symbolic MusicXML, we obtain the performance audio from YouTube by querying the metadata followed by manual correction to enforce piece alignment. Note that the performances are sourced from different levels of playing rather than virtuoso recordings only, with the aim of learning a more general view of audio difficulty. In the CIPI dataset, difficulty labels are annotated by Henle Verlag⁵, a renowned publisher in the music education community. The ratings range from 1-9 and span 29 composers. Note that we split the movements from sonata or other multi-movement compositions, resulting in the 737 audio tracks shown in Table 2 compared to 637 compositions in the original metadata. We also use the same train-test split as the original dataset.

4.3 Techniques

The technique dataset contains 222 recordings with an average duration of 45 seconds, demonstrating one or more canonical piano techniques from seven categories taken from piano practice literature [51]. The excerpts are taken

from etude books like Beyer or Czerny, or passages from performance repertoire (e.g. dense octave run from *Chopin op.25 no.10*). Besides YouTube sourcing, 41 out of 222 recordings are recorded by the authors, if the specific passages containing the techniques are not publicly available in any recording. The categories of techniques are:

- **Scales** (48): Pure scale run across octaves. Can be both hands or one hand.
- **Arpeggios** (40): Pure arpeggio run across octaves, or music passages that are accompanied with arpeggios, or melody that is constructed on arpeggiated chords.
- **Ornaments** (31): Including grace notes, trills, *mordents*, *acciaccatura*. Note that we do not balance these subclasses, and the most common ornament in our samples is grace note.
- **Repeated notes** (35): Musical passages that feature a series of repeated single notes.
- **Double notes** (36): Musical passages that feature sequences of simultaneous intervals (mostly thirds, but also fourths and sixths), where the intervals are performed with one hand.
- **Octaves** (35): We differentiate octaves from double notes because of their sheer importance in piano repertoire, as well as their distinctive sonority.
- **Staccato** (41): Musical passages that are predominately performed by *staccato* articulation.

We formulate the prediction task as multi-label classification since a musical passage is often associated with multiple techniques. Among the 222 recordings, we have 40 labeled with two techniques and two recordings with three techniques. Note that besides scales and arpeggios, few other techniques exist in their pure form (e.g. an entire music passage of trills). Thus we aim to identify the most prominent technique present in the recording.

5. RESULTS

5.1 Expertise Ranking

We train the projection module in 2-way and 4-way ranking as described in Section 3.1.1, and show results in Table 3 (left). For 2-way ranking, we achieve up to 93.56% accuracy, indicating a clear distinction between recordings of varying levels of expertise in most cases. Audio-MAE outperforms the other three audio encoders while Jukebox embeddings contain the least information for discerning the level of playing. The result of 4-way prediction is similar with Audio-MAE performing the best with 84% accuracy, indicating a good capability to distinguish larger expertise differences (beginner vs. virtuoso) from smaller ones. The baseline spectrogram achieves much lower metrics on both classifications, indicating that the pre-trained encoders capture more relevant nuances of musical performance. However, we are also aware that the three levels of data differ not only on performance but also on repertoire and recording environment. The effect of fine-tuning with solo piano domain data is not salient in this task: the fine-tuned Audio-MAE achieved roughly the same performance while DAC actually declined.

Table 3. From left to right: results of 2-way and 4-way expertise ranking, 9-way and 3-way difficulty estimation, multi-label and single-label technique prediction. Best results are highlighted in bold.

5.1.1 Discussion: How far are we from predicting the Chopin Competition winner?

From the trained 2-way expertise ranking module, we apply the *ICPC-2015* pairs as a testing set as described in Section 4.1.1. Ideally, the model should discern the three levels of piano expertise by identifying specific nuances in performance that distinguish, for example, virtuosi from advanced students. Such insights could then be applicable to evaluating competition-level performances. In Table 4, “fitting” indicates that we first fit the trained model on half of the candidates’ pairs for 5 epochs and test on the other half. Without fitting, we only evaluate on these same testing pairs using the model trained in Section 5.1.

	w/o. fitting		w. fitting	
	Acc	F1	Acc	F1
<i>pre-trained</i>				
Spec	52.91	52.79	49.27	49.04
Jukebox	46.63	44.92	48.27	47.13
Audio-MAE	56.86	55.86	59.08	58.76
MERT	49.07	46.78	53.05	52.54
DAC	42.17	41.71	53.67	53.67
<i>fine-tuned</i>				
Audio-MAE	54.32	50.14	54.89	49.81
DAC	60.49	60.27	59.87	59.84

Table 4. 2-way paired-ranking test result for the competition dataset *ICPC-2015*.

Several interesting observations are made from this experiment: 1) Transferring the learnt expertise ranking into assessing competition-level playing (which should all belong to the virtuoso tier within our training) is challenging, considering the random guess baseline of 50% accuracy in predicting the better performer within a pair. The best we achieve is slightly above 60%, possibly because the outcomes of competitions often transcend mere audio content to include performative expression like gestures, resulting in a *sight over sound* phenomenon [52]. 2) Adaptation on the competition set does not significantly boost the performance. For the pre-trained embeddings the accuracies slightly increase after fitting, but it has no effects on the fine-tuned embeddings. 3) The fine-tuned DAC embeddings, despite having a lower performance in the ranking

task with three levels, largely outperform other models in ranking the candidates in a competition setting.

Using the paired prediction results from best model (fine-tuned DAC w/o. fitting), we translate pair-wise predictions into a global ranking. Each candidate is ranked by how many wins they obtain in the ‘paired matches’. Each candidate is involved in 272 pairs, given 137 candidates and we infer on each pair (136) and its inverse. Figure 2 shows the relationship between our predicted candidate win counts and the preliminary round pass hit-rate (i.e. what proportion of candidates actually passed the preliminary round). *Michał Szymanowski* is the predicted best candidate who wins in the most pairs. Overall, there exists a good correlation between our predicted win counts rank and candidates’ ground truth performance: the top 18 predicted candidates all passed the preliminary round, with many of them progressing into round 2 or 3 (demonstrated by the color in Figure 2). Down to the cut-off threshold of half of the candidates, 65% of them passed the preliminary round. Finalists, however, are not necessarily predicted accurately: the winner *Seong-Jin Cho* only “wins” 39 matches and is placed towards the end in this rank, as is the third placed *Kate Liu*. Only *Charles Hamelin* (2nd place) is placed relatively high in our ranking.

Figure 2. Paired win count threshold vs. hit-rate for preliminary round pass prediction. Each candidate is a data point colored by their ground-truth result tier (i.e. the highest round they progressed from). The red dashed line is the cut-off of half the candidates.

5.2 Difficulty estimation

The difficulty estimation experiments are defined in Section 3.1.2 on the *CIP1* dataset. In Table 3 (middle), we report the *accuracy within n* (Acc_n) for the 9 class prediction. Defined as Eq. 2, Acc_n aligns with the ordinal nature of the task and we observe results for $n = 0$ (exact match) and $n = 1$ (allowing for one-class deviation).

$$Acc_n = \frac{1}{|C|} \sum_{c \in C} \frac{|\{y \in S_c : |\hat{f}(x) - c| \leq n\}|}{|S_c|} \quad (2)$$

The Audio-MAE embeddings yield overall the best performance for both 9-way and 3-way estimation. But it is worth noting that the untrained spectrogram baseline actually achieved accuracy metrics on-par with the audio encoders (32.98% vs. 33.67% in 9-way estimation), even higher than the worst-performing embedding of DAC.

The best we achieve with 9-class Acc_0 is 33.67% (compared to the same-set symbolic data baseline [35] of 39.47%). However, this is based on the fact that our audio embeddings are capped to 5 minutes, removing the effect of the major feature of piece length. For the 3-way classification we achieved accuracy that is on-par with the symbolic baseline, with the best Acc of 79.03%, demonstrating that the complexity of piano repertoire can also be encoded with the current pre-trained representation.

Interestingly, the Acc_0 and Acc_1 metrics do not improve hand-in-hand: Jukebox embeddings achieved the highest Acc_0 among the pre-trained models, but performed worst on Acc_1 since its prediction is sparse and scattered from observing the confusion matrix. The fine-tuned models exhibit a modest enhancement in performance metrics, as in the Acc_0 for Audio-MAE and 3-way FI for DAC, as well as better generalization and less overfitting.

5.3 Technique identification

The technique identification experiment is performed as both multi-label and single-label prediction, as formulated in Section 3.1.3. In Table 3 (right), we report the mean-Averaged-Precision (mAP) and Area Under the Receiver Operating Characteristic Curve (AUC). The former accounts for the balance between precision and recall, while the latter computes area under the false positive rate and true positive rate (recall) which reflects the influence of the true negatives. We also note the multi-label accuracy Acc which accounts for all binary predictions of each class.

The most important observation on the result is that the spectrogram representation easily outperforms the audio encoder embeddings on this task, especially on the single-label prediction case (46.67%). This offers an interesting perspective on the learned embedding content: exact note onsets and texture patterns (that are associated with the piano technique classes) seem to be overlooked by the embeddings, capturing less performance-related details compared to the lower-level spectrogram. The results demonstrate that DAC and JukeBox are the least informative audio embeddings for this task (24.44% and 25.44%). Audio-MAE is the best-performing audio encoder, but the single-label prediction results do not improve with fine-tuning. On the

other hand, fine-tuning DAC on the solo piano data improved performance on this task by 2%, compared with its pre-trained version.

To gain a better understanding of the identified techniques we observe the class-wise mAP from the best-performing representation of spectrogram. As depicted in Figure 3, Repeated Notes emerge as the most accurately identified technique. Conversely, the Staccato class exhibits a decline in performance throughout the training, hinting at a potential acoustic overlap with Repeated Notes, as suggested by prior research [53]. Meanwhile, the precision for other techniques shows consistent improvement during training, achieving 40% to 60% even in more distinct technique categories like Scales and Arpeggios. However, with the highest accuracy for single-label 7-way prediction being 46.67%, it is clear that the model’s ability to pinpoint techniques could be further refined, especially considering these are easily discernible to the human ear.

Figure 3. Average Precision for each class over epochs in multi-class prediction, from spectrogram representation.

6. CONCLUSION

Our research aimed to extend the capabilities of audio encoding models to the domain of solo piano performance understanding. Through this effort, we addressed tasks such as expertise ranking, difficulty estimation, and solo piano technique detection. The study introduced the Pianism-Labeling Dataset (PLD) and utilized a range of pre-trained audio encoders for evaluation. The curated set of performance-related attribute labels can contribute to multi-task learning or contrastive learning tasks in the future.

Our results, with the highest accuracy of 93.6% in expertise ranking, suggest that models like Audio-MAE hold promise for assessing aspects of musical performance, while the codified representations such as DAC or Jukebox struggle with capturing performance nuances. However, the studies on difficulty and especially techniques suggest the limitations of current pre-trained representations in capturing pianistic textures and patterns, as they fail to outperform the spectrogram baseline, prompting for the design of a performance-oriented audio representation. Meanwhile, the case study on the Chopin Piano Competition via transferring the assessment objective confirmed that we are still far from capturing the nuances of top-level human performance.

7. ACKNOWLEDGEMENT

This work is supported by the UKRI Centre for Doctoral Training in Artificial Intelligence and Music, funded by UK Research and Innovation [grant number EP/S022694/1], and the Engineering and Physical Sciences Research Council [grant number EP/T518086/1]. We are grateful for pianist Yan Zhou for helping with data verification.

ABSTRACT

Estimating music piece difficulty is important for organizing educational music collections. This process could be partially automatized to facilitate the educator’s role. Nevertheless, the decisions performed by prevalent deep-learning models are hardly understandable, which may impair the acceptance of such a technology in music education curricula. Our work employs explainable descriptors for difficulty estimation in symbolic music representations. Furthermore, through a novel parameter-efficient white-box model, we outperform previous efforts while delivering interpretable results. These comprehensible outcomes emulate the functionality of a rubric, a tool widely used in music education. Our approach, evaluated in piano repertoire categorized in 9 classes, achieved 41.4% accuracy independently, with a mean squared error (MSE) of 1.7, showing precise difficulty estimation. Through our baseline, we illustrate how building on top of past research can offer alternatives for music difficulty assessment which are explainable and interpretable. With this, we aim to promote a more effective communication between the Music Information Retrieval (MIR) community and the music education one.

1. INTRODUCTION

Estimating the difficulty of music pieces aids in organizing large collections for music education purposes. However, manually assigning difficulty levels is laborious and might lead to subjective errors [1]. To address this, Music Information Retrieval (MIR) research has focused on automating this process for piano works represented in various modalities [2–6] as well as repertoires from other instruments [7, 8]. Furthermore, the interest of companies like Muse Group [9, 10] and Yousician [11] highlights the industry’s recognition of the importance of the task.

Previous work in this field has mainly focused on processing machine-readable symbolic scores [1–4, 12–15].

Figure 1: To promote a more objective and transparent assessment, in our white-box model *RubricNet*, similarly as educational rubrics, scores (here difficulty) are dependent on descriptors’ values. The Rubric Interpretability table displayed at the right is inspired by [17, Fig. 1]

These, unlike acoustic features extracted from audio whose understanding depends on signal processing knowledge, are both analyzable by computers and interpretable by humans. Musicians find also easier to understand symbolic features since based on music theory knowledge. Initial works towards interpretable difficulty assessment focused on visualization [12], with Chiu and Chen [13] making the first attempt to classify difficulty in the piano repertoire with explainable descriptors. Still, the continually increasing trend towards deep-learning based solutions [3,4], whose lack of transparency limits users’ understanding and therefore leads to an eventual non-acceptance in real life applications [16], can impair a fruitful implementation of such technologies in music educational practices.

With this background, we propose a white-box [18] model (cf. Figure 1), which through the concept of a rubric, i. e., an evaluation instrument from music education used to support objective assessment [19–22], allows a transparent interpretation of music difficulty. From this point forward, the white-box model will be denoted by *RubricNet*. Furthermore, to gain a profound understanding of what music difficulty means from an explainable perspective, we build upon the descriptors of Chiu and Chen [13] by proposing a new one focusing on music repetitive patterns. We also provide an interactive companion page¹ to visualize the evaluated data and scrutinize the results in light of its interpretability from a musical point of view.

Through eXplainable Artificial Intelligence (XAI), we

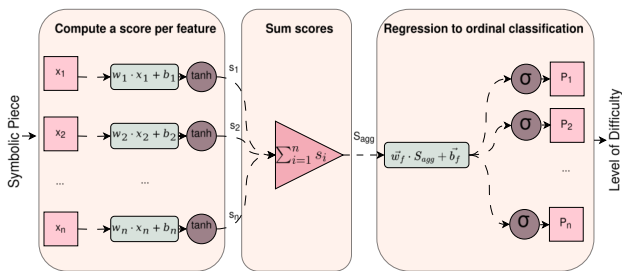

Figure 2: Detailed *RubricNet*'s architecture.

aim to contribute to music education by facilitating the understanding of measurable factors that determine a piece's difficulty. Our work builds on methods from music education, where objectively assessing abstract competences through measuring concrete criteria is consolidated by employing rubrics, i. e., tools which, unlike a black-box, break down complex concepts into simpler ones [19, 22].

Our interpretable methodology aims to bridge the gap between computational models and practical music education needs, enabling educators to make facilitated, but also informed decisions about curriculum development based on the difficulty levels of pieces. We release all the code and models of this research², in order to offer a baseline for further research in music difficulty assessment.

2. RELATED WORKS

Previous research aiming to automatically assess the difficulty of piano repertoire examined the link between fingering patterns and the pieces' difficulty level [2, 14, 15]. Recent studies [1, 3, 4, 23] have also made significant contributions. In [3], representations are used to feed three deep learning models—covering music notation, physical gestures, and expressiveness—to emulate Cook's dimensions [24]. These models' predictions are merged using an ensemble method to estimate the scores' difficulty. While we appreciate their musicology-inspired approach, its lack of interpretability harms its usability.

Difficulty estimation of piano pieces has also been investigated through hybrid methods that merge features with deep learning models [1, 23]. However, the absence of publicly shared data and code complicates performing comparative analyses with reference to these works. In [23], the authors combine the methods from Chiu and Chen [13] with deep learning models trained using piano roll as input. In a similar vein, [1] uses JSymbolic features [25] and deep learning models on a proprietary dataset.

In the study by Chiu and Chen [13], 159 pieces from the *8notes* website were used, whereas [23] utilized 1800 MIDI files from the same source. The categorization of these pieces, provided by users of *8notes*, raises concerns about their reliability. Unfortunately, neither study provides access to their data or details on how they were segmented. Other work [26] has attempted to understand the effectiveness of various features, including those proposed in [13] for categorizing the grade levels of a specific piano curriculum. Recent efforts by Zhang et al. [4] and

Ramonedá et al. [3] have focused on compiling datasets with difficulty annotations from the established piano publisher Henle Verlag, with the latter's dataset not only being the most extensive but also the only one made publicly available. Therefore, for our comparative analysis, we will use the open-source datasets presented in [3], namely *Can I Play It?* (CIPI), which has 9 levels of difficulty, and *Mikrokosmos-difficulty* (MKD), which includes 3 levels.

Finally, in order to validate our approach, we consider a different and established feature set, i.e., the standard music symbolic features available through Music21 library [27], which includes (amongst others) established JSymbolic features [25], thus facilitating a meaningful comparison with our proposed descriptors. In addition, we also contrast the results achieved with our novel descriptors with those obtained with the features by Chiu and Chen [13], which are also reimplemented and open-sourced in this study. Note that none of the approaches previously mentioned has focused on the interpretability of the descriptors, which is a key contribution of our work.

3. INTERPRETABLE *RubricNet*

The *RubricNet* model (cf. Figure 2) is designed to provide interpretability akin to a rubric, enabling its analysis and results to be intuitively aligned with established practices in music education. This approach ensures that the model's logic and outcomes are easily comprehensible, facilitating their usage in music education along to traditional tools.

3.1 Model Architecture

The network, comprising a series of linear layers dedicated to process individual input descriptors and followed by a nonlinear activation function, is formulated as follows:

Given a set of N input descriptors, each descriptor x_i is first processed through its dedicated linear layer with weight w_i and bias b_i , followed by a hyperbolic tangent activation function to yield:

$$s_i = \tanh(w_i \cdot x_i + b_i) \quad (1)$$

where s_i represents the processed score for the i -th descriptor. Scores are then aggregated in a single score S_{agg} :

$$S_{agg} = \sum_{i=1}^n s_i \quad (2)$$

The aggregated score S_{agg} is then passed through a final linear layer to obtain the logits for the class predictions, which are mapped to probabilities with a sigmoid function:

$$\vec{P} = \sigma(S_{agg} \cdot \vec{w}_f + \vec{b}_f) \quad (3)$$

where σ denotes the sigmoid function, \vec{w}_f and \vec{b}_f are the weight and bias of the final linear layer, respectively.

3.2 Ordinal Optimization

This model applies an ordinal optimization approach [28], predicting ordered categorical outcomes, i. e., difficulty

²At: <https://github.com/pramonedá/rubricnet>

Descriptor	Explanation
Pitch Entropy	Indicates pitch variety; higher values mean more diverse pitch collection
Pitch Range	Distance between the lowest and highest notes.
Average Pitch Displacement	Indicating the central pitch level.
Rate	Measures hand movement intensity across keys reflecting physicality in performance.
Average IOI	The average timing between note onsets, indicative of rhythmic density.
Pitch Set LZ	Indicative of structural complexity and repetitiveness within a pitch set sequence.

Table 1: Explanation of descriptors in musical terms.

levels such as beginner (1), intermediate (2), and advanced (3), through logits. These logits, computed using a mean squared error (MSE) loss, indicate the model’s predictions on the ordinal scale. Difficulty level is then obtained as:

$$\max\{i \text{ where } P_i \geq 0.5 \text{ and } P_j \geq 0.5, \forall j < i\} \quad (4)$$

3.3 Interpretability

In *RubricNet*, the *descriptors* (automatically computed from the data) are, to some extent, comparable to the formalized *evaluation criteria* defined in traditional rubrics; similarly, the *aggregated score*, might be comparable to a final *grade/mark* assigned in an educational scenario. Given the correspondences between both, we could consider the model a “white-box” approach, able to promote transparency and interpretability, similarly to a rubric.

It uses independent linear transformations on input descriptors to generate scores between -1 and 1, which directly influence the regression output, S_{agg} . Since negative scores, might be not fully understood in terms of difficulty level, we normalize scores between 0 and 1, rescaling S_{agg} between 0 and 12. This approach mirrors rubric’s ability to provide objective and structured feedback, with the simplicity of these transformations aiding in understanding the impact of features in predictions.

The interpretability of the model lies in its ability to dissect each descriptors’ influence on a piece’s difficulty level. Consequently, analyzing each descriptor’s scores might reveal its overall importance on the prediction. Lastly, S_{agg} is a continuous-ordered scalar with rank correlation to difficulty. Therefore, from S_{agg} , we retrieve ordered and discrete categories with clear decision boundaries.

4. EXPLAINABLE DESCRIPTORS

From codified musical scores, we extracted numeric features which are feed to a classification algorithm. We re-implemented a set of features from the literature [13] while proposing a novel one, Pitch Set LZ. In addition to explaining the features (cf. Table 1), we will provide their technical descriptions and analyze their relevance to difficulty and interdependencies using the data.

4.1 Descriptors

In our work, we analyze music sheets encoded in symbolic format, focusing on extracting pitch and timing. Following the approach suggested by Chiu and Chen [13], we

process left and right hand parts separately to clarify pedagogical aspects of musical difficulty. Our primary analysis involves sequences of pitch set events, each characterized by a pitch set S and onset time T . Pitch sets, represented by sets of MIDI numbers, are defined over the alphabet of all pitch sets \mathbf{S} that occurred in a score part, while onset times are calculated in seconds from the performance start by the music21 library [27] with reference to marked tempo information. This method emphasizes the timing of note attacks, duration and rests. Additionally, we consider a collection of pitch events, each defined by pitch P over the alphabet of all pitches \mathbf{P} . Our analysis started with the five features identified by Chiu and Chen [13] as most relevant to understanding musical difficulty.

Pitch Entropy. The entropy of pitches in the pitch events:

$$-\sum_{i \in \mathbf{P}} p(P = i) \log_2 p(P = i) \quad (5)$$

Pitch Range. The distance between the minimum and maximum MIDI pitches in a score part.

Average Pitch. The average MIDI pitch in a music sheet.

Displacement Rate. Initially proposed by [13], it quantifies the extent of hand movement across the keyboard during the performance of a score. It analyzes maximum pitch distances between consecutive pitch set events and is calculated as a weighted average of three categories: distances less than 7 semitones (assigned a weight of zero); distances over 7 semitones but under an octave (assigned a weight of one); and distances of an octave or larger (assigned a weight of two to emphasize larger movements).

Average IOI: Average Inter Onset Interval. A concept similar to the “Playing speed” introduced by [13], a term we consider deceptive since it actually decreases as the hand’s “speed” increases. This is an average time in seconds between onsets of two consecutive pitch set events. Let’s denote i^{th} onset time with T_i , then the value is:

$$\frac{\sum_{1 \leq i \leq N_{events}-1} (T_{i+1} - T_i)}{N_{events} - 1} \quad (6)$$

In 23% of the scores, information about the recommended performance tempo is missing. We then assume the tempo is 100 beats per minute (bpm). Thus, in cases of missing bpm, the Average IOI feature might not be relevant.

Pitch Set LZ. Lempel-Ziv complexity of pitch set sequence. Before introducing our proposed descriptor, it is crucial to provide context and motivation. Pitch Entropy, as emphasized by Chiu and Chen [13], is particularly relevant—a conclusion supported by the analysis of correlations between difficulty and features in the following section, as well as by informal experiments. As Sayood discusses [29], there’s a link between entropy of a task and the cognitive load it imposes on the performer, a concept that may also apply to music performance [30]. However, music is often perceived in terms of larger structures like phrases and sections, not just isolated pitches, prompting us to seek a descriptor that captures the “repetitiveness”

Feature	τ_c
Pitch Entropy (R)	0.583
Pitch Set LZ (L)	0.583
Pitch Entropy (L)	0.582
Pitch Set LZ (R)	0.573
Pitch Range (L)	0.567
Pitch Range (R)	0.554
Displacement Rate (R)	0.332
Displacement Rate (L)	0.273
Average IOI (R)	-0.209
Average IOI (L)	-0.208
Average Pitch (R)	0.088
Average Pitch (L)	0.017

Table 2: Features ordered by absolute values of their τ_c rank correlation with the difficulty level.

of music on a broader scale. To this end, we employ LZ-complexity, a measure of redundancy introduced by Lempel and Ziv [31]. In context of music research, it was used for binary encoded rhythm analysis by Shmulevich and Povel [32]. We apply LZ-complexity to sequence of pitch sets: scan a score part, identify all subsequences of pitch sets that cannot be reproduced from preceding material through a recursive copying procedure. The number of such unique subsequences is defined as the LZ-complexity of the part. This approach allows us to assess the structural complexity and redundancy of a musical piece, highlighting the cognitive demands placed on performers.

4.2 Feature Analysis

We assume that, for easier interpretability, features must on average change monotonically with the difficulty level. To measure this quality, we use the τ_c version of Kendall rank correlation coefficient due to its ability to deal with “heavily tied” rankings [33] (many musical pieces have the same difficulty, hence, we have multiple ties in the ranking by difficulty). τ_c is equal to 1 when feature and difficulty rankings are perfectly aligned in the same direction, -1 if they are aligned in opposite directions. As the number of nonconcordant cases increases, the coefficient approaches zero. In Table 2, the results show that the features related to pitch organization are the most correlated to difficulty. Hand displacement and Inter-onset intervals are less correlated, while average pitch seems almost irrelevant.

In addition, we aim to uncover dependencies among the features themselves while mitigating the influence of difficulty, with whom most features are correlated. To achieve this, we calculate conditional τ_c correlations for all feature pairs given a fixed difficulty level, and average the coefficients across all difficulty levels. We then convert these coefficients into a distance matrix and apply hierarchical agglomerative clustering based on average distance to identify clusters of correlated features. From the resulting dendrogram (cf. Figure 3), we observe that features correlated with difficulty—namely Pitch Entropy, Pitch Set LZ, and Pitch Range—are also interrelated. This is remarkable because the three most correlated features are not inherently dependent: one could envision a music piece with any of them maximized while maintaining low values for the others. However, pieces in CIPI typically exhibit coordinated

Figure 3: Hierarchical clustering of features based on their average correlation distance within each difficulty class.

values in these descriptors. Thus, we mostly observe the combined effect of these features, making it challenging to reliably decompose “difficulty” into an aggregate of independent components.

5. EXPERIMENTS

5.1 Experimental Setup

To evaluate the effectiveness of our proposed method, we utilized the *Mikrokosmos-difficulty* (MKD), and *Can I play it?* (CIPI) datasets [3]. For fair comparison, we use the 5-fold cross-validation approach defined in [3]. In each split, 60% of the data is used as a train set, while the remaining is equally divided into validation and test sets.

As in [3], we employ mean squared error (MSE) and accuracy within n classes ($\text{Acc-}n$) for evaluation. These metrics are chosen for their applicability to ordinal classification challenges, with $\text{Acc-}n$ assessing the model’s accuracy for n classes from the true labels, and MSE measuring the average squared prediction error across classes. The effects of dataset imbalances and a fair evaluation across classes are mitigated by macro-averaged metrics.

We optimize the models during training through Adam optimizer with a learning rate of 10^{-2} . The training process incorporates early stopping, based on the $\text{Acc-}n$ and MSE metrics from the validation set, to prevent overfitting. Through Ordinal Loss, we frame difficulty prediction as an ordinal classification task, as mentioned in Section 3. We apply a standard scaler and dropout to the features to prevent individual ones from dominating. For each experiment, we look for the best hyperparameters using Bayesian optimization [34]: batch size within the range from 16 to 128, dropout rate between 0.1 and 0.5, learning rate decay from 0.1 to 0.9, and the learning rate itself, tested over a logarithmic scale from $1e-5$ to $1e-1$. This approach allows us to systematically explore the hyperparameter space and identify the optimal settings for our models; thus, enabling a fair comparison between experiments.

5.2 Experimental Results

In Table 3, the results from the comparison between the performance of our novel approach with the presented de-

	CIPI		MKD
	Acc-9	MSE	Acc-3
argnn [3]	32.6(2.8)	2.1(0.2)	75.3(6.1)
virtuoso [3]	35.2(7.3)	2.1(0.2)	65.7(7.8)
pitch [3]	32.2(5.9)	1.9(0.2)	74.2(9.2)
ensemble [3]	39.5(3.4)	1.1(0.2)	76.4(2.3)
Ours	41.4(3.1)	1.7(0.5)	79.6(8.8)

Table 3: Experiment comparison of previous individual deep learning models [3], their ensemble and our explainable and interpretable method on CIPI and MKD.

Experiment	Acc-9	MSE
<i>RubricNet</i> proposed	41.4(3.1)	1.7(0.5)
"" with Chiu and Chen [13] descriptors	36.2(5.2)	1.7(0.3)
"" with Music21 descriptors	36.7(6.0)	1.3(0.2)
"" with ALL descriptors	38.9(4.3)	1.3(0.1)
"" proposed without Avg P.	39.0(5.6)	1.5(0.4)
"" with positive scores	38.5(3.5)	1.6(0.6)
"" without ordinal regression	36.2(1.3)	2.1(0.4)
Logistic regression	40.0(4.3)	1.5(0.3)

Table 4: Ablation study results for different feature sets (5 first rows) and model configurations (last 3 rows) on CIPI.

scriptors (cf. Sections 3 and 4) and the results achieved by three previous models from the literature (argnn [35], virtuoso [36], pitch) as well as their collective ensemble, are shown. Our model achieves the highest Acc-9 score of 41.4(±3.1) in CIPI, surpassing the ensemble’s 39.5(±3.4), while displaying the second lower MSE of 1.7(±0.5), only overtaken by the ensemble’s 1.1(±0.2). With an Acc-3 score of 79.6(±8.8) in the MKD dataset, our approach is superior to previous ones but with a higher standard deviation.

In the following, we examine the impact of various feature and model configurations on *RubricNet* performance (cf. Table 4). As baseline for comparison, we consider the configuration previously discussed (cf. Ours in Table 3).

Employing only the five Chiu and Chen [13] descriptors, i.e., excluding Pitch Set LZ, leads to a decrease in Acc-9 by −5.2, reflecting a performance drop from the baseline. The use of Music21 [27] descriptors, which include JSymbolic [25] and other descriptors widely used in the community, results in a decrease in Acc-9 by −4.7 and a decrease in MSE by −0.4, showing slight improvements in MSE but not in accuracy. However, note that a larger number of descriptors could decrease the explainability. Combining all the descriptors slightly decreases Acc-9 and MSE: −2.5 and −0.4, respectively; with the accuracy results still under the baseline. These results indicate that the descriptors discussed in Section 4 constitute the best option for difficulty estimation on CIPI. Since average pitch showed no relation to difficulty in the feature analysis, we repeated the experiments without this feature. This lead, however, to non-significant worsening of the results.

Concerning the impact of different model configurations, we replace the tanh by sigmoid non-linearities to guarantee positive scores. The obtained MSE rate is similar but the accuracy drops by −3.1. This means that negative scores could aid in training, which is why we keep them, but normalize the scores after the training phase. Besides, substituting the ordinal encoding used in the base-

Figure 4: Decision boundaries of the model between grades on S_{agg} (X axis) for all splits (Y axis) on CIPI.

line with a traditional one-hot encoding with cross-entropy loss, results in a decrease in Acc-9 by −5.2 and an increase in MSE by +0.4, highlighting the importance of ordinal regression in achieving lower MSE rates. Lastly, logistic regression with ordinal loss decreases the Acc-9 by −1.4 while showing a decrease of MSE by −0.2. This offers a compromise for both metrics but without beating our setup and to our understanding, being less interpretable.

Overall, the gains offered by *RubricNet* with the features proposed are relatively modest compared to the baselines. However, having a smaller feature set is necessary for explainability. The novelty of our approach lies in aligning the interpretability of music education with rubric-like interpretability feedback. This alignment is essential for a successful application of our model in practice, as we will discuss in further sections.

5.3 Decision Boundaries

In *RubricNet*, the input features are combined into a single scalar before performing the final ordinal classification. Analysis of the results shows that the final layer defines optimized decision boundaries, setting thresholds for S_{agg} that progressively increase along with difficulty levels. Because of the final sigmoid activation, once S_{agg} exceeds a boundary, the corresponding difficulty level will always be active, which guarantees the ordinality of the predictions. By examining the decision boundaries (cf. Figure 4), we observe that the trends are similar across splits, displaying shorter valid ranges around intermediate levels. Note that in split 2, there are only 8 classes because the model ignored the last class. This can happen as we use numeric optimization, which sometimes falls into local minima. These minima might seem optimal based on the validation metrics but do not meet our overall performance expectations.

6. DISCUSSION AND LIMITATIONS

Now, we analyze whether *RubricNet* is interpretable from a musical point of view. To understand how features impact the final level suggested by the model, we evaluate the contribution of each descriptor to the aggregated score. Since learning to play an instrument is a progressive process, relative contributions of features to different levels

Figure 5: Average relative contribution of descriptors (Y axis) normalized between 0 and 1, across grades (X axis).

Descriptor Name	Score	Grade Divergence	Accumulative Score
Pitch Set Lz	+ 0.08	- 0.23	0.08
Pitch Range	+ 0.42	- 0.37	1.04
Average Pitch	+ 0.07	- 0.04	1.21
Average Ioi Seconds	+ 0.09	- 0.04	1.38
Displacement Rate	+ 0.63	- 0.25	2.85
Pitch Entropy	+ 0.4	- 0.2	3.82
...
Final Score	—	—	3.9

Figure 6: Simplified difficulty interpretable rubric for the *Nocturne op. 9, no. 3* (F. Chopin). Descriptors' values for the right hand and final score (for both hands) are shown.

with reference to the grade 1 are displayed instead of absolute values. These contributions are averaged across splits on the test set and shown in Figure 5.

We observe a trend of higher contributions when the level increases for every descriptor. This observation is consistent with the fact that S_{agg} value increases for higher levels (cf. Figure 4). The most discriminative features are pitch entropy and pitch range, as well as the LZ descriptor for higher levels. Conversely, some features, e.g., average IOI or the average pitch, have low contribution to the model's decisions, as shown by their relatively constant and small values across grades. The latter is expected, since very different pieces could have the same average pitch, not disclosing anything about difficulty. The former might be explained by the averaging, which can remove information, especially when a piece can alternate between fast and slow parts. Besides, as mentioned before, tempo is often poorly annotated in the dataset.

To better understand the explainable capabilities of the proposed descriptors, in the following, we provide a musical examination of two concrete samples, by this demonstrating the interpretability of our approach. *Nocturne op. 9, no. 3* by F. Chopin, is labelled as level 7, but classified as level 2. All the descriptors are below the grade average, as shown in the rubric (cf. *Grade Divergence* in Figure 6). Our hypothesis is that this nocturne contains many challenges that go beyond the descriptors used. There are constant changes in dynamics, a variety of articulations, and as a key difficulty aspect, many types of polyrhythms between the right and left hands. Further research should address all the types of difficulty challenges, probably underrepresented in the existing datasets.

(a) *Berceuse in D-flat major, Op.57* (F. Chopin). Bars 6-10.

(b) Distance to the average for the grade of the scores. Extracted from original rubric (grade divergence column).

Figure 7: Musical excerpt (a) and a rubric outcome (grade divergence) plotted (b) from a piece in level 7.

The piece *Berceuse in D-flat major, Op.57* by F. Chopin, shown in Figure 7 is appropriately classified as grade 7. This is because it maintains a left-hand accompaniment with few changes, in contrast to the higher virtuosity of the right hand. The left hand has scores below average in most descriptors because of its few changes: Pitch Range (-0.41), Average IOI (-0.04), Pitch Set LZ (-0.34), Average Pitch (-0.01), and Pitch Entropy (-0.52). In contrast, the right hand shows more virtuosity, with higher than average scores for all the right hand features. These scores collectively contribute to a final cumulative score that accurately reflects the overall difficulty.

Finally, it should be noted that our approach primarily focuses on descriptors related to pitch sequences and onsets, while disregarding others. Still, the ablation study showed that other features sets (e.g., those from music21), even covering aspects like rhythm variety, do not enhance our classifier's performance either. In addition, expressive elements [37] such as dynamics, tempo changes, and articulation, since often left to performers' interpretation, are not always captured in musical notation [3], and therefore is a dimension our score-based model does not consider.

7. CONCLUSION AND FUTURE WORK

In our study, we proposed a novel white-box parameter-efficient model aligned with the music education community tools, i.e., rubrics, which outperforms previous approaches on difficulty estimation. In addition, we created an interactive companion page for visualizing CIPI and MKD datasets. In summary, we showed that analyzing explainable descriptors, unlike deep learning models, offers clarity, which gives both teachers and students specific insights into pieces. This approach not only underscores the importance of explainable artificial intelligence (XAI) in understanding music difficulty, but also emphasizes the potential for such technologies to contribute to the broader field of music education. For future research, we consider interesting to creating a dataset based on technical challenges like finger fluency and polyphonic complexity, as well as user studies for understanding the perception of interpretable feedback by music education community.

8. ETHICS STATEMENT

The system presented in this paper aims at obtaining the difficulty of a musical piece through several descriptors. In previous work, descriptors were not available, limiting access to the area. This situation underscores the need for open science practices. Therefore, we open our implementation, to facilitate access for new researchers. Besides, the dataset used for this study is available upon request for non-profit and academic research purposes. While this limits its use in commercial applications, it ensures the reproducibility of the results. The data consists of open-source scores of music that is no longer copyrighted, its use for open research can thus be considered fair.

The proposed work belongs to the area of assisted music learning. One might argue that such a tool can have a detrimental impact on music teaching jobs. While this is a valid concern, we think that an eventual solution of the addressed task, would not endanger music educators profession, whose role naturally goes much beyond than categorizing music in difficulty levels. Instead, this technology should be seen as a way to support them in the own teaching practices, for instance, by alleviating their burden on some duties, such as exploring large collections, and by this enabling them to easily discover forgotten musical works from our cultural heritage which fit students' needs. Moreover, through this research, we also aim to convey the message that the path to advancement does not solely lie in acquiring more data or creating larger models. By highlighting what drives its decisions, our proposed model aligns with the goals of eXplainable AI, something crucial for its acceptance in music education. Although our efforts in making the system interpretable and explainable will partly answer the common criticisms made to black-box approaches, the real impact of our system remains to be verified by its future use in real scenarios.

9. ACKNOWLEDGEMENTS

We want to thank Alia Morsi's previous work on difficulty estimation from a feature engineering perspective, which encouraged research in tabular data [26]. The team would also acknowledge Marius Miron for continuously insisting on aligning difficulty estimation with explainability. He also highlighted the direction of using a rubric-like explainability feedback, pointing out Ustun et al.'s work [17]. We also thank Roser Batlle-Roca for helping to discuss some concepts between interpretability and explainability based on her research [38].

ABSTRACT

The rise of digital technologies has increased interest in democratizing music creation, but current creativity support tools often prioritize literacy and education over meeting children’s needs for casual creation. To address this, we conducted Participatory Design sessions with children aged 6-13 to explore their perceptions of casual music creation activities and identify elements of creative applications that support different expressions. Our study aimed to answer two key questions: (1) How do children perceive casual music creation activities and which elements of creative applications facilitate expression? and (2) What insights can inform the design of future casual music creation tools? Our findings indicate that children view casual music creation as involving diverse activities, with visuals aiding in understanding sounds, and engaging in various playful interactions leading to creative experiences. We present design implications based on our findings and introduce casual creation as "purposeful play". Furthermore, we discuss its implications for creative MIR.

1. INTRODUCTION

Digital technologies have sparked interest in democratizing creation as they enable diverse individuals to produce cultural objects [1–3], suggesting we may understand these tools as enhancers of human creativity [4–7]. For example, over the past two decades, there has been a rise in the development and study of Creativity Support Tools (CSTs) in the field of Human-Computer Interaction (HCI) [8]. Despite the abundance of music-related CSTs, including tools such as digital audio workstations [9–11], notation software [12, 13], style-specific composition/identification tools [14, 15], and music generation systems [16, 17], many fail to cater to children.

Children’s creative experiences are often shaped by a limited understanding of social norms [18], implying that systems designed for adults may not fully support their creative endeavors. Moreover, many music applications designed for youth primarily focus on literacy or are deployed in formal education contexts [19, 20]. However, previous work highlights the value of informal and casual music experiences in education [21, 22]. Building on this work, we explore the potential of casual music experiences for children, focusing on casual music creation. We define casual music creation as *creative musical experiences prioritizing the process of enjoyment over product outcome*, drawing inspiration from Compton’s research on casual creation systems [23, 24]. While casual musical experiences relate to informal learning [22], this study focuses on how music technology as part of CSTs supports these experiences, providing new ways for children’s self-expression rather than skill development. Research shows that supporting creativity is vital for children, as it helps to foster children’s identities [25, 26], develop confidence in their creative abilities [27, 28], as well as support brain development [29, 30] and social skills [31].

However, there is a gap in understanding children’s MIR needs. This is particularly true in creative MIR, or the use of retrieved music information for creative purposes [7, 32], despite growing interest in creative applications [7, 33]. For instance, only two ISMIR papers address children: one develops the *Children’s Song Dataset* for song synthesis [34], and the other involves children in designing a music organization app [35]. While these studies provide insights to children’s experiences with MIR tasks, there is still a broader question about how children interact with MIR tasks to meet their unique creative needs. Building off this prior research in MIR, music education, and HCI, we utilized a method of Participatory Design (PD) called Cooperative Inquiry, a type of PD that focuses on designing technology *with* and *for* children [36]. As children are a growing user group of creative technologies, PD can generate developmentally appropriate design ideas and feedback [37, 38], boosting children’s self-esteem through facilitating design in a casual setting [39]. We examine children’s creative needs while using musical CSTs within creative MIR contexts through two PD sessions with children aged 6-13, addressing two questions: (1) How do chil-

dren perceive casual music creation activities and which elements of creative applications facilitate expression? and (2) What insights can inform the design of future casual music creation tools? This paper contributes to the democratization of music creation by addressing children’s unique creative needs in casual music application design. Furthermore, we present a set of design principles to support more playful interactions with music and discuss their implications for future work in creative MIR.

2. RELATED WORK

2.1 Children’s Musical Creativity

Creativity is the ability to generate original and valuable ideas [4]. In the realm of music, this translates to realizing such ideas through composition, analysis, or performance [40]. Scholars argue that musical creativity is embodied, meaning environmental factors play a role in shaping creative cognition in music [40–43]. Furthermore, music educator Peter Webster has suggested that musical creativity is more akin to creative processes, or what he terms as moving from a musical idea to a product [44].

For children, there has been a particular focus on understanding their creativity in reference to composition [45–47] in music education contexts. Yet, musical experiences begin early in childhood and are increasingly impacted by popular music experiences with new forms of technology [48–51]. Therefore, children experience music via playful interactions in a variety of modalities [52]. Notably, social-emotional environments, especially those shaped by parents and teachers, can serve as catalysts for children’s musical creativity through play [53–55], suggesting that children’s musical experiences are impacted by their development, environment, and interactions with technology. While play and technology are crucial in music education and cognitive development, questions remain about how CSTs can enhance casual music experiences and whether these interactions impact children’s creativity.

2.2 Creativity Support Tools

Creativity Support Tools (CSTs) are digital resources designed to enhance creativity [8]. Interactive musical systems (IMSs) have shown promise in supporting non-musicians’ engagement in music making [56], but domain expertise can influence creativity [40, 57]. Hence, specialized tools have been developed to meet novices’ needs, often incorporating critique [58], such as those for novice filmmakers [59] or digital painting systems [60]. Recognizing the importance of personally meaningful creative activities, referred to as "mini-c" creativity, there is a growing emphasis on integrating this perspective into CST evaluation methods [61, 62]. This acknowledgment underscores the significance of understanding children’s creative experiences with musical CSTs and adapting design and evaluation approaches accordingly [63]. While technology’s impact on children’s creativity has been explored in areas like storytelling and video creation [64, 65], its effects on musical creativity remain relatively unexplored

Pseudonym	Age	Gender	Ethnicity	Sessions
Annie	6	Female	Latino	DS2
Emma	9	Female	Black / White	DS1, DS2
Han	10	Male	Latino	DS2
Jayden	9	Male	Asian / Black	DS2
Keon	9	Male	Asian / Black	DS1, DS2
Liam	9	Male	Asian / White	DS1
Jin	13	Female	Asian / White	DS1, DS2
Taylor	10	Female	Asian / White	DS1, DS2
Seiko	10	Female	Asian	DS1
Zachary	8	Male	Asian / White	DS1, DS2

Table 1. Demographics of Child Participants

[50, 58, 66]. Though tools aiding children in music composition exist, they are often designed for general novices [63], even though previous work has suggested specific design recommendations for other musical acts by children, such as composition at home [45]. Previous research recognizes children’s unique creative needs and the potential of CSTs to foster creativity and learning. However, there is still uncertainty about the differences between children’s structured and casual creation with CSTs, and how these differences relate to creative MIR.

3. METHODS

3.1 Participatory Design

For this study, we utilized Cooperative Inquiry (CI) [36, 67], a Participatory Design (PD) method facilitating collaboration between designers and users, thus democratizing the design process. CI specifically emphasizes allowing children and adults to design as equals. This method offers insights into children’s learning [67], empowering them to articulate thoughts on complex issues such as family finances [68], gender [69], and creativity [70, 71].

3.2 Participants

The **KidsTeam UW** co-design group comprises adult design researchers (investigators, master’s students, and undergraduate students) and 10 child participants, using pseudonyms for confidentiality (see Table 1). Children were recruited through mailing lists and snowball sampling with parental consent and child assent obtained. The research received approval from the university’s Institutional Review Board. Two 90-minute design sessions were held in January and February 2024, with five to eight adult facilitators serving as design partners in each session.

3.3 Design Sessions

Our design sessions started with a 15-minute *Snack Time* for socializing, followed by a 15-minute *Circle Time* featuring a "Question of the Day" to warm up for the design activity. Then, participants engaged in small group design activities for 45 minutes in *Design Time*, followed by a 15-minute *Full Group Discussion* for presentations and reflection.

Child	App Name	Description
Annie	Color Block	Users compose by dragging and dropping colored blocks. Users can download the music to share.
Emma	Cat Choir	An app where users may drag different clothing representing different sounds onto cats to compose songs.
Han	Mixtape	Users create and share "mixtapes" by pulling music from streaming services and creating playlists. Also allows for composing with provided sounds and AI.
Jayden	Untitled	Users organize their music and can search, filter, and create albums. They can also remix other songs.
Keon	Untitled	An app to store music files, allowing users to drag and drop music files from other apps.
Jin	Dreamer	A music composition app that acts as a game where users are able to manipulate different environments to create music for a story.
Taylor	Sing-a-Song	Users can create songs by dragging instruments onto tracks and export them with a video or animated characters. Others can remix these songs.
Zachary	Piano God	An app meant to help pianist practice songs using animations to tell users which keys to play.

Table 2. Descriptions of Applications designed by children in DS2

3.3.1 Design Session 1: Playing with Casual Music CSTs

Design Session 1 (DS1) took place in January 2024. We asked the children to play with four different casual music tools to elicit their feedback on different types of casual music applications. The first is *TextAlive* [72, 73], a website that automatically synchronizes lyrics text with music, detects timing information of beats and other musical elements, and allows users to interactively create “lyric videos” – music videos in which lyrics animate in sync with the music. The second tool, *TextAlive Flow* [74] (available on tablet and desktop), is an extension of *TextAlive* that has a more casual user interface. It allows users to touch the screen to change the video’s visuals (typography, colors, motion patterns, etc.) while listening to the music. *Incredibox* [75] lets users create songs by dragging and dropping outfits onto animated characters, combining pre-recorded beatbox sounds and melodies. Lastly, *Sketch-a-Song* [76] is a tablet application that lets users tap and drag to add different pitches and sounds. These tools were selected to allow children to engage with various modes of interacting and making with music. During the session, we captured what the children liked, disliked, and design ideas for each app on a sticky note, organizing them into thematic groups on a whiteboard [36].

3.3.2 Design Session 2: Designing Casual Music CSTs

Design Session 2 (DS2) took place in February 2024. We asked the children to “design a casual music creation app.” We asked them to define what their app allowed them to do with music, and develop a user flow including how they moved between the homepage, creation interface, and to sharing their creations with others. We derived these design aspects from the themes that arose during DS1. Before breaking into our design groups, we shared an example of what a user flow looked like using *TextAlive Flow*. We supplied the children with a large bag with different craft materials and paper, asking them to engage in low-fidelity prototyping of their application [77].

3.4 Data Collection and Analysis

Our hybrid design sessions utilized Zoom for video and screen recordings across three computers for each design group. We recorded a total of 6 hours and 10 minutes of video. Researchers also documented creative artifacts

with a camera and took notes on a legal pad. Children’s thoughts were summarized during group discussions and collected on a *Google Slides* deck.

We utilized an inductive qualitative approach for data analysis [78]. The initial codebook was developed by the first author through inductively coding recorded session videos. Codes like “*Musical Activities – Remixing*” and “*Control – Variety of Options*” were included in the first iteration. Subsequently, two authors conducted consensus coding [79] on design artifacts, researcher memos, and session videos, adjusting the codebook as needed. In cases of disagreement, a third team member resolved discrepancies. This process led to the final version of the codebook. For example, we applied the code “*App Elements – Control*” to the quote “when you could see or hear a difference, it makes you feel like you’re in more control.” Further descriptions of design artifacts and applications of our codes can be found in our supplemental material.¹

4. FINDINGS

4.1 Children’s Perceptions of Casual Music Creation

Consistent with previous work [48,52], children saw music making as a holistic, process-focused experience [44], and expected to engage in multiple musical activities within a single app. Composing was the most referenced activity, as all DS2 apps except Keon’s, which stored music files, involved music composition. Listening to music was also prominent (Han, Jayden, Jin, & Taylor, DS2). Remixing, proposed only in Taylor’s and Jayden’s apps, was the least suggested activity.

Children’s views on the applications were shaped by their past experiences with music and technology, indicating their preferences often reflect experiences with other applications such as music streaming apps [48], as well as their cultural backgrounds and existing knowledge [80]. For example, many applications from DS2, shown in Table 2, also included references to other applications. Emma and Taylor’s applications referenced *Incredibox* and *Sketch-a-Song* respectively, imitating the drag and drop features for layering musical sounds. The interface of Zachary’s application was similar to the application *Syn-*

¹ Our supplemental material can be found at: <https://doi.org/10.17605/OSF.IO/5DNS6>.

thesia, with falling blocks that demonstrated which keys to play on a piano keyboard. Additionally, there were various ways suggested to supplement listening methods that were similar to other applications such as organizing playlists (Han & Jayden, DS2) or watching music videos (Jin & Taylor, DS2). Additionally, some of the children referenced their previous music education experiences. In our study, Jin, who has taken piano lessons, found *Sketch-a-Song* limiting due to its representation of musical pitches stating it felt “pedantic” (DS1). Zachary’s app included a piano in the interface, including letters for the different keys. Similarly, Annie included *solfège* (i.e., do, re, mi) as the notes for her app “Color Block.”

While the children’s interactions initially focused on the process of exploring with music, they mentioned the importance of these customization options to give them a sense of control as they created. This was especially important as the children formed creative products. As an illustration, reflecting on *TextAlive* and *Sketch-a-Song*, Taylor noted “You can’t create your own song [in the apps], you’re just designing it, and even then, you don’t have much control over it” (DS1).

4.2 Visuals as a Bridge to Music

Within our sessions, we found a connection between visuals and sounds, with children noting that the aesthetics of an application changed the way the music was perceived. For example, Jin stated: “I liked changing the colors because even if you’re given this format [in *TextAlive Flow*], since colors have a strong effect on how music is portrayed, you can change the whole vibe, even if you are restricted” (DS1). Other children noted changing colors to fit their experience was important demonstrated by three distinct sticky notes expressing appreciation for “many options for colors,” “all the color options,” and “cool color range” when discussing customization in *TextAlive*. During DS1, an adult co-designer also noted that children also became visibly excited when able to use animations in using *TextAlive* and *TextAlive Flow*, as evidenced by a sticky that read the options for animation in *TextAlive Flow* “are cool” and another that they liked the “active lyrics” as they moved across the screen (DS1 – Sticky Note²). Animations also were added into some of the children’s apps, such as Zachary, who had boxes that represented musical notes “fly down” from the top of the screen.

Furthermore, the children in our study showed a propensity toward characters and narrative to support their experiences with music. Children noted the reason they enjoyed *Incredibox* was because they “liked [the] *incredibox* character’s designs” (DS1 – Sticky Note). Yet, other children highlighted with their dislike of the “bad outfits,” (DS1 – Sticky Note), suggesting they would like other options that suited their ideas. Children extended the idea of characters into their own apps, such as Taylor and Emma who included an option to have animated characters sing or

perform the song the user created (DS2). During the full group discussion in DS1, Jin summed up the importance of the visuals noting, “when you could see or hear a difference, it makes you feel like you’re in more control of what is going on.”

Our analysis further suggests that the visual aspects of an app act as a bridge to better understand musical possibilities. One sticky note from DS1 captured that the kids disliked that the “*MVs [referencing the animation of the characters in Incredibox] don’t seem to match/vibe [of the music] naturally*” with the sounds and that it was distracting that the people were “not wearing clothes before you dress them” (DS1). In DS2, children also considered colors and aesthetics in their own designs. The sounds in Emma’s remixed version of *Incredibox*, “Cat Choir,” were all related to cats and cat activities (e.g., scratching, meowing, and purring), to match the sounds to the visuals of cats. Similarly, Annie used different colors to represent different pitches. Jin created the app “Dreamer,” a game that lets users play through a young girl’s dreams. Each dream had its own visual aesthetic or “vibe,” corresponding with the sounds and instruments, such as clam shells as percussion instruments in an “aquatic dream” as seen in Figure 1.

4.3 Interface Preferences and User Interactions

Children also showed a preference for direct interactions, preferring the ability to manipulate elements through touch, drag, and drop actions. For example, Taylor noted that she “like[ed] touching [the iPad] instead of the mouse because the mouse was harder to use” (DS1). Similarly, many of the children’s designs in DS2 also included the ability to drag and drop elements, such as the outfits that could be dragged onto cats in Emma’s application or the color blocks that could be dragged in Annie’s app.

When the gulf of execution [81] in the interfaces was large (i.e., the interfaces do not afford what happens when manipulated), children became frustrated. For example, some disliked the “confusing” parameter tuning interface of *TextAlive* that appears next to the video, sometimes forcing them to tweak parameters indirectly. They favored the more direct control of *TextAlive Flow* instead, which allows them to touch the video and change the parameters with their hands. They recommended design enhancements to improve interface usability, citing dislikes such as the absence of instrument labels and clarity on color-to-instrument/note mapping in *Sketch-a-Song* (DS1 - Sticky Note). In contrast, Emma noted a preference for *Incredibox* because it was “less frustrating” and “ignited creativ-

Figure 1. Jin’s app “Dreamer” from DS2

² We use “DS1–Sticky Note” to refer to Likes/Dislikes/Design Ideas captured on stickies during the design activity that were not attributed to a specific child, but instead to the design group.

ity" by representing sounds with symbols rather than traditional instruments (DS1). This suggests that achieving a balance between visual interface design and a certain level of ambiguity is crucial to foster casual creative experiences.

4.4 Sharing and Casual Creative Experiences

In our study, participants highlighted the importance of sharing their creations and ensuring the quality of the final product. For example, children suggested that a sharing option should be added to *Sketch-a-Song* (DS1 – Sticky Note), a feature present in the application, though many of the children were unable to find it. During DS1, another adult facilitator noted some children physically left their groups to share their creations with friends, explaining interesting interactions and experiences documenting their creative choices while using the apps. Taylor and Seiko requested time to share their song from *Sketch-a-Song* with the entire group, indicating pride in their work (DS1), and noted that they felt that it sounded good enough to share. In DS2, Emma, Han, Taylor, and Jin incorporated features allowing users to share and listen to others' creations or playlists in their apps as well. Jin and Taylor's apps even enabled users to create songs with accompanying videos inspired by others (DS2). This suggests that though children were exploring, they also wanted the output of these casual systems to sound good enough to share with others.

5. DISCUSSION

5.1 Purposeful Play: From Process "to" Outcome

Children in our study attempted to balance exploring the possibilities provided by the application with creating personal intermediate outcomes to help express themselves, seeing casual interactions with music as a form of *purposeful play*. We suggest that casual creation is better understood as a "process to outcome" rather than "process over outcome," as we initially stated. In this view, children see themselves as designers of creative works, with the play experience focused on expression.

In our findings, we observed that children wanted the ability to have some sense of control over their experiences (4.1) but that these came via scaffolds such as the visuals of the application (4.2) and interactions with the application (4.3) that lead to shareable outcomes (4.4). This conception of supported play aligns with previous work within music education [22] as well as MIR. Cunningham and Zhang, who conducted PD sessions with children to create a music organizer called *Kids Music Box* suggested the final design of their application offered a "*playground*" for interaction while listening to songs [35, p.190]. Similarly, *PlaceAndPlay*, an application design for creating and recording music, focused on children's ability to simply try things out, with their results noting "*all children had a great time when allowed to just play with the system*" [82, p.738]. Facilitating children's enjoyment and understanding of musical involvement entail not only promoting play

but also nurturing their comprehension of cultural contexts [18] and social conventions [25]. More broadly, play can be understood in relation to creative processes [83–85], as many of the cognitive and emotional functions linked to creativity are also evident during play [86].

Importantly, children also expressed a desire for their final product to be share-worthy (4.4), indicating an expectation that their experience would yield a creative product representing their musical experience and tastes (4.1). We suggest that what sets casual CSTs apart from other educational technologies are the creation of "intermediate products." The term "intermediate" can be understood as creative products that move users from what Beghetto and Kaufman suggest are "*intrapersonal creativity that is part of the learning process*" [61], to products recognized by others as creative. This concept of creativity is increasingly integrated into the evaluation of CSTs [62]. Furthermore, our findings underscore the importance of ensuring that casual CSTs for children focus on helping users create intermediate creative outcomes that remain coherent and aesthetically pleasing to support users' creative self-efficacy [28].

5.2 The Purposeful Play Design Toolbox

In this section, we introduce four design principles, deemed "tools," to foster the elements that lead to purposeful play, suggesting specific design features for each.

5.2.1 Controlled Serendipity

Previous work in creative MIR has shown that serendipity is a crucial aspect for supporting meaningful interactions with music information during the creative process [32]. This was an important element in supporting non-musicians in musical creativity [56]. When surprised by an app, children in our study felt excited and inspired, like Emma's excitement with *Incredibox* (4.3). However, they also wanted their creations to feel genuinely theirs, i.e., their individual exploration mattered (4.4). Therefore, casual music tools should offer structured control while guiding users towards aesthetically pleasing results that reflect their goals. Novices often do not have the domain knowledge to identify how to execute specific creative goals or whether those goals are domain relevant [87, 88]. Therefore, a system taking on the role of the guiding professional by supplying options that support a pleasing final product, may help children to feel excited about their creative outputs. For example, both *Incredibox* and *Sketch-a-Song* only supplied notes that corresponded to a specific chord progression, and as a result, any "seemingly" random combination of sound layers or feature options also sounded good to the children. Similarly, *TextAlive* and *TextAlive Flow* supplied templates or color combinations that looked aesthetically pleasing and matched the music. The carefully and intentionally constrained environment was able to provide the sense of serendipity but at the same time produce outcomes that children felt good about and wanted to show off.

Design Features. Implementing structured guidelines alongside controlled randomness provides a framework for fostering creativity. Feedback mechanisms that allow transparency serve to facilitate children in revisiting and elaborating upon moments of unexpected discovery.

5.2.2 Visual Scaffolds

The term scaffold can be understood as the use of a temporary framework for supporting learners as they aim to gain new skills [89]. During our analysis, children expressed consideration of the role of an application’s visuals when creating (4.2). In a sense, musical experiences were “scaffolded” by the visual aesthetics of the application, since the intention of the musical technology is to encourage children to develop an aesthetic perspective [90] through clear and direct visual communication of the application’s possibilities for creation. When visuals do not align with the sounds, or at least align in a way that a child expected, such as when the animations in *Incredibox* did not align with the music, it can be distracting and take away from understanding of the music, even if the UI design is clear. Yet, as Emma noted (4.3), some ambiguity in the visual scaffolding can also spark creative experiences as well. Specifically, our results emphasize that *color* and *characters* are two visual scaffolds that are effective for children. Furthermore, our findings suggest that children perceive casual creation as encompassing multiple mediums, often utilizing sound and video, aligning with the conception of children’s musical experiences being multimodal [52]. Prior research advocates for multimedia authoring activities that enable collaborative reflection among children [91, 92], promoting self-expression [93] at both individual and social levels.

Design Features. Visual elements like real-time visualizations, character-based imagery, customizable aesthetics, and visual ambiguity, when integrated into features designed to evoke serendipitous moments, along with multimodal outputs like videos, can act as scaffolds to support children’s musical interest.

5.2.3 Direct Manipulation

Children in our study preferred the ability to directly interact with the interface, which can be understood as a form of direct manipulation [94]. Shneiderman, who suggested the term, notes four features of user interfaces that utilize this concept: continuous representation of the object of interest, physical actions, immediate feedback, and the ability of novices to gain knowledge of the system quickly. Moreover, helping kids manipulate things effectively means showing clear connections within the subject area, which helps them link new skills with what they already know [95]. Furthermore, computer scientist Alan Kay [96] suggests that visuals play an important role in digital spaces—they offer representational systems that through manipulation lead to chains of abstract reasoning that creates *symbols*; in the semiotic terms, these symbols allow a user to externalize through the manipulation of representations [97]. This suggests a connection between the

visual scaffolds and potential direct interactions that lead to moments of play in digital creative systems.

Design Features. Interactive elements such as drag-and-drop functionalities, objects responding to user actions, and tactile interactions, will enhance children’s engagement and maintain their interest over time.

5.2.4 Shareable Intermediate Outputs

The children in our study wanted the ability to share the creative outputs they were proud of during their exploration of different tools (4.4). Allowing children to share their creative outputs can help build creative self-efficacy [28], which is essential to fostering their view of themselves as creators. Allowing children to share these objects encourages creativity at not only an individual level, but also a social level, which is particularly important as social-environmental factors have been shown to influence creativity of individuals [98]. This is particularly important for children as creativity is largely social for them [53, 55].

Design Features. Sharing options (email, file downloads, replay), galleries of user-generated content, ability to remix or elaborate on others outputs will help support self-efficacy of children as developing creators.

6. LIMITATIONS AND FUTURE WORK

While our research follows established precedents, it has limitations. The small sample size of 10 children, while comparable to similar co-design studies [68, 69], may limit the generalizability of the result. Participants were mainly from a single geographic area, with privileged backgrounds, and familiar with technology and co-design, which may not represent diverse socio-economic perspectives. Future studies should include more diverse demographics, explore evaluation methods for supporting design principles, and investigate features tailored to different MIR tasks in support of purposeful play.

7. CONCLUSION

Our study explored the creative preferences of one user group, children, in casual music creation applications. Through two Participatory Design sessions, we observed children’s perceptions of casual musical creation as a personally-oriented process, where visuals and direct interactions allowed children to generate creative works they wished to share with others. We highlighted the importance of purpose in play during casual music creation, suggesting that casual creation applications should facilitate the process of exploration of music with the intention of expression. Additionally, we discussed the potential impact of this playful approach on creative MIR by presenting four design tools to support purposeful play and suggesting a set of design features that support these principles. We further believe that these insights transcend children, offering design implications for individuals of various musical skills and recreational adults who wish to explore musical experiences in a variety of ways.

8. ACKNOWLEDGMENTS

We thank the child participants and adult co-designers for their contributions to the study, without whom this work would not be possible. This material is based upon work supported by the Institute of Museum and Library Services under Award #LG-252291-OLS-22. This work was supported in part by JST CREST Grant Number JP-MJCR20D4, Japan.

ABSTRACT

We present El Bongosero, a large-scale, open-source symbolic dataset comprising expressive, improvised drum performances crowd-sourced from a pool of individuals with varying levels of musical expertise. Originating from an interactive installation hosted at Centre de Cultura Contemporània de Barcelona, our dataset consists of 6,035 unique tapped sequences performed by 3,184 participants. To our knowledge, this is the only symbolic dataset of its size and type that includes expressive timing and dynamics information as well as each participant’s level of expertise. These unique characteristics could prove to be valuable to future research, particularly in the areas of music generation and music education. Preliminary analysis, including a step-wise Jaccard similarity analysis on a subset of the data, demonstrate that this dataset is a diverse, non-random, and musically meaningful collection. To facilitate prompt exploration and understanding of the data, we have also prepared a dedicated website and an open-source API in order to interact with the data.

1. INTRODUCTION

Symbolic drum datasets derived from live performance typically feature a select number of experienced drummers improvising or playing a composed piece. However, given that rhythm perception is a fundamental human trait [1], we contend that an expressive crowd-sourced drum dataset representing a diverse range of musical expertise could offer unique research utility not fulfilled by existing datasets. Although it may be possible to compile a dataset of this nature by scraping the web for recorded performances, it would be unlikely that a web-scraped dataset would include expressive performance information along with the level of expertise of each performer.

* Equal contribution

This past year, our research lab participated in an exhibition at Centre de Cultura Contemporània de Barcelona (CCCB) centered around the history, ethics, and creative possibilities of Artificial Intelligence. More specifically, we were tasked with preparing a 6-month installation that would be included in the "Data Worlds" section of the exhibition, the purpose of which was to examine the role of data in generative systems and the methods employed to gather data. We addressed both of these aspects with a two-part installation. In the first activity, participants used a “bongo-like” two-voice MIDI pad to interact with a Variational Auto-Encoder (VAE) model. This model had the capability to transform the participant’s tapped rhythmic sequences into symbolic multi-voice, expressive drum patterns [2,3], which were subsequently synthesized to audio. In the second activity, which serves as the focus of this paper, participants were given the opportunity to contribute to a crowd-sourced dataset that may later be used to improve the generative model they had just interacted with. They were invited to use the MIDI pad to tap along to a multi-voice drum pattern in a genre and tempo of their choosing. Providing minimal instructions, this task serves as an examination of how participants freely improvise alongside another rhythm. Upon completing the task, the participant could choose to contribute their tapped, improvised sequence to our public dataset or to submit nothing and delete their data.

In this paper, we present El Bongosero, a crowd-sourced expressive symbolic dataset consisting of 6,035 improvised tapped sequences performed by 3,184 participants with varying levels of musical expertise. Each sample contains expressive timing and dynamics information and is annotated with the participant’s level of musical expertise, the genre of the selected pattern, the chosen tempo, the total duration to complete the activity, and a user-rating for their performance and how much they enjoyed the exhibit. We anticipate that this dataset can promote further research in the following areas:

- Advancing the development of more nuanced generative models capable of accommodating a range of skill levels.
- Facilitating music education studies focused on music understanding and rhythm expertise.

Jordà, “El Bongosero: A Crowd-sourced Symbolic Dataset of Improvised Hand Percussion Rhythms Paired with Drum Patterns”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

- Evaluating the proficiency, diversity, and creativity with which humans improvise rhythms.

Furthermore, the collection of data in this study adheres to rigorous ethical standards. Unlike other collection methods such as web-scraping, which may involve utilizing data in ways unintended by the original providers, our approach prioritizes clarity and consent with the participants throughout the entire process.

2. RELATED WORK

In this section, we will review other notable datasets consisting of human-performed recordings or synthesized web-scraped symbolic sequences. Reviewing these datasets aims to underscore the various applications and constraints associated with each approach.

The earliest open-source drum dataset we identified is the ENST-Drums dataset [4]. This is a fairly comprehensive dataset, consisting of around 225 minutes of annotated audio and video recordings of 3 live drummers. While still useful, this is significantly smaller than other datasets compiled via web-scraping or crowd-sourcing.

The TMIDT (Towards Multi-Instrument Drum Transcription) dataset, consisting of 259 hours worth of synthesized audio, was created via web-scraping every MIDI track from a freely available online collection¹ [5]. In a similar manner, the ADTOF (Automatic Drums Transcription On Fire) dataset, containing over 114 hours of annotated music, is constructed of openly shared² crowd-sourced symbolic annotations, typically a MIDI file, of real songs for use in rhythm games [6]. As such, this data does not contain detailed expressive information unlike Magenta’s MAESTRO (MIDI and Audio Edited for Synchronous TRacks and Organization) [7]. Although MAESTRO consists of ten years of International Piano-Competition performances on a Yamaha Disklavier, it is relevant to include here as it is a large-scale, crowd-sourced dataset. This dataset, which has been used effectively in generative models, is comprised of over 172 hours of finely aligned (~3 ms) audio waveforms and expressive MIDI information.

Similar to MAESTRO, Magenta’s Groove MIDI Dataset (GMD) is composed of 13.6 hours of aligned MIDI and (synthesized) audio of human-performed, expressive drumming [8]. The nature of this dataset has proven to be useful for predictive generative models such as GrooVAE [8] as well as for perceptual experiments such as TapTamDrum [9].

The TapTamDrum dataset was the result of an experiment in which 4 experienced drummers were given the task of reducing expressive, multi-voice drum patterns from Magenta’s GMD to dual-voice representations. The resultant dataset includes 1,116 total dualizations annotated with expressive timing and velocity from 345 unique patterns.

Dataset	Format			Annotations		
	Audio	Symbolic	Human-Performed	Velocity	Genre	Level of Expertise
ENST	✓	✓	✓			
TMIDT	✓	✓				
ADTOF	✓	✓				
GMD	✓	✓	✓	✓	✓	
MAESTRO	✓	✓	✓	✓		
TapTamDrum	✓	✓	✓	✓		
MAST	✓		✓			
El Bongosero		✓	✓	✓	✓	✓

Table 1. Comparison of datasets.

Lastly, there is the MAST (Musical Aptitude Standard Test) Rhythmic Dataset, sourced from university examinations in which candidates were expected to reproduce a tapped rhythmic pattern after it had been played two times by a member of the jury [10]. Therefore, this audio dataset includes 2,681 recordings of jury members performing the target rhythm, along with 1,040 recordings of student attempts annotated with their grade (pass or fail).

Table 1 offers a comparison of the datasets based on two key attributes: format and annotations. Format indicates whether the dataset comprises audio or symbolic samples and whether these samples are derived from recorded human performances. Annotations, on the other hand, encompass details such as the presence of velocity annotations for each onset, the genre of the sample, and the level of expertise of the performer. As shown in the table, El Bongosero is the only dataset that annotates the performer’s level of expertise.

3. METHODOLOGY

As mentioned above, the installation consisted of two parts. In the first part, participants were to engage with a generative model. In the second part, they were asked to contribute to a dataset that may be used for training future iterations of the generative model used in the first part. The focus of this paper is on the latter part of the installation, specifically, the collection of a symbolic dataset of rhythmic improvisations played alongside a selected number of drum patterns.

As the installation was to be used in a public exhibition space, it was imperative to design an interface that could accommodate a broad spectrum of participants without assuming specific technical or musical expertise. To this end, we made several decisions in designing the data collection stage of the installation. First, we ensured that the interactive elements in the system were nearly identical to the first stage of the installation. This strategy was aimed at eliminating any need for participants to acquaint themselves with the mechanics of the system. Second, we minimized the instructions provided to participants. The intention here was to encourage the participants to improvise freely using their personal intuition and creativity, rather than adhering to a very specific procedure. Lastly, before initiating the second part of the installation, we informed the participants that we would ask for their consent to contribute to our dataset at the conclusion of this activity. The purpose of this approach was to ensure that participants

¹ <http://www.midiworld.com>

² <https://rhythmgamingworld.com/>

were fully aware of this aspect of the activity prior to deciding if they wished to interact. While the primary motivation behind implementing this level of transparency was to adhere to ethical principles, it was also our aim to foster more open and genuine interaction with the installation by making participants feel valued and secure.

In the following subsections we discuss the tasks presented to the participants (3.1), the installation setup (3.2), and the drum pattern curation process (3.3).

3.1 Overview of Tasks

Figure 1 provides an overview of the tasks involved in the installation.

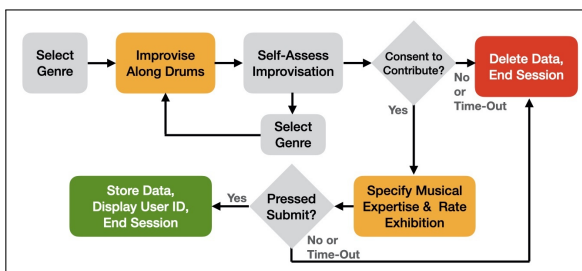

Figure 1. Flow-chart of the installation steps

The main objective of the data collection part of the installation was to present the participants with a randomly selected drum pattern and ask them to improvise alongside the pattern. To accommodate the diverse musical tastes and backgrounds of the participants, we allowed the participants to select the genre of the drum pattern.

Once the genre was selected, the improvisation environment was initiated. In this environment, the participant was presented with a looping 2-bar drum pattern and was asked to improvise alongside it using a provided two-voice MIDI pad.

The starting tempo of the session would be associated with the selected drum pattern, however, to accommodate participants of various skill levels, we allowed them to modify the tempo of the session. Each tap on the MIDI pad was recorded in a real-time looping 2-bar buffer, allowing participants to listen to previous taps and overdub additional taps. Lastly, participants were given as much time as needed.

Once the participant stopped the session, we asked them to self-assess their performance using a 5-level Likert scale. Once the assessment was provided, the participant was given two choices. They could select a new pattern to improvise alongside or they could finish the session. Once the participant finished the session, they were asked if they wish to contribute to the dataset. If they decided not to contribute, the session would end. Otherwise, they were presented with a brief questionnaire and then subsequently asked to press a button to explicitly submit their data.

Given that this was a public installation, we presented consenting users with only 2 questions: (1) "How would you assess your level of musical expertise?", and (2) "How much did you enjoy this exhibit?". In order to assure the

participants that the only aim of the installation was to collect improvisations, as opposed to metadata related to the participants, we avoided any demographic questions on gender, age, and occupation. Recognizing the vast spectrum of musical proficiency among participants, from novices to experienced musicians, the question on "Musical Expertise" aimed to contextualize the improvisational outcomes within a broader narrative of skill and experience. Furthermore, we recognize that the term "expertise" in this context may be subject to interpretation, with participants not necessarily associating it solely with musical proficiency. Our intention was to allow participants to define "expertise" based on their own understanding within the context of their improvisations.

Once the final questions were answered, the submission button would be enabled to finalize the contribution. Note that participant data was only added to the dataset if the "Submit" button was pressed. That is, we wanted to ensure that participants explicitly consented to the contribution. In any case that the participants left the session mid-experiment, explicitly chose not to contribute, or forgot to press the submission button, their data was immediately deleted.

3.2 Installation Setup

The installation, shown in Figure 2, consisted of a touch screen application and an *Embodme's ERAE Touch MPE* controller³ for registering the improvisations.

Figure 2. A photo of the installation (photo credit: CCCB)

The touchscreen application was used to prompt the participant and to allow the user to navigate through different stages of the installation. During the improvisation sessions, the graphical interface visualized the "bongo" performance using a circular representation of the 2-bar looping buffer filled with each tap onset registered on the MIDI pad (refer to the center of Figure 3 for the actual graphic representation). In this section, the participant was allowed to remove a specific onset by double tapping its location in the buffer, or to remove all of the onsets using a dedicated button; however, they were not allowed to reposition any registered onsets. In other words, the timing of the onsets were only to be associated with the timing registered from the performed taps on the MIDI pad.

The visual interface was implemented using the *PyQt5*⁴ Graphical User Interface (GUI) toolkit. To ensure

³ <https://www.embodme.com/erae-touch>

⁴ <https://www.qt.io/>

Figure 3. Installation setup

precise synchronization between the synthesis and playback of the source drum pattern and the MIDI recording of each improvisation, we developed a C++ backend using *JUCE* framework⁵. The recorded performances are provided in two formats: (1) a linear sequence preserving the timing of each tap onset throughout the activity’s entire duration, and (2) a 2-bar loop preserving the timing of each overdubbed onset within the 2-bar recording buffer.

As shown in Figure 3, the touch MIDI pad was customized into two distinct pitch regions, with the right region pitched lower than the left. Each “bongo” tap was displayed on the graphical interface using a circle located within the 2-bar looping buffer. Each circle was color-coded to match the region from which the tap onset was registered and the radius of the circle was correlated with the velocity of the registered tap onsets.

In order to ensure that participants could properly listen to the sounds of the installation and to reduce the the possibility of a participant feeling that their performance was being judged by other visitors, we decided to only provide headphones to the participants rather than loudspeakers⁶.

Lastly, dedicated sliders were provided on the interface to allow the participant to adjust the volumes of the bongo sounds and the drum sounds as needed. Moreover, a dedicated slider (initially muted) was also provided to participants to utilize a synchronized metronome track if needed.

3.3 Drum Pattern Selections

The source drum patterns were in a 4/4 metric, selected from a large in-house collection of over 200,000 MIDI files, which included both open-source and proprietary MIDI collections. The MIDI files in this collection were divided into 10 genres: Afrobeat, Afrocuban, Bossanova, Disco, Electronic, Funk, Hiphop, Jazz, Rock, and Soul.

For each pattern in the collection, we extracted the rhythmic features provided in *GrooveToolbox* [11] and *Rhythm Toolbox* [12]. The extracted features were normalized and subsequently mapped to a two-dimensional

space using Principal Component Analysis (PCA). For each genre, the mapped values were grouped into 100 clusters using k-means clustering method, and subsequently, a single pattern was randomly selected from each cluster.

In order to ensure a small subset of patterns with a sizeable collection of varied responses per pattern, we opted to limit the Electronic genre to 16 patterns. We selected this genre as we suspected it would be the most popular choice among participants.⁷

4. DATASET

In this section the contents of the collected dataset are described. A total of 4 variables were recorded per participant (ID, number of attempts, level of musical expertise, and exhibition rating). The ID was assigned in sequential order and each participant could attempt multiple improvisations. For each attempt 8 variables were collected (attempt duration, assessment time, attempt tempo, drum pattern, genre, improvisation pattern, level of expertise, and exhibition rating).

Table 2 presents a summary segmented by participants’ level of musical expertise. The mean level of musical expertise is 2.95 (std = 1.25). The most common level of musical expertise is level 2 (915 participants) and the least common is level 1 (392 participants). The mean number of attempts per participant is 1.89 (std = 1.32). The highest amount of attempts were carried out by participants of musical expertise level 2 (1692) and the lowest amount of attempts were carried out by participants of musical expertise level 1 (691). The mean number of unique patterns presented per level is 591.8 (std = 103.8). Participants with musical expertise of level 2 were exposed to the largest number of unique musical patterns (720) while participants with musical expertise of level 1 were exposed to the least number (433). The mean number of attempts increases with the level of musical expertise, as participants with more expertise made more attempts on average.

Figure 4 presents the number of attempts per genre. The mean number of attempts per genre is 603.5 (std =

⁵ <https://juce.com/>

⁶ A loudspeaker was available in the setup (as in Figure2), however, it was only used in special occasions decided by CCCB organizers.

⁷ The results discussed in next section confirm this speculation.

	Level of Musical Expertise				
	1	2	3	4	5
No. participants	392	915	805	594	478
Attempt count	691	1692	1536	1074	1042
Mean no. attempts	1.76	1.85	1.91	1.81	2.18
Unique patterns	433	720	691	562	553

Table 2. Summary of participants, attempts, patterns, and musical expertise.

169.67). The Electronic and Rock genres represent the highest amount of attempts (919 and 850 respectively) while the Soul genre represents the lowest amount (371).

Figure 4. Histogram of attempts per genre.

Figure 5 presents an overview of the number of attempts per level of expertise and genre. The combination with the highest number of attempts is the Rock and Electronic genres combined with expertise levels 2 and 3. The combination with the least attempts is the Afrobeat genre and expertise level 1.

Figure 5. Attempts per genre and level of expertise.

As described in Section 3.3, all drum patterns used in the installation are in the 4/4 metric. Figure 6 presents the step densities of both the original patterns and the recorded improvisations, obtained by adding onsets at each step and dividing by the step with most onsets. Patterns are wrapped to 16 steps for convenience and onsets quantized to the closest 16th note. In order to establish a comparison, the normalized theoretical metrical weight is displayed. Notice how densities at each inter-pulse group of steps (0-3, 4-7, 8-11, 12-15) complies with the "high, low, mid, low" contour expressed in the theoretical metrical weights for a 4/4 rhythmic pattern. This suggests that participants consistently induced a meter from the source drum patterns. The improvised rhythms by the participants (Figure 6 below) showcase the same general intra-pulse contour with two differences. First, the low contours are higher (uneven

steps), and second, the first step contains less onset density than its intra-pulse set (steps 1, 2 and 3). However steps 1, 2, and 3 comply with the "low-mid-low" contour observed in the original pattern's intra-pulse density. We believe many of the participants were slightly inaccurate at the beginning of the loop, thus causing onsets intended for the first step to be played early, registering in the last step of the previous bar, or played late, registering in the second step of the current bar.

Figure 6. Onset density and metrical weight per step.

Typical of crowd-sourced datasets, these general observations led us to identify some instances of crowd-driven bias. Specifically, we observed a preference for two genres (Rock and Electronic) out of a possible ten, along with a distribution of musical expertise leaning towards mid-low levels. On the other hand, the general compliance of participants' patterns with metrical expectations suggest that their improvisations were carried out under expected pulse-entrainment conditions. Thus, in general, it seems that the data gathered corresponds to sensory-motor activities and not a random collection of taps.

5. PRELIMINARY INSIGHTS

As explained in Section 3.3, we limited the number of Electronic patterns to 16 in order to increase the number of reproductions per pattern for different levels of musical expertise. The brief preliminary analysis presented here focuses solely on the Electronic genre and explores the patterns used and assesses the similarity between the reproduced drum patterns and the participants' improvisations.

The number of attempts per Electronic pattern is presented in Figure 7. The range of attempts fluctuates between 46 (pattern 1) and 65 (pattern 9). The mean is 57.44 attempts and the standard deviation is 5.33.

Figure 7. Number of attempts per Electronic pattern.

In order to establish a first metric that can account for comparing the multi-voice drum patterns with the participants' tapped improvisations, the Jaccard similarity metric is used. Jaccard is a common similarity metric used in data analysis, especially suited for comparing two sets of elements. The simplest implementation of the metric is the quotient of the sum of the intersection elements with the sum of the union elements. The more elements in common between the intersection and the union, the closer the Jaccard similarity gets to 1.

We implemented Jaccard similarity comparing a step-wise flattened version of the drum pattern and participants' improvisations. The rationale of this metric is: in a step where (at least) one onset in the drum pattern is observed, (at least) one onset is expected in the participant's improvisation. The intersection is composed of steps with onsets in the drum pattern that coincide with steps with onsets in the improvised pattern. The union comprises all steps from the pattern and the improvisation containing an onset. If a participant produces an onset every time the drum pattern produces an onset, Jaccard similarity is equal to one. If all of a participant's onsets are on steps where the drum pattern is silent, Jaccard similarity is 0.

Figure 8. Jaccard similarity means and standard deviation for every pattern in the Electronic music genre.

Figure 8 shows that all participant improvisations to Electronic patterns exhibit a very similar mean (from 0.348 for pattern 8 to 0.574 for pattern 4) and spread standard deviation (from 0.115 for pattern 12 to 0.249 for pattern 13). There is no apparent agreement (there are no high mean values) towards any of the Electronic patterns, suggesting diversity in the improvisations for all patterns of this genre.

For more detail, Figure 9 presents a spread of similarity by Electronic pattern and level of musical expertise. The expertise level with the highest Jaccard similarity sum for all patterns (5.98) is level 1 while level 2 has the lowest Jaccard similarity sum for all patterns (5.63). The most diverse case, signified by a low mean Jaccard similarity (0.18), is observed in improvisations for pattern 7 performed by participants of expertise level 5. On the other hand, improvisations with the most average agreement with the reference, signified by a high mean Jaccard similarity (0.51), is observed in improvisations for pattern 10 performed by participants of expertise level 1.

The consistent mid agreement presented in Figure 8 and Figure 9 suggests improvisations were not exhibiting an automatic onset-for-onset behavior. On the contrary, there seems to be rich musical behavior to be explored within the Electronic genre.

Figure 9. Jaccard similarity among all improvisations for different musical levels and pattern.

6. DISCUSSION AND CONCLUSION

In this paper, we introduced El Bongosero, a crowd-sourced dataset consisting of 6,035 tapped improvised rhythms performed by a total of 3,184 participants with varying levels of musical expertise. The improvisations are collected across 10 genres, each corresponding to a set of 100 unique drum patterns selected for that genre, except for the Electronic genre, which includes 16 samples. The main focus of this work was the collection, curation, and organization of this data from an interactive public exhibit.

Preliminary analysis, including a step-wise Jaccard similarity analysis on the Electronic genre data subset, demonstrate that this dataset is a diverse, non-random, and musically meaningful collection of improvised rhythms. Through our review of existing datasets, we identified the unique qualities of El Bongosero that could make it particularly useful for music generation and music education research. More specifically, it is the combination of the sheer number of participants, the diverse range of participants' level of musical expertise, and the inclusion of expressive performance information that distinguishes this dataset.

For example, in the context of a model that generates music based on a rhythmic input, a skilled musician may have different expectations than a novice musician regarding how a model should interpret an input rhythm or how it should respond to subtle variations in timing or dynamics. Integrating a diverse crowd-sourced dataset, such as El Bongosero, with the development of generative models could prove to be an effective approach to constructing more nuanced models that are capable of adjusting to individuals with varying skill levels.

Similarly, in the context of music education, deep analysis of El Bongosero may allow educators to gain insights into the learning trajectory of percussion students and help them to better develop a curriculum that supports skill development. As an evaluation tool, this dataset could serve as a valuable resource for developing assessments and criteria for drumming proficiency. Furthermore, researchers may be able to identify key indicators of musical growth and proficiency by comparing performances across different levels of expertise.

To conclude this work and facilitate prompt exploration of the collected data, we have prepared a dedicated website and an open-source API available at:

<https://elbongosero.github.io/>

7. ETHICS STATEMENT

Conscientious consideration of ethical principles has been central throughout this project. We recognize that as researchers it is our responsibility to ensure that there is complete transparency of the collection process and that participants have a full understanding of their involvement. Accordingly, this study attempts to uphold ethical standards at every stage of the data life cycle, from collection to utilization.

Firstly, the installation was crafted so that prior to starting the activity, participants were explicitly notified that we would later request their permission to store the data they generate while interacting with the exhibit. At the end of the activity, participants had to explicitly consent once more in order to be included in the dataset. If they declined, or took no action, their data was not stored.

In addition to ensuring explicit consent from participants, we also gave careful consideration to exactly which data we collected. To this end, we opted to collect no personal or demographic information from the participants. The collected data from consenting participants included only their interactions with the installation, resulting in a symbolic representation of their tapped improvised pattern, along with their responses to two questions: “How would you assess your level of musical expertise?” and “How much did you enjoy this exhibit?”.

Moreover, ethical considerations extend beyond the initial data collection phase to encompass the subsequent use and application of the data. As stewards of this dataset, we are committed to employing the collected data solely for academic research purposes, ensuring that it is used in a manner consistent with what was communicated to participants.

8. ACKNOWLEDGMENTS

This research was partly funded by the Secretaría de Estado de Digitalización e Inteligencia Artificial, and the European Union-Next Generation EU, under the program Cátedras ENIA 2022. "IA y Música: Cátedra en Inteligencia Artificial y Música" (Reference: TSI-100929-2023-1).

UTILIZING LISTENER-PROVIDED TAGS FOR MUSIC EMOTION RECOGNITION: A DATA-DRIVEN APPROACH

J. Affolter, M. Rohrmeier

Ecole Polytechnique Fédérale de Lausanne, EPFL

ABSTRACT

This work introduces a data-driven approach for assigning emotions to music tracks. Consisting of two distinct phases, our framework enables the creation of synthetic emotion-labeled datasets that can serve both Music Emotion Recognition and Auto-Tagging tasks. The first phase presents a versatile method for collecting listener-generated verbal data, such as tags and playlist names, from multiple online sources on a large scale. We compiled a dataset of 5,892 tracks, each associated with textual data from four distinct sources. The second phase leverages Natural Language Processing for representing music-evoked emotions, relying solely on the data acquired during the first phase. By semantically matching user-generated text to a well-known corpus of emotion-labelled English words, we are ultimately able to represent each music track as an 8-dimensional vector that captures the emotions perceived by listeners. Our method departs from conventional labeling techniques: instead of defining emotions as generic “mood tags” found on social platforms, we leverage a refined psychological model drawn from Plutchik’s theory [1], which appears more intuitive than the extensively used Valence-Arousal model.

1. INTRODUCTION

Several studies on music listener behavior have identified an increasing interest in music discovery based on its emotional content [2]. It is therefore hardly surprising that the field of Music Emotion Recognition (MER), which explores how emotions can be identified in music [3], is a growing area of research.

MER research is dominated by the use of supervised machine learning methods, in which systems are trained on music excerpts previously labeled with emotion descriptors through crowdsourcing. A major hurdle in this field is the lack of large-scale emotion-annotated datasets [4]. The complexity of collecting suitable training data contributes significantly to this issue, as the process is time-consuming, labor-intensive and expensive. The subjective

nature of musical emotions further complicates the data collection process [5].

Recognizing language as a powerful medium for conveying musical signification, we proceed on the premise that emotions can be inferred from textual data—specifically, from listener-generated tags and playlist names on music platforms. We thus introduce a novel method for assigning, to any given song, an emotion vector within an 8-dimensional space defined by Plutchik’s model. This enables us to propose a new dataset comprising 5,892 tracks, specifically tailored for Music Emotion Recognition (MER) tasks.

2. RELATED WORK

Yuan et al. [4] propose the Music Audio Representation Benchmark for universal Evaluation (*MARBLE*) as a unified standard for assessing various Music Information Retrieval (MIR) tasks. They employ 12 publicly available datasets to evaluate 18 distinct tasks, including the *Emo-music* [5] and *MTG-MoodTheme* [6] datasets for MER evaluation. Table 1 provides an overview of commonly used datasets in MER research, along with their size, data collection method and emotion labeling approach.

Dataset	Size	Data collection	Emotion model	Ref.
Emomusic	744	C	AV	[5]
MTG-MT	17,982	DM	56 labels	[6]
AMC	600	C	5 clusters	[7]
EMMA	364	C	GEMS	[8]
CAL500	500	C	174 labels	[9]
MoodSwings	240	Game	AV	[10]
NTWICM	2,648	C	AV	[11]
Soundtracks	470	C	9 labels	[12]

Emotify	400	Game	GEMS	[15]
Moodo	200	C	AV	[16]
4Q-emotion	900	C	AV	[17]
PMemo	794	EEG	AV	[18]

Table 1: Overview of existing MER datasets.

C: crowdsourcing, DM: data mining, AV(D): arousal/valence/dominance, EEG: electroencephalography, GEMS: Geneva Emotion Music Scale

Through the examination of these datasets, three areas for potential improvement have been identified.

Dataset size. Datasets annotated with labels according to a psychological emotion model (AV, AVD, GEMS) do not exceed 2,648 tracks, with an average size of 801. Furthermore, most datasets fail to cover a wide range of

musical genres—they are often limited to four or fewer, or do not provide clear genre definition, resulting in imbalanced datasets. This limited size and diversity complicate the training of accurate music emotion recognition models, raising concerns about issues such as group fairness and generalization capability.

Data collection. Most datasets rely on human annotations from crowdsourcing/online games, or from EEG experiments, which, while reliable, are both expensive and time-consuming. Moreover, these datasets encounter challenges in participant diversity. Typically, the assignment of an emotion label to a track requires consensus between few annotators. In the case of datasets featuring mood tags, it is common for tracks to have, on average, no more than two tags associated with them, potentially leading to misleading data.

Emotion model. Emotion labeling generally falls into two categories. (1) Mood-based emotion tags. For instance, in *MTG-MoodTheme*, the 56 emotion labels correspond to tags directly retrieved from the Jamendo music platform. This can result in a large number of emotion labels, making it difficult for end-users to understand and use the system. This approach may also not align with an established emotion model. (2) Discrete- or continuous-based annotations derived from a predefined emotion model. While the VA model, with its two-dimensional structure, has been criticized to be restrictive and open to overly subjective interpretation [19], the Geneva Emotion Music Scale (GEMS) is specifically crafted for the music domain, and proposes a more detailed taxonomy.

3. APPROACH

This section introduces the key design decisions underlying our methodology for inducing music-evoked emotion descriptors from a collection of tracks. Our approach aims to enhance the study of emotions in music by introducing a novel representation of emotions based on a psychological model that has been hitherto unacknowledged in the field of MER.

3.1 Plutchik’s Emotion Model

We recognize the importance of grounding our research framework in a well-established emotion model. In search of a more intuitive alternative than the Valence/Arousal (VA) framework, we opted for Plutchik’s model, which, to our knowledge, has not yet been utilized in the field of music and, we believe, strikes a good balance between complexity and usability. Plutchik’s emotion model is founded on eight primary emotions (joy, fear, anger, sadness, disgust, surprise, anticipation, trust) that we believe are accessible and instinctive for listeners. As a recognized model in psychology, it has been employed across various domains beyond music, enabling us to leverage existing resources, such as the *NRC Lexicon* [20], a crowdsourced list of 14, 182 English words and their binary associations with Plutchik’s primary emotions. Highly aligned with

our research goal, its single-word structure bears a strong resemblance to our textual data, which includes tags and playlist names. Its origin in actual annotations by human subjects, rather than derivative interpretations, is also crucial to the accuracy of our emotion mappings. Furthermore, the model’s categorical approach can be expanded by combining emotions as depicted in Figure 1, thus enabling the representation of more complex emotions.

Figure 1: Plutchik’s wheel of emotions [1].

3.2 Emotion Vector Representation

Instead of viewing emotions as discrete labels, as traditional classification MER systems do, we propose to represent a music track as an 8-dimensional emotion vector that captures the emotions perceived by listeners. We define our emotion domain mathematically as a vector space V , represented by a basis $B = \{\text{joy, fear, anger, sadness, disgust, surprise, anticipation, trust}\}$. Each emotion in B corresponds to a standard basis vector in V , with $e_{\text{joy}} = [1, 0, \dots, 0]$ through $e_{\text{trust}} = [0, \dots, 0, 1]$. The emotion vector v of a track is defined as

$$v = \sum_{i \in B} \lambda_i e_i, \tag{1}$$

where $\lambda_i \in [0, 1]$ represents the intensity of emotion i .

By representing emotion intensities within an 8-dimensional vector, our framework aims to effectively capture the complex spectra of music-evoked emotions and discern the subtle emotional nuances of music tracks.

3.3 Textual Data Encoding

To effectively encode textual data, we selected the Sentence-BERT (SBERT) model [21], an NLP neural network known for generating semantically meaningful embeddings at the sentence level. Specifically fine-tuned for semantic similarity tasks, SBERT enhances the original BERT architecture by integrating siamese and triplet network structures. NLP techniques such as Semantic Search are significantly enhanced with this encoding model, as it enables the retrieval of the closest elements in the embedding space based on semantic similarity.

By using SBERT, we are able to create single embeddings that accurately encode the semantic content of each

textual element while preserving context. This choice is particularly suitable for our data, which includes short phrases—such as single- and multi-word tags, playlist names, and English words from the *NRC Lexicon*—that need to be compared in terms of semantic similarity.

4. IMPLEMENTATION: A TWO-STAGE FRAMEWORK FOR EMOTION ATTRIBUTION

Building upon the challenges and insights discussed in Section 2, we introduce a two-stage framework for extracting music-evoked emotions from a collection of tracks. Drawing inspiration from *MTG-MoodTheme*, the first phase focuses on collecting verbal tags through data mining across platforms such as *Last.fm* and *Spotify*, while the second phase leverages NLP techniques to computationally associate emotion vectors with music tracks by relying solely on the tags acquired during phase one.

4.1 Large-Scale Listener-Generated Data Collection

4.1.1 Track Selection Process.

We started with a baseline dataset of 20,000 music tracks, spanning 20 distinct genres. We selected the top 1,000 tracks with the highest popularity index on *Spotify* for each genre, in order to increase the likelihood of finding them in multiple sources when retrieving tags.

4.1.2 Data Mining.

We extracted listener-generated tags from three popular rating websites—*Last.fm*, *AllMusic*, *Rate Your Music*¹—and retrieved playlist names from the dataset provided for the *Spotify Million Playlist Dataset Challenge*, which includes 1,000,000 playlists created by *Spotify* listeners between 2010 and 2017 [22].

4.1.3 Data Pre-Processing.

While the tags from *Rate Your Music* and *All Music* were already normalized by the platform, those from *Spotify* and *Last.FM* required extensive cleaning. The objective was twofold: first, to eliminate irrelevant data, such as playlist names along the lines of ‘*Favorite hits*’, and second, to remove tags that could introduce bias when assigning emotions. Indeed, some tags—such as album names, artist names, or musical genres—are intended as mere filters for finding music. Others, like ‘roadtrip tunes’, are too neutral and may suggest contexts unrelated to emotions, while tags such as ‘love it’ reflect personal opinions and could bias our results by conflating perceived with induced emotions [23].

We first translated multilingual text into English, expanded abbreviations, replaced slang words and emoticons with their standard equivalents, and corrected misspelled words. We then implemented four iterative filtering processes to eliminate listener-generated tags that cannot be considered emotion descriptors.

Metadata Filtering. Since artists, song titles, album names, and musical genres were retrieved as metadata for all tracks in our dataset, we first eliminated any textual inputs containing terms from these categories. The set of musical genres was expanded to include a broader range beyond the 20 genres under study.

Named Entities Filtering. We then used the pre-trained BERT model fine-tuned for Named Entity Recognition (NER)² to identify named entities within predefined categories, such as person names, song titles, and locations. We filtered out sequences containing at least one token classified as a named entity of a target category with a confidence score above 0.9.

Neutral Tag Filtering. Sentiment analysis was subsequently performed using the pre-trained RoBERTa model fine-tuned for this task³. We removed tags with a neutral sentiment proportion greater than 70% (where 100% was distributed among positive, neutral, and negative sentiments for each input sequence). This threshold was deliberately chosen to avoid losing potentially useful tags like ‘energetic’. In subsequent stages of this framework, tags that are too neutral and not intended for emotion description will nonetheless be matched with words from the *NRC Lexicon* that do not have associated emotions, thereby not impacting the final emotions associated with music tracks.

Listener Judgment Filtering. Finally, we eliminated tags closely tied to listener preferences and judgments. Briefly put, we established predefined categories specifically designed to capture tags for exclusion, based on their semantic content. For example, we defined a category titled ‘*This track is great*’ and tags like ‘*Love it!*’ would semantically align with this category and be filtered out. To do so, we computed sentence-level embeddings for both the tags and the categories (augmented by the *NRC Lexicon*) using the SBERT model to capture their semantic content. We then matched each tag to its closest category using cosine similarity on their embeddings, removing tags that fell into any unwanted category.

4.2 Emotion Vector Attribution

The second phase of our approach relies on the *NRC Lexicon* to computationally associate emotion vectors with music tracks by relying solely on the acquired tags. We decided to represent words from the *Lexicon* as vectors w within the Plutchik emotion space, where $w = \sum_{i \in B} c_i e_i$ and c_i is a binary indicator denoting the absence or presence of the corresponding emotion.

Given that tags are assigned by individual listeners on music platforms, we can treat them as independent entities. This assumption enables us to first assign emotions to each unique tag in the dataset, and then derive the emotion vector of a track by combining the emotions of its associated tags.

² <https://huggingface.co/dslim/bert-base-NER>

³ <https://huggingface.co/cardiffnlp/twitter-roberta-base-sentiment-latest>

¹ <https://www.last.fm/>, <https://www.allmusic.com/>, <https://rateyourmusic.com/>

4.2.1 Assigning Emotions to Individual Tags

To infer the emotions connoted by a given tag, we first input both the tag and words from the *NRC Lexicon* into the **SBERT model**. This model generates embeddings for each, representing both the tag and words in the same semantic space.

We then perform **semantic search**, which involves retrieving the top- k entries $\{y_i\}_{i=1,\dots,k} \in Y$ of a corpus (NRC Lexicon) that are closest to a query x (the tag) by maximizing the cosine similarity on their embeddings, effectively identifying the words that are semantically similar to the tag: $y_i \in \arg \max_{y \in Y} \frac{x \cdot y}{\|x\| \|y\|}$.

Finally, a **weighted majority vote** is performed. This method involves directly selecting emotion vectors when a match with a high similarity score is found. If no such match exists, emotions with the highest consensus among a broader set are chosen.

Algorithm 1 Weighted Majority Vote

- 1: **Input:** Hyperparameters $\alpha_1, \alpha_2, \alpha_3, \beta$; tag embedding x ; embeddings, similarity scores, and emotion vectors from the top- k matches $\{(x_i, s_i, w_i) \mid s_u \geq s_v \text{ when } u < v\}_{i=1,\dots,k}$;
 - 2: **Output:** Emotion vector of the tag $v \in R^8$
 - 3: Initialize the set of chosen matches : $m \leftarrow \emptyset$.
 - 4: **if** $s_1 \geq \alpha_1$ **then**
 - 5: $m \leftarrow \{w_1\}$
 - 6: **else**
 - 7: $m \leftarrow \{w_i \mid s_i \geq \alpha_2\}$
 - 8: **if** $m = \emptyset$ **then**
 - 9: $m \leftarrow \{w_i \mid s_i \geq \alpha_3\}$
 - 10: $\mu \leftarrow \sum_{w_i \in m} s_i w_i \in R^8$
 - 11: $v \leftarrow (v_i)_i$ where $v_i = 1$ if $\mu_i > \beta$, 0 otherwise
 - 12: **Return** v
-

We conducted hyperparameter tuning using Grid Search to optimize the parameters $\alpha_1, \alpha_2, \alpha_3, \beta$ and k with the evaluation method outlined in Section 5.2. By selecting hyperparameters that maximize the F1-score between the original and inferred vectors, we ensured optimal accuracy in identifying the correct emotion vectors from words in the lexicon, considering both false positives and false negatives. The optimal values obtained were 0.95, 0.9, 0.5, 0.5, and 7, respectively.

4.2.2 Deriving the Emotion Vector for Each Track

Now that each tag is assigned an emotion vector with binary values indicating the presence or absence of each primary emotion, we can derive the emotion vector for each track. However, two issues must be addressed first. Tag occurrences should be normalized to ensure comparability across different sources; and intersubjective variability in music perception should be accounted for, since it can lead to differing tags among listeners and misleading inferred emotion vectors.

Tag Occurrences Normalization. We divide each occurrence by the maximum occurrence encountered within the source, resulting in normalized occurrences within the [0,1] range. For tags from *Rate Your Music*, where occurrences were not provided, we set their count to the average occurrence at the track level.

Tag Selection for Inter-rater Agreement. For each track, we select tags that exhibit good inter-rater agreement, estimated using the Intra-class Correlation Coefficient (ICC) with one-way random effects for absolute agreement [24]—a widely used metric for assessing inter-rater reliability when the same set of raters evaluates all subjects. In our approach, each emotion is treated as an individual "subject" and each tag as a "rater". The emotion vectors of each tag, weighted by their normalized occurrences, serve as ratings for the respective emotion.

To attain the acceptable threshold of 0.75 for inter-rater agreement (values between 0.75 and 0.90 indicate good reliability, according to [24]), we perform backward selection to iteratively eliminate conflicting tags. Starting with the initial set of tags for a given track, we remove the tag whose exclusion results in the highest ICC score. This process continues until the threshold is attained or only two tags remain.

Track Emotion Vector. We derive the emotion vector of a track by calculating the weighted average of the emotion vectors v_i from the p tags that demonstrated good inter-rater agreement. The weights α_i are set to the tags' normalized occurrences, thus giving more importance to emotions from prevalent tags.

$$v = \frac{1}{\sum_{i=1}^p \alpha_i} \sum_{i=1}^p \alpha_i w_i = \sum_{j \in B} \lambda_j e_j, \quad (2)$$

5. EVALUATION

5.1 Tag Extraction Method

To assess the reliability of our tag extraction method, we compared our tags to *human-generated* annotations from two crowdsourced MER datasets: *AMC Mirex* [7] and *Cal500* [9]. These datasets were selected for being the only ones to include emotion tags and share common tracks with our collection.

First, we calculate the percentage of common tags at the track level between each dataset and ours. Next, to assess the alignment between emotion tags, we derive emotion vectors of tracks from the two crowdsourced datasets using our method for emotion vector attribution (see Section 4.2), and then compare them with ours using semantic similarity.

	AMC		Cal500	
	mean	med.	mean	med.
Percentage of common tags for each track	56.0	100.0	3.24	0.0
Similarity score between emotion vectors	0.68	0.78	0.75	0.82

Table 2: Comparison of tags and emotion vectors

Comparing the resulting tags either directly or via the emotions they convey, our findings demonstrate that our method's results align well with human-generated annotations. In the *AMC* dataset we observed a strong direct match with our tags, with an average tag overlap of 56% at the track level ([41.69, 70.81] 95% CI) and a median reaching 100%. Considering the structure of the *AMC* dataset,

whose tracks are usually assigned only one tag, this means that for 56% of the tracks the *AMC* tag is contained in the set of tags we collected from music platforms. For *Cal500*, despite a low tag overlap of 3.24%, we observed significant alignment, with a mean similarity score of 0.75 between the derived emotion vectors. Note that the lower similarity score observed in *AMC* (0.68) may be attributed to its limited number of tags—with an average of one per track—compared to ours (~8 tags per track) and that of *Cal500* (~15 tags per track).

5.2 Tag Emotion Assignment Method

To assess the reliability of our method for assigning emotions to individual tags (see Section 4.2.1), we applied the same technique to the words in the NRC Lexicon. By treating each word as a ‘query’ and using the NRC Lexicon, excluding the query word itself, as the ‘corpus’, we derive emotion vectors for each word and compare them with the original vectors provided by the NRC Lexicon.

We achieved an average accuracy of 84% in identifying emotions represented by a given tag, with balanced scores across emotions. Joy was the most accurately identified emotion (93%), while fear had the lowest score (76%). Our F1-score was 77%—an expected result, as our method prioritizes emotions that align across all matched words, leading to a higher number of false negatives and thus lower recall. Nonetheless, the method’s ability to generally identify emotions demonstrates its overall effectiveness.

6. DISCUSSION

In this section, we discuss the strengths and weaknesses of our approach for generating emotion-labeled datasets.

6.1 A Dual-Use Model and a Reproducible Framework

The proposed framework, methodically divided into two distinct phases, facilitates the creation of synthetic datasets suitable for both Music Emotion Recognition (with emotion vectors) and auto-tagging tasks (with tags retrieved from music platforms). Its flexibility renders it applicable to any existing dataset that includes tags on music tracks, therefore allowing researchers to create their own emotion-labeled dataset⁴.

Additionally, our work can be easily extended to incorporate future resources similar to the NRC Lexicon, albeit based on other emotion models (GEMS etc.), as such resources become available. Since this approach only requires a mapping from English words to emotion labels, collecting these resources is significantly easier than obtaining direct emotion annotations on music excerpts.

6.2 Large-Scale Data Collection with Emphasis on Data Quality

Our method for extracting listener-generated textual data from music platforms overcomes the usual limitations

of data collection—including time, cost and feasibility constraints—through crowdsourced experiments and therefore enables data collection on a larger scale. Our final collection contains 5,892 emotion-labelled tracks, more than twice the size of the hitherto largest emotion model-based dataset of 2,648 tracks (*NTWICM* [11]).

Notably, specific attention was paid to retain only relevant tags, removing those that lack overt emotional significance, represent value judgments, or describe musical genres. Consequently, our dataset underwent significant refinement, with only a small percentage of total and unique tags retained (4.8% and 1.1%, respectively), enhancing its quality while maintaining its diversity (see Table 3). We actually ended up with 1,013 unique emotion tags, significantly more than the 157 emotion labels in the *MER* dataset with the largest number of labels to our knowledge (*Cal500*). Tag distribution across the dataset and within each source is presented in Figure 2, where the size of each tag reflects its frequency, taking into account its occurrence.

	Before	After
Tags across all tracks	1,007,847	48,737 (4.8%)
Unique tags	90,699	1,013 (1.1%)
Unique tracks	12,515	5,892 (47.1%)

Table 3: Data filtering overview, before pre-processing, after pre-processing

Figure 2: Tag Frequency Across Dataset and Sources

6.3 Reliance on Music Platforms

Our proposed framework relies on the availability of data on music platforms and may face challenges due to the under-representation of certain musical genres. Indeed, the final dataset exhibits a significant imbalance across genres, with world music and classical music represented only by 29 and 24 tagged tracks. We nonetheless pursued the creation of a balanced dataset by selecting the 280 most popular tracks for the top 15 most-represented genres, yielding 4,200 tracks in total⁵.

The tag frequencies (see Figure 2) reveal a prevalence of certain tags, with positive-emotions particularly prominent. However, it is uncertain whether this reflects listener preferences, a wider music industry trend, or a tendency of listeners to engage with music platforms when in a positive mood. The latter possibility could potentially introduce bias into our results.

⁴ Python code to derive emotion vectors from a set of tags is provided: <https://github.com/joanne-affolter/PlayMood>

⁵ The dataset and its balanced version are made public: <https://github.com/joanne-affolter/PlayMood>

6.4 Emotion Association: A Focus on Explainability

Some critics might argue that our methodology for generating emotion-labeled datasets could introduce bias when training Music Emotion Recognition (MER) systems, as it relies on synthetic data. However, the use of a direct mapping from tags to emotions using a crowd-sourced Lexicon aims to ensure model explainability and interpretability. We deliberately chose not to use machine learning models to predict word emotions, opting instead for a resource curated by humans. However, we acknowledge that the strong reliance on the NRC Lexicon renders our work subject to the latter’s limitations, including socio-cultural biases [25], the possibility of incorrect, nonsensical, or pejorative entries due to human error—inevitable with large-scale annotations—and potential ambiguities due to a lack of context in the lexicon [26].

6.5 Towards More Generalizable Findings

In addition to significantly reducing the need for human-generated annotations, our synthetic dataset in fact leverages the size and diversity of social music platforms. For instance, it features a larger average number of tags per track (mean: 7.52, min: 1, max: 171) compared to crowd-sourced datasets, which typically rely on a few tags (on average 1.62 for *MTG-MT* and 1.01 for *AMC Mixex*). This variety enables a broader range of interpretations and a more nuanced evaluation of listener feedback, although it may also present challenges in identifying emotions. Furthermore, agreement among listeners on music platforms tends to be relatively high, as indicated by the frequency of tag occurrences at the track level (mean: 6.01, min: 1, max: 200). In contrast to crowdsourced studies that generally require agreement between a few annotators, our method has an intrinsic potential for more robust and generalizable findings thanks to the higher number of listeners involved in the tagging process.

6.6 Emotion Modeling: Paving the Way for Future Research

By grounding our method on a set of eight primary emotions, we offer an intuitive alternative to the VA framework. Meanwhile, by using a continuous vector representation in the Plutchik emotion space, our framework is also able to capture subtle emotional nuances of music tracks, as illustrated by the emotional profiles in Figure 3⁶.

Notably, we found that as the number of tags increased, the emotional spectra of a track became more complex, involving a wider variety of emotions with varying intensities. One may wonder whether to consider feedback from all listeners, resulting in more intricate emotion representations, or retain the best-aligned tags alone, thereby increasing consistency at the risk of missing individual nuances. In this work, we opted for mutually consistent emotion vectors with an emphasis on inter-rater agreement. By

filtering out tags that represent contrasting emotions, we negotiated, on the one hand, the intersubjective variability of music perception and, on the other hand, its socially communicative potential by selecting a significant number of tags with high agreement, effectively producing complex emotion representations validated by the majority. We thus achieved an average ICC score of 0.76 for the emotion ratings associated with the selected tags for each track, indicating *good reliability* according to [24], compared to the initial score of 0.52, which suggested *moderate reliability*. It is noteworthy that, despite the filtering process, the average number of tags per track decreased only slightly from 7.52 to 6.55, demonstrating that our dataset still reflects the diversity of its participant pool.

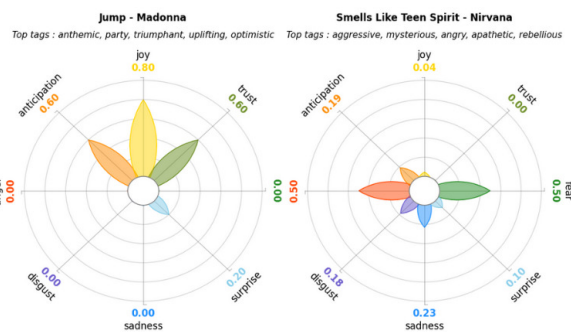

Figure 3: Visualization of tracks’ emotions.

7. CONCLUSION

Our investigation introduces a novel approach to Music Emotion Recognition (MER) by benefiting from large-scale, listener-generated tagging alongside an original application of Plutchik’s emotion model. With this work we aimed not only to address the scarcity of annotated datasets in the MER domain, but also to challenge traditional paradigms of music emotion by adopting an intensely empirical, psychological model-based framework. Through meticulous data collection and cleaning, we generated a dataset that surpasses existing collections in size and diversity, while maintaining a high degree of alignment with human-generated annotations. We believe that the integration of Natural Language Processing techniques in the semantic analysis of music tags is a methodological innovation that may effectively transpose the problem from audio to the textual domain. Furthermore, our approach’s dual utility in MER and Auto-Tagging tasks demonstrates its versatility and potential for wide-ranging applications in Music Information Retrieval. By narrowing the gap between psychological emotion theories and computational music analysis, we pave the way for future research endeavors aimed at enriching our understanding of listeners’ emotional engagement with music.

⁶ A notebook for visualizing the emotional profiles across all tracks in our collection is available: <https://github.com/joanne-affolter/PlayMood>

8. ETHICS STATEMENT

Ethical Considerations in Data Handling It is important to note that our dataset does not contain any listener-specific information; our research involved the analysis of publicly available data only. By design, our approach prevents any direct links to individual listeners within the dataset, mitigating concerns around privacy and data security.

Addressing Societal and Cultural Considerations

The diversity of music across cultures presents a challenge for Music Information Retrieval technologies, which should strive to prevent cultural homogenization in interpretive systems. Despite efforts to include a wide range of genres and styles, our dataset may not fully capture the breadth of global musical diversity. Additionally, the platforms from which data was sourced may primarily serve specific demographics, potentially biasing our dataset towards the musical preferences and emotional expressions of a particular segment of the global population. Future research should prioritize the collection of tags from a more culturally diverse set of sources, work towards the further mitigation of such biases, and enhance the inclusivity of MIR technologies.

9. ACKNOWLEDGMENTS

I would like to sincerely thank I. Rammos for his invaluable supervision throughout the entire project and his significant contributions to the review and correction of the paper. His expertise and support greatly enhanced the quality of this work.

ABSTRACT

Piano cover generation aims to create a piano cover from a pop song. Existing approaches mainly employ supervised learning and the training demands strongly-aligned and paired song-to-piano data, which is built by remapping piano notes to song audio. This would, however, result in the loss of piano information and accordingly cause inconsistencies between the original and remapped piano versions. To overcome this limitation, we propose a transfer learning approach that pre-trains our model on piano-only data and fine-tunes it on weakly-aligned paired data constructed without note remapping. During pre-training, to guide the model to learn piano composition concepts instead of merely transcribing audio, we use an existing lead sheet transcription model as the encoder to extract high-level features from the piano recordings. The pre-trained model is then fine-tuned on the paired song-piano data to transfer the learned composition knowledge to the pop song domain. Our evaluation shows that this training strategy enables our model, named PiCoGen2, to attain high-quality results, outperforming baselines on both objective and subjective metrics across five pop genres.

1. INTRODUCTION

Piano cover generation, which involves recreating or arranging an existing music piece as a new piano version, is popular within music-creative communities and the music production industry. On media sharing sites like YouTube, piano cover creators often have lots of subscribers. Additionally, many music producers create and distribute piano arrangements on music streaming platforms.

Attempts have been made in the field of music information retrieval (MIR) to automatically generate piano covers from existing musical pieces. Takamori *et al.* [1] proposed a regression method to generate piano reductions, which can be considered simplified versions of piano covers, using acoustic features and structural analysis of the

Figure 1. The proposed model is trained with two stages: firstly pre-trained on piano-only data and then fine-tuned on the weakly-aligned song-to-piano pairs.

input music. With the recent surge in deep learning, Choi *et al.* [2] introduced a model named Pop2Piano that tackles piano cover generation by leveraging the concept of piano transcription and employing the MT3 architecture [3], originally designed for transcription, as their model backbone. They collected pop songs and the corresponding piano covers from the Internet, and built a song-piano *synchronized* dataset by “remapping” the piano notes to the song audio with a warping algorithm (thereby modifies, or warps, the piano cover). The algorithm entails evaluating the similarity between the pitch contour of the vocal signal extracted from the song audio with the top line of the piano MIDI. They then trained the model with the synchronized data, guiding the model to learn the pitch and onset/offset timing of each note in the generated piano cover.

However, as shown in Table 1, the statistics in the ratio of audio length difference and tempo difference between the original songs and original piano covers (i.e., before note-remapping) they collected¹ show that a piano cover and its original song are not perfectly aligned to each other (for otherwise the difference ratio would be equal to 1.00). This indicates that the tasks cover generation and transcription are inherently different, and that forcing a piano cover to be synchronized with its original song may be inappropriate. Actually, we notice that the note-remapping process of Pop2Piano—i.e., adjusting piano note timing according to the time mapping function obtained by synchronizing piano notes to the song audio—breaks the relation of original piano notes and thereby incurs loss of piano informa-

Guan, and Y.-H. Yang, “PiCoGen2: Piano cover generation with transfer learning approach and weakly aligned data”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

¹ https://github.com/sweetcocoa/pop2piano/blob/main/train_dataset.csv

duration deviation	tempo deviation	IOI deviation
1.10 ± 0.12	1.16 ± 0.25	1.14 ± 0.17

Table 1. The first two statistics contrast the original songs with their original piano covers (i.e., no note-remapping) in the Pop2Piano dataset [2], evaluating the length of the **duration** (in seconds) of the longer one divided by that of the shorter one, and similarly the deviation ratio in **BPM**. The last statistic is similarly the deviation ratio in terms of the average inter-onset intervals (**IOIs**; in seconds), but between the original & adjusted (synchronized) piano covers.

tion. Moreover, from a musical perspective, the way human creates piano covers is by nature different from the way human transcribes music. For cover generation, musicians may firstly analyze the original song in terms of aspects such as melody, chord progression and rhythm section, then decide how to interpret the original song with their composition knowledge, and finally make the piano cover based on the piano performance techniques.

Inspired by the process of human composition for piano cover songs, we propose in this paper a novel approach for piano cover generation by involving the concept of transfer learning [4]. Instead of relying on the *strongly-aligned* pairs [5] that necessitates note-remapping, we use *weakly-aligned* data with the correspondence in “beat” level between song-piano pairs. This approach incurs no rhythmic distortion of the piano covers, retaining their musical quality. Besides, to mitigate the inaccuracy of data alignment, the model is pre-trained on piano-only data to learn the concept of piano performance first, and then fine-tuned on the weakly-aligned paired data to learn the conversion of song to piano, as shown in Figure 1. We also employ a prior model SheetSage [6], pre-trained for lead sheet transcription, as an encoder component that helps our model learn high-level musical concepts for cover generation.

We compare the proposed model, named “PiCoGen2”, against other baselines with objective and subjective measures, validating the effectiveness of the weak-alignment method for pairing and the two-step training strategy. We share source code and audio samples at a project page.²

2. BACKGROUND

Piano arrangement, i.e., the process of reconstructing and reconceptualizing a piece, is related to various conditional music generation tasks, including lead sheet³-conditioned accompaniment generation, transcription and reorchestration, and piano reduction [7–9]. Beyond arrangement, piano cover generation involves creating new musical elements and modifying the original elements via improvisation, tempo changes, stylistic shifts, etc. We briefly review some related topics below.

Symbolic-domain music generation is about generating music in a symbolic form such as pianorolls [10] and dis-

crete MIDI- (Musical Instrument Digital Interface) [11] or REMI-like tokens [12–15], rather than audio signals. The task encompasses unconditional generation (i.e., from-scratch generation) and conditional generation. While the goal of piano cover generation is to generate piano audio given a song audio input, we can treat it as a conditional symbolic music generation task, for we can generate piano in the MIDI domain first, and then use off-the-shelf high-quality piano synthesizers to convert it into audio.

Automatic music transcription (AMT), which aims to precisely transcribe music content from audio signals into a symbolic representation over time, is also related to piano cover generation. AMT tasks can be categorized based on the completeness of information captured from the input audio. One category of AMT tasks aims to capture all music content presenting in the audio, such as automatic piano transcription [3, 16–20]. These methods transcribe the complete polyphonic piano performance from the audio signal. Another category focuses on transcribing a reduced representation of the input, like melody transcription [21, 22] and lead sheet transcription [6, 23, 24]. These tasks extract only the lead melody line and chord progressions, representing a sparse subset of the full musical content. Piano cover generation also requires the exploration of music content reduction and additionally relies on generative modeling conditioned on the reduced representation. For example, Pop2Piano uses MT3 [3] as its backbone to convert audio features into a symbolic piano performance representation. However, following the paradigm of transcription approaches, Pop2Piano requires paired data consisting of pop songs and their corresponding temporally-synchronized piano cover.

Transfer learning is generally consider as the concept of adopting the model to the target domain by re-using parameters that are trained on a source domain, thereby transferring the knowledge between the domains [25]. There have been several works on transfer learning in the field of MIR, e.g., music classification [26–28] and music recommendation [29, 30]. However, to our best knowledge, little attempts have been made to apply transfer learning to the task of cover song generation.

Besides Pop2Piano [2], this work is also closely related to PiCoGen [31], an early version of the current work. We explore the two-stage training strategy for piano cover generation for the first time there. However, in PiCoGen we use discrete symbolic lead sheet as the intermediate representation, instead of continuous conditions supplied by an encoder as done here (see Section 3.2). We note that the sampling process of lead sheet extraction in PiCoGen might loss musical information such as instrumentation and vibes of the input audio. Moreover, we do not explore the idea of transfer learning (Section 3.3) there.⁴

The work of Wang *et al.* [32] is also related, for they deal with the similar problem of converting audio signals

² <https://tanchihpin0517.github.io/PiCoGen/>

³ A music notation consisting of lead melody and chord progression.

⁴ As the previous work [31] was also under review at the time we submitted the current paper, we did not empirically compare PiCoGen and PiCoGen2 in the experiments here. Instead, we provide examples of their generation results for the same input songs on the demo page, which should demonstrate that PiCoGen2 works better than PiCoGen.

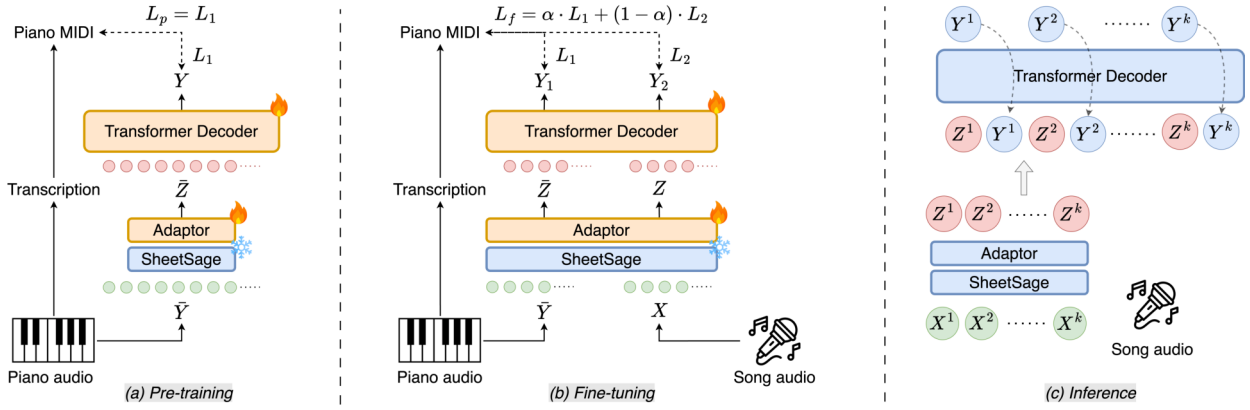

Figure 2. A diagram of the proposed model, PiCoGen2. The fire and snowflake symbols indicate the trainable and frozen parts. For example, the parameters for SheetSage [6], a model pre-trained for lead sheet transcription, are always frozen.

into piano MIDI performances. However, they apply a piano transcription prior and thus using strongly-aligned data as Pop2Piano [2], and they employ a more sophisticated disentanglement-based method to get an intermediate representation. Moreover, they assume that the vocal of the input audio has been removed beforehand, thus actually generating a piano backing track rather than a piano cover.

3. METHODOLOGY

Viewing piano cover generation as a conditional symbolic music generation task, we formulate it as a sequence-to-sequence problem. The objective is to generate a sequence of symbolic tokens Y representing the piano performance, conditioned on the input audio X of the original song.

3.1 Weakly-Aligned Data

In Pop2Piano, Choi *et al.* [2] propose a data preprocessing algorithm to synchronize the piano MIDI to the song audio. They utilize SyncToolBox [33] to analyze the chroma features of two audio segments to obtain a warping path of mapping the time from the piano performance to the song audio. Based on the analysis, they adjust the timing of notes transcribed from the piano performance by using a linear mapping function calculated from the temporal warping information. These remapped notes is then quantized to align with the beat locations of the song audio. However, the rhythmic distortion caused by note-remapping is practically unavoidable, even disregarding the inaccuracy of the synchronization process. The chroma feature only reflects a rough overall alignment between the piano performance and song audio which cannot precisely describe the nuanced amount of timing shift for each individual note. This is evident when examining the changes in the inter-onset intervals (IOIs) between the original piano notes and the remapped version, shown in Table 1.

To avoid the rhythmic distortion of note-remapping, we propose a weak-alignment approach that does not change the timing of piano notes. The idea is to let the alignment rely on only the *beats* of each song-to-piano pair. We construct the time mapping function F_{time} by computing the

warping path for the audio pair like the way of Pop2Piano. Given a time of piano performance t_p , the function outputs the corresponding time of song audio $t_s = F_{\text{time}}(t_p)$ according to the temporal warping information. Specifically, we detect the beat locations with Beat Transformer [34] to get the beat times $Q^p = [q_1^p, \dots, q_{l_p}^p]$ of the piano performance and $Q^s = [q_1^s, \dots, q_{l_s}^s]$ of the song audio, where l_p and l_s denote the number of beats of each of them. Then we define an aligning function F_{beat} as:

$$F_{\text{beat}}(i) = \arg \min_j (F_{\text{time}}(q_i^p) - q_j^s). \quad (1)$$

For any beat index $i \in [1, \dots, l_p]$ of the piano performance, the aligning function outputs the corresponding beat index $j \in [1, \dots, l_s]$ of the song audio, and q_j^s is the nearest beat time to $F_{\text{time}}(q_i^p)$. We consider a song-piano pair to be weakly-aligned if the correspondence between them is determined by F_{beat} . See the project page for an illustration.

3.2 Model

An aerial view of our model is depicted in Figure 2. We employ a decoder-only Transformer to accept an input sequence bundling condition X (song audio) and target Y (piano performance) together, and generates the output tokens for Y autoregressively. This approach of providing both the condition and target as a bundled input sequence to the Transformer has been applied in previous studies [13, 14, 35] and has shown success in better informing the model of the temporal correspondence between the condition and desired output. We divide Y into *bars* with the detected beat information and get $Y = [Y^1, \dots, Y^{B_p}]$, where B_p is the number of bars in the piano cover, and there exists an song audio sequence $X = [X^1, \dots, X^{B_p}]$ for Y , where each sub-sequence X^k is weakly aligned to Y^k . We then rearrange them with an interleaving form and train the decoder with the bar-wise mix $S = [X^1, Y^1, \dots, X^{B_p}, Y^{B_p}]$. The decoder model would learn to generate k -th bar of piano performance Y^k depending on (i.e., can attend to) the current and preceding sub-sequences of song audio $[X^1, \dots, X^k]$ and the preceding sub-sequences of piano performance $[Y^1, \dots, Y^{k-1}]$.

To reduce the sequence length of X and extract better musical information, we employ a prior audio encoder to transform X into an intermediate representation Z . Different from those works which use Mel-spectrograms [3] or audio codecs [36] for Z , we use SheetSage [6], which is trained for lead sheet transcription, cascaded with a neural adapter as the prior audio encoder. We consider the output embeddings of SheetSage more suitable for representing the input, since they carry information of musical elements connecting a cover with the original song, such as melody, chords and vibes. With the prior encoder, the song audio $[X^1, \dots, X^{B_p}]$ is transformed into a sequence of latent embeddings $[Z^1, \dots, Z^{B_p}]$ before being passed to the decoder, yielding the input sequence $[Z^1, Y^1, \dots, Z^{B_p}, Y^{B_p}]$ of the decoder, as illustrated in Figure 2c.

3.3 Transfer Learning

While the weak-alignment approach eliminates inner temporal distortions for piano performance, there can still be alignment errors between the piano segments and their corresponding song segments. This is because a piano cover is not guaranteed, in the beat level, to have a strict one-to-one mapping with the original song.

To abate such alignment errors, we propose a transfer learning-based training strategy, dividing the training into two steps: pre-training (Figure 2a) and fine-tuning (Figure 2b). In the *pre-training* stage, we train the model with an input sequence $\bar{S} = [\bar{Y}^1, Y^1, \dots, \bar{Y}^{B_p}, Y^{B_p}]$ where \bar{Y} is the original piano audio recording of the symbolic piano tokens Y . The same as the song audio, the original recording \bar{Y} is encoded to an inter-representation \bar{Z} by the prior encoder. We expect the model to learn to generate piano performances Y with high-level musical features extracted by SheetSage from the piano audio \bar{Y} , rather than merely detecting note onsets/offsets like in a piano transcription task. Importantly, there will be no alignment errors between Y and \bar{Y} , ensuring that the model can firstly learn the complete concept of piano composition and generation in the pre-training stage, without being impeded by cross-domain alignment issues.

In the *fine-tuning* stage, we train the model with the mixture of \bar{S} and S . Following [36–38], we train the model with the objective of minimizing the cross entropy loss on the tokens of piano performance Y . Let L_1 and L_2 stand for the cross entropy losses for \bar{S} and S , respectively. The loss L_p in the pre-training stage and the loss L_f in the fine-tuning stage can be written as:

$$\begin{aligned} L_p &= L_1, \\ L_f &= \alpha \cdot L_1 + (1 - \alpha) \cdot L_2, \end{aligned} \quad (2)$$

where α is the weighting factor determining the proportion of losses contributed from \bar{S} and S during fine-tuning. We expect that α helps the model retain the knowledge about piano performance learned from the pre-training stage.

3.4 Data Representation

For the piano performance sequences Y , we adopt a modified version of the REMI token representation [12], which

has been shown to work well for modeling pop piano. Our representation consists of 7 token classes. `Spec` contains special tokens such as `[bos]` (beginning-of-sentence) and `[ss]` (song-start) for controlling the model behavior. `Bar` indicates the property of each bars. `Position`, `Chord` and `Tempo` are metric-related tokens for 16th-note offsets within bars, chord changes (11 roots \times 12 qualities), and tempo changes (64 levels). `Pitch`, `Duration` and `Velocity` are note-related tokens for note pitches (A0 to C8), durations (1 to 32 16th-notes), and note velocities (32 levels). There are in total 428 tokens in the vocabulary. In our implementation, `[Bar_start]` and `[Bar_end]` always occur at the start and end of each bar in the input sequence S and \bar{S} .

4. EVALUATION

4.1 Dataset

We follow the instructions provided in the Pop2Piano source code to rebuild the training dataset, collecting 5,844 pairs of pop songs and their corresponding piano covers from the Internet. We filter out song pairs with a melody chroma accuracy (MCA) [39] lower than 0.05 or an audio length difference exceeding 15%, leaving 5,503 remaining pairs. In the pre-training stage, all the piano performances from these remaining pairs are used for training. In the fine-tuning stage, we remove invalid bars from the piano performances where the first and last beats of a bar were mapped to the same beat of the original song by the mapping function F_{time} . Around 50% of the bars are removed from the piano performances accordingly. We note that the large number of such invalid bars implies the alignment algorithm of Pop2Piano [2] may not be robust enough and future work can be done to study this.

For objective and subjective evaluations, we collect additional 95 song-to-piano pairs from the Internet, containing 19 Chinese Pop (**Cpop**), 20 Korean Pop (**Kpop**), 16 Japanese Pop (**Jpop**), 20 Anime Song (**Anime**), 20 Western Pop (**Western**) pairs. All the songs contain vocals. We share the URLs of these songs at the project page.

4.2 Experiment Setup

We implement PiCoGen2 using GPT-NeoX [40] as the piano token decoder and SheetSage [6] cascaded with an adapter network as the song audio encoder. The decoder consists of 8 layers, each with 8 attention heads. The adapter is a 4-layer Transformer encoder with 8 attention heads per layer. Our full model has approximately 39M learnable parameters, not counting the SheetSage part for we use it as is with its parameters frozen.

There are 2 ablations compared in the experiment, both of them sharing the same architecture as our full model, but one ablation (Ablation 1) is trained on song-to-piano data *without pre-training*, and the other ablation (Ablation 2) is trained on piano-only data (i.e., *without fine-tuning*). For baselines, besides Pop2Piano, we also include the piano transcription model by Kong *et al.* [20] to validate the effectiveness of the encoder component in our model.

Model	objective evaluation			subjective evaluation ($\in [1, 5]$)		
	$MCA \uparrow$	$GS \uparrow$	$H_4 \downarrow$	$OVL \uparrow$	$SI \uparrow$	$FL \uparrow$

Table 2. The results of objective evaluations and the MOS of the subjective study (\uparrow/\downarrow : the higher/lower the better).

We train the models with Adam optimizer, learning rate $1e-4$, batch size 4 and segment length 1,024. The full model is pre-trained for 100K steps on the piano-only data, and then fine-tuned for an additional 70K steps on the song-to-piano paired data. Ablation 1 is trained from scratch for 100K steps directly on the paired data. Ablation 2 is trained for 50K steps only on the piano-only data, without any exposure to the song-to-piano pairs. During the fine-tuning stage for the full model, we tune the weighting factor α that controls the balance between the piano-only loss and song-to-piano loss, and find that the model achieved the best performance when α is set to 0.25.

For the objective and subjective evaluations, all models are used to generate piano covers of the 95 testing songs (cf. Section 4.1). To eliminate the bias caused by the varying quality of piano recordings, the ground truth human piano performances are first transcribed into MIDI note sequences. These MIDI sequences are then synthesized back into audio using the same FluidSynth-based MIDI synthesizer [41] employed for the model outputs.

4.3 Objective Metrics

We adopt the following existing metrics to assess the quality of the generated piano covers from different aspects, including similarity to the original song and coherence of the piano performance itself.

- **Melody Chroma Accuracy (MCA)** [39] evaluates the similarity between two monophonic melody sequences. The melody line plays a crucial role in deciding whether a song cover resembles the original song. Following Pop2Piano [2], we compute the MCA between the vocals extracted by Spleeter [42] from the test song audio, and the top melodic line extracted from the generated piano cover MIDI using the skyline algorithm [43].
- **Pitch Class histogram Entropy (H_4)** [37] evaluates the harmonic diversity of a musical segment by computing the entropy of the distribution of note pitch class counts. A lower entropy value indicates lower harmonic diversity, but implies a more stable and consistent tonality across the segment. The subscript (“4”) indicates the number of bars over which the entropy is calculated.
- **Next-Bar Grooving Pattern Similarity (GS)** is modified from the grooving pattern similarity proposed in [37]. It originally measures the global rhythmic stability across an entire song. Instead of calculating over all

pairs in the target, we adapt the metric to focus on local rhythmic stability within a song, evaluating the rhythmic coherence between each bar and its succeeding bar.

4.4 User Study

For subjective evaluation, we conduct an online listening test involving 52 volunteers: 5 professional music producers, 13 amateurs, and 34 pro-amateurs with more than 3-year music training. The volunteers are randomly assigned to distinct test sets, with each set containing 3 songs randomly selected from different genres, and for each song, there are 6 piano performances presented anonymously in random order. These piano performances include: a human piano performance, outputs of our full model and the two ablated versions, and outputs of the Pop2Piano and piano transcription model baselines. All of them are truncated to 40-second audio clips from the beginning. Subjects are asked to listen to these audio clips and provide ratings on a 5-point Likert scale for the following aspects:

- **Similarity (SI):** The degree of similarity between the piano performances and the original song.
- **Music Fluency (FL):** The degree of perceived fluency in the music, representing the smoothness and coherence of the piano performances.
- **Overall (OVL):** How much do the participants like the piano cover in the personal overall listening experience?

4.5 Results

Table 2 displays the results of the objective evaluation metrics and mean opinion scores (MOS) from the user study. In the objective evaluation, Pop2Piano shows a leading MCA score compared to other models and the human piano performances, which indicates it excels at matching the original song’s melodic contour. Except for the transcription baseline model, there is no significant difference in GS and H_4 across models, suggesting comparable local rhythmic coherence and harmonic variety.

Next, we pay attention to the result of user study. Much to our delight, the full model leads with the best scores across all aspects in the user study with statistical significance ($p < 0.05$), but there remains a gap compared to the human reference performances. Ablation 1 achieves higher scores than Pop2Piano in all aspects of the user study, both of which are trained on the paired data. This suggests that

Figure 3. The MOS in overall scores (OVL) of the user study in different genres.

utilizing the weakly-aligned paired data, which avoids distorting the original piano performances, helps increase the overall listening experience quality of the model outputs for human raters. Moreover, both Ablation 2 and the transcription baseline are trained on piano-only data, but Ablation 2 performs significantly better than the baseline in both objective and subjective evaluations. This can be seen as evidence that SheetSage, as the encoder, extracts more relevant features beneficial for the piano cover generation task compared to the baseline transcription model.

5. DISCUSSION

In the experiment, we note that while Pop2Piano exhibits a significantly higher MCA score than the other models, even higher than the human performances, it fails to achieve comparably high SI ratings in the user study. We suggest this conflict arises from the assumption in MCA that two melodies must temporally correspond to each other on a fixed “time grid.” That is, the corresponding chroma features must be located at precisely the same time instants. For human listening experiences, two similar melodies only need to be coordinated on beats rather than a rigid time grid. Specifically, human perception of melodic similarity allows for the tempo or duration to be slightly changed in the same ratio, as long as their notes are located on the same underlying musical beat positions. As mentioned in Sections 1 & 2, different from transcription or arrangement, a cover song is not usually temporally aligned to the original song, i.e., the musical elements such as tempo, melody, rhythmic changed in the composition process of the piano cover. This temporal flexibility suggests that MCA as an objective measure for the cover generation task may not be adequate and calls for future endeavor to develop better alternatives.

We also find that the two ablated models have the same OVL scores in the subjective evaluation, even though Ablation 2 has never seen any pop song data during training. To investigate the reason behind this, we first examine the piano covers generated by Ablation 2. Figure 4 shows a snippet of a cover generated by this model. We note that it tends to generate repeated short notes, resulting in an unnatural-sounding performance. However, Figure 3 demonstrates the OVL scores across different music genres. Interestingly, we see that Ablation 2 outperforms Ablation 1 for the Cpop, Jpop, and Anime genres. Additionally, as shown in Table 2, the former ablation also achieves higher SI and lower FL scores than the latter. From this

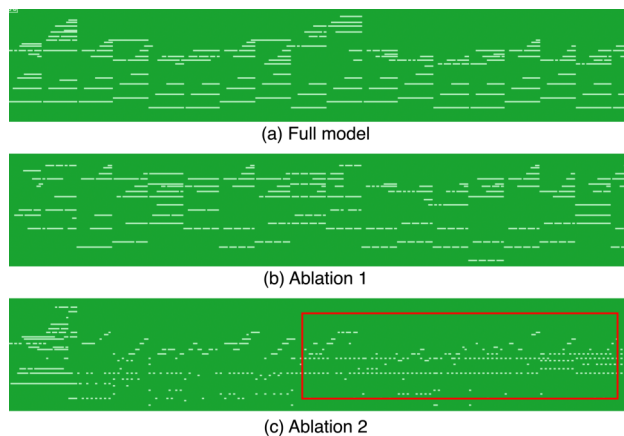

Figure 4. The pianoroll representation of a snippet from an example generated by the models. We observe that Ablation 2, which trained on piano-only data, tends to generate repeated short notes.

observation, we suggest that (i) for short audio clips (less than 40 seconds), human raters may place more emphasis on initial melodic accuracy when judging the overall perceived quality, even if Ablation 1 tends to generate more coherent and natural-sounding results; (ii) Ablation 1 does not effectively learn to precisely capture the melodic contour from the reference song condition due to the inherent alignment errors present in the weakly-aligned song-to-piano paired data it was trained on.

6. CONCLUSION

In this paper, we have presented PiCoGen2, which applies the concept of transfer learning to the piano cover generation task. We propose a training strategy that involves two stages: pre-training on piano-only data to learn fundamental piano performance skills, followed by fine-tuning on weakly-aligned song-to-piano paired examples for the cross-domain translation. A comprehensive set of experiments validate the effectiveness of the proposed transfer learning approach and the use of weakly-aligned data.

As we still require weakly-aligned data, future work can be done to tackle cover generation without relying on data alignment at all. Moreover, it is useful to have a systematic analysis to evaluate the quality of piano covers and identify the key factors influencing the result, e.g., by studying the performance difference between PiCoGen [31] and PiCoGen2. It is also interesting to generate other covers, such as orchestral covers, and to develop better objective metrics.

7. ACKNOWLEDGMENT

The work is supported by a grant from the National Science and Technology Council of Taiwan (NSTC 112-2222-E-002-005-MY2). We are also grateful to the reviewers and meta-reviewer for helpful comments that help improve the quality of the paper.

ABSTRACT

Mixing style transfer automates the generation of a multi-track mix for a given set of tracks by inferring production attributes from a reference song. However, existing systems for mixing style transfer are limited in that they often operate only on a fixed number of tracks, introduce artifacts, and produce mixes in an end-to-end fashion, without grounding in traditional audio effects, prohibiting interpretability and controllability. To overcome these challenges, we introduce **Diff-MST**, a framework comprising a differentiable mixing console, a transformer controller, and an audio production style loss function. By inputting raw tracks and a reference song, our model estimates control parameters for audio effects within a differentiable mixing console, producing high-quality mixes and enabling post-hoc adjustments. Moreover, our architecture supports an arbitrary number of input tracks without source labelling, enabling real-world applications. We evaluate our model’s performance against robust baselines and showcase the effectiveness of our approach, architectural design, tailored audio production style loss, and innovative training methodology for the given task. We provide code and listening examples online¹.

1. INTRODUCTION

Music mixing involves technical and creative decisions that shape the emotive and sonic identity of a song [1]. The process involves creating a cohesive mix of the given tracks using audio effects to achieve balance, panorama, and aesthetic value [2]. Given the complexity of the task, mastering the task of mixing often requires many years of practice. To address this, several solutions have been proposed to provide assistance or automation [3,4]. Automatic mixing systems have been designed using knowledge engineering [5,6], machine learning, and more recently deep learning methods [7–11]. Automatic mixing systems can

[†]These authors contributed equally to the work.

be further subdivided into direct transformation systems and parameter estimation systems, as shown in Figure 2. Direct transformation systems operate on tracks and predict a mix directly, in an end-to-end fashion, with the loss calculated between the ground truth mix and the predicted mix. On the other hand, parameter estimation systems take input tracks and predict control parameters for a dedicated mixing console. In such systems, the loss can either be calculated on the predicted control parameters (parameter loss) based on the availability of ground truth, or on the predicted audio against the ground truth mix (audio loss). Parameter loss, calculated on the parameters, may not be optimal for multiparameter signal processing blocks since various combinations of parameters could potentially produce similar outcomes. [7, 11] utilizes a deep learning-based direct transformation system for mixing, while [8] employs a parameter estimation-based deep learning approach. However, many of these systems are constrained

to a small number of input tracks or struggle to generalize effectively to real-world mixing scenarios. Furthermore, most of these approaches generate a mix without accounting for the desired sound and emotion. Due to the subjective nature of the task, an end-to-end approach without user control is less desirable in professional practice [12].

1.1 Mixing Style Transfer

In professional practice, the audio engineer often uses reference songs and guidelines provided by the client to make mixing decisions [13]. This encourages the development of automatic mixing systems that are aware of the intention of the mixing engineer. In our context, mixing style transfer refers to mixing in the style of given reference songs [14]. This pertains to capturing the global sound, dynamics and spatialisation of the reference song. Recently, deep learning systems have been proposed for audio production style transfer. While some approaches have considered estimating the control parameters for audio effects [15], they are so far limited to controlling only a single or small set of effects with a singular input. Whereas [16] have implemented an end-to-end style transfer system between two mixed songs which limits controllability and full raw tracks mixing. In this work, we introduce a novel deep learning-based approach to mixing multitrack audio material using a reference song, which utilises a differentiable mixing console to predict parameter values for gain, pan, 4-band equalization, compressor, and a master bus. Our proposed system is differentiable, interpretable and controllable, and can learn the mixing style from the given reference song. The contributions of this work can be summarised as follows:

1. A framework for mixing style transfer that enables control of audio effects mapping the production style from a reference onto a set of input tracks.
2. A differentiable multitrack mixing console consisting of gain, parametric equalisation, dynamic range compression, stereo panning, and master bus processing using `dasp-pytorch`², which enables end-to-end training.
3. Demonstration of the benefits of our system, including generalisation to an arbitrary number of input tracks, no requirement for labelling of inputs or enforcement of specific taxonomies, high-fidelity processing without artifacts, and greater efficiency.

2. METHOD

2.1 Problem Formulation

We can formulate the mixing style transfer task as follows. Let T be a matrix of N mono input raw tracks $\{t_1, t_2, t_3, \dots, t_N\}$ and M_r be the matrix of stereo reference mix containing two channels. A shared weight encoder f_{θ_r} and f_{θ_t} are employed to extract information from

the reference and input tracks respectively. This information is then aggregated and fed into a transformer controller network comprising a transformer encoder and a multi-layer perceptron (MLP) g_ϕ . The primary task of this network is to estimate the parameter matrix P , which consists of N parameter vectors p , each responsible for configuring the chain of audio effects for a respective track in T . Subsequently, the differentiable mixing console $h(T, P)$ processes the input tracks T using the parameters P to generate a predicted mix M_p that mirrors the style of the reference mix M_r .

$$P = g_\phi(f_{\theta_t}(T), f_{\theta_r}(M_r)) \quad (1)$$

$$M_p = h(T, P) \quad (2)$$

2.2 Differentiable Mixing Style Transfer System

We propose a differentiable mixing style transfer system (Diff-MST) that takes raw tracks and a reference mix as input and predicts mixing console parameters and a mix as output. As shown in Figure 1, our system employs two encoders, one to capture a representation of the input tracks and another to capture elements of the mixing style from the reference. A transformer-based controller network analyses representations from both encoders to predict the differentiable mixing console (DMC) parameters. The DMC generates a mix for the input tracks using the predicted parameters in the style of the given reference song. Given that our system oversees the operations of the DMC rather than directly predicting the mixed audio, we circumvent potential artefacts that may arise from neural audio generation techniques [17, 18]. This also creates an opportunity for further fine-tuning and control by the user.

2.3 Differentiable Mixing Console (DMC)

The process of multitrack mixing involves applying a chain of audio effects, also known as a channel strip, on each channel of a mixing console. The audio engineer may use these devices to reduce masking, ensure a balance between the sources, and address noise or bleed. Incorporating this prior knowledge of signal processing in the design of our mixing system, we propose an interpretable and controllable differentiable mixing console (DMC). Our console applies a chain of audio effects comprising gain, parametric equaliser (EQ), dynamic range compressor (DRC), and panning to each of the tracks to produce wet tracks. The sum of wet tracks is then sent to a master bus on which we insert stereo EQ and a DRC. This produces a mastered mix of the given tracks. We incorporate a master bus in our console as it is usual to use a mastered song as a reference in workflows. Therefore, having a master bus in the mixing console chain allows for easier optimisation of the system. To enable gradient descent and training in a deep learning framework, we require the mixing console to be differentiable. To achieve this, we use differentiable effects from the `dasp-pytorch`². The pipeline of the DMC is presented in Figure 3.

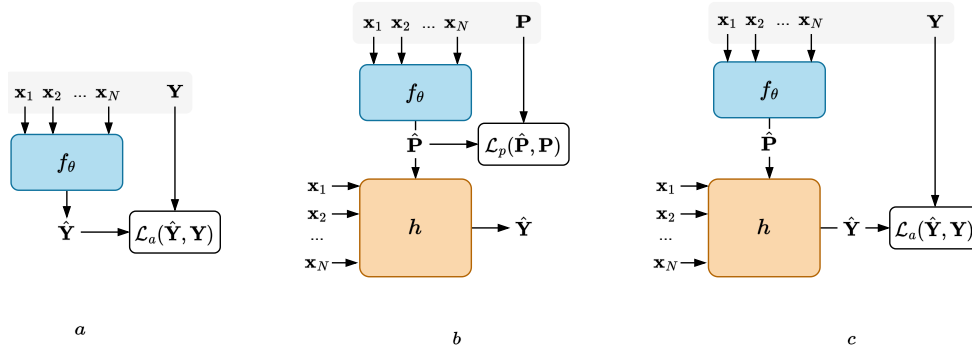

Figure 2. Formulations for deep learning-based automatic mixing systems [4]. (a) Direct transformation (b) Parameter estimation on parameter loss (c) Parameter estimation on audio loss. Here, x_i for $i \in [1, N]$ are the N input tracks, f_θ is the transformation, h is the dedicated mixing console, Y and \hat{Y} are the ground truth and predicted mix, P and \hat{P} are the ground truth and predicted control parameters and L_a and L_p are the audio and parameter loss respectively.

Figure 3. Differentiable Mixing console

2.4 Spectrogram Encoder

The encoder consists of a convolutional network based on the magnitude spectrum. It computes spectrograms by employing a short-time Fourier transform with a Hann window of size $N = 2048$ and a hop size of $H = 512$. The generated magnitude spectrogram is then processed through the convolutional layers. The resultant convolutional encodings are subsequently fed into a linear layer, producing a final embedding of size 512. The model includes separate shared-weight encoders: f_{θ_r} for the reference mix and f_{θ_t} for the input tracks. Each channel of stereo audio is treated as an individual track. Consequently, the stereo mix and any other stereo input tracks are loaded as separate tracks. Embeddings are computed by passing T and M_r through the encoder.

2.5 Transformer Controller

The controller features a transformer encoder and a shared-weight MLP. The transformer encoder generates style-aware embeddings using self-attention across the output of the spectrogram encoder f_{θ_r} and f_{θ_t} and a master bus embedding which is learned during training. The MLP predicts the control parameters corresponding to the channel strip for each track, and the master bus embeddings are

used to predict the master bus control parameters. A shared weight MLP is used to predict channel strip parameters for each channel. We generate the predicted mix M_p by passing the control parameters through the DMC along with the tracks. This architecture enables our system to be invariant to the number of input tracks as shown in Figure 1.

2.6 Audio Production Style Loss

The style of a mix can be broadly captured using features that describe its dynamics, spatialisation and spectral attributes [13]. We propose two different losses to train and optimise our models.

Audio Feature (AF) loss: This loss is composed of traditional Music Information Retrieval (MIR) audio feature transforms [19]. The T transforms include the root mean square (RMS) and crest factor (CF), stereo width (SW) and stereo imbalance (SI) and bark spectrum (BS) corresponding to the dynamics, spatialisation and spectral attributes respectively. We optimise our system by calculating the weighted average of the mean squared error on the audio features that minimises the distance between M_p and M_r . We compute the audio feature transforms T along with the weights w as follows:

$$T_1(\mathbf{x}) = \text{RMS}(\mathbf{x}) = \sqrt{\frac{1}{N} \sum_{i=1}^N x_i^2} \quad ; w_1 = 0.1 \quad (3)$$

$$T_2(\mathbf{x}) = \text{CF}(\mathbf{x}) = 20 \log_{10} \left(\frac{\max(|x_i|)}{\text{RMS}(\mathbf{x})} \right) \quad ; w_2 = 0.001 \quad (4)$$

$$T_3(\mathbf{x}) = \text{BS}(\mathbf{x}) = \log(\mathbf{FB} \cdot |\text{STFT}(\mathbf{x})| + \epsilon) \quad ; w_3 = 0.1 \quad (5)$$

$$T_4(\mathbf{x}) = \text{SW}(\mathbf{x}) = \frac{\frac{1}{N} \sum_{i=1}^N (x_{Li} - x_{Ri})^2}{\frac{1}{N} \sum_{i=1}^N (x_{Li} + x_{Ri})^2} \quad ; w_4 = 1.0 \quad (6)$$

$$T_5(\mathbf{x}) = \text{SI}(\mathbf{x}) = \frac{\frac{1}{N} \sum_{i=1}^N x_{Ri}^2 - \frac{1}{N} \sum_{i=1}^N x_{Li}^2}{\frac{1}{N} \sum_{i=1}^N x_{Ri}^2 + \frac{1}{N} \sum_{i=1}^N x_{Li}^2} \quad ; w_5 = 1.0 \quad (7)$$

where N represents the sequence length, x is the input tensor, \mathbf{FB} is the filterbank matrix, $\text{STFT}(x)$ represents the short-time Fourier transform of x , and ϵ is a small constant of value 10^{-8} added for numerical stability. x_{L_i} and x_{R_i} represent the input tensor corresponding to the left and right channels, respectively. The net loss is computed as follows:

$$\text{Loss}(\mathbf{M}_p, \mathbf{M}_r) = \frac{1}{2} \sum_{i=1}^2 \sum_{j=1}^5 w_j \cdot \text{MSE}(T_j(\mathbf{M}_{p_i}), T_j(\mathbf{M}_{r_i})) \quad (8)$$

where w_j is the weight associated with j^{th} transform T_j and MSE corresponds to mean squared error. The weights for the transforms were determined through empirical testing to balance the scale of various losses.

MRSTFT loss: The multi-resolution short-time Fourier transform loss [20, 21] is the sum of L_1 distance between STFT of ground truth and estimated waveforms measured in both log and linear domains at multiple resolutions, with window sizes $W \in [512, 2048, 8192]$ and hop sizes $H = W/2$. This is a full-reference metric meaning that the two input signals must contain the same content.

3. EXPERIMENT DESIGN

The task requires a dataset with multitrack audio, style reference, and the ground truth mix of the multitrack in the style of the reference for training. However, due to the lack of suitable datasets, we deploy a self-supervised training strategy to enable learning of the control of audio effects without labelled or paired training data. We achieve this by training our model under two different regimes which mainly vary in data generation and loss function.

Method 1: We extend the data generation technique used in [15] to a multitrack scenario as shown in Figure 4. We first randomly sample a $t = 10$ s segment from input tracks and generate a random mix of these input tracks by using random DMC parameters. We then split the segment of the randomly mixed audio and the input tracks into two halves, namely, M_{rA} and M_{rB} and T_A and T_B of $t/2$ s each, respectively. The model is input with T_B as input tracks and M_{rA} as the reference song. The predicted mix M_p is compared against M_{rB} as the ground truth for backpropagation and updating of weights. Using different sections of the same song for input tracks and reference song encourages the model to focus on the mixing style while being content-invariant. This method allows the use of MRSTFT loss for optimisation as we have the ground truth available. The predicted mix is loudness normalised to -16.0 dBFS before computing the loss.

Method 2: We sample a random number of input tracks between 4-16 for song A from a multitrack dataset and use a pre-mixed real-world mix of song B from a dataset consisting of full songs as the reference. We train the model using AF loss mentioned in Section 2.6 computed between M_p and M_r . This method also allows us to train the model

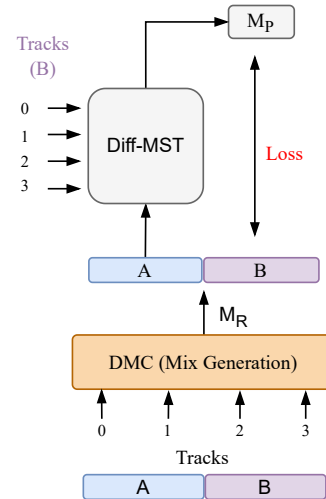

Figure 4. First training strategy from Section 3.

without the availability of a ground truth. Unlike Method 1, this approach exposes the system to training examples more similar to real-world scenarios where the input tracks and the reference song come from a different song. However, due to random sampling, some input track and reference song combinations may not be realistic.

3.1 Datasets

Multitrack: For both training methods, we utilise multitrack from MedleyDB [22, 23] and Cambridge.mt³ which contains a total of 196 and 535 songs respectively, sampled at $f_s = 44100$ Hz. For both datasets, we generate a train/test/validation split of 4:1:1. During training, songs are picked at random from the training split of both datasets. Thereafter, we randomly sample a section of the song as input tracks. We find a random offset for sampling multitrack by finding a section of the mix $x[i]$ that has mean energy above the threshold, $\frac{1}{N} \sum_{i=1}^N |x[i]|^2 \geq 0.001$. During training, each channel corresponding to a stereo raw track is treated as a separate mono track. We check the mean energy of each track to avoid loading silent tracks. All input tracks are loudness normalised to -48.0 dBFS.

Reference Songs: For Method 1 we generate a random mix using random parameters and input tracks as mentioned in Section 3 and loudness normalise the random mix to -16 dBFS. For Method 2, we use real-world songs from MTG-Jamendo which contains more than 55k songs in MP3 format [24]. We pick a random segment $y[i]$ of a random song from the dataset as a reference and check for mean energy above the threshold, $\frac{1}{N} \sum_{i=1}^N |xy[i]|^2 \geq 0.001$. We loudness normalise the reference to -16 dBFS and load stereo information on separate channels.

3.2 Training Details

Our model contains 190M trainable parameters, 76.5M corresponding to the track and mix encoder, and 37.9M

³<https://cambridge-mt.com/>

for the transformer controller. We train five variations of our model differing in the number of tracks, methodology and loss function used. To remedy the bottleneck of reading multitrack audio data from disk, we load data into RAM every epoch from both the training and validation sets respectively. The number of training steps per epoch is comprised of passing over these examples 20 times for training and 4 times for validation, sampling random examples at each step. This provides a tradeoff between training speed and data diversity. We train all our models with a batch size of 2 and a learning rate of 10^{-5} with the *Adam* optimiser. We accumulate gradients over 4 batches and use `pytorch` for training.

Diff-MST-MRSTFT: We generate data using the method 1 described in Section 3 and calculate MRSTFT loss for weight update and backpropagation. We train two variations of the model with a maximum of 8 tracks and 16 tracks as input, each for 1.16 M steps.

Diff-MST-MRSTFT+AF: We fine-tune both versions of the pre-trained Diff-MST-MRSTFT using the synthetically generated data of method 1 in Section 3 with AF loss described in Section 2.6 for 20k steps.

Diff-MST-AF: We follow the training strategy mentioned in method 2 of Section 3 and use real-world songs as the reference. We train this model for 1.16 M steps using the AF loss described in Section 2.6. We train with a varying number of tracks with an upper limit of 16.

3.3 Baselines

We compare the performance of our model against three baselines: an equal loudness mix (lowest anchor), the mix generated using the pre-trained mixing style transfer (MST) model by [16] (state-of-the-art), and two human mixes. We picked three songs from the Cambridge online multitrack repository belonging to the genres of electronic, pop, and metal for our main evaluation. Each of the songs contains between 12 and 22 input tracks. We selected references from popular songs.

Equal Loudness: We loudness normalise the tracks to -48.0 dBFS and take the mean among the tracks to generate the mix which is then normalised. This generates a loudness-normalised sum of input tracks. We consider this system to be the lowest anchor as it does not consider any style information or mixing transformations.

MST [16]: The method uses a pre-trained source separation model to generate stems from input and reference mix and perform stem-to-stem style transfer using a contrastive learning-based pre-trained audio effect encoder. The stems are mixed using a TCN-based model conditioned on style embeddings. Since the model performs a mix-to-mix transformation, we make use of the equal loudness mix of input tracks as the input to be transformed by the model. This allows us to extend the system to perform mixing

style transfer for any number of input tracks. This puts the system at a disadvantage as it is trained to work for mix-to-mix scenarios where good-quality mixes are used as input, leading to better-quality extracted stems.

Human Mixes: We asked two audio engineers with professional practice to mix the three songs using the corresponding references. Each of them mixed all three songs until the end of the first chorus.

4. OBJECTIVE EVALUATION

We evaluate the performance of our model against three baselines listed in Section 3.3. For the first evaluation, we compare the mixes generated by all five of our systems described in Section 3.2 and the baselines for three songs belonging to the genres of pop, electronic and metal. We manually picked the songs for the input tracks and the references for each of these cases. A 10-second section ranging between the middle of the first verse to the middle of the first chorus was used for evaluation in Table 1. We loudness normalise the reference mix to -16 dBFS and the predicted mix to -22 dBFS before predicting the metrics.

We report the average AF loss and individual weighted audio feature transforms from Section 2.6 for all three songs. Our Diff-MST system trained on real-world songs as reference using AF loss performs the best, closely followed by the MST [16], human engineer mix, and the mix from our Diff-MST-MRSTFT+AF-16 system.

For the second evaluation, we compute average metrics across 100 randomly sampled examples with multitrack taken from the unseen set of Cambridge multitrack and reference songs from MUSED18 [25]. We compare the performance of our systems and the baselines MST [16] and the equal loudness system as shown in Table 2. We report individual weighted audio features from the AF loss along with average loss and Fréchet Audio distance (FAD) [26]. The FAD metric is employed to gauge the efficacy of music enhancement approaches or models by comparing the statistical properties of embeddings generated by their output to those of embeddings generated from a substantial collection of clean music. In this context, we analyze the distributions of real-world songs against the mixes generated by various systems using the VGGish model. Again, Diff-MST-AF-16 outperforms other approaches at capturing the dynamics, spatialisation and spectral attributes of the reference songs.

5. DISCUSSION

Overall, the results indicate the effectiveness of our approach, architecture choice, custom audio production style loss, and novel training regime for the task. The reported metrics for both evaluations show improved performance when trained on a larger number of tracks. Furthermore, we also see that the systems trained or fine-tuned using AF loss generally perform better than those trained with MRSTFT loss, specifically in improving the spatialisation and dynamics of the mixes, thus showing the efficacy of

Method	RMS ↓	CF ↓	SW ↓	SI ↓	BS ↓	AF Loss ↓

our hand-crafted audio feature-based loss function. The significant difference in the Bark spectrum values between the equal loudness and our system’s mixes suggests that mixes generated using our system have undergone significant spectral processing, resulting in an increased spectral similarity between the reference song and the predicted mix. The metrics indicate inferior performance for the Diff-MST-MRSTFT-8/16 model compared to all our proposed models. This may be attributed to the training data, which is generated using random mixing console parameters, often resulting in mixes that sound unrealistic. However, fine-tuning with AF loss during the last steps notably enhances performance. This improvement could be attributed to AF loss compelling the model to enhance dynamics and spatialization, as evidenced by the reported metrics. We observe a notable enhancement in performance through training on real-world songs, underscoring the significance of high-quality real-world data. Although the system demonstrates promising outcomes, it is not without its limitations. While we note higher metric values for certain features on the human mixes, this can be explained by the fact that human engineers often strive to capture the overall essence of the reference song. However, they may also incorporate creative elements leading to spatialization and dynamics that diverge significantly from the reference. Our metrics serve to quantify the similarity between the reference song and the predicted mix, which is suitable for the task at hand but may fall short in assessing the creative or unconventional decisions made by human

engineers during the mixing process. Additionally, while FAD indicates the predicted audio quality, it might not capture the intricate nuances involved in the mixing process, such as frequency masking and achieving balance and spatialization.

Moreover, we noticed a decline in the system’s mixing capabilities as the number of input tracks increased beyond what it was trained on. Additionally, our mixing console lacks a crucial reverb module essential for comprehensive mixing tasks. Determining the optimal method for processing the entire song poses a challenge, as inferring over the entire song length may result in overly sparse embeddings. Our current system also falls short in modelling mixing context in all possible senses as discussed in [27]. However, we address this challenge by incorporating a reference input, typically selected by the mixing engineer or client. The reference song serves as a proxy for some of the contextual information that engineers typically rely on when making mixing decisions. Lastly, while real-world mixing often entails dynamic adjustments to effect parameters over the course of a song, our system is presently constrained to static mixing configurations.

6. CONCLUSION

In this work, we proposed a framework for mixing style transfer for multitrack music using a differentiable mixing console. Our system is rooted in strong inductive bias, taking inspiration from real-world mixing consoles and channel strips and predicts control parameters for these signal processing blocks allowing interpretability and controllability. Our system supports inputting any number of raw tracks, without source labelling. Furthermore, we circumvent possibilities for audio degradation and artifacts with our design choice for a parameter estimation-based system. Objective evaluations demonstrate that our Diff-MST-MRSTFT+AF-16 system surpasses all baseline methods. The reported metrics give us an insight into the impact of architectural and training design choices. We show that training on a larger number of input tracks improves the performance substantially while running inference on real-world examples that generally contain a larger number of input tracks. We also demonstrate the benefits of training on real-world quality audio examples. While our research has produced promising results based on objective metrics, it is important to acknowledge our evaluation’s constraints, as we have not conducted subjective assessments via listening tests. While objective metrics offer valuable insights into the model’s performance, integrating subjective evaluations would provide a more comprehensive understanding of its efficacy in practical applications. Future work includes conducting an extensive subjective evaluation alongside assessing the usability of a prototype of the system that is integrated into the real-world workflow in the digital audio workstation (DAW). Further, work towards developing a robust understanding and objective metrics for mix similarity and mixing style is imperative for enhancing these systems.

7. ACKNOWLEDGMENTS

We express our sincere gratitude to the ISMIR reviewers for providing valuable feedback on our work. Further, we extend our thanks to Steinberg’s research and development team for their unwavering support and honest feedback throughout this project.

This work is funded and supported by UK Research and Innovation [grant number EP/S022694/1] and Steinberg Media Technologies GmbH under the AI and Music Centre for Doctoral Training (AIM-CDT) at the Centre for Digital Music, Queen Mary University of London, London, UK.

8. ETHICAL STATEMENT

We utilized open-source multitrack data from MedleyDB [22, 23] and the web forum Cambridge.mt³ as well as full songs from MTG-Jamendo [24] to train our models. MedleyDB and MTG-Jamendo are available under the licenses CC-BY-NC-SA and Apache 2.0, respectively. Cambridge.mt is an educational web platform managed by Mike Senior, a professional mixing engineer, where artists and professional engineers consensually share audio files for multitracks and corresponding mixes. The terms and conditions permit educational and non-commercial research usage.

The design of our system integrates user-centric principles and has been built upon extensive qualitative research involving professional engineers [13]. Moreover, the design of this system is grounded in traditional mixing methods and expert knowledge, incorporating context and ensuring controllability and interpretability. In professional environments, our system can provide technical assistance for mixing, allowing more time for creative expression. Additionally, our system aims to make music mixing more accessible for beginners and non-specialists, promoting the democratisation of music production. The system can be used as a tool for learning basic mixing skills using the reference method. This system has the potential to support musicians and bands to create and distribute their music affordably, resulting in diverse representation within the music industry. However, there are potential drawbacks. Automated mixing systems might reduce the need for professional audio engineers in budget productions, impacting their job opportunities. Moreover, the widespread use of these tools may lead to homogenization in music production, resulting in algorithmically driven mixes overshadowing unique stylistic traits.

ABSTRACT

Despite the success of contrastive learning in Music Information Retrieval, the inherent ambiguity of contrastive self-supervision presents a challenge. Relying solely on augmentation chains and self-supervised positive sampling strategies can lead to a pretraining objective that does not capture key musical information for downstream tasks. We introduce semi-supervised contrastive learning (SemiSupCon), a simple method for leveraging musically informed labeled data (supervision signals) in the contrastive learning of musical representations. Our approach introduces musically relevant supervision signals into self-supervised contrastive learning by combining supervised and self-supervised contrastive objectives in a simpler framework than previous approaches. This framework improves downstream performance and robustness to audio corruptions on a range of downstream MIR tasks with moderate amounts of labeled data. Our approach enables shaping the learned similarity metric through the choice of labeled data that (1) infuses the representations with musical domain knowledge and (2) improves out-of-domain performance with minimal general downstream performance loss. We show strong transfer learning performance on musically related yet not trivially similar tasks - such as pitch and key estimation. Additionally, our approach shows performance improvement on automatic tagging over self-supervised approaches with only 5% of available labels included in pretraining.

1. INTRODUCTION

Self-supervised learning (SSL) has emerged as a powerful paradigm for learning structured representations of data without the need for costly and time-consuming labeling. SSL approaches have achieved competitive performance on downstream tasks with minimal labeled data in many domains [1–8]. In the field of Music Information Retrieval (MIR), the complexity of labeling for many

tasks - due to the high technicality and subjectivity - underscores the importance of such self-supervised methods [5,8–14]. Instance-discriminative SSL specifically, such as contrastive learning, has proven to be effective in learning meaningful representations for a multitude of downstream tasks [8,9,15]. However, major design choices such as positive mining strategies and augmentations are crucial to downstream performance [8,16–19], and selecting a strategy for a given task remains a challenge, prompting the reintroduction of supervision within the SSL framework. In MIR, the key notion of “similarity” in contrastive learning can derive from a variety of musical attributes. Guiding the model towards a musically informed similarity metric is an objective that may be achieved by leveraging supervised labeled data, i.e. *supervision signals*.

In this work, we propose a novel semi-supervised contrastive learning method, SemiSupCon. Our method leverages both unlabeled and labeled data for contrastive learning, an extension of Contrastive Learning of Musical Representations (CLMR) in the music domain [8] and SupCon [20] in Computer Vision. Our approach differs from previous attempts at combining self-supervised contrastive learning with an auxiliary supervision signal in that it is the first to our knowledge to implement a fully-contrastive semi-supervised learning pipeline. The simple machinery of this method allows for leveraging new supervision signals beyond labels within the contrastive objective.

Briefly, the contributions of this work are the following: (1) We propose an architecturally simple extension of self-supervised and supervised contrastive learning to the semi-supervised case with the ability to make use of a variety of supervision signals. (2) We show the ability of our method to shape the representations according to the support supervision signal used for the learning task with minimal performance loss on other tasks. (3) We propose a representation learning framework with low-data regime potential and higher robustness to data corruption. Our implementation and experiments are made publicly available at <https://github.com/Pliploop/SemiSupCon>

2. RELATED WORK

Self-supervised learning aims to learn representations that capture the semantic structure of data without labels in order to utilize these representations on downstream tasks. Among self-supervised learning approaches, Contrastive

Learning teaches a model to identify augmented samples originating from the same data point amongst distractor negative samples [1, 8]. Beyond its success in neighboring fields, MIR and audio representation learning have largely benefited from Contrastive Learning approaches [2, 8, 9, 21–23]. From the implementation of CLMR, several works have expanded on contrastive learning for music, with competitive results on many downstream tasks and in multiple modalities [9, 10, 13, 24, 25]. One of the key challenges of contrastive learning is establishing an effective positive mining strategy to select positive and negative samples [16–18]. Previous studies show that both the positive mining strategy and the augmentation chain are crucial toward the performance on a given downstream task [16–19] - an inappropriate sampling strategy can lead to treating similar samples as negatives, to the detriment of downstream performance [26–28]. In MIR specifically, even the temporal proximity of two positive segments within an audio clip is influential on downstream performance depending on the task, as shown in [18]. Previous works have attempted to design domain-appropriate strategies for music and audio contrastive learning, including auxiliary similarity metrics [24, 29–31], weak supervision [15, 32–34], as well as music-specific preprocessing and augmentations [8, 10, 25].

Self-supervision is inherently limited by the ability of the positive mining strategy to select semantically relevant positives. Some approaches have attempted to reintroduce supervision signals for positive mining within the contrastive objective to reduce noise induced by self-supervised pseudolabels. SupCon [20] introduces supervised contrastive learning, which uses class labels to mine positives. Other approaches have extended contrastive learning to the semi-supervised regime by leveraging both labeled and unlabeled data. However, these approaches often use complex machinery, such as auxiliary classification modules or multiple losses [29, 35–37], making them inflexible and difficult to balance with regard to the supervision signal. Recently, in MIR, Akama *et. al* [29] employ contrastive learning as an auxiliary loss for automatic tagging, with improved results over supervision alone.

3. METHODS

3.1 Self-Supervised contrastive learning

In the SSL setting for contrastive learning [1, 8], each sample in a N -sample batch is augmented into two views through a stochastic augmentation chain. Let B be a batch of these augmented views x_i . Indices $i \in I = \{1, 2, \dots, 2N\}$ represent the index of a data point in the batch (anchor). $p(i)$ is the index of the augmented data point originating from the same original sample as the anchor (positive sample). $N(i)$ is the set of negatives: data points in the augmented batch excluding the anchor and positives: $N(i) = I \setminus \{i, p(i)\}$. Let z_i be the embedded representation of the data point by an encoder $E : x \mapsto E(x) \in \mathbb{R}^{d_E}$ and a projection head $g : E(x) \mapsto g(E(x)) = z_i \in \mathbb{R}^{d_g}$ into the contrastive latent space. In the SSL setting, the objective function for the contrastive method is the nor-

malised temperature-scaled cross-entropy loss [1] between samples i and $p(i)$ for all pairs in the batch:

$$\mathcal{L}_{ssl}^i = -\log \frac{\exp(\text{sim}(z_i, z_{p(i)})/\tau)}{\sum_{n \in N(i) \cup \{p(i)\}} \exp(\text{sim}(z_i, z_n)/\tau)} \quad (1)$$

Where τ is a temperature hyperparameter, sim is a similarity function - usually, cosine similarity [1, 8]. For the sake of brevity we notate $\sigma_{i,j} = \exp(\text{sim}(z_i, z_j)/\tau)$ in the rest of this work.

3.2 Supervised contrastive learning

In the supervised setting [20], the set of *supervised* positives $P_s(i)$ are now defined by the label information in the set of labels y_i : $P_s(i) = \{p \in I | y_p = y_i\} \setminus i$. As in [20], the supervised contrastive loss objective is given by:

$$\mathcal{L}_{sl}^i = \frac{-1}{|P_s(i)|} \sum_{p \in P_s(i)} \log \frac{\sigma_{i,p}}{\sum_{n \in N(i) \cup P_s(i)} \sigma_{i,n}} \quad (2)$$

The contrastive matrix \mathbf{M} is constructed by leveraging class information obtained by mining the labels, i.e. if two samples x_i and x_j are in the same category then $\mathbf{M}_{i,j} = 1$.

3.3 Semi-supervised Contrastive Learning

Let \mathcal{U} be a set of unlabeled samples, and \mathcal{S}^* be a set of labeled samples. We sample a proportion p_s of the labeled dataset for training such that $|\mathcal{S}| = p_s |\mathcal{S}^*|$. Let $\mathcal{A} = \mathcal{U} \cup \mathcal{S}$ be the set of all data points seen during training. During training, we use both labeled and unlabeled data points by sampling batches B comprised of proportions b_s (resp. $1 - b_s$) of labeled (resp. unlabeled) samples. $P_s(i) = \emptyset$ if i is the index of an unlabeled data point. We now define our semi-supervised contrastive loss, with $P_A(i) = P_s(i) \cup P_u(i)$, where $P_u(i)$ is the set of self-supervised positives ($\{p(i)\}$ in Eq. 1):

$$\mathcal{L}_{sem}^i = \frac{-1}{|P_A(i)|} \sum_{p \in P_A(i)} \log \left(\frac{\sigma_{i,p}}{\sum_{n \in N(i) \cup P_A(i)} \sigma_{i,n}} \right) \quad (3)$$

With the inclusion of both sets of positives, we generalize to both labeled and unlabeled data in our representation learning task: Note that if $\mathcal{U} = \emptyset$ or $\mathcal{S} = \emptyset$, the semi-supervised contrastive loss reverts back to the fully-supervised loss or the fully self-supervised loss (as $P_s(i) = \emptyset$) respectively. The approach is shown Figure 1.

This approach differs from simply adding the supervised and self-supervised contrastive losses together, as our objective maintains the number of samples to discriminate against in the self-supervised setting by leveraging labeled data as negatives for the self-supervised samples.

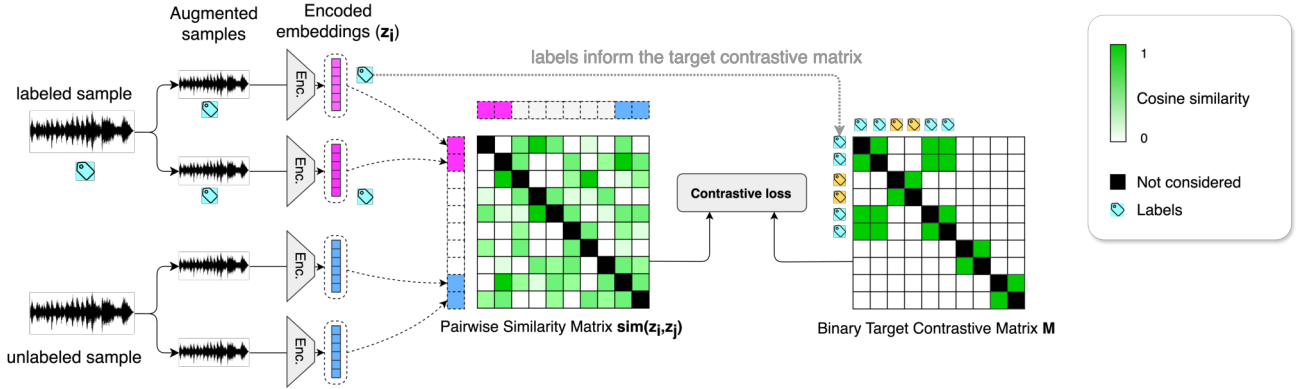

Figure 1: Semi-Supervised Contrastive Learning. The sparsely labeled dataset contains a mix of unlabeled data and labeled data. Given a batch, available labels (blue and yellow tags) are used to augment \mathbf{M} . Unlabeled samples degenerate back to the self-supervised case. Loss is computed between the pairwise similarity matrix from the encoded embeddings and the target matrix using Equation 3

3.3.1 Extension to other supervision signals

The range of supervision signals this method can leverage are limited only by the ability to construct the target contrastive matrix. In this, SemiSupCon can make use of support data beyond single label multiclass tasks. To demonstrate this, we devise two strategies for training on MagnaTagATune [38], which are studied in Section 5.4. For a multi-label signal, if $C \in \mathbb{N}$ labels coincide between two samples, we set the corresponding index in the target contrastive matrix $\mathbf{M}_{i,j} = 1$. The criterion C is a hyperparameter which is studied in Section 5.4. By default we use $C = 1$, i.e., if any labels coincide between two samples they are considered as positives.

Further, we can construct a target continuous similarity metric factor $\alpha_{i,j}$ which denotes the degree of “semantic similarity” between the samples by weighing the common classes by the total number of labels:

$$\alpha_{i,j} = \frac{2C_{i,j}}{(C_i + C_j)}$$

$C_{i,j}$ is the number of common classes for x_i and x_j , C_i and C_j are the number of classes of x_i and x_j . The similarity term $\sigma_{i,j}$ is then weighted by $\alpha_{i,j}$ in Eq. 3.

4. EXPERIMENTS AND RESULTS

4.1 Datasets

For our experiments, we use The Free Music Archive (FMA) dataset [39] as a self-supervised dataset, i.e., we do not use its labels. To match the scale of the supervised datasets, we elect to use the *medium* subset, containing 25000 clips of 30 seconds of audio.

We utilize several labeled datasets as support labeled data for training and for evaluation to demonstrate the cross-domain usefulness of SemiSupCon. For automatic tagging and most of our experiments, we use MagnaTagATune (MTAT) [38] as labeled data as a proxy evaluation of general music understanding. We reproduce the canonical 12:3:1 train-test-validation splits [8]. We use MTG-Jamendo (all subsets, including the top 50 tags,

genre, mood/theme, and instrument) [40] as another tagging dataset. We use NSynth [41] for pitch and instrument classification of short snippets, and MedleyDB [42, 43] for instrument classification with longer audio clips than NSynth. We use Giantsteps [44] as a key classification dataset - as in [45], we use the original dataset as our training set and the MTG-Giantsteps dataset as our test set. For genre classification, we use the fault-filtered GTZAN dataset [46, 47]. We use the VocalSet dataset [48] for two additional tasks: singer identification and technique classification. Finally, we regress Arousal (A) and Valence (V) on EmoMusic [49] as a downstream evaluation task only, with the same train-test split as [45].

4.2 Model input, augmentation chain

As in [8, 9], we crop 2.7 second segments of mono 22050kHz audio as input to the encoders, SampleCNN [50] or TUNE+ [9]. We sample and augment 2 adjacent non-overlapping segments as positives. The dimensions of the encoders and the 2-layer ReLU-nonlinear projection head are $d_E = 512$ and $d_g = 128$. We implement a stochastic augmentation chain similar to CLMR [8], TUNE [9], and [10]. In order, we apply (Table 1):

Augmentation	probability	parameter	Min/Max	unit
Gain	0.4	Gain	-15 [‡] / 5 [‡]	dB
Polarity inv.	0.6	-	-	-
Colored Noise	0.6	Signal/noise ratio	3 [‡] / 30 [‡]	dB

Table 2: Performance on automatic tagging. Results denoted by \dagger are reported in their original paper. In our experiment, we constrain $p_s = b_s$ except for one run where $p_s = 1, b_s = 0.5$. We trained our own end-to-end supervised SampleCNN with the same compute budget as SemiSupCon and report results with *.

4.3 Training and evaluation details

For our baseline models, we adopt a training setup similar to TUNe [9] and CLMR [8]. Models are trained for 200k steps on semi-supervised batches sampled from MagnaTagATune as labeled data and FMA-Medium as unlabeled data [38,39] using the Pytorch Adam optimiser with a learning rate of $1e^{-4}$. For ablation and variation studies, we train our models for 50k steps unless otherwise stated. All models are trained with $\tau = 0.1$ with a non-augmented batch size of 96 on a single RTX A5000 GPU unless otherwise specified. We report steps instead of epochs to standardise the amount of data seen during training.

To evaluate pretrained models, we freeze the encoder and discard the projection head. Frozen representations are fed into a 2-layer ReLU-nonlinear MLP for probing on downstream tasks. For probing, we use the Adam optimizer with a learning rate 0.0003 and an early stopping mechanism conditioned on validation loss. For automatic tagging tasks, we report area under receiver-operator curve (AUROC) and mean Average Precision (AP). For classification tasks, we report top-1 accuracy except for key classification: the metric for this task is a weighted score taking into account reasonable errors [45] - We use the `mir_eval` [51] implementation for evaluation. For emotion regression we report R^2 values between predicted and actual values.

5. RESULTS

5.1 Automatic tagging with semi-supervised contrastive learning

We train a self-supervised baseline, a supervised contrastive baseline with and without augmentations, an end-to-end supervised baseline using the sampleCNN architecture, and five variants of our semi-supervised approach with different proportions of labeled data ($p_s \in [0.01, 0.05, 0.1, 0.2, 0.5]$) for Automatic Tagging on MTAT. MTAT labels augment the contrastive matrix \mathbf{M}

Figure 2: Evolution of AUROC and AP on MTAT probing with proportion of supervised MTAT data used for training.

with positives in the case of supervised or semi-supervised pretraining. We vary the in-batch and global proportion of supervised data b_s and p_s simultaneously. We report results on the same task in the literature in Table 2 for comparable datasets and training scales.

When trained for 200k steps, the supervised contrastive model is competitive with larger self-supervised approaches. Furthermore, it outperforms both our implementation and the results claimed in CLMR for self-supervised contrastive and end-to-end supervised models. Figure 2 shows the influence of $p_s = b_s$ on AUROC and AP. As the proportion of supervised data increases, so does the performance on the downstream evaluation. Including only 5% of labeled data leads to an increase in performance from 88.8 to 89.4 in AUROC. For our experiment with $p_s = 1$ and $b_s = 0.5$, both architectures perform worse than $p_s = b_s = 0.75$, as the model has seen 100k steps of supervised data versus 150k.

5.2 Influence of pretraining labeled dataset

In this experiment, we pre-train multiple semi-supervised models using datasets described in Section 4.1 as support labeled data and FMA as unlabeled data - one model per dataset, each for 50000 steps. We then freeze all models and train shallow MLP probes on all downstream tasks for each model. We train a self-supervised baseline for comparison. Semi-supervised approaches are trained with $b_s = 0.5$ and $p_s = 1$. Table 3 shows these results.

Semi-supervised training on the target dataset always surpasses the self-supervised baseline by a significant mar-

Table 3: Results for cross-task evaluation. Models are trained for 50k steps on FMA [39] as the self-supervised dataset and support supervised datasets (rows), and evaluated on target datasets (columns). Giantsteps[†], NSynth[†] are trained without pitch shifting augmentation. Results in bold are the best results obtained for evaluation on a target dataset. SOTA results are included for illustration purposes, but do not necessarily leverage comparable methodologies.

gin when evaluating on the same dataset - with minimal loss of performance on other downstream tasks.

Some complementary tasks improve performance on other downstream datasets, proving semi-supervised contrastive learning a viable transfer learning strategy. Expectedly, training on genre tagging data increases out-of-domain performance on genre classification, instrument tagging on instrument classification, etc. Training on mood data from MTG-Jamendo provides a performance boost on emotion regression. A notable example is the improvement in performance on NSynth pitch when training with key data as support labeled data and *vice versa*. This demonstrates an improvement in the understanding of *pitch* by the model on tasks which are musically related but not trivial transfer learning instances. Most importantly, this occurs without performance loss on general music understanding, *i.e.* automatic tagging. Other musically grounded examples are pitch pretraining improving instrument classification performance and instrument pretraining improving emotion regression performance.

5.3 Robustness to in-domain data corruption

In this section, we evaluate the robustness of our semi-supervised, supervised, and self-supervised contrastive approaches to audio corruptions compared to the end-to-end baseline. We train the probing head without augmentation until convergence and evaluate the model *with* augmentations applied. We design different severity degrees of our augmentation chain (See Subsection 4.2) by applying a modifier to the application probabilities: for severity $s \in [0, 1...4]$, we scale probabilities of application of each augmentation by $s/2$ such that $s = 2$ is the chain applied during training. We sensibly multiply or divide the min and max values of each augmentation hyperparameter (see Table 1) by $s/2$. We then evaluate all models with these augmentation chains on MagnaTagATune. The results are

Figure 3: Effect of corruption severity on downstream performance. Contrastive models are more robust than Cross-entropy trained models.

shown in Figure 3. Contrastive approaches are more robust to in-domain corruption than end-to-end approaches - hypothetically because we train contrastive models to be invariant to such transformations through the augmentation chain - which is not an objective of the end-to-end supervised approach.

5.4 Multilabel positive mining strategy

In this experiment, we test multiple label-based positive mining strategies. First by varying the number of common labels for mining positives - *i.e.* $C \in \{1, 2, 4, 6\}$. Further, we explore the “semantic weighing” strategy described in Section 3.3.1, in which the target similarity between two tracks is weighed by the number of common labels and the total number of labels. We test these strategies on both semi-supervised and supervised contrastive models. Results are reported in Table 4.

For supervised approaches, the continuous target produced by semantic weighing produces the best results, on par with 4x training steps with a criterion $C = 1$ (as shown in Table 2). In the supervised case, as the criterion in-

Positive strategy Class criterion	Supervised		Semi-Supervised	
	AUROC	AP	AUROC	AP
$C = 1$	90.1	44.2	89.3	41.3
$C = 2$	90.1	43.9	89.0	41.6
$C = 4$	89.3	42.8	89.0	41.3
$C = 6$	88.9	42.3	89.0	41.5
Weighing	90.6	45.3	88.9	41.6

Table 4: Multilabel positive mining strategy as described in Section 3.3.1.

creases, performance deteriorates. We hypothesise that this could be because it is an *easier* task for the model to discern that two tracks with many common tags are similar (higher C), as they likely share many attributes, therefore providing a weaker training signal. Understanding what links two tracks from a single tag is more challenging and appears to yield more robust representations. The continuous “relative similarity” target created by the weighing strategy is a more nuanced task and appears to be a stronger supervision signal. This guides the model towards more robust representations, which explains the higher performance. In the semi-supervised case, we speculate that the binary self-supervision signal overpowers the continuous target as a less nuanced objective with harsher penalties for failure. These penalties could overpower softer penalties from the continuous target in the loss, preventing optimal convergence. Future work should focus on understanding and reconciling these aspects of the semi-supervised approach to leverage other continuous signals.

5.5 Qualitative analysis

The results reported in Section 5.2 show that performance on downstream tasks improves when labels from a related task are used for model training, with minimal loss of performance on other tasks. We hypothesise that the internal latent representations are given structure relative to the supervision signal while maintaining the semantic structure given by the self-supervision signal. To illustrate this, we perform t-SNE dimension reduction on embeddings produced by the semi-supervised model from Table 3 trained with NSynth (Figure 4a) as support labeled data and fully self-supervised (Figure 4b) evaluated on the test set of NSynth-pitch.

In the set of Figures 4, the latent spaces for the NSynth test set produced by these two models are shown. When pretrained on NSynth-pitch, the latent space is highly organized. Separability by class is much clearer than when pretrained on FMA. We notice that several musical structures emerge in this latent space. Notably, octaves go from low to high clockwise. Pitches that are “similar” are close together, i.e., semitones and octaves of the same pitch class.

6. CONCLUSION AND FUTURE WORK

We presented SemiSupCon, a simple method for leveraging both supervision and self-supervision signals in contrastive representation learning. By leveraging reduced amounts of labeled data during pretraining, SemiSupCon outperforms end-to-end comparable supervised baselines

(a) Latent embeddings of the NSynth-pitch test set from a semi-supervised model trained on FMA+NSynth-pitch

(b) Latent embeddings of the NSynth-pitch test set from a self-supervised model trained on FMA

Figure 4: Exploration of the NSynth pitch latent space. Octaves are denoted by size and pitch class by the color of the dot. Each dot is a full audio sample

on downstream tasks. We find that SemiSupCon is more robust to data corruption at inference compared to end-to-end supervised methods. Additionally, SemiSupCon can utilize various supervision signals with minimal performance loss on out-of-domain tasks and achieve performance transfer on similar tasks. While performance gains might seem moderate on automatic tagging for instance, other downstream tasks show more distinct improvements. Furthermore, the contrastive objective can lead to explicitly structured latent spaces with emergent musical structures - enhancing the musical interpretability of latent spaces by design of the support supervision signal - i.e. labeling small amounts of data.

Future work will focus on exploring additional supervision signals and tasks such as perceptual metrics, tempo estimation, and chord estimation. Other avenues include leveraging the low-data proficiency of SemiSupCon for human-in-the-loop representation learning. The architecture of SemiSupCon being very flexible, it can be further adapted to multimodal approaches or hierarchical representation learning. A more comprehensive exploration of the influence of the proportion of labeled data and the exact effect of labels and contrastive matrix sparsity on downstream performance will also be undertaken.

7. ACKNOWLEDGMENT

ABSTRACT

Deep learning models have become a critical tool for analysis and classification of musical data. These models operate either on the audio signal, *e.g.* waveform or spectrogram, or on a symbolic representation, such as MIDI. In the latter, musical information is often reduced to basic features, *i.e.* durations, pitches and velocities. Most existing works then rely on generic tokenization strategies from classical natural language processing, or matrix representations, *e.g.* piano roll. In this work, we evaluate how enriched representations of symbolic data can impact deep models, *i.e.* Transformers and RNN, for music style classification. In particular, we examine representations that explicitly incorporate musical information *implicitly* present in MIDI-like encodings, such as rhythmic organization, and show that they outperform generic tokenization strategies. We introduce a new tree-based representation of MIDI data built upon a context-free musical grammar. We show that this grammar representation accurately encodes high-level rhythmic information and outperforms existing encodings on the GrooveMIDI Dataset for drumming style classification, while being more compact and parameter-efficient.

1. INTRODUCTION

In the last few years, machine learning (ML) has significantly changed how the Music Information Retrieval (MIR) community deals with tasks such as style and composer classification, music generation, pitch and rhythm detection, etc. Yet, training deep learning models on music raises the question of the representation of this data. Depending on the input format (audio, MIDI, musical score. . .), different representations, *i.e.* different *encodings*, are possible. Each encoding has advantages and drawbacks: some representations, *e.g.* waveforms, focus on raw low-level acoustic features, while others, *e.g.* sheet music, encode high-level abstract semantics of the musical language.

While deep neural networks had great success on audio signal, *i.e.* waveforms and spectrograms, machine learning

for symbolic MIDI remains understudied. In this work, we seek to build effective representations of symbolic music, with a focus on recorded MIDI performances. Multiple possible representations of MIDI music coexist in the literature. Most of them contains only low-level information, such as the timing of the onset and the offset of each note and their velocity. This is due to practical constraints: typical MIDI recordings usually do not contain any information about tonality, tempo, time-signature or rhythm. Hence, a model trained on such MIDI samples typically needs to allocate a part of its weights to extract these relevant high-level features from the data. Building better representations of MIDI data to encode semantic musical information could therefore be beneficial to the training of deep models and their efficiency, as they could directly focus on using these features rather than extracting them from the data first.

Music classification has been a task of choice for MIDI performances. Preliminary works from [1] in 2007 encoded MIDI as strings and used Kolmogorov complexity to compare music pieces. [2] introduced jSymbolic, a library to extract high level features from MIDI files, such as pitch histograms, a line of work extended by `music21` [3] and `musif` [4]. As new MIDI datasets have been introduced for composer [5] and style classification [6], efforts have been made to evaluate how MIDI representations affect deep models. [7] introduced MidiTok, a tokenization framework to encode MIDI files as a sequence of tokens, suitable for Transformers and Recurrent Neural Networks (RNN). More recently, [8] compared different neural architectures for various MIDI encodings: Convolutional Neural Networks (CNN) trained on Piano rolls, Transformers trained on sequences of tokens, and Graph Neural Networks (GNN) trained on graphs extracted from MIDI files.

In this line of work, we aim to design a representation of MIDI files that is both efficient and discriminative for classification tasks, by incorporating high level musical information directly in the preprocessing. To do so, we explore a new representation based on the *rhythmic tree* structure, built from a context-free grammar tailored to symbolic music. We show that this representation outperforms existing encodings, such as tokenizations or piano rolls, on a drumming style classification built upon the GrooveMIDI Dataset [6]. In addition, our rhythmic tree-based encoding results in smaller deep models, with less parameters, able to be trained on less data compared to existing representations.

2. BACKGROUND

2.1 MIDI Representations

MIDI is a lightweight musical information exchange format. It does not carry audio data, but only timestamped events, *e.g.* a note being played, featuring its pitch and velocity, a note being released, a pedal change, etc. It is suitable for recording as it captures the performer’s expressiveness, but does not require metadata that are found in a score, such as tempo, time-signature¹, tonality and voices [9]. We discuss below the most common MIDI representations for ML.

2.1.1 Piano Roll

The piano roll is a visual representation of MIDI files inspired by the analog rolls for piano players. It consists in a 2D matrix with one dimension for pitches, and one for time. A note at pitch p with a NOTE_ON event at x_{on} and NOTE_OFF event at x_{off} is given a positive value at positions $(x, p)_{x \in [x_{on}, x_{off}]}$, as shown in Figure 1b. Often, the value in a matrix cell is one of the properties of the MIDI event, *e.g.* the velocity. This representation is popular, as its 2D structure allows to easily adapt deep models inspired by image processing (*e.g.* CNN) to music tasks [10–12]. However, it can result in large sparse matrices with many zeros, since the time dimension must be discretized with a time step smaller than the shortest MIDI event. In addition, piano rolls tend to be very long and redundant, since many successive vectors will be identical.

¹ MIDI recordings can contain tempo and time-signature, but only through manual addition *a posteriori*.

2.1.2 Sequence of Tokens or Notes

Similar to Natural Language Processing (NLP) techniques, recent works have adopted sequence-like representations, especially suitable for RNN and Transformers architectures. They encode MIDI files as sequences of events. These events are in turn transformed into *tokens*, *i.e.* discrete values from a vocabulary V . Many tokenizations exist, some consisting in a simple token/event mapping with MIDI files (MIDI-Like [13, 14], see Figure 1c), while others include note durations (Structured [15], TSD [16]). More sophisticated tokenizers include higher level information about bar and position in the bar, such as REMI [17].

Finally, MIDI files can be represented as “note tuples”, *i.e.* sequences of notes with attributes. For example, [18] represents each note by a set of four values: pitch, velocity, duration and time-shift compared to the previous note (cf. Figure 1d). This representation is much more compact than piano rolls or sequence of tokens.

2.2 Formal Grammar

This work designs a symbolic music representation for deep networks based on a grammar-based rhythmic tree. As a starting point, a formal grammar defines the syntax of a language L . It consists in a set of symbols, associated with production rules used to rewrite non-terminal symbols into other (non-)terminal symbols. Applied successively, those rules can produce every possible sentence of L .

2.2.1 Context-Free Grammar

Succinctly, a context-free grammar [19] is a type of formal grammar for which the production rules do not depend on other context than the left-hand-side symbol. It is defined as a 4-tuple $G = (V, \Sigma, R, S)$. V is a finite set of non-terminal symbols, including the special *start symbol* S . Σ is a finite set of terminal symbols, called the alphabet. Finally, R is a finite set of production rules of the form $a \rightarrow b$, where $(a, b) \in V \times (V \cup \Sigma)^*$ in which $*$ denotes the Kleene star operator, *i.e.* a pattern repeated of 0, 1 or more times.

The application of a sequence of rules can be represented as a tree, in which the parent node is represented by the left-hand-side of each rule, and the child nodes are the symbols on the right-hand-side. Once every non-terminal symbol has been resolved into a terminal symbol, we obtain a *parse tree* representing the structure of a sentence of L according to G , with elements of Σ as leaves, and S as root.

2.2.2 Musical Grammar

In a homophonic musical score (monophonic voice that can include chords [20]), rhythm can be represented as a tree [21, 22]. For example, in a 4/4 music piece, a measure could be split into two half notes. Then, each half note can be further divided into two quarter notes, or into a triplet of quarter notes, etc. The `qparse` library [23] is a MIDI-to-score transcription framework that produces a sheet music by parsing a MIDI file with a weighted context-free grammar and dynamic programming, with applications *e.g.* to automatic drum transcription [24]. While designed for a handcrafted music transcription algorithm, the intermediate

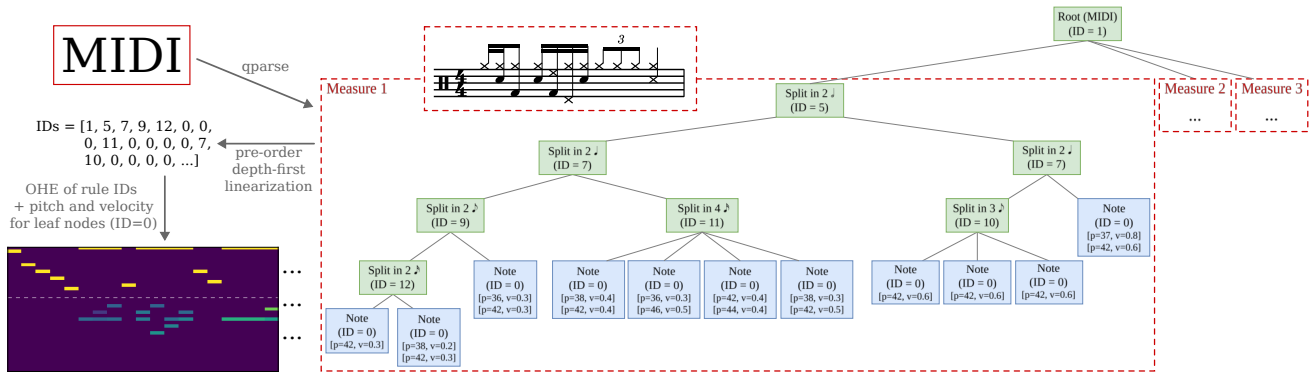

Figure 2: Example of tree built by `qparse` after rules simplification and re-rooting of measures (right), with its associated linearization and vector representation (left). In the matrix, the part above the dashed line contains the one-hot encoded rules (blue/yellow for 0/1), and the one below contains the playing instruments for terminal nodes (color representing velocity).

parsing tree computed by `qparse` contains rich rhythmic information that is also valuable as an input to deep models. Note that, while we our work uses `qparse` to obtain rhythmic trees, our contribution lies in evaluating this tree representation of music, regardless of its construction. We expect our representation to generalize to other parsers.

3. METHODOLOGY

3.1 Linearized Rhythmic Tree

To build our high-level MIDI representation, we linearize a rhythmic tree obtained using a context-free grammar, enriched by information about pitch and velocity in leaves. We call this representation Linearized Rhythmic Tree (LRT). To achieve this goal, we leverage the transcription framework `qparse` [23] to extract its internal intermediate rhythmic tree representation. Note that we only consider homophonic inputs since this is what `qparse` MIDI grammar supports. `qparse` needs the time-signature and the tempo of the track (because measures are parsed separately), as well as the specification of a weighted grammar. We use a rhythm-oriented grammar similar to [24], detailed in appendix.

As described in [25], the root of the intermediate rhythmic tree is the first measure. Its left child is a tree describing its beat decomposition, and its right child is a node pointing at the root of the next measure. We rewrite this tree so that all measures are children of the same global root. A n -measures-long track will therefore have a root with n children. This rewriting allows us to reduce the maximum depth of the rhythmic tree, which would otherwise grow linearly with n . The resulting tree is shown on the right of Figure 2. In this tree, each node is labeled by the identifier of the associated production rule in the grammar.² Each leaf is a terminal symbol, labeled by the note and properties from the associated MIDI events, *i.e.* pitch³ and velocity. Note that multiple instruments can be playing at the same time, so a leaf can be associated to several events.

As an example, in Figure 2, the first bar (red frame) is split in two sections, each of half note length (rule 5). Then,

² See the ruleset with IDs in Section 2 of the supplementary material.

³ In the case of drums, the “pitch” corresponds to the drum used, *e.g.* cymbal, snare, tom, etc.

the first half gets split into two quarter-length sections (rule 7). The second child of this node, a quarter note, is split into four sixteenth notes (rule 11). Finally, each of those sixteenth notes leads to a terminal symbol (rule 0), with MIDI events attached to it, *e.g.*, the second child has two `NOTE_ON` events, respectively with pitch 36 and velocity 0.3, and with pitch 46 and velocity 0.5.

As we cannot directly feed the tree structure to the models, we first linearize it using a pre-order depth-first traversal: we start from root, and traverse the nodes recursively following the left-most child, only going back up when the current branch has been fully traversed. This produces a sequence of nodes containing the identifier of their rule in the grammar, as well as, in the case of leaves, the list of playing instruments and their velocity. We encode every node into a $d = (m + n)$ -dimensional vector. m is the number of rules in the grammar, and the first part of the vector is the one-hot-encoded identifier of the production rule associated with the node. n is the number of possible instruments, and the second part of the vector contains the normalized velocity for each instrument. If an instrument is not playing for this note, its velocity is set to zero. For non-terminal rules, this second part is entirely zero. This linearization results in the matrix on the left of Figure 2, *i.e.* a sequence $S = \{s\}_{t \in [1, T]}$ where $s_t \in \mathbb{R}^d$ is the vector associated to a node, and T is the total number of nodes. Therefore, our linearized rhythmic tree results in a multi-dimensional sequence S , that can be fed in all usual deep models such as RNN and Transformers.

Note that this representation is significantly shorter than tokenizations or piano rolls. In average, the sequences are only around 18% longer than note tuples, while containing much more information about the rhythm structure.

3.2 Tree-based Positional Encoding for Transformers

While RNN can model the position in the sequence through their hidden state, Transformers process sequences as a bag of words, without any positional information. To overcome this issue, positional encoding [26] was introduced to incorporate information about the position of an element in the Transformer model.

Classical positional encoding [26] creates a vector PE of dimension d using sine and cosine functions of increasing frequencies:

$$\omega_{pos,i} = \frac{pos}{\tau \left(\frac{2^i}{d}\right)}, \quad \text{PE}(pos, 2i) = \sin(\omega_{pos,i}) \quad (1)$$

$$\text{PE}(pos, 2i+1) = \cos(\omega_{pos,i})$$

where pos is the position of the element in the sequence, d the size of the embedding, $i \in \llbracket 1, d/2 \rrbracket$ the dimension, and $\tau = 10000$ as in [26].

3.2.1 Continuous Positional Encoding

For musical data, this positional encoding is not related to the temporal organization of the notes. Depending on how the sequence S was built, the position pos of an element can be arbitrary, such as *e.g.* tokenizations where a note is split into several tokens for pitch, velocity and duration, or note tuples where two simultaneous notes can be interchanged. For encoding note tuples, we therefore introduce a continuous positional encoding that replaces the position in the sequence by the timestamp of the note in the track:

$$\omega_{t,i} = \frac{2\pi}{T_S} \cdot \frac{t}{(T_L/T_S)^{\frac{2^i}{d}}}, \quad \text{PE}(t, 2i) = \sin(\omega_{t,i}) \quad (2)$$

$$\text{PE}(t, 2i+1) = \cos(\omega_{t,i})$$

where t is the absolute starting time of the note in seconds and T_S and T_L are respectively the smallest and largest periods of the sine functions. This encoding allows two simultaneous notes to share the same positional encoding.

3.2.2 Tree-based Positional Encoding

A downside of linearizing the rhythmic tree is that we lose the explicit hierarchical structure between a parent node and its children. The structure is still implicitly encoded in the linearized sequence S in the rule identifiers, but the model would have to learn how the grammatical rules operate to rebuild the tree and leverage its structure.

To better represent the rhythmic tree, we use a hierarchical tree-based positional encoding (TBPE) that encodes the position of a node *in the tree*, rather than its position in the linearized sequence. Some TBPE have been proposed in the literature, *e.g.* for code translation to help Transformers process abstract syntax trees [27, 28]. Since our trees are bounded in depth at d_{\max} , we associate to each node \mathcal{N} a vector of size $2d_{\max}$ that represents the path to a node from the root of the tree. This process is illustrated in Figure 3. Element k represents the index of the child traversed at depth k , while element $k + d_{\max}$ is the total number of children of the parent node at depth k . For example, to reach node F , we go through node R (child #1 over 1), then node A (child #1 over 4), then node F (child #2 over 2). If the depth of the node \mathcal{N} is less than d_{\max} , then the remaining elements of the vector are padded with zeros. This makes explicit in the positional encoding the *parent* \rightarrow *child* relations, along with depth and breadth properties. It becomes easier for the model to understand that notes can belong to a larger structures (*e.g.* triplet or four semiquavers).

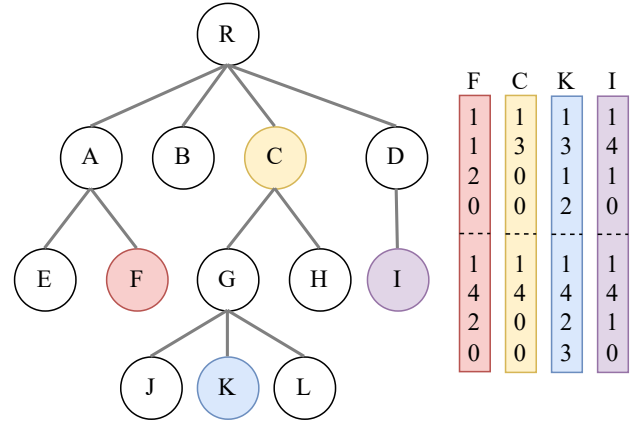

Figure 3: Example of tree-based positional encoding (TBPE) for a tree of maximum depth $d_{\max} = 4$.

4. EXPERIMENTS AND RESULTS

4.1 Dataset and Task

Our models are trained and evaluated for style classification on the Groove MIDI Dataset (GMD) [6]. It consists in 13.6 hours of drumming music, played by humans with a metronome. Each track is labelled with a style provided by the drummer, alongside tempo and time-signature. The dataset is composed of long sequences (few minutes) and short beats and fills. We only consider long sequences, as short sequences are less representative of a specific style. We also discard non-4/4 tracks (around 1% of the dataset), as we use a 4/4 musical grammar, and a few tracks that `qparse` failed to parse⁴. We focus on the 4 most represented styles: funk, jazz, latin and rock. The final subset contains 326 tracks, representing 7.5 hours of drumming, split into the train/validation/test sets (80%/10%/10%) as the original dataset [6]. Each track is then further divided into multiple chunks of n measures with a sliding window.

4.2 Representations

In addition to our LRT, we evaluate common representations of MIDI data for style classification.

Piano Roll We sample the MIDI data at frequency f . We compare $f = 30$ Hz ≈ 33.3 ms per time step, as 30 ms is considered as the simultaneity threshold for the human ear [29], and $f = 50$ Hz = 20 ms per time step, to see if models would improve with finer granularity, at the expense of sequence length. Every time step is represented by a vector in $v \in [0, 1]^{22}$. Each dimension represents one of the 22 instruments of the drum kit. v_i encodes the velocity of the i -th instrument, normalized between 0 and 1 using maximum normalization. Note that the duration of notes in drums MIDI files is arbitrary, as only onset and velocity matter. All durations are set to 100 ms in the Groove MIDI dataset. In our dataset, the average length of a piano roll is around 2455 for $f = 30$ Hz, and 4092 for $f = 50$ Hz.

Sequence of Tokens We experiment with various tokenizers from the literature, that quantify velocities and tim-

⁴ As these tracks are only in the train and validation sets, this does not affect the fairness of the final comparison.

Table 1: Performance of the different representations and model combinations on the GrooveMIDI dataset. We report macro F1 scores on the test set for the best model of each couple model/representation, alongside the model’s number of parameters, the length (in bars) of input samples, and the average sequence length of each representation. Best results for each model type are in **bold**, second best in *italics*.

ings to limit the size of the vocabulary: MIDI-Like [13, 14], TSD [16], Structured [15] and REMI [17] tokenizers. We use the default parameters from [7], except for pitch range which is set to the min/max instrument ID from the GMD. Models trained on tokenizations use a 64-dimensional embedding, as recommended in [8]. Akin to piano rolls, tokenizers produce sequences with 2400 to 2800 elements.

Note Tuples We also consider the note tuples [18] representation that uses a single vector for each note. Each vector has 25 dimensions: the 22 one-hot-encoded instrument, followed by normalized velocity, note duration and time-shift to the previous note. This results in shorter sequences, with as many elements as there are notes. Average sequence has 733 elements, $3.5\times$ less than tokenization methods.

Linearized Rhythmic Tree We use a simplified rhythm grammar of 15 rules on the GMD. As this grammar does not allow notes shorter than a $1/32$ nd note, the maximum depth d_{\max} of a leaf in the rhythmic tree is 6. Although slightly longer than note tuples, the resulting sequences remain on the smaller side with an average of 863 elements.

4.3 Models

We chose to focus on sequential representations and therefore consider two popular architectures: LSTM [30] and Transformers [26]. The model inputs are fed as chunks of 2, 4 or 8 measures. We perform a hyperparameter search for the number of bars, number of layers and layer width on the validation set and retain the best architectures for each (model, representation) combination. As our grammar parser uses the track’s tempo, we inject this information in non-grammatical models for a fair comparison by concatenating the tempo to the features vector in the last layer.

LSTM architecture We consider bidirectional LSTM models [31] and we experiment with a depth of 1 to 4 layers and a fixed width of 8 to 256 neurons per layer. Even though LSTMs do not require positional encoding, we also evaluate our LRT representation with TBPE to assess whether the explicit rhythmic structure is beneficial to the model.

Transformer architecture We use standard Transformers with an embedding layer, *i.e.* a linear projection, between the input and the first Transformer block. The models have 1 to 4 encoder layers, each with 2 to 16 attention heads. We also experiment with a feature size of 2 to 32 dimensions per head and 8 to 64 neurons in the feedforward network. We use the classical positional encoding for token sequences, the continuous positional encoding for piano rolls and note tuples, and either the classical or the tree-based positional encoding for LRTs. Regarding continuous encoding, we use $T_S = 100$ ms so that even close notes have a different encoding, and $T_L = 300$ s, as temporal context is unlikely to matter beyond several minutes.

Final models are trained with a batch size of 128, using the AdamW optimizer [32] with a learning rate of 0.001, decayed by a factor 10 every 50 epochs with weight decay and dropout. Early stopping occurs when the validation F1 score plateaus with a patience of 200 epochs. Models are trained using the standard cross-entropy loss. To alleviate the class imbalance (185 rock tracks versus 50 for the other classes), we use class inverse median frequency weighing. We report the macro F1 scores averaged over all classes.

4.4 Main Results

We report in Table 1 the test scores of the best combinations from the hyperparameter search, averaged over five runs.

LSTM with 30 Hz piano rolls and Transformer with LRT/TBPE are the combinations that lead to the best F1 scores overall (≈ 0.66). The former is a 3-layer LSTM model, each composed of 64 neurons, performing on 2-bar-long samples. The latter is a 4-layer Transformer model, each using 2 heads with 32 features per head (so a 64-dimensional input vector), and a feedforward network of 32 neurons trained on 4-bar-long chunks. Although both models achieve comparable performance, note that the Transformer model needs $6\times$ fewer parameters than the LSTM.

We observe that the TBPE provides important information for style classification. Transformer models using a

Figure 4: F1 scores on the validation set vs. number of parameters for a selected set of models. We observe that Transformers trained on LRT consistently outperform other models at similar capacity.

classical positional encoding achieve lower classification performance (≈ 0.56). Surprisingly, using TBPE is beneficial for LSTMs also: both our LSTM models trained on LRT achieve nearly identical F1 scores (≈ 0.6), however injecting the TBPE allows us to use a RNN with $5\times$ fewer parameters. This confirms that explicitly encoding the node position in the tree makes it easier for the models to understand the rhythmic structure of the track.

Finally, we observe that tokenization and note tuples tend to underperform overall. Structured MIDI tokenization achieves the best of tokenizer F1 score (≈ 0.6) both for LSTM and Transformer architecture, followed by MIDI-Like, however at the cost of a higher number of parameters. Token or note tuple sequences seem difficult to learn for the models. For RNN, we hypothesize that this is due to the regular sampling assumption made by these models. Each element is processed by the same recurrent loop, meaning that the model needs to learn the structure of the sequence, *e.g.* what each token represents. In comparison, piano rolls with a fixed time step where all elements represent the same object tend to have higher performances with LSTMs.

4.5 Model Parameter Efficiency

We evaluate some representative models by varying their capacity, *i.e.* number of parameters. More specifically, we experiment with 4, 8, 32 and 64 number of features per head for the Transformer, and 16, 32, 48, 64, 96 and 128 neurons in the hidden layers for LSTM. We report F1 scores on the validation set in Figure 4. We observe that, at comparable number of parameters, the Transformer trained on the LRT always lead to higher F1 scores than the compared models. This demonstrates that the rhythmic information embedded in our rhythmic tree not only results in shorter sequences, but also can be leveraged by smaller models for better or on par performance compared to existing works.

4.6 Training Samples Efficiency

Finally, we evaluate how representation affects the amount of data needed to train our models. We compare the same

Figure 5: F1 scores on the validation set vs. percentage of training samples used. Transformers trained on LRT exhibit a less severe performance drop when the number of training samples decreases compared to existing models.

models as in Section 4.5 and train them with a random subset of 75%, 50%, 25% and 10% of the training set. F1 scores on the validation set are reported in Figure 5. We observe that the Transformer model trained with the linearized rhythmic tree and the tree-based positional encoding consistently outperforms the structured tokenizer and the piano roll. The performance drop between 100% and 75% is minimal, and overall the LRT-based Transformer degrades more gracefully when the number of training samples decreases compared to the other models. This underlines the relevance of the LRT, that encodes higher level musical information and better represents the invariance of musical style to spurious variations in the input MIDI file, such as slight changes in timings or velocity.

5. CONCLUSION AND FUTURE WORK

We evaluated different representations of MIDI data for drumming style classification. We introduced a new representation based on the linearization of a rhythmic tree obtained by parsing a MIDI file using a musical grammar. This representation provides richer features while being more compact than traditional piano rolls or tokenization strategies. Associated with a Transformer architecture using a tree-based positional encoding, we show that this representation achieves style classification performance on par with the best models from the literature with much fewer parameters. We also provide evidence that our representation is more resilient when trained on smaller datasets.

Future works involve extending this tree-based representation beyond homophonic input, *e.g.* for polyphonic piano pieces. Building the parsing tree could also be achieved on music scores, making it possible to directly classify scores at the mere symbolic level. In addition, we would like to evaluate this approach on more diverse tasks, as representation could be beneficial not only for discriminative models, but also for generative models, *e.g.* in music generation tasks, to produce syntactically correct performances with respect to the specified grammar [33].

6. ACKNOWLEDGEMENTS

We thank Florent Jacquemard for his work on `qpparse`, fruitful discussions on the design of the rhythmic grammar for drums and advice throughout this project. Additional thanks are dedicated to Lydia Rodriguez de la Nava for her help in adapting `qpparse` to drums rhythm parsing.

ABSTRACT

Representing symbolic music with compound tokens, where each token consists of several different sub-tokens representing a distinct musical feature or attribute, offers the advantage of reducing sequence length. While previous research has validated the efficacy of compound tokens in music sequence modeling, predicting all sub-tokens simultaneously can lead to suboptimal results as it may not fully capture the interdependencies between them. We introduce the Nested Music Transformer (NMT), an architecture tailored for decoding compound tokens autoregressively, similar to processing flattened tokens, but with low memory usage. The NMT consists of two transformers: the main decoder that models a sequence of compound tokens and the sub-decoder for modeling sub-tokens of each compound token. The experiment results showed that applying the NMT to compound tokens can enhance the performance in terms of better perplexity in processing various symbolic music datasets and discrete audio tokens from the MAESTRO dataset.

1. INTRODUCTION

The effectiveness of the autoregressive language model becomes dominant in generative tasks in various domains, including music. The language model has been the most widely used generative model in symbolic music generation [1–4]. After the success of vector quantization or residual vector quantization [5], the language model is also widely applied to audio-domain music generation [6–8].

The power of the language model comes from its autoregressive modeling of sequential information. Once the data is *flattened* to a sequence of discrete tokens, the language model can be applied in a straightforward manner. There have been many successive works on representing symbolic music data in a sequence of flattened tokens, such as MIDI-like encoding [9] or REMI [3].

However, a limitation of this approach is that the sequence length is quite lengthy, with the average number

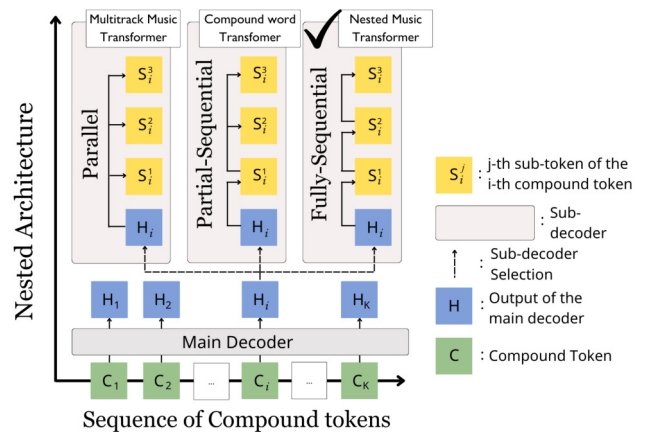

Figure 1: Diagram of the nested architecture with three different methods for predicting sub-tokens.

of tokens for pieces within the Lakh MIDI dataset [10] reaching 14,647. To overcome this limitation, the Compound Word Transformer [4] proposed an encoding scheme named Compound word that represents symbolic music as a sequence of compound tokens, in which several musical features or attributes are encoded into a single multi-dimensional token. By grouping musical features into two different compound token types, metric and note, Compound word shortens the sequence length to less than half of what is encoded with REMI as depicted in Figure 2. Similarly, Multitrack Music Transformer [11] employed a compound token scheme that encodes beat position, instrument, pitch, and duration into a single token, resulting in a sequence length approximately one-third of that encoded with REMI. Furthermore, note-level compound tokens demonstrated a clear advantage in performance for discriminative tasks such as identifying the genre or style of music and suggesting accompaniments [12].

Despite these attempts to reduce the sequence length by packing musical features into a single compound token for various purposes, encoding schemes which flatten tokens like REMI are still dominant in symbolic music generation. Both [4] and [11] in symbolic music generation showed that the generation with REMI was favored in their listening tests. One of the causes is that the previous models are designed to predict multiple features in a parallel [11] or partial-sequential [4] way without considering interdependencies between different musical features encoded within

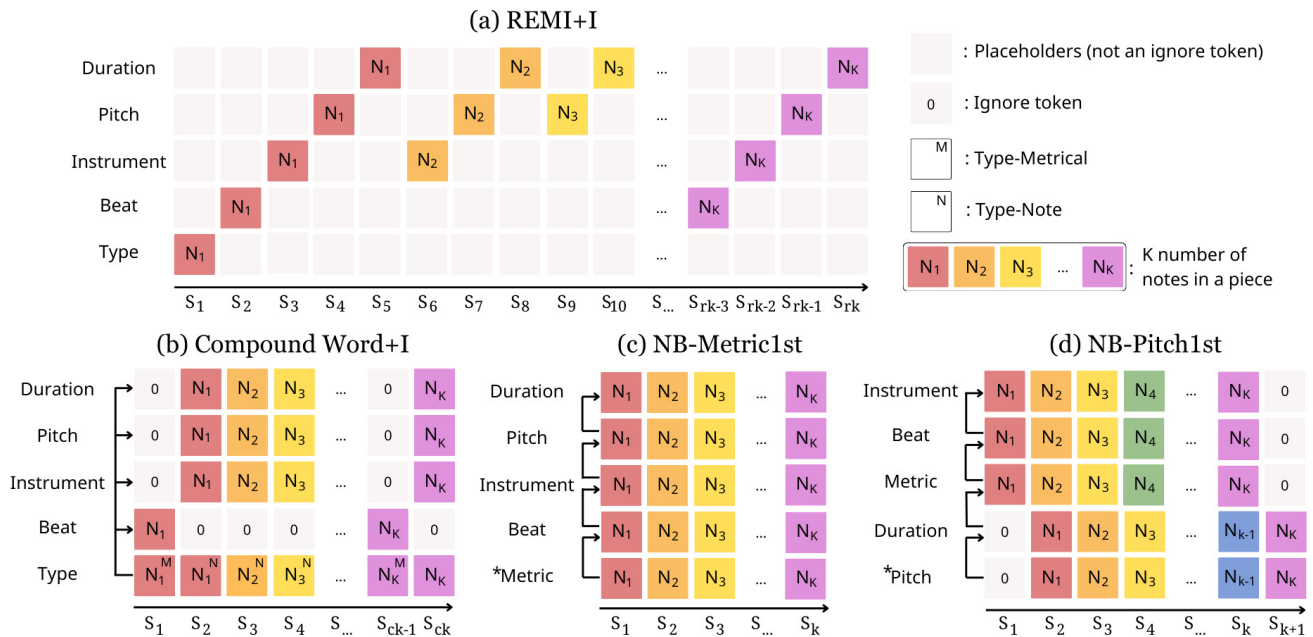

Figure 2: An example illustrating the proposed representations, note-based (NB) encoding (c) NB-Metric1st and (d) NB-Pitch1st, alongside REMI and Compound word. All encodings represent the same piece of music by using five musical features. Specifically, REMI and Compound word were not originally designed for multi-instrument pieces, which is why we renamed the encodings with “+I” to (a) and (b). Here, k denotes the number of notes and sequence length for NB, while r and c represent the ratios for REMI and Compound word, with values greater than 1.

the compound token, as depicted in Figure 1.

To address this challenge, we introduce a novel decoding framework called the Nested Music Transformer (NMT). The primary goal of this framework is to decode compound tokens in a fully sequential manner while maintaining efficient memory usage. The proposed NMT combines two distinct cross-attention architectures within its sub-decoder: the intra-token decoder and the Embedding Enricher. The intra-token decoder autoregressively decodes the sub-tokens of a single compound token, while the Embedding Enricher updates embedding of each sub-token by attending to the hidden states of previous compound tokens.

We demonstrated that our proposed architecture achieves performance comparable to that of flattening-based models, while requiring fewer computational resources in terms of GPU memory and training time. This was confirmed through both quantitative evaluations and subjective listening tests for symbolic music generation. Furthermore, our experiments showed that the NMT and other nested architectures perform similarly to strong baseline models when generating audio samples using discrete audio tokens. All source code, pretrained models and generated samples are available at <https://github.com/JudeJiwoo/nmt>.

2. NOTE-BASED ENCODING

Before we introduce the Nested Music Transformer, we explain Note-based encoding (NB), a compound token encoding scheme that we utilized as the primary encoding method. NB stands out for its ability to encapsulate the most comprehensive set of musical features within a single compound token, as illustrated in Figure 2.

2.1 Musical Features in Symbolic Encoding

As depicted in Figure 2, REMI, Compound word, and NB utilize several musical features to represent music pieces. We used a total of eight features: beat (position), pitch, and duration were essential, while instrument, chord, tempo, and velocity were selectively included based on the dataset characteristics. To encode other information, such as measure boundary and change in time signature, we also employed one additional feature *Type* or *Metric* following [4].

In Compound word (CP), musical features are categorized into two groups: “metrical” and “note.” Consequently, the encoding employs two *Type* tokens to specify the group of each compound token. Unlike CP, NB does not require group indicator tokens however, since each note token in NB is assigned a beat, unlike REMI and CP, we designed the *Metric* feature to encode changes in the metrical structure. This allows the model to efficiently represent metrical changes within a single sub-token. Specifically, the *Metric* feature indicates whether the current note introduces a new time signature, measure, or beat, or continues the previous metrical context. For this purpose, we define four distinct values for the *Metric* feature vocabulary, each representing a different combination of metrical changes or continuations.

The *Beat* indicates the relative position of each note within a measure. The *Chord* was derived using a rule-based algorithm from [4]. The *Tempo* was set to follow an exponential scale for value changes, with this application varying across datasets. The *Instrument* feature specifies the instrument playing the note. In order to keep the variety of instruments manageable, we adopted the approach suggested in [11], trimming to 61 types of instruments. The

Pitch feature utilized 128 categories of pitch values represented in MIDI. The *Duration* refers to the length of time each note is played. The *Velocity* represents MIDI velocity (dynamics) of each note.

For the NB encoding method, a music piece P with K number of notes, $P = \{n_1, n_2, n_3, \dots, n_K\}$ can be conceptualized as a sequence of compound tokens, denoted by $P_{nb} = \{x_1, x_2, x_3, \dots, x_K\}$, wherein each event x_i is a compound token comprising up to eight sub-tokens in the orders like followings:

$$(x_i^{\text{metric}}, x_i^{\text{beat}}, x_i^{\text{chord}}, x_i^{\text{tempo}}, x_i^{\text{inst}}, x_i^{\text{pitch}}, x_i^{\text{dur}}, x_i^{\text{vel}})$$

2.2 Compound Shift

By reordering the sub-tokens within a compound token, we can position the target sub-token to be predicted first. This adjustment enhances the objective metric of the target sub-token, as it benefits from being processed primarily by the more powerful main decoder rather than the sub-decoder. Each event x_i which is shifted to pitch-first option comprises features like following:

$$(x_{i-1}^{\text{pitch}}, x_{i-1}^{\text{dur}}, x_{i-1}^{\text{vel}}, x_i^{\text{metric}}, x_i^{\text{beat}}, x_i^{\text{chord}}, x_i^{\text{tempo}}, x_i^{\text{inst}})$$

Note that the order of prediction of each sub-token in the entire *flattened* sequence does not change, and only the grouping boundary for a single compound token is shifted as depicted in Figure 2 (d). We will refer to the non-shifted representation as *NB-MF* and the shifted version as *NB-PF*.

3. NESTED MUSIC TRANSFORMER

In this section, we introduce the architecture of Nested Music Transformer (NMT), which is designed to handle compound tokens. The structure is composed of three primary components: token embedding, main decoder, and sub-decoder. The token embedding component summarizes the embeddings of each sub-token into a single vector which represents each compound token. Subsequently, the main decoder processes the sequence of these vectors using a decoder-only transformer architecture. Lastly, the sub-decoder decodes sub-tokens from the output of the main decoder. The proposed NMT integrates two distinct cross-attention architectures within its sub-decoder: the intra-token decoder and the Embedding Enricher. As the NMT generates sub-tokens, their embeddings are updated with contextual information by the Embedding Enricher, as illustrated in Figure 3.

3.1 Token Embedding & Main Decoder

To summarize multiple embeddings from each sub-token, we simply sum them along the sub-token axis following [6, 11]. Additionally, we integrate learnable absolute positional embedding [13] to denote the position of compound tokens within the sequence. Specifically, the i -th compound token x_i in the sequence is converted into a vector through the token embedding process and aggregated with its positional embedding. This combined vector is then fed into the main decoder, producing the output of the main decoder, also known as the hidden vector h_i .

3.2 Sub-decoder with Cross Attention

The main goal of the sub-decoder is to obtain proper hidden state to predict output sub-token s_i^j which is j -th sub-token of i -th compound token, based on output of the main decoder h_i and the preceding output sub-tokens s_i^0, \dots, s_i^{j-1} that are predicted before.

Many previous works have suggested using a similar sub-decoder to sequentially predict the sub-token sequence, such as updating hidden state by concatenating with the embedding of sub-tokens [4], using RNN [14] or causal self-attention [8]. However, through comparative experiments presented in Section 4, we found that applying cross-attention is one of the most effective way to model the compound token sequence in symbolic music.

The cross-attention-based sub-decoder operates by iteratively concatenating a key/value pair sequence K/V_i with embeddings of sub-tokens $\text{Emb}(s_i)$, starting with an initial key/value sequence that contains only the beginning-of-sequence *BOS* token. For each sub-token to be sampled, the architecture computes multi-head scaled dot-product cross-attention between the query sequence, consisting of positionally encoded output of the main decoder h_i , and the current key/value sequence. The positional encoding of h_i ensures that the hidden vector has a distinct bias for predicting target sub-token. From the attention output a_i^j , the matrix W_{logits}^j is applied to create logits. This iterative process continues until all sub-tokens are sampled. The process can be expressed as follows:

$$\text{Query}_i^j = \text{PositionalEncoding}(h_i), \quad (1)$$

$$K/V_i^j = \begin{cases} \text{BOS} & \text{if } j = 0, \\ \text{Concat}(\text{BOS}, \dots, \text{Emb}(s_i^{j-1})) & \text{if } j > 0, \end{cases} \quad (2)$$

$$a_i^j = \text{Cross-Attention}(\text{Query}_i^j, K/V_i^j), \quad (3)$$

$$s_i^j = \text{Sampling}(\text{Softmax}(a_i^j W_{\text{logits}}^j)) \quad (4)$$

3.2.1 Embedding Enricher

Since the embedding of a sub-token is a shallower vector compared to the output of the main decoder, we designed a cross-attention architecture called the Embedding Enricher. This architecture updates embedding of sub-token $\text{Emb}(s_i)$ with a context sequence derived from the prior outputs of the main decoder $h_{i-(w-1)}, \dots, h_i$, where w represents the window size.

$$\text{Context}_i = \text{Concat}(\text{BOS}, h_{i-(w-1)}, \dots, h_i), \quad (5)$$

$$\text{Enriched}_i = \text{Cross-Attention}(\text{Emb}(s_i), \text{Context}_i) \quad (6)$$

In the Nested Music Transformer, the output vector Enriched_i replaces the original embedding of sub-tokens before being concatenated into the key/value pair sequence in Equation (2) as depicted in Figure 3. These context-enriched embeddings allow the architecture to process attention with deeper vectors than the original embeddings, resulting in better performance on the objective metric compared to the standalone cross-attention-based sub-decoder, as demonstrated in Table 1.

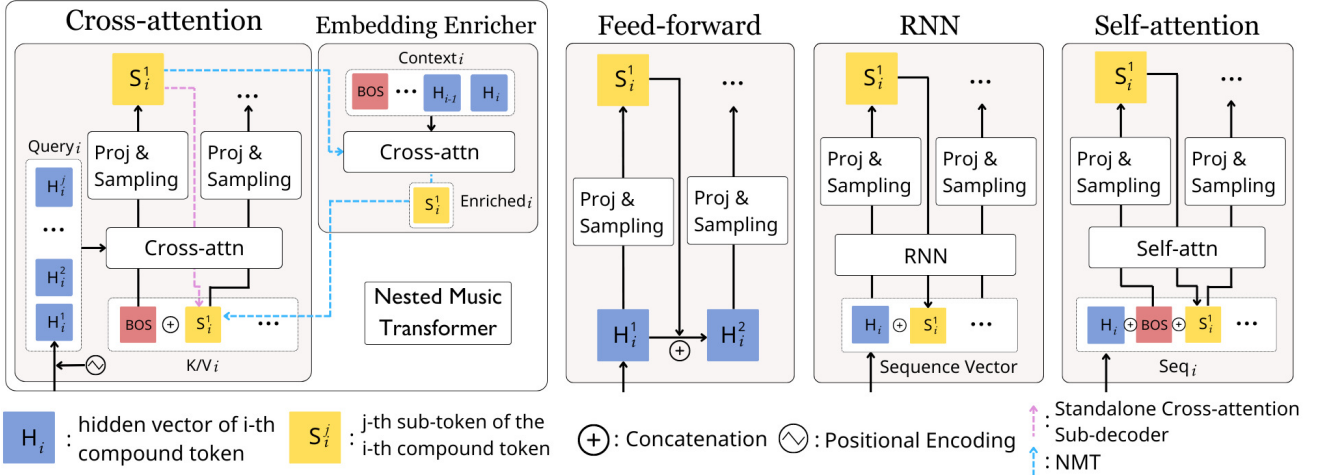

Figure 3: Illustrations of the proposed Nested Music Transformer (NMT) and other sub-decoder structures

3.3 Other Comparative Structures

3.3.1 Feed-forward-based Architecture

The Feed-forward-based sub-decoder, inspired by [4], iteratively updates the output of the main decoder to predict sub-tokens. It concatenates the previously used hidden state with the embedding of the last sampled output to predict the next sub-token.

3.3.2 RNN-based Architecture

RNN-based sub-decoder capitalizes on the sequential nature of recurrent neural network to update hidden state. The initial input sequence and hidden state utilize the output of the main decoder h_i , and through the iteration the embedding of the sampled output is appended to the input sequence until all the sub-tokens are generated.

3.3.3 Self-attention-based Architecture¹

The self-attention-based sub-decoder aims to get the sequence vector Seq_i by iteratively concatenating it with the embeddings of the sampled output $\text{Emb}(s_i)$. The initial sequence vector consists of the output of the main decoder h_i and BOS token to ensure that the initial attention values can be properly processed. This sequence vector Seq_i is then used as the query, key, and value in the self-attention mechanism. The process can be summarized as follows:

$$\text{Seq}_i^j = \begin{cases} \text{Concat}(h_i, \text{BOS}) & \text{if } j = 0, \\ \text{Concat}(h_i, \text{BOS}, \dots, \text{Emb}(s_i^{j-1})) & \text{if } j > 0, \end{cases} \quad (7)$$

$$a_i^j = \text{Self-Attention}(\text{Seq}_i^j), \quad (8)$$

$$s_i^j = \text{Sampling}(\text{Softmax}(a_i^j W_{\text{logits}}^j)) \quad (9)$$

¹ The proposed self-attention-based sub-decoder operates differently from the method described in [8]. Unlike ours, [8] used h_i as a base of every vector in the sequence, which is updated by the embedding of generated sub-tokens, similar to the operation of our proposed cross-attention-based sub-decoder. Experimental results indicate that the architecture in [8] outperforms our self-attention-based architecture and delivers comparable results to our cross-attention-based architecture.

3.4 Self-attention versus Cross-attention

The preference for cross-attention over self-attention arises from the observation that the output of the main decoder, h_i , already contains sufficient information to predict sub-tokens, as demonstrated in the parallel prediction method used in the Multitrack Music Transformer [11]. On the other hand, the embedding of the sampled output is comparatively shallow, lacking the previous context despite having the same dimension as h_i . Additionally, since both attention layers use a residual connection for the vectors used as keys, utilizing h_i as the key facilitates a direct gradient flow. Therefore, updating h_i as the key with cross-attention can be more advantageous than updating the embedding of the sampled sub-token with self-attention.

3.5 Applying to Audio Tokens

MusicGen [6] has employed a four-level residual vector quantization technique for a single token, which bears similarity to using four musical features or sub-tokens for compound tokens in symbolic music. Given that the optimal architecture, particularly for decoding compound features in a fully-sequential manner, is still being explored for audio tokens [8], we employed the Nested Music Transformer on discrete audio tokens to assess the potential of our proposed architecture.

4. EXPERIMENTS

4.1 Dataset Preparation

We selected four datasets to conduct our experiments on symbolic music generation: Pop1k7 [4], Pop909 [15], the Symbolic Orchestral Database (SOD) [16], and the clean version of the Lakh MIDI Dataset (LMD clean) [10], which is free of data leakage problems. During preprocessing, MIDI files without a time signature or with excessive or insufficient length were filtered out, and we specifically selected pieces featuring a minimum of four instruments for LMD clean. Note quantization varied across datasets: twelve resolutions per beat for SOD and four resolutions

per beat for the others. We also filtered out MIDI files with expressive tempo and timing. We split the prepared data, reserving 10% for validation and 10% for testing. Additionally, augmentation techniques for pitch and chord involved random semitone shifts $s \in \mathbb{Z}$ within a range of $s \sim U(-5, 6)$.

4.2 EnCodec for MAESTRO

For discrete audio tokens, we prepared MAESTRO dataset [9], which has 200 hours piano performance audio files. We fine-tuned the audio tokenizer proposed by [6] with MAESTRO audio files to create sequences of discrete audio tokens, each with 30 seconds of length. The sampling rate of the token is 50 Hz, which means 30 seconds of audio is represented with 1500 audio tokens, each with 4 different codebooks.

4.3 Model and Hyperparameter Configuration

The baseline models for symbolic music generation are defined as follows: flattening for REMI [3], partial-sequential Feed-forward-based sub-decoder for Compound word [4], and parallel prediction with NB-MF [11]. Additionally, the *delay* method proposed by [6] is explored as a baseline for generating audio tokens, which utilizes rearranged residual vectors or sub-tokens in a parallel manner. In exploring both symbolic music and audio token generation, we conducted experiments using the Nested Music Transformer (NMT) and various sub-decoder architectures to assess the effectiveness of our proposed model. To ensure a fair comparison among these models, we aimed for a comparable number of model parameters, approximately 40 million for symbolic music and 62 million for discrete audio tokens². To enhance efficiency in processing long sequences within the transformer architecture, we integrated Flash attention [17].

Training the model entailed 100K steps for symbolic music and 200k for discrete audio tokens, utilizing the

² Both models have 8 attention heads and a dimension size of 512, with a single layer for all sub-decoder architectures and an additional single layer for the Embedding Enricher when using the NMT. However, they have a total of 12 and 15 decoder layers, respectively.

AdamW optimizer [18], with a segment batch size of 8 and 16 for each task, where β_1 were set to 0.9, β_2 to 0.95, and a gradient clipping threshold was set to 1.0. We implemented a cosine learning rate schedule with a warm-up phase of 2000 or 4000 steps for each task. During this warm-up phase, the learning rate gradually increased before reaching its maximum value $1 \times e^{-4}$. To address overfitting concerns, we applied dataset-specific dropout rates instead of using early stopping. These dropout rates were chosen to ensure that the optimal validation loss remained stable until the end of training. We utilized mixed precision techniques.

4.4 Quantitative Evaluation on Symbolic Music

We evaluated the symbolic music generation task using the average negative log-likelihood (NLL). However, directly comparing the loss values across models using different encoding schemes posed challenges. To address this, we first adjusted the input sequence length for each encoding scheme to ensure that the NLL is derived from a similar amount of context regardless of the encoding scheme. Furthermore, instead of calculating the average NLL as done during the training steps, we calculated it based on the set of probabilities of tokens processed with full context. To achieve this, we used a moving-window method with a window size equal to the input sequence length to create a set of overlapping input sequences.

Secondly, we adjusted the probabilities for each sub-token in a compound token to account for discrepancies between REMI and other encoding schemes like CP and NB. REMI omits redundant tokens such as repetitive positions (beat), as depicted in Figure 2. Thus, when predicting a new note, a model based on REMI must decide whether to add the note at a new position by predicting a new beat token, or to add the note at the same position by predicting a pitch token. In contrast, CP and NB, due to the nature of their encoding schemes, split this prediction into two steps: first, they determine the beat position, and then they predict the pitch. This means they have more prior information when predicting the pitch token since changes in beat are already fixed and provided as a condition. To ad-

	FAD-uncon↓	FAD-cond↓	KLD↓	mean NLL↓
Parallel	0.166	0.206	0.075	4.669
Flatten	0.140	0.176	0.068	4.482
Delay [6]	0.168	0.188	0.066	4.564
Self-attention	0.131	0.186	0.074	4.353
Cross-attention	0.145	0.190	0.065	4.314
NMT	0.165	0.198	0.067	4.318

Table 2: Model comparison for discrete audio tokens

just the probability of sub-tokens in NB and CP, which differ due to the discrepancy, we accumulated the probability of each sub-token to the next token in NB or CP if that sub-token was omitted in its corresponding REMI encoding. For example, when predicting a pitch token at the same beat, $P(\text{pitch} \mid \text{context})$ in REMI can be compared to $P(\text{same_beat} \mid \text{context}) \times P(\text{pitch} \mid \text{context, same_beat})$ in NB or CP.

From the results, we observe several key tendencies. First, applying the Nested Music Transformer (NMT) enhances the overall performance across all types of compound token encodings, including previously suggested schemes like CP and NB-MF (similar to [11]). Second, the NMT demonstrates a clear advantage in using the cross-attention-based sub-decoder and the Embedding Enricher compared to other baseline architectures. Finally, our pitch-first NB (NB-PF) encoding outperforms the metric-first NB (NB-MF) encoding in predicting pitch. This is because the model can predict the next pitch feature through the main decoder by leveraging the previously inferred note position information. Conversely, NB-MF showed lower loss in beat prediction. This difference arises from which sub-token relationships are calculated through the main decoder instead of the sub-decoder. Overall, the results indicate that pitch-first token grouping is an efficient strategy.

4.5 Quantitative Evaluation on Discrete Audio Tokens

We evaluated models with discrete audio tokens using following metrics: Fréchet Audio Distance (FAD), Kullback-Leibler Divergence (KL), and the mean NLL loss over sequences. A lower FAD score suggests that the generated audio is more plausible. To mitigate sample number bias for the test set, we employed adaptive FAD as proposed by [19], along with CLAP [20] embeddings for each sample. FAD scores were computed based on 500 unconditionally generated samples and 345 samples generated given prompts. Following [6], we computed the KL-divergence over the probabilities of the labels between the original and the generated audio samples. Table 2 shows the evaluation results.

We observe that using a cross-attention-based sub-decoder or the NMT achieves better NLL compared to a self-attention-based sub-decoder. However, the tendency differs from that seen in symbolic music. Adding the Embedding Enricher did not significantly improve performance in the audio domain. We hypothesize that this disparity arises from the distinct characteristics of tokens in both domains. In the symbolic domain, each musical feature requires context to form sufficient semantic information, whereas each token in the audio domain, with a 2048 vocab-

	Coherence↑	Richness↑	Consistency↑	Overall↑
	Mean(±margin of error)			
REMI [3]	3.18 ± 0.20	3.33 ± 0.18	3.33 ± 0.18	3.17 ± 0.18
CP [4]	2.94 ± 0.22	3.24 ± 0.18	2.97 ± 0.20	3.06 ± 0.20
CP + NMT	3.22 ± 0.19	3.35 ± 0.17	3.39 ± 0.17	3.32 ± 0.17
NB-PF + NMT	3.37 ± 0.19	3.44 ± 0.18	3.37 ± 0.19	3.36 ± 0.20

Table 3: Results of subjective listening test, presenting mean values with 95% confidence intervals.

ulary size codebook, contains more standalone information. This observation suggests potential avenues for future research, such as exploring effective methods to integrate the semantic information of symbolic music with discrete audio tokens.

4.6 Subjective Listening Test

For the subjective listening test, we used the Symbolic Orchestral Database (SOD) [16] to generate MIDI samples given four-measure prompts. We carefully selected eight prompts from the test split and generated continuation results using four different models: two baseline models (REMI and CP) and two proposed models (CP + NMT and NB-PF + NMT). We applied different sampling methods to each model.³ We conducted the test with 29 participants, asking them to evaluate the generated outputs based on three criteria: *Coherence* (the naturalness of transitions), *Richness* (the variety of harmony and rhythm), and *Consistency* (the lack of errors in composition), as well as an *Overall* rating for the perceptual quality of the samples as a whole.

As summarized in Table 3, our proposed models generated samples of comparable quality to REMI, outperforming the baseline CP. The smaller gap between REMI and NB + NMT in the subjective listening test compared to the teacher-forcing NLL evaluation suggests that NB + NMT may be more robust to exposure bias during sequence generation. Another possible explanation is that compound tokens are more effective at capturing the given context, as also demonstrated in the experiments of [4].

5. CONCLUSION

In summary, this work presents the Nested Music Transformer, an advanced architecture that decodes compound tokens in music generation, applicable to both in the symbolic and audio domain. Our architecture distinguishes itself by addressing the twin challenges of sequence length and feature interdependencies through a nested transformer setup that efficiently manages GPU resources and training processes. The experiments validate the competitiveness of our model over previous methods, achieving on par results in both objective metrics and subjective listening tests while lowering training costs.

³ During the generation process, we used nucleus sampling (top-p sampling) with $p = 0.99$. Our proposed models were sensitive to the choice of the temperature parameter, where an improperly selected temperature would result in excessive repetition regardless of encoding schemes. Therefore, we searched for the optimal temperature value for each model within the range of [1.0, 1.3] on the validation set.

ABSTRACT

Music classification is a prominent research area within Music Information Retrieval. While Deep Learning methods can adequately perform this task, their classification space remains fixed once trained, which conflicts with the dynamic nature of the ever-evolving music landscape. This work explores, for the first time, the application of Continual Learning (CL) in the context of music classification. Specifically, we thoroughly evaluate five state-of-the-art CL approaches across four different music classification tasks. Additionally, we showcase that a foundation model might be the key to CL in music classification. To that end, we study a new approach called *Pre-trained Class Centers*, which leverages pre-trained features to create fixed class-center spaces. Our results reveal that existing CL methods struggle when applied to music classification tasks, whereas this simple method consistently outperforms them. This highlights the need for CL methods tailored specifically for music classification.

1. INTRODUCTION

Music Information Retrieval (MIR) is a multidisciplinary field dedicated to retrieving information from music sources [1]. Within the MIR domain, music classification stands as one of the most widespread research topics [2]. It involves the categorization of music into various predefined classes, with these categories defining the ultimate task at hand. There is a diverse range of classification tasks, including genre classification [3], vocal technique identification [4], instrument classification [5], and singer identification [4], among others. These tasks are essential for organizing and retrieving music efficiently, enabling applications such as recommender systems and music search engines to better serve the needs of users in the ever-evolving music landscape [6].

Traditional music classification approaches predominantly relied on signal processing methods, accompanied

by heuristics and handcrafted features, to categorize music data [7, 8]. However, these schemes often struggled to capture the complex and nuanced aspects of musical content, thus limiting their practical application. With the rise of Deep Learning (DL) strategies, alternative solutions emerged to ease this task [9, 10]. DL models address these issues by automatically learning hierarchical representations from the data itself, thereby improving the accuracy and flexibility of music classification systems.

However, DL models become static once they are trained; their feature space is fixed. Consequently, they may struggle or fail to accommodate new classes. This does not align well with the dynamic nature of music itself—characterized by evolving genres, emerging artists, and shifting musical trends. We could approach this challenge in two ways: either (i) retrain the model from scratch when new music data is introduced, which is computationally expensive, inefficient, and not always possible due to privacy or storage issues [11], or (ii) fine-tune the model only on the newly acquired music data. The latter alternative is known to lead to the so-called “catastrophic forgetting”, where the knowledge acquired from previous data diminishes as new information is incorporated [12]. This situation highlights the need for robust and adaptable music classification systems that can be updated with just new data.

Continual Learning (CL) promises a solution to catastrophic forgetting by enabling models to gradually incorporate new knowledge without forgetting previously acquired information [11, 13]. Fig. 1 graphically depicts this scenario. This adaptability is vital for music classifiers to stay up-to-date, ensuring they can accurately categorize a continuously evolving musical landscape. While some previous works in zero-shot [14] and few-shot learning [15] propose methods for recognizing new, unseen classes, they do not maintain nor update the knowledge acquired in one session in subsequent sessions. In contrast, our work introduces the use of CL in music classification, with the goal of not only recognizing unseen classes but also retaining this knowledge over time.

CL approaches are generally classified according to the following taxonomy [16]: (i) *data-centric* methods, which focus on preserving important data from previous tasks using *data replay* or *data regularization* techniques; (ii) *model-centric* methods, which focus on model development through *parameter regularization* or model structure

Figure 1. Graphical representation of class-incremental learning for music classification tasks. The process begins with Model 1, trained to differentiate some initial classes during session S^1 . Through a continual learning algorithm, Model 1 preserves its acquired knowledge while incorporating new classes in a subsequent learning session, S^2 , thus evolving into Model 2. This iterative learning process continues, enabling the model to progressively expand its repertoire of recognizable classes.

expansion, i.e., *dynamic networks*; and, (iii) *algorithm-centric* methods, which focus on the learning process itself, employing *knowledge distillation* techniques or *rectifying model biases*.

In this work, we investigate the applicability of state-of-the-art CL techniques, originally designed for computer vision, in the context of music classification tasks. Additionally, we explore the use of foundation models to introduce a new CL method based on pre-trained representations to create fixed class-centers, showcasing the utility and robustness of foundational models. Our results reveal that existing CL methods, traditionally evaluated on image classification, struggle when applied to music, whereas our proposed method consistently outperforms them. This raises questions regarding the effectiveness and transferability of existing CL techniques to music classification. Moreover, it prompts us to consider whether leveraging foundational models might represent a better approach for addressing the CL paradigm in certain scenarios.

To summarize, the contributions of this work are as follows: (i) a first-time analysis of the applicability of CL techniques to music classification tasks, (ii) the introduction of a simple yet effective CL method that relies on the generalizability of large pre-trained models, and (iii) extensive experimentation to quantitatively evaluate five different CL approaches across four music classification benchmarks with two different pre-trained feature extractors.

2. METHODOLOGY

In this work, we address the music classification task from a CL perspective, with a specific focus on Class-Incremental Learning (CIL). In each learning *session*, the model is trained with new audio tracks from a new set of classes. Ideally, the model should learn to classify the new classes introduced in each session while retaining its capacity to classify classes from previous sessions (see Fig. 1).

Formally, let us assume a sequence of M training sessions $\{S^1, S^2, \dots, S^M\}$, where each session has a different set of non-overlapping classes. $S^m = (X_m, Y_m)$ represents the m -th incremental step, with X_m containing audio tracks whose labels belong to Y_m , and Y_m denoting the label space of session m , where $Y_m \cap Y_{m'} = \emptyset$ for $m \neq m'$. Note that the audios in X_m are in the format $[0, 1]^{l_j \times c}$, being l_j the length of the j -th audio.¹ In this work, we consider mono audio signals as input ($c = 1$), although other considerations may be applicable. After each session, the model is evaluated on all seen classes $Y_m = Y_1 \cup \dots \cup Y_m$. The main objective of CIL is to sequentially build a classification model capable of classifying all seen classes.

2.1 Classification model

For this learning framework, our classification model consists of a fixed pre-trained model, serving as the feature extractor, and an out-of-the-box fully connected network, acting as the downstream task classifier. We use this *same* learning framework with different CL strategies to compare their performance. In order to make our experimentation agnostic to a certain degree to the pre-trained model selected as the feature extractor, we consider two state-of-the-art pre-trained models:

1. **MERT** [10] is a recently released foundational model specifically designed for extracting rich representations from music data. It follows a self-supervised pre-training paradigm that relies on two teacher models, one for the acoustic aspect and one for the musical aspect, to generate pseudo-labels for sequential audio clips. This multi-task paradigm allows for a balanced acoustic and musical representation learning, guiding a BERT-style transformer encoder to better model music audio. Its state-of-the-art performance across various MIR tasks, including

¹ Audio chunks of l_j are considered to accommodate different lengths, as typically done in the literature.

those relevant to this work, makes it a compelling choice for our purposes.

2. **CLMR** [17] adapts the image self-supervised learning strategy SimCLR [18] to the domain of music. This method employs contrastive learning to train a convolutional feature extractor [19] to extract meaningful and transferable representations from music data. It achieves this by learning to predict similar representations for slightly altered versions of the same audio sample. We consider CLMR to be a robust classification model for our work, given its demonstrated effectiveness across various music classification tasks, along with its lightweight architecture.

A summary of the characteristics of these two models can be seen in Table 1. Both of these pre-trained models use raw audio samples as inputs. We chose them with the presumption that their differences in architecture and size would enable us to extract more nuanced insights and conclusions from our experiments. It is worth noting that, in order to have comparable results with recent research works, we adhere to the same evaluation protocol as outlined in [10].

Table 1. Overview of the feature extractor models used in this work, depicting their characteristics (architecture, number of trainable parameters, input audio length, and feature embedding size).

	Architecture	Audio length (s)	Embedding Size
MERT	Transformer (94.9M parameters)	5	764
CLMR	CNN (2.4M parameters)	2.7	512

2.2 Selected methods

We select a diverse range of state-of-the-art methods in CL, emphasizing the inclusion of methods from different subtypes across the entire taxonomy. Specifically, we consider five CL approaches:

1. **Replay** aims to prevent catastrophic forgetting by employing a data-centric approach, which involves revisiting past data during the learning process [20].
2. **GEM** adopts a data-centric strategy based on data regularization to stabilize continuous training. It constrains the model’s parameter updates to prevent significant forgetting of previously learned tasks, ensuring a balanced learning experience over time.
3. **EWC** employs a model-centric approach through parameter regularization [21]. It assigns importance to specific parameters based on their relevance in previously learned tasks, thereby preventing excessive adjustments during subsequent training on new tasks.
4. **L2P** utilizes a model-centric approach based on dynamic networks [11]. It aims to learn to prompt a pre-trained Transformer to adapt it to the new

tasks, managing both task-invariant and task-specific knowledge while maintaining model plasticity.²

5. **iCaRL** adopts an algorithm-centric strategy of knowledge distillation [22]. It leverages distillation from frozen models of past learning sessions, combined with data replay, to avoid forgetting.

As a baseline method, we fine-tune the model for each session without applying a CL strategy, referred to as **Fine-tune** in the experiments, following the fine-tuning protocol used in state-of-the-art research [11]. This serves as our lower bound, potentially leading to the strongest occurrence of catastrophic forgetting.

2.3 Pre-trained Class Centers

In addition to the CL methods considered, we explore a novel approach that relies on the generalizability of the representations of a foundation model. We use this method to showcase the potential efficacy of using pre-trained models with self-supervised learning for CL. The idea is to use the latent representations produced by pre-trained models to capture the underlying semantics of the data itself, causing these representations to be distributed in a way that enables classification. Our approach seems particularly well-suited for music classification tasks because there exist publicly available foundation models (e.g., MERT and CLMR) known for their strong generalization capabilities. The proposed method, termed as *Pre-trained Class Centers* (PCC), can be separated into three different stages:

1. **Feature Extraction.** We extract a pre-trained feature embedding for each training sample.
2. **Prototype Generation.** We compute *prototype* class-centers by averaging all the feature embeddings obtained for each class in a training session and store them in a prototype buffer.
3. **Similarity Calculation.** During the inference phase, the class of a given test audio track is determined by the class associated with the nearest class-center, calculated through the Euclidean distance between the pre-trained feature vector of the test audio and the class-center prototype.

Although PCC is conceptually simple, it has never been considered. The method belongs to the data-centric category of CL methods because it focuses on leveraging the generalizability of pre-trained representations. One notable advantage is its memory efficiency (only one prototype per class), making it suitable for scenarios with limited computational resources. Just as important, this method stores representations rather than the original data, thus avoiding privacy issues. Furthermore, in PCC, the training process for each new class is independent of the other classes, making it a robust method for CL.

² Given that this method assumes a Transformer architecture as the backbone, it cannot be evaluated with CLMR.

3. EXPERIMENTATION

This section encompasses the experimental setup, including the music classification tasks, evaluation protocol, and implementation details.

3.1 Tasks

To conduct an extensive and diverse analysis, we evaluate the selected CL methods on four distinct music classification tasks using three different datasets:

Genre classification estimates the most appropriate genre for a given song. We use the standard curated split of the GTZAN dataset [23, 24], which consists of 930 30-second audio tracks from 10 different genres.

Instrument classification determines the specific musical instrument present within a given sound. We consider the NSynth dataset [5], which contains 306 000 4-second audio samples of an instrument playing a single note. There are 11 instrument classes in this dataset. Due to the high computational cost associated with the large size of the training partition,³ we consider only 5 000 training samples for each class while keeping the validation and test sets intact.

Singer identification classifies the identity of a given vocal performer in an audio track. We employ the VocalSet dataset [4], which comprises 3 613 recordings of variable length from 20 professional singers performing using different vocal techniques.

Vocal technique detection recognizes the specific singing technique present within a given audio recording. We resort to the aforementioned VocalSet dataset, considering a subset of 10 different singing techniques, consisting of 1 736 audio samples, similar to referenced work [4].

For all tasks, we consider a sequence of $M = 5$ training sessions. Given a task comprised of C different classes,⁴ each session will have an equally distributed randomly selected subset of C/M non-overlapping new classes. To avoid any bias related to the order of the sessions or the order in which the classes are learned, we report the average performance over three scenarios, each with a different sequence of training sessions. In each scenario, we randomly arrange the classes and create random groups of C/M classes. Our goal is to obtain a better estimate of the expected performance of the CL methods under unknown learning situations. Table 2 provides a summary of the characteristics of CL paradigm posed for each task.

3.2 Implementation details

As mentioned in Section 2, our classification model comprises two fundamental components: a feature extractor, which can be either a MERT or CLMR model, and a downstream task classifier. The feature extractors are used out-

³ For each task, we launched 212 training processes following the experimental setup considered (2 feature extractors \times (3 scenarios \times 7 CL methods \times 5 sessions + 1 oracle baseline)).

⁴ Each dataset is balanced, i.e., the same number of samples, or a very similar number, is considered for each class.

Table 2. Overview of the continual learning scenario posed for each music classification task: the number of learning sessions, the total number of classes, and the number of classes per session.

Classification task	Number of learning sessions, M	Total number of classes, C	Classes per learning session, C/M
Genre		10	2
Instrument	5	11	2*
Singer		20	4
Vocal Technique		10	2

*The remaining class is randomly introduced in one of the learning sessions, i.e., there is one session with 3 classes.

of-the-box.^{5 6} These remain frozen during training not only for efficiency but also to improve stability and mitigate the effects of forgetting in CL. The classifier is an MLP with 512 hidden units. When using MERT, a one-dimensional convolutional layer is employed prior to the MLP to extract a weighted average embedding from the frame-level features obtained by MERT.

We follow the details provided in the work of Li et al. [10] to train the architecture described previously for the different considered tasks. To attain state-of-the-art results while keeping the feature extractor frozen, we train the downstream classifier for a maximum of 200 epochs using the ADAM optimizer with a fixed learning rate of 10^{-3} and a batch size of 64 audio chunks. We use early-stopping with the number of patience epochs adjusted accordingly to each task. Additionally, we employ a 25% dropout rate to mitigate overfitting and improve performance.

For the methods that require data storage from past sessions (Replay, GEM, iCaRL), we use a memory buffer of 100 memories equally distributed among the classes seen up to that session, following the implementation used in [25]. Moreover, we use PyTorch as the implementation framework. We rely on the PyCIL toolbox⁷ for all the considered CL methods, except for L2P, for which we adhere to the official implementation.⁸

The length of the audio chunks used for training and evaluating the models depends on the feature extractor used and can be seen in Table 1. For the task of singer identification and vocal technique, we use 3-second audio chunks as input, as in previous works [4, 10]. Finally, regarding the evaluation protocol, we segment each audio file into chunks (as aforementioned) and obtain a prediction for each chunk. The predictions for each chunk are then averaged to obtain a final prediction for each given audio file.

4. RESULTS

Table 4. Comparison of the final accuracy after the last session across the four tasks.

Task	Genre		Instrument		Singer		Vocal Tech	
	MERT	CLMR	MERT	CLMR	MERT	CLMR	MERT	CLMR
Finetune	18.5	19.4	10.1	10.3	19.7	19.3	17.6	17.0
Replay	28.4	22.4	14.4	14.3	29.5	21.3	27.2	19.8
iCaRL	29.0	23.1	12.4	13.4	37.5	21.6	28.1	20.6
GEM	26.8	24.5	14.3	13.4	24.9	22.5	26.4	28.5
EWC	18.6	17.1	10.1	10.1	19.8	19.3	16.2	17.4
L2P	19.0	-	10.9	-	19.8	-	13.9	-
PCC	59.0	61.4	31.0	32.9	56.1	41.5	61.1	60.5
Oracle	72.4	67.9	63.7	55.4	98.2	86.7	78.4	74.0

The first observation is the limitation of the existing CL literature, where methods are primarily evaluated over well-established computer vision tasks [11]. As evidenced by the reported results, such methods fall short in terms of generalization to other domains. Specifically, the considered state-of-the-art CL methods suffer from significant catastrophic forgetting, resulting in poor final performance for class-incremental music classification. This underscores the need to develop CL methods for this specific domain and encourages the assessment of CL methods across different fields to measure their overall performance more precisely.

Focusing our attention on the similarities illustrated in Fig. 2 for the two different feature extractors, MERT (left column) and CLMR (right column), we can observe that the accuracy curves for all tasks exhibit very similar trends across sessions. While the baseline performance—training directly with all data in a single session—is better when using MERT, this difference between the two feature extractors diminishes when comparing against the different CL methods, as similar performance is achieved. Consequently, we can conclude that the effectiveness of the CL methods is not solely attributable to the feature extractor.

If we examine each task separately, we observe a similar pattern in both music genre and vocal technique classification tasks. State-of-the-art methods exhibit signs of catastrophic forgetting, whereas PCC achieves a final performance that is relatively close to the reference bound. For singer identification, PCC starts with a lower accuracy but maintains good stability throughout the sessions.

However, despite achieving the highest final performance among the methods, it still falls considerably short of the task reference. Finally, instrument classification emerges as the most challenging task, with all methods displaying significant signs of catastrophic forgetting. As a result, their final performance remains far from reaching reasonable results, once again highlighting the existing room for improvement and the need to find new methods that can reduce catastrophic forgetting in music classification.

Among the considered state-of-the-art CL methods, both data-centric (Replay and GEM) and algorithm-centric (iCaRL) approaches outperform the results obtained by model-centric methods (EWC and L2P). However, it is worth noting that these first three methods rely on input data stored from previous sessions, which may not always be feasible due to privacy or storage issues. In contrast, our proposed method, PCC, remarkably surpasses all of them across all tasks without storing the original data (but their representations), thus avoiding such privacy issues.

5. CONCLUSIONS

This work studies the goodness of five state-of-the-art CL methods (Replay, EWC, iCaRL, GEM, and L2P) in the context of CIL for music classification. Additionally, we propose a simple yet effective CIL method (PCC) that relies on the generalizability of foundation models.

Our results reveal that current state-of-the-art CL methods suffer from catastrophic forgetting, whereas the proposed approach achieves the best results over four different music classification tasks. This highlights the need to investigate specific CL methods for music classification.

The results obtained with PCC showcase the robustness and utility of the features extracted with foundation models. We can only expect these models to improve over time, managing to extract more generalizable features for a wider range of tasks. This leads us to believe that it is worth further exploring these approaches for CL in music classification.

In future work, we also plan to study more sophisticated strategies for selecting the prototypes in PCC to improve both accuracy and robustness.

THEGLUENOTE: LEARNED REPRESENTATIONS FOR ROBUST AND FLEXIBLE NOTE ALIGNMENT

ABSTRACT

Note alignment refers to the task of matching individual notes of two versions of the same symbolically encoded piece. Methods addressing this task commonly rely on sequence alignment algorithms such as Hidden Markov Models or Dynamic Time Warping (DTW) applied directly to note or onset sequences. While successful in many cases, such methods struggle with large mismatches between the versions. In this work, we learn note-wise representations from data augmented with various complex mismatch cases, e.g. repeats, skips, block insertions, and long trills. At the heart of our approach lies a transformer encoder network — TheGlueNote¹ — which predicts pairwise note similarities for two 512 note subsequences. We postprocess the predicted similarities using flavors of weightedDTW and pitch-separated onsetDTW to retrieve note matches for two sequences of arbitrary length. Our approach performs on par with the state of the art in terms of note alignment accuracy, is considerably more robust to version mismatches, and works directly on any pair of MIDI files.

1. INTRODUCTION

Note alignment refers to the task of matching individual symbolically encoded notes in two versions of the same piece. Note matches can be derived for any two versions, however, this task is usually addressed for pairs of MIDI performances and scores encoded in various formats. The resulting performance-to-score alignments provide the data for several research directions in MIR and computational musicology, such as expressive performance generation, score quantization, and performance research.

To match notes can sometimes be a near-trivial task, especially with well corresponding versions, minimal expressive playing, and simple pieces. However, more often than not the unaligned data of interest and availability does not fit these criteria: performers make mistakes; play extra

repeats, variations, and ornamentations; rehearsal recordings discontinue or restart; automatic transcriptions contain various amounts of note mismatches; and the musical material tends towards the virtuosic, dense, and complex.

Due to its close similarity with sequence alignment, note alignment is usually approached with flavors of Dynamic Time Warping (DTW) or Hidden Markov Models (HMM) based on note or chord representations. Such representations are typically localized, and the alignment methods process them sequentially. The aforementioned common difficulties in MIDI performances do not harmonize well with these constraints: e.g., differently ordered chord onsets clash with DTW’s monotonicity condition, trills create (sometimes substantial) mismatches with similar pitches and thus misleading local distances, and repeats, skips, recording takes, etc. introduce large mismatches between the sequences which require a more zoomed-out perspective. To be clear, there is nothing that a priori prevents sequence alignment methods from working in these scenarios, however, in practice, the propensity of alignment methods for propagating errors render the matching quality hit-and-miss.

In this work, we address note alignment via learned representations which leverage non-local information, i.e., the entire sequence of notes influences the representation of each note. We train an attention-based encoder — TheGlueNote — to predict note representations for two 512 note subsequences. Before being passed to the network, the subsequences are augmented with a variety of challenging and large mismatch cases. At the network’s output, we compute a pairwise similarity matrix between the note representations and compare this matrix to target note matches via two classification loss terms. That is, the notes are guided towards similar representations if they match, and dissimilar representations for all others. In the process, TheGlueNote is trained to robustly predict note similarities even in the presence of substantial mismatches.

We took care to design TheGlueNote as annotation-agnostic as possible. Prior approaches mitigate edge cases by introducing additional submethods, e.g., by modeling left-right hand streams separately, excluding notated ornaments from certain steps, or requiring coinciding chord notes (see section 2). This introduces limitations on the types of files which can be processed, requiring staff or voice information, scores with ornament information, or even just quantized scores. In contrast, our model is trained

¹ <https://github.com/sildater/theglue-note>

directly on data from MIDI files with no quantization or score annotation requirement.

To extract final note matches from the similarity matrix, we present three possible additional methods. First, we simply match the notes with maximal similarity. Second, we add a decoder head to our note representation backbone – a network which predicts matching notes based on the similarity matrix. Third, we use DTW alignment techniques to extract a mapping from the similarity matrix and in turn use this mapping to match individual notes. Putting the pieces together, TheGlueNote leverages learned representations for note alignment, performs on par with the state of the art, excels at complex mismatch cases, and works with plain MIDI input data.

The rest of the paper is structured as follows: Section 2 discusses related work. Section 3 describes the model architecture and match extractor variants. Section 4 introduces training specifications, data processing, and metrics which are applied in Section 5 where we evaluate the trained model in an ablation study on the variations of architecture and match extraction, and in comparison with state-of-the-art methods both in regular and complex mismatch cases. Section 6, the discussion, concludes the paper.

2. RELATED WORK

Note alignment is a basic technology vital to many downstream tasks in symbolic music processing and computational musicology. We structure this review of related literature into a part on current state-of-the-art methods, relevant work in the neighboring domains of audio and real-time alignment, and pertinent literature on matching tasks for non-music data.

Note alignment methods almost universally make use of either Dynamic Time Warping or Bayesian Networks on pitch-based representations of either individual notes or chords [1–9]. As the principal formulation is straightforward, most recent efforts have focused on formalizations and heuristics that mitigate specific problems in edge cases. Skips and repeats present a major difficulty which can be directly modelled at the cost of computational complexity [5] or side-stepped if the use of annotated anchor points is possible [8]. Another difficulty are ornamentation notes which can be modelled as separate states [4] or excluded from a first coarse alignment and handled separately in a fine-grained note matching step [9]. Nakamura et al. [3] further model left-right hand asynchrony in piano performance. In their most recent work, note alignment is framed as a hierarchical refinement with explicit modelling of an alignment error identification step [6]. In recent work by Peter [9], sequence non-ordinality is mitigated by a score-based chord representation, the resulting model is thus limited to performance to score alignment. The current state of the art (SOTA) which we will use for reference in this work is given by two DTW-based methods [8, 9] and one HMM-based method [6].

Realtime alignment or score following methods have been developed since the 1980s [10, 11] and largely mir-

ror the previous methods in their core elements: On-Line Time Warping (OLTW), [12] and Bayesian Networks, in particular HMM [3, 7, 13].

Alignment of musical audio is an important idea generator for symbolic note alignment. For introductions of audio alignment, we refer the reader to Arzt [14] and Müller [15]. Audio alignment is prone to memory and compute bottlenecks. Several versions of DTW addressing these issues have been developed [16].

Deep Learning has largely been absent from music alignment, with notable exceptions in real-time audio-image matching [17, 18] and in symbolic score following [9]. On the other hand, we take inspiration from image processing, in particular from the task of local feature matching [19]: the matching of pixels encoding the same location on an object in two images of the same object. Local feature matching often uses neural network-based feature extractors [20, 21] and our proposed model in particular is informed by the MatchFormer [21].

3. MODEL

In this article, we present a model which is trained to create note representations for two sequences such that the representations’ pairwise similarity corresponds to the sequences’ alignment ground truth. Using these representations, we aim to uniquely match individual notes. The proposed model consists of a fixed-length tokenization, an encoder backbone, and a dual classification loss. Furthermore, we introduce three variants of match extraction from the model’s output similarity matrix: direct similarity matrix processing, using a decoder head for classification, and DTW-based match extraction. Figure 1 presents an overview of the components.

3.1 TheGlueNote

At the heart of our model is a non-causal transformer encoder (see Figure 1 middle left). Its purpose is to learn note representations for two note sequences s_1 and s_2 , and its target is the alignment between the sequences. A pairwise similarity matrix computed between the note representations of two sequences mediates between output and target. We treat the matrix as a match classifier for each note, i.e., for each row (a note in s_1) the column (a note in s_2) with maximal similarity should correspond to matching notes, and vice versa.

Technically, two at least partially matching subsequences s_1 and s_2 of 512 notes each are prepended with a default note and processed using the fixed-length structured tokenization [22, 23], which encodes relative onset, pitch, duration, and velocity. The now 513 note (2052 token) sequences s_1 and s_2 are concatenated and passed to the encoder. The encoder sums the four tokens per note and adds a learned positional embedding for a note-wise sequence of length 1026. Layer normalization is applied before the first encoder block and within the attention and feedforward blocks but not again on the residual stream. Self-attention is applied to the full concatenated

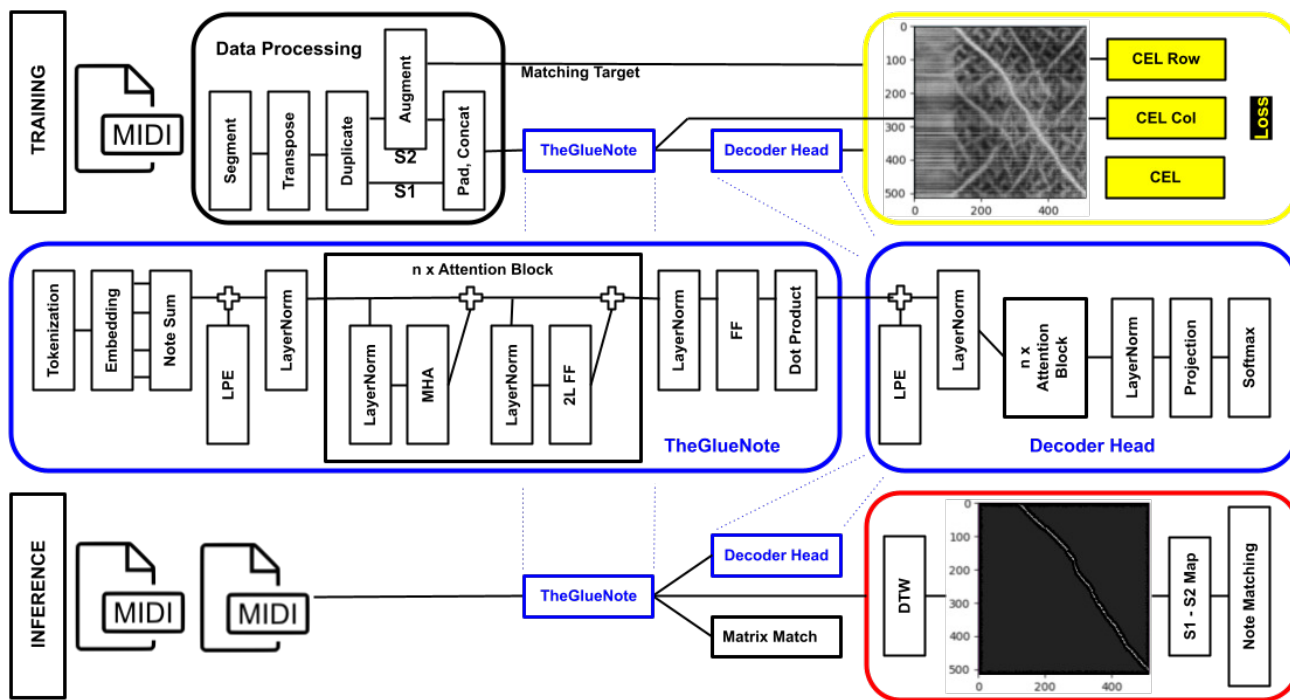

Figure 1. Overview of the proposed model. During **training** (top row), the data flows from Data Processing (black, top left) through TheGlueNote (blue, middle left) into the Decoder Head (blue, middle right) and the aggregated Loss (yellow, top right). Concretely, a MIDI file is loaded into the Data Processing module which outputs matching targets to the loss module and the concatenated sequences s_1 and s_2 to TheGlueNote. TheGlueNote (middle row) consist of a transformer encoder with learned positional embeddings (LPE) and repeated attention blocks (center module with multihead-attention MHA and a two-layer feedforward network 2L FF). The note-wise representations are split and multiplied for a pairwise similarity matrix with s_1 in the row and s_2 in the column dimension shown in the loss module. Two cross-entropy loss terms are computed from this matrix and it is also forwarded to the decoder head whose classifier output adds a third loss term. During **inference** (bottom row), two MIDI files to be matched are directly passed to TheGlueNote. The resulting similarity matrix can be processed in three ways: 1) direct maximal similarity match extraction (Matrix Match box) 2) using the decoder head’s output, or 3) using a DTW-based match extraction (red, bottom right).

sequence, which amounts to combined within-sequence attention (s_1-s_1, s_2-s_2) and between-sequence attention (s_1-s_2, s_2-s_1). The final residual is normalized after the last block and fed through a single dimension-conserving linear layer. For dimensions and hyperparameters of different versions see section 4.2 and in particular Table 3.

The 1026 final output vectors of size corresponding to the residual stream are treated as representations of individual notes. The sequences are split again and pairwise similarities between all 513 notes of s_1 and all 513 notes of s_2 are obtained via dot product. The resulting similarity matrix (s_1 in the rows and s_2 in the columns, see Figure 1 top right) is compared to two classification targets: Softmax across row dimension is the model’s prediction of the matching note in s_1 for each note in s_2 (except for the prepended default note), and softmax across the column dimension is the model’s prediction of the matching note in s_2 for each note in s_1 (again, except for its prepended default note). Both are compared against the ground truth via a cross-entropy loss (CEL). Unmatched notes in the ground truth receive a target corresponding to the default note in the other sequence, the default notes itself receive no loss.

3.2 Match Extractors

Note similarities are a useful intermediary, however, they do not yet define note matches. In this section, we detail three possible note match extractors. The simplest way of producing matches is to directly use **similarity matrix-based match extraction**. That is, for each note in s_2 , we match it to its most similar note in s_1 , including the default note (=unmatched) as possibility. A little bit of index housekeeping avoids conflicting matches and notes without prediction.

A second approach is to train TheGlueNote with an additional **decoder head for match extraction**. The decoder is also a non-causal neural network with the same high-level structure as the encoder² (see Figure 1 middle right). The decoder head processes the pairwise similarity matrix for each actual note of s_2 (hence a 512 by 513 matrix, excluding the default note in s_2) and directly predicts the matching note in s_1 via 513 output logits (including the default note in s_1 for unmatched notes). During training, its classification CEL is added to the other two losses in an

² The "decoder head" is technically also a transformer encoder without memory input, however, it decodes the representation towards classification logits, so we opt for this name.

unweighted fashion (see Figure 1 top right).

DTW match extraction offers a way of introducing meaningful constraints to the note matching. Concretely, naive note matching via maximum similarity in the prediction treats every note separately and ignores information on predictions for notes in its vicinity and previously matched notes. To introduce this information, we adapt the DTW-based mapping and matching procedure introduced by Peter [9] for similarity matrix post-processing.

DTW extraction is split in two processes (see Figure 1 bottom right). First, understanding similarity as the reciprocal of learned pairwise distance, we use the network’s output as input to a weighted DTW with possible directions $[[0, 1], [1, 1], [1, 0]]$ and associated weights $[1, 2, 1]$. This choice of weights normalizes the directions under the Manhattan distance, i.e., any direction is equally costly overall and the diagonal is not favored. A standard DTW path is computed starting at the top left and ending at the bottom right of the similarity matrix. Note that extracting a minimizing path through the learned distances discards information relevant to local non-ordinality in favor of added information about each note’s neighborhood. The extracted path should not be used as direct note match prediction, instead it defines a coarse sequence to sequence mapping $m : \mathbb{R} \rightarrow \mathbb{R}$ by linear interpolation between the onset times of notes in the path.

In a second process, we separate all notes in both sequences by pitch. For subsequences s_1^p and s_2^p of pitch p , we match onset sequences using a DTW pass to find onset pairs that minimize the distance between s_2^p and $m(s_1^p)$. Newly matched notes are then added to or overwritten in the original DTW path and the mapping m is updated. If the MIDI files to be aligned do not fit within the 512 note contexts of the model, which is often the case, we compute several similarity matrices for 512 note windows with a stride of 256 notes. We then aggregate the resulting output matrices to a global similarity matrix.

Feature	Noise and Mismatch Probabilities
Tempo T_t	$gT_t 2^{n_t}, g \sim \mathcal{N}(1, 0.5), n_t \sim \mathcal{N}(0, 0.5)$
Onset O_t	$O_t + n_t, n_t \sim \mathcal{U}(-50, 50)$
Velocity V_t	$V_t + n_t, n_t \sim \mathcal{U}(-10, 10)$
Duration D_t	$D_t + n_t, n_t \sim \mathcal{U}(-250, 250)$
Repeats	$\mathcal{P}_{repeat} = 1, \#note_{repeat} \sim \mathcal{U}(8, 200)$
Skips	$\mathcal{P}_{skip} = 1, \#note_{skip} \sim \mathcal{U}(8, 200)$
Insertions	$\mathcal{P}_{insertion} = 0.2, \text{random location}$
Deletions	$\mathcal{P}_{deletions} = 0.2, \text{random location}$
Trills	$\mathcal{P}_{trill} = 1, \#note_{trill} \sim \mathcal{U}(20, 100)$

Table 1. Augmentations to synthesize complex mismatch cases. Four noise terms are added to note features in the first row terms. Sampled noise is clipped to avoid degenerate cases like negative durations. Duration and onset noise are indicated in MIDI ticks. Skips, repeats, and trills are introduced with the indicated probability and uniformly sampled length. Insertions and deletions are added at random locations with overall probabilities given.

4. EXPERIMENTS

We report several experiments to assess the qualities of our proposed model. In this section, we describe the dataset, data preprocessing, and training as well as model configurations.

4.1 Data

A data sample for our model is a pair of 512 note subsequences. Note alignment ground truth data of real pieces and performances is available [8,24,25], however, this data is biased towards cases where prior note alignment methods could successfully be applied. To present the model with a wide variety of (mis)match cases we use synthetically augmented MIDI data for training. The original MIDI tracks are taken from the (n)ASAP dataset [8], albeit not its note alignments, only the score and performance MIDI files directly.

Ground truth match data is created entirely synthetically by copying each MIDI file and augmenting it with a combination of the processes which we describe in the following, and whose parameters are given in Table 1. The original inter-onset intervals (as a proxy for tempo) are stretched by a global factor g , and by note-wise factors n_t , these factors are multiplicative and normally distributed. Note onsets and durations are also changed note-wise, yet by additive uniform noise in MIDI ticks. All MIDI files are encoded using 480 ticks per beat and 120 beats per minute, one MIDI tick is thus slightly longer than one millisecond. Velocities are modified by additive uniform noise within the 128 standard MIDI velocity values. For repeats, skips, and trills, the probability of generating the mismatch per 512 note sequence is given, as well as note quantities sampled uniformly. The mismatches are inserted contiguously into the sequence and there is at most one augmentation of each mismatch type per 512 note sequence. Finally, insertions and deletions are generated from the existing notes, each note is deleted or copied and randomized (i.e., inserted) with the given probability. All augmentations are recomputed for every batch of training data. The values in Table 1 are given for reproducibility and transparency, although different variations were tested, we do not claim that these are optimal values.

We further add transposition to the maximal extent available on a piano keyboard as general augmentation affecting both subsequences. The augmentation is carried out in the data loader so each epoch will produce different samples from the 1032 valid MIDI files in our dataset. Data augmentation is only used during training, at inference two MIDI files are matched as is (see Figure 1).

For testing, we obtained the exact test files used in the reference literature [9]. These files stem from proprietary datasets [26, 27] and were chosen due to the alignment complexity they provide. To test for robustness under challenging mismatch scenarios, we augment these performances for an experiment including extended (100+ note) mismatches that cover approximately 20% of the notes. Each 512 note subsequence pair contains exactly two mismatching segments, one in s_1 and one in s_2 , each segment

Table 2. Ablation of Model configuration and match extraction. All match results are computed on the Vienna4x22 Dataset. Values reported are average note match precision, recall, and F-score across all performances. The results are computed for each match extractor / model combination. The first line serves as a simple baseline for the similarity matrix-based and the DTW-based match extractors: we report results of their processing a pitch and onset-based similarity matrix. We further report the average training loss (TL), validation loss (VL), and validation accuracy (VA) in the final epoch for each model.

is contiguous and its notes are randomly sampled. Note that such randomized contiguous mismatches are different from the synthetic mismatch segments seen during training (i.e., trills, repeats, skips, see Table 1). For comparison with our reference models, we have to limit ourselves to score to performance alignment instead of general MIDI to MIDI alignment, as some of the compared models only work with this type of musical material. To compare different model configurations and match extractors, we further use the public Vienna 4x22 Dataset [24]. This dataset consists of 4 pieces with 22 performances each. The pieces are comparatively simple and mismatches minimal.

Model	#p	rd	#b	#h	bs	#ph
TGN-large	28M	512	8	8	8	27M
TGN-mid	5.7M	256	6	8	16	2M
TGN-small	1.1M	128	4	8	24	0.6M

Table 3. Hyperparameters for TheGlueNote (TGN) variations: #p = parameter count, rd = residual dimension, #b = number of blocks, #h = number of attention heads, bs = batch size, and #ph = parameter count of decoder head. Parameter counts of the TheGlueNote models (#p) and their decoder heads (#ph) are approximate.

4.2 Training Setup

We train model variations differentiated in three sizes. All our models are trained on a single GeForce GTX 1080 Ti with 12 GB of memory. We train for 200k steps, independent of batch size, which is set to the maximal capacity of the GPU for each model. The learning rate is initialized at $5 * 10^{-4}$ and is scheduled using cosine annealing with warm restarts at an interval of 2k steps. Table 3 details the hyperparameters for model variations. For all attention blocks, the inverted bottleneck of the feedforward network is four times the residual dimension.

5. EVALUATION

In this section, we evaluate our proposed model. The first part compares different model configurations, the second part compares against state-of-the-art reference methods. To evaluate our models, we use note matching precision,

recall, and F-score as our main metrics. We further report mean final classification losses of the predicted similarity matrix which corresponds to direct note matching on the training and validation data as well as the runtime of different model setups.

5.1 Ablation Study of Model Configurations

In a first experiment we train three model configurations. We evaluate their note matching quality on the Vienna4x22 dataset using three different match extractors: direct similarity matrix processing, decoder head prediction, and DTW-based match extraction. Table 2 details the results. For all model configurations the match extractors are clearly ranked with DTW-based processing the most promising. DTW-based match extraction in itself is, however, not enough for good matching. To illustrate this point, we compute a simple pitch and onset based similarity matrix (the closer in pitch and onset, the higher the similarity) akin to what would be used to assess local distances in standard approaches. We then apply the similarity matrix-based match extractor and the DTW-based match extractor directly on this matrix. The first row in Table 2 shows these reference methods, which perform subpar.

5.2 Comparison to Reference Models

We compare our proposed model against three SOTA reference models: Nakamura’s HMM matcher [6], Peter’s DualDTWMatcher [9] and AutomaticNoteMatcher [8]. The first one is implemented in C++ and compiled locally³, the other’s are part of a python package⁴. The test data consists of five challenging pieces for solo piano in two settings, one default and one with mismatches. Table 4 details the results. All values are note match F-scores given in percent, except for the runtime given in seconds. In the default setting, all three model configurations perform on par with the best model with the best reference model "DualDTWMatcher". In the mismatch setting, all reference models show (partial) failure. Note that not all alignments fail, however, no reference model stays consistently

Table 4. F-scores of three reference models and our proposed models across five challenging pieces. The matching results are given as f-scores in % and the runtime in seconds. The data is split in two groups: a default case with the original performances, and a mismatch case, where challenging skips and repeats which in total constitute 20% of the notes have been introduced. The models are split in two groups: three state-of-the-art reference models and our proposed model in three configurations.

above 90 %. Our proposed models take a performance loss as well, yet only in the range of 0-7 % and the F-score stays above 92 % throughout. In terms of F-score, no significant difference between TheGlueNote configurations is found. Despite several forward passes to retrieve local similarity matrices, TheGlueNote configurations also require the lowest runtime. Unlike for the reference models the runtime does not seem to vary with the complexity of the match to be performed, only with the number of notes and the network size. The advantageous runtime comparison with the reference models is surprising and to be taken with a grain of salt as implementation details possibly outweigh the merits of each algorithm.

6. DISCUSSION

In this article, we presented TheGlueNote, a note representation model which effectively predicts note matching similarities. Despite the fundamental role of (note) alignment in several MIR areas, machine learning approaches have seen limited adoption so far — in contrast with many other areas of MIR, where machine learning models virtually superseded more traditional approaches. We can only conjecture on the reasons for this absence, however, it seems to us that sequence alignment methods faithfully model a variety of alignment problems and the established methods’ correspondingly high performance leaves little room for improvement. However, this observation does not hold for the question which sequence representations are to be processed by alignment algorithms, a question that is not settled, neither in the symbolic nor in the audio domain. Feature representations and local metrics abound, and have myriad downstream implications for alignment success or failure which are often hard to predict.

Our approach excels at this point by producing learned representations which leverage non-local information. The representations play well with DTW-based post-

processing, however, end-to-end note matching remains challenging. Learning representations shifts the problem of edge cases from the modeling stage (or even post-hoc engineering) towards the training data. Augmenting data with complex mismatches in combination with a model that effectively predicts matches frees us from having to address all possible cases explicitly. Randomized training mismatches enable the model to learn robust representation for a variety of mismatching sequences. In practice, this also leads to greater flexibility, as no quantized music, score annotations, or any attributes beyond the basic MIDI notes are required.

Many extensions of our approach are possible. The hyperparameter and architectural space of plausible representation models open several possibilities for future research. Furthermore, the data used to train and test the model is specific: solo piano pieces and performances of common practice period music. This is due to the fact that reference models work on the piano data, and large symbolic piano datasets are available. Note that this data presents one of the most challenging note alignment scenarios and we expect our core ideas to translate to other symbolic data — after retraining. An open question is whether this type of token-based match representation learning can be used in audio or multimodal domains, e.g. by applying it to discrete audio encodings. Lastly, the representation learning backbone is trained without any information about the DTW post-processing. SoftDTW [28] approaches appear promising to bridge this gap while keeping sensible alignment constraints in an end-to-end model. However, we want to stress again that the monotonicity condition of (soft)DTW does not strictly hold in symbolic music even though it has proven an effective heuristic. Many questions remain open, yet we hope to have shown that representation learning can be integrated successfully and beneficially into note alignment methods.

GAPS: A LARGE AND DIVERSE CLASSICAL GUITAR DATASET AND BENCHMARK TRANSCRIPTION MODEL

Xavier Riley Zixun Guo Drew Edwards Simon Dixon

Centre for Digital Music, Queen Mary University of London

j.x.riley@qmul.ac.uk, s.e.dixon@qmul.ac.uk

ABSTRACT

We introduce GAPS (Guitar-Aligned Performance Scores), a new dataset of classical guitar performances, and a benchmark guitar transcription model that achieves state-of-the-art performance on GuitarSet in both supervised and zero-shot settings. GAPS is the largest dataset of real guitar audio, containing 14 hours of freely available audio-score aligned pairs, recorded in diverse conditions by over 200 performers, together with high-resolution note-level MIDI alignments and performance videos. These enable us to train a state-of-the-art model for automatic transcription of solo guitar recordings which can generalise well to real world audio that is unseen during training.

For each track in the dataset, we provide metadata of the composer and performer, giving dates, nationality, gender and links to IMSLP or Wikipedia. We also analyse guitar-specific features of the dataset, such as the distribution of fret-string combinations and alternate tunings. This dataset has applications to various MIR tasks, including automatic music transcription, score following, performance analysis, generative music modelling and the study of expressive performance timing.

1. INTRODUCTION

Automatic Music Transcription (AMT) for instruments other than piano has faced challenges due to a lack of high-quality datasets [1]. This gap has limited the development of accurate transcription systems compared to those available for the piano, which benefit from comprehensive datasets like MAESTRO [2] and MAPS [3]. However, recent developments in audio-score alignment methods have shown promising results in improving transcription accuracy [1, 4].

With 2.7 million guitars sold in the US alone in 2019¹, the guitar is a popular instrument and retains a widespread cultural significance. Around 6% of these guitars sold were

of the classical or flamenco types (roughly 162,000 units). For comparison, around 31,000 acoustic pianos were sold in the US that year. Despite this popularity, we believe that the study of the guitar in the field of Music Information Retrieval (MIR) is underrepresented. Reviewing the paper titles for ISMIR conferences from 2013-2023 we find that publications with the word “piano” in the title outnumber those with “guitar” by 3 to 1². This imbalance may be due to the availability of high quality datasets for piano; new datasets and methods for guitar will help to address this.

In this paper, we present GAPS, a large and diverse classical guitar dataset that contains 14 hours of matched nylon string guitar audio recordings, note-level MIDI annotations, and corresponding music scores, where the recordings feature over 200 performers in diverse recording conditions. This is several times larger than GuitarSet [5], the EGDB dataset [6], the FrançoisLeduc dataset [4] and the IDMT-SMT-Guitar dataset [7] (see Section 2 for a detailed comparison). We use this data to train a benchmark transcription model which achieves state-of-the-art results for solo guitar transcription across 4 dataset splits.

The contributions of this paper are as follows:

- the largest available dataset consisting of real guitar audio, performance video, corresponding music scores and aligned MIDI annotations;
- metadata and external links for composers and performers, plus statistics of guitar-specific features;
- an efficient pipeline for verifying alignments of scores to audio;
- a benchmark state-of-the-art guitar transcription model trained on our dataset; and
- analysis and discussion of the effects of dataset quality, quantity and variety on AMT performance.

2. RELATED WORK

GuitarSet [5] is the most widely used MIR dataset for guitar. It provides around 3 hours of annotated guitar performances, where the data collection process required the use of a specialised guitar fitted with a hexaphonic pickup which was able to capture the output of individual strings. The use of a single guitar severely limits the diversity of

² 46 piano and 15 guitar

Name	Audio type	Track count	Duration (m)	Note count	Scores
GuitarSet [5]	Real	360	180	62,476	No
IDMT-SMT-Guitar [7]	Real	1173	340	*5,767	No
EGDB [6]	Real	240	118	35,700	No
FrançoisLeduc [4]	Real	79	240	75,312	Yes (commercial)
GAPS (ours)	Real	300	843	259,410	Yes
SynthTab [8]	Synthetic	20,715	786,774	-	Yes, via DadaGP

Table 1. Comparison of existing guitar datasets, split into real and synthetic sources. * For IDMT, the note count is shown only for notes with annotations available.

timbres and recording conditions, and in turn makes it harder for AMT models to generalise from this data [4].

The EGDB [6] dataset contains 2 hours of guitar audio recorded by a professional guitarist using a hexaphonic pickup and recorded via DI (direct input). The DI signal is then further rendered using 6 different amplifier emulation plugins. The onsets and offsets of each note are annotated.

The IDMT-SMT-GUITAR database [7] is recorded by 3 musicians using 6 different guitars (5 electric, 1 acoustic). The final audio is either obtained from DI or microphone output. It contains 4 subsets each targeting a different MIR task, ranging from single notes to chords to various short musical pieces. Its utility in transcription tasks is limited however, as only a subset of the audio has corresponding time-aligned note annotations.

Improvements in diversity of audio sources were achieved by Maman and Bermano [1] through the use of score alignment techniques. Digital scores (in MIDI format) were aligned to the activations of the Onsets and Frames transcription model [9] trained on synthetic data. Low quality alignments were discarded and the remaining data was used to fine tune the model further. This expectation maximisation approach yielded a new state-of-the-art result on GuitarSet in the zero-shot setting, which demonstrated a generalisable model. The authors collected 5 hours of classical guitar recordings and scores in this work but these were not released as part of the publication.

Building on this approach, Riley et al. [4] published a new state-of-the-art model for guitar transcription. Instead of the Onsets and Frames model, they use the high resolution piano transcription model by Kong et al. [10], which was shown to be more tolerant of misaligned labels. Furthermore, instead of bootstrapping the process with synthetic data, they employ a pre-training step where a model is trained on the MAESTRO dataset with data augmentation, which was shown to improve generalisation. A dataset of around 4 hours of audio-MIDI pairs was published with their work, however the scores are not freely available as they were purchased from a commercial source.

As an alternative to annotating real world audio, Zang et al. [8] recently proposed a large scale dataset of synthesised audio from a subset of the DadaGP dataset [11]. When used as a pre-training step, the authors note improvements in multi-pitch estimation over 3 guitar datasets. De-

spite the large volume of additional training data, their note level results on the GuitarSet test split (86.1% F1 no off-set) are lower than those of several other methods which use GuitarSet alone (see [4]). This suggests that synthetic data alone is not sufficient to improve AMT systems, but a full comparison with consistent use of model architectures would be needed to establish this with certainty.

3. OVERVIEW OF DATASET

3.1 Dataset Curation

In an effort to improve the amount of available labelled, non-synthetic data, we have curated a new dataset of classical guitar recordings based on freely available scores from the ClassClef website³, together with matching performances on YouTube⁴. We align these sources using the automatic process described in [4] and then manually verified each alignment using the synchronised score viewer at soundslice.com. Following another alignment stage, any remaining scores with inaccurate alignments are rejected (using the criteria described below). This resulted in 300 performances sampled from the entire classical guitar canon totalling over 14 hours of music and over 250,000 note events. We have also curated extensive metadata, including information about the pieces, composers and performers, in order to enrich the dataset with details of the cultural context.

Our curation process is shown in Figure 1. It begins with the ClassClef website which provides around 5,500 pieces for download in PDF and GuitarPro formats. These focus mainly on the classical guitar with some flamenco and fingerstyle pieces included. Additionally, 547 of the pieces include links to videos on YouTube of a performance of the same piece. We first collected all GuitarPro files and converted them to MusicXML and MIDI formats using the free MuseScore software package⁵. We also downloaded the audio and video for the 547 pieces where YouTube links were available.

Using the alignment method described in [4], we produce an initial alignment between the score and the recording for each piece. This proceeds in two stages: an initial

³ classclef.com

⁴ youtube.com

⁵ musescore.org/en

Figure 1. Flowchart of the dataset creation process.

alignment via Dynamic Time Warping (DTW), and a further fine alignment stage in which the notes of each chord are aligned to their closest activation from an existing transcription model. We emphasise this point as the resulting alignments are fully polyphonic in nature and as a result are more accurate than those produced by DTW alone, as described in [4].

In some cases the automatic alignment will not succeed, for example, when a linked video contains audio for an entire suite but the score only contains a single movement. For this reason a manual verification step was required. Using the `soundslice.com` website, we upload the automatically aligned downbeats to synchronize playback between the audio and the score. This allowed the authors of the paper (each with over 10 years of music experience) to review 474 of the scores (chosen at random) in an efficient workflow. More specifically, we manually verified the alignment between each downbeat location and the score for all 474 pieces. Particular attention was paid to the beginning and ending of each piece as these were a frequent source of issues in the DTW process. Moreover, any differences between the score and the performance that were identified were corrected, if feasible. In the end, 74 pieces were rejected for various reasons – for example those containing 7-string guitars, guitar duets and pieces where the edition did not match the performance. Out of the remaining 400 pieces examined, 280 were usable without corrections to the score and the remaining 120 required intervention to obtain correct downbeat alignments.

The 400 reviewed scores were then re-aligned using the same alignment method from step two of figure 1. The corrected downbeats were used as anchor points during this alignment stage to ensure that any alignment errors would be localised to one measure of music. To validate accuracy, we then compared our aligned versions of the score to outputs of the guitar transcription model from [4]. We retained the 300 scores with the highest agreement, measured using the “F-measure no offset” metric from the `mir_eval` library [12]. We retained scores which had an F-measure of more than 75%, yielding 300 audio-score pairs. We manually reviewed the lower scoring alignments and found a number of issues including errors with the processing of anacrusis bars, non-440Hz tunings and discrepancies between the performance and score editions. We hope to address these where possible as part of future work.

A summary of existing guitar datasets is shown in Table 1. When considering datasets with real (as opposed to syn-

thesised) audio, GAPS represents a significant advance in terms of the duration of audio and number of note events. In addition, ours is the first dataset of real audio to include freely available full music scores, tablatures in MusicXML format, and accompanying performance videos.

3.2 Composers

Works from 93 different composers are included, ranging from the Renaissance (Luys Milan, c.1500-1561) to the present day. The majority of works are from the classical guitar repertoire, with a small number of flamenco pieces and arrangements of popular music. We include the dates, nationality and presumed gender of each composer with links to canonical URLs (IMSLP and Wikipedia) where possible.

Examining the diversity of composers contained in the dataset, Figure 2 shows their nationalities, according to data from the canonical URL for each composer. This shows they are broadly divided between Europe and Latin America. In terms of chronology Figure 3 shows the distribution of pieces according to the year in which the composer was born. This shows that the included pieces are mainly weighted around the Romantic era (1850-1900). The peak around 1650 is almost entirely due to J.S. Bach, who is the second most common composer in our dataset with 23 pieces. We also include information about the presumed gender of composers in our metadata, however only two female composers (Maria Linnemann and Luise Walker) are included who together represent 2% of the total by piece count. We acknowledge that this is a shortcoming of the current dataset and we will seek to address this in future work.

3.3 Performances

The accompanying videos are drawn from 205 different performers with YouTube views totalling over 35 million across all videos. Some are professionally produced recordings whereas others are recorded on commodity equipment such as phones and laptops. We believe this is an advantage of this dataset in that recordings are drawn from a wide variety of real world recording conditions, which in turn helps to increase the robustness of trained AMT models.

In the metadata we include information about the name of the performer (where available), their social media links (if available), the YouTube channel, the view count and

Figure 2. Nationalities of the composers

Figure 3. Histogram of works according to composer’s birth year at 50 year intervals

Tuning	Count	% of total

FADGBE	1	0.33
CGDGBE	1	0.33
EBDGBE	1	0.33

Table 2. Distribution of guitar tunings in GAPS. The tuning is expressed from low to high pitch.

the presumed gender of the performer. This was gathered to examine the extent to which classical guitar is a male dominated field. We find that female performers are better represented than composers in our dataset, but still only comprise 23% of the total.

3.4 Guitar-Specific Features

The large number of scores allows us to examine several guitar-specific features of the data. In Table 2 we see that two different tunings account for 97% of the data. While standard tuning is most common, almost 20% of pieces have the lowest string tuned down one tone to D. Other alternate tunings account for around 3.3% of the total.

To see the distribution of notes across the guitar neck in

this dataset, we have plotted a heat map as shown in Figure 4 using the fret information contained in the MusicXML tablature. Over the 259,000 note events we see that the pieces in the classical guitar repertoire favour the use of open strings and the first position. The strong peak at the 2nd fret A on the G string also suggests a preference towards “guitar friendly” keys such as E and A which allow the performer to use the open bass and top strings. While this distribution is uneven, we consider this to be representative of the classical guitar repertoire. We encourage other dataset authors to explore similar visualisations in future work to see if this varies with other genres.

Since most pitches can be played on more than one position on the guitar, there is an exponentially large number of tablatures that correspond to any one given score, including many physically unplayable versions. While each tablature in our dataset represents one valid way to play the score, we have not verified the extent to which the tablatures correspond to the choices of the performers in the specific performances in the GAPS dataset. This is left for future work. As we were not able to trace the provenance of the ClassClef data, we presume the data is crowdsourced and reflects the playing habits of a subset of computer-literate guitarists. It is also possible that some of the tabs were generated algorithmically from the score data.

4. TRANSCRIPTION BASELINE

4.1 Experimental Settings

To demonstrate the utility of the GAPS dataset of aligned score-audio pairs, we trained several guitar transcription models using the high resolution model of Kong et al. [10], which achieved state-of-the-art performance when trained for guitar transcription [4]. This model is a convolutional recurrent neural network (CRNN) that is trained in a supervised manner to map log mel-spectrograms of 10-second segments of audio to MIDI. The convolutional layers span only across the frequency dimension, maintaining the time-resolution of the original spectrogram (10ms). These features are then processed by a gated recurrent unit (GRU) to produce the final outputs of onset, offset, frame activity, and velocity activations per pitch per time window.

There are two reasons why we used the high resolution model [10]. Firstly to ensure fair comparisons with the state-of-the-art model in [4] as it shares the same architecture. This allows us to examine how our GAPS dataset influences the same transcription model. Secondly, fine-tuning becomes feasible due to the shared architecture among multiple piano transcription models [10, 13]. This allows us to investigate whether different pre-trained piano transcription models can improve guitar transcription through domain adaptation.

For our experiments, we trained 2 sets of models. The first set of models is trained only on the GAPS dataset and the second set of models is trained with a combination of GuitarSet and GAPS. We employ the first set of models for zero-shot inference on the complete GuitarSet, while the

Figure 4. Heat map of the fret/string combinations in the GAPS MusicXML tablatures.

second set is utilised to evaluate guitar transcription performance across the test splits of GuitarSet, theFrançoisLeduc dataset and GAPS. To study the effects of pre-training and finetuning [8, 13], each set of models has 3 variants: one trained from scratch and two finetuned from one of two published checkpoints for piano transcription [10, 13]. This also allows for a more direct comparison with results reported in [4].

Regarding our training data and strategy, we randomly divide the GAPS dataset with a 90:10 split by piece, for training and testing respectively. Following [4], each audio file is split into 10-second chunks, using a hop size of 1 second. We adopt the same train-test split from [4, 14] for GuitarSet. During training, pitch shifting of up to ± 3 semitones was randomly applied as data augmentation [14].

4.2 Transcription Results

In Tables 3 to 6, we report the evaluation results for the models described in Section 4.1. Our proposed combination of model, pre-training checkpoint and dataset achieves state-of-the-art performances on all 4 test sets mentioned in Section 4.1. Considering the similarities to the approach used by Riley et al. [4], our larger dataset appears to drive the improvement in results.

4.2.1 Generalisation and Guitar Types

GuitarSet contains audio for one acoustic steel string guitar recorded via microphone and also via the guitar pickup (the “DI” outputs). Despite our GAPS data containing only performances on nylon-stringed classical guitars, our model is able to generalise well to GuitarSet in the zero-shot setting (F-measure 88.1% - see Table 4). This result is interesting as it appears that timbral differences between guitars are not a strong factor in the success of the model for this task. On the other hand, GAPS does include a large range of guitars and recording conditions (unlike GuitarSet’s one guitar), which we expect would contribute to the generalisation performance of models trained on it.

We also note that for the other solutions based on encoder-decoder architectures [14, 16], the strong results in the supervised setting on GuitarSet fail to perform as well on unseen data. Table 4 shows the transcription accuracy on GuitarSet in the zero-shot setting, i.e. where models are trained without any access to GuitarSet. F-measure scores

for MT3 fall from 90.0% to 32.0% on GuitarSet. The previous state-of-the-art model (Time-Frequency Perceiver) from Lu et al. [14] attains 91.1% in the GuitarSet supervised task but drops to 80.0% on the unseen FrançoisLeduc test set. It may be the case that these architectures require more data to generalise effectively and we hope to explore training them on GAPS in future work.

For the FrançoisLeduc test split in Table 5, our proposed model outperforms Riley et al. [4] by a small margin, however their model was trained in a supervised fashion whereas this dataset was unseen by our model.

Conversely, our proposed method outperforms Riley et al. [4] on the GAPS test split by a margin of 2.2% (see Table 6). This indicates that, despite our method’s strong generalisation (see Table 4), it is somewhat specialised to classical guitar timbres and that the strongest results in the future may rely on the use of specific training data.

4.2.2 Effects of Pre-training

In each of our evaluations, we see a consistent trend whereby the model with no pre-training is surpassed by the model pre-trained on piano (MAESTRO) and fine-tuned on GAPS, which in turn is surpassed by the model pre-trained on an augmented version of MAESTRO [13] before fine-tuning on GAPS. This illustrates the importance of pre-training and fine-tuning, as well as data augmentation as important drivers of success in the transcription task (see Edwards et al. [13] for a detailed analysis of the effect of data augmentation on transcription generalisation).

We also note that strong results for other methods on the GuitarSet test split are obtained from models trained with a mixture of datasets [4, 14, 16]. One exception is Zang et al. [8], who use a large corpus of synthetically rendered guitar samples for pre-training. This does not perform as well as other methods but their results were obtained from a model (TabCNN) designed for guitar tablature prediction, as opposed to a state-of-the-art transcription model. A full comparison of synthetic and real audio for pre-training is something we also hope to explore in future work.

5. CONCLUSION

We present GAPS, a large dataset of score and audio pairs for solo classical guitar which comprises a wide range of composers, performers and real-world recording conditions, totaling 14 hours of recordings. The MIDI annotations are made freely available and the audio is available at the YouTube links provided. This represents the largest dataset of freely available guitar audio-score pairs to date.

We included analysis of the overall statistics of the GAPS dataset, but further musicological work could be done to examine connections between the composers, performers and musical features. The published MIDI annotations could be useful for generative modelling of classical guitar and other instruments. For future work we will look to expand the dataset and enhance the diversity where possible, particularly for the range of composers we include.

One application of this dataset is AMT for guitar, which we demonstrate through a comprehensive evaluation of a transcription model trained on our data. This shows state-of-the-art results when compared with existing methods trained on other datasets. In future work we look to examine further issues around pre-training for guitar transcription.

6. ETHICS STATEMENT

In addition to our role as researchers, we are also members of the global community of musicians and we seek to respect their important role in our culture. Our work here raises several issues which may have wider impact on this community which we hope to address as follows.

Firstly, we believe that using sources which are publicly available (subject to licence conditions) is important to reduce barriers to future research. At the time of writing, neither the scores nor their audio recordings are behind any kind of paywall. We have processed this data and make the results available on the basis of fostering research. We also obtained permission from the website owner of `classclef.com` to make use of their materials.

By publishing work on YouTube, artists do grant some kind of implicit licence that the data can be viewed, however the specific terms of the licence may restrict further use cases. We believe that our work is justified in using this data under fair use or fair dealing exemptions defined for research, but we are mindful that further use of the data may require express permission from the performers, composers or copyright-holders. We have attempted to address this by including detailed information about all performers and composers in the accompanying metadata to allow interested parties to contact them directly.

Finally we recognise that AMT models which approach human-level accuracy might pose a threat to those who are employed in music transcription and related fields. On the other hand, such models could also assist such work and become tools for improving the efficiency and accuracy of their daily work. For this reason we are carefully considering whether to make our model weights freely available.

ABSTRACT

The synchronization of motor responses to rhythmic auditory cues is a fundamental biological phenomenon observed across various species. While the importance of temporal alignment varies across different contexts, achieving precise temporal synchronization is a prominent goal in musical performances. Musicians often incorporate expressive timing variations, which require precise control over timing and synchronization, particularly in ensemble performance. This is crucial because both deliberate expressive nuances and accidental timing deviations can affect the overall timing of a performance. This discussion prompts the question of how musicians adjust their temporal dynamics to achieve synchronization within an ensemble. This paper introduces a novel feedback correction model based on the Kalman Filter, aimed at improving the understanding of interpersonal timing in ensemble music performances. The proposed model performs similarly to other linear correction models in the literature, with the advantage of low computational cost and good performance even in scenarios where the underlying tempo varies.

1. INTRODUCTION

Synchronization of motor responses to rhythmic auditory cues represents a biological phenomenon found across various species [1], and social collectives often engage in activities necessitating precise temporal coordination among members, a crucial factor for successful group endeavors. For example, in scenarios such as rowing eights, temporal alignment may not be the primary focus, but individual timing remains tied to collective timing dynamics [2]. In domains like musical performances, achieving precise temporal synchronization serves as a prominent goal [3].

Typically, musicians do not adhere strictly to the exact timing of note onsets as indicated in the musical score: due to expressiveness, they often introduce deviations from the

prescribed timing [4]. These fluctuations require a high level of control over relative timing, where the phase of notes produced by the musician deviating from the timing aligns differently with the phases of other musicians. Rehearsals often involve reaching a consensus on expressive variations, ensuring that timing deviations are synchronized among players while maintaining relative timing [5]. Nevertheless, even with a unified understanding of the musical interpretation, individual musicians may opt to vary the timing of note onsets in specific passages between different performances [5,6]. Musical performance timing is also susceptible to inadvertent variations due to factors such as rhythmic intricacies, technical demands beyond timing (e.g., pitch, volume), lapses in concentration, and the inherent variability of biological timing [7]. While extensive individual practice can mitigate some of these unintended variations, complete elimination is unlikely.

The previous discussion raises the inquiry: how do musicians within an ensemble modulate their temporal dynamics to achieve synchronization with one another? In this paper a novel feedback correction model is presented, based on the Kalman Filter and aimed at improving timing accuracy in ensemble music performances. The proposed model generalizes the linear autoregressive model in [8] with the improvement of allowing two important quantities, the *phase* and *period correction gains*, to vary along time, since it makes the model suitable to describe synchronization in scenarios where the underlying tempo greatly varies (a realistic case in ensemble performance).

The paper is organized as follows: Section 2 recalls some linear models for synchronization, and the dynamic generalization of the model in [8] is presented, which is formulated as a Kalman Filter in Section 4; the fundamentals of the Kalman Filter are briefly recalled in Section 3; the computational experiments are shown and discussed in Section 5; conclusions are presented in Section 6. Directions for future work are identified throughout the paper.

2. LINEAR MODELS FOR ENSEMBLE SYNCHRONIZATION

The starting point for contextualizing the proposed model is [9], where a phase-correction model is presented as a method for an individual performer to achieve synchrony with a periodic metronome click or with another performer

© H. T. Carvalho, M. S. Li, M. di Luca, and A. M. Wing. Licensed under a Creative Commons Attribution 4.0 International License (CC BY 4.0). **Attribution:** H. T. Carvalho, M. S. Li, M. di Luca, and A. M. Wing, "A Kalman Filter model for synchronization in musical ensembles", in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

(see also [10]). The fundamental concept revolves around utilizing the asynchrony, termed as a *phase error*, between a tone onset and the metronome click (or between two tone onsets produced by different performers) in a feedback mechanism, that guides the performer to adjust the time interval preceding the next tone onset. Consequently, the performer either decreases or increases the interval leading up to the subsequent tone onset proportionally to the preceding asynchrony. This process aims to achieve greater synchrony (“in phase”) between the next tone onset and the metronome click (or pair of tone onsets). This synchronization scheme can be represented by Equation (1):

$$t_n = t_{n-1} + T_n - \alpha A_{n-1} + \varepsilon_n, \quad (1)$$

where t_n and t_{n-1} represent the current and previous observed tone onset event times respectively, T_n denotes the time interval generated by an internal timekeeping mechanism, α is the *phase correction strength* or *phase correction gain*, A_{n-1} refers to the asynchrony of the previous onset event, and ε_n represents a random error term, which includes the internal timekeeper noise. The complete reduction of asynchrony to zero hinges on the value assigned to the gain, α , since this parameter determines the proportion of the preceding phase error that the performer endeavors to eliminate.

Following [11], *period correction* can also be incorporated in the model in Equation (1), by imposing that

$$T_n = T_{n-1} - \beta A_{n-1}, \quad (2)$$

where β is the *period correction strength* or *period correction gain*. Phase correction involves a local, within-cycle adjustment to the timing, while period correction entails a more enduring alteration to the underlying tempo, influencing subsequent cycles as well. Phase correction typically occurs automatically, without the need for conscious awareness of synchronization discrepancies. However, period correction appears to be more cognitively demanding, relying on the conscious detection of tempo variations in the external rhythm [12, 13].

As previously mentioned, Equations (1) and (2) model the asynchrony correction of an individual tapping according to a periodic metronome, or between two individuals tapping together. In [8] it is argued that the same modeling framework is also suited to describe synchronization in music ensemble performance, where a specific musician now tries to reduce asynchrony between him/her and every other performer. Therefore, Equations (1) and (2) can be jointly generalized to an ensemble of K performers as:

$$t_{i,n} = t_{i,n-1} + T_{i,n} - \sum_{\substack{i=1 \\ j \neq i}}^K \alpha_{ij} A_{ij,n-1} + \varepsilon_{i,n} \quad (3)$$

$$T_{i,n} = T_{i,n-1} - \sum_{\substack{i=1 \\ j \neq i}}^K \beta_{ij} A_{ij,n-1}, \quad (4)$$

where $i = 1, \dots, K$ indicate a specific performer, $t_{i,n}$ and $t_{i,n-1}$ are respectively the current and previous ob-

served tone onset event times for player i , $T_{i,n}$ is the timekeeper interval for player i at time instant n , $A_{ij,n-1} = (t_{i,n-1} - t_{j,n-1})$ is the asynchrony at the time instant $n-1$ between players i and j , α_{ij} and β_{ij} are respectively the phase and period correction gain applied by player i to compensate for $A_{ij,n-1}$, and $\varepsilon_{i,n}$ is a noise term identified with the internal timekeeper. Estimation of the values of α_{ij} and β_{ij} can be performed using the *bounded Generalized Least Squares* method (bGLS) [14, 15].

In [8], the model in Equation (3) is implemented and largely investigated for the case of a string quartet ensemble playing a homophonic section from the string quartet Op. 74 no. 1 by Joseph Haydn (fourth movement, bars 13–24), as this part has a steady tempo and all player’s quarter notes are aligned. In [14] the coupling of Equations (3) and (4) is investigated, with a simulated string quartet data with mild tempo changes, and the bGLS algorithm is shown to be capable of recovering the values of α and β . However, due to the nature of the bGLS algorithm, the authors point out that many data points are necessary for robust estimation of these variables, which may not be available or is an unrealistic aim in the case of a real-time implementation of the correction model (eg. for a virtual reality musical ensemble). In [16] the ADAM model (ADaptation and Anticipation Model) is proposed, including not only correction terms but also anticipatory ones, and in [17] this model is tested with tempo-changing tapping data, but since there is no adaptation of the bGLS algorithm to this new set of equations, the parameter estimation is done by exhaustive search, which is infeasible for real-life applications. Moreover, due to the nature of its parameters, the ADAM model is non-identifiable, meaning that more than one configuration of the parameters leads to the same estimate.

In order to circumvent the aforementioned issues, an alternative is to consider not a single value of α and β for each pair of performers through time, but *time-dependent correction gains*. Developing this intuition, a dynamic α_{ij} allows that a performer changes the phase correction at each onset, and a dynamic β_{ij} would allow him/her to correct differently for tempo variations during the performance of an excerpt. To model a dynamic variable, a good balance between simplicity and accuracy is a random walk, and in this case phase and period correction occur according to Equations (3) and (4), respectively, but with additional equations to allow the evolution of both correction gains. This new model is summarized in Equations (5), (6), (7), and (8):

$$t_{i,n} = t_{i,n-1} + T_{i,n} - \sum_{\substack{i=1 \\ j \neq i}}^K \alpha_{ij,n} A_{ij,n-1} + \varepsilon_{i,n} \quad (5)$$

$$T_{i,n} = T_{i,n-1} - \sum_{\substack{i=1 \\ j \neq i}}^K \beta_{ij,n} A_{ij,n-1} \quad (6)$$

$$\alpha_{ij,n} = \alpha_{ij,n-1} + w_{ij,n}^{(\alpha)} \quad (7)$$

$$\beta_{ij,n} = \beta_{ij,n-1} + w_{ij,n}^{(\beta)}, \quad (8)$$

where $w_{ij,n}^{(\alpha)}$ and $w_{ij,n}^{(\beta)}$ are independent zero-mean Gaussian random variables, allowing the evolution of $\alpha_{ij,n}$ and $\beta_{ij,n}$ through time, respectively (notice the novel subscript “ n ” in both α_{ij} and β_{ij}).

However, in the model proposed in Equations (5), (6), (7), and (8), it is not clear how to employ the bGLS method to obtain estimate of the variables of interest, and two distinct paths can now be followed: generalize the bGLS algorithm to this new situation, or resort to estimation techniques within the theory of dynamic models [18]. This work follows the latter, adopting the Kalman Filter as a framework to analyze Equations (5), (6), (7), and (8), due to its balance between flexibility and simplicity, as well as its simple and highly interpretable update equations. Section 3 recalls the basics of the Kalman Filter and Section 4 formulates the proposed model in this scenario.

3. A BRIEF RECALL ON THE KALMAN FILTER

The Kalman Filter (KF) was developed in the 1960’s, and served originally as a way to produce accurate estimates of variables of interest (eg. position of an object) by reaching a consensus between physical models and noisy measurements [19]. More generally, the KF can be seen as a state-space dynamic model, employed to describe more general time-series as a dynamic linear regression model as function of an underlying Markov model [18].

The main contribution of this paper is to propose the model in Equations (5), (6), (7), and (8), and formulate it as a KF, employing its filtering and smoothing equations to estimate the phase and period correction gains through time. The choice of a KF to achieve this goal are: linear nature of the model in Equations (5), (6), (7), and (8), high interpretability of the KF and its update equations, and potential low computational cost of its implementation.

The notation and basic equations of the KF are now briefly recalled, following [18]. In what follows, the index n ranges from 1 to N . Let $\mathbf{y}_n \in \mathbb{R}^m$ be a sequence of *observed variables* (or *measurements*), and $\boldsymbol{\theta}_n \in \mathbb{R}^p$ be a sequence of unobserved vectors, which are called the *hidden* (or *state*) variables. The KF model assumes that these two entities are related by Equations (9) and (10):

$$\mathbf{y}_n = \mathbf{F}_n \boldsymbol{\theta}_n + \mathbf{v}_n \quad (9)$$

$$\boldsymbol{\theta}_n = \mathbf{G}_n \boldsymbol{\theta}_{n-1} + \mathbf{w}_n, \quad (10)$$

where $\mathbf{F}_n \in \mathbb{R}^{m \times p}$ and $\mathbf{G}_n \in \mathbb{R}^{p \times p}$ are sequences of known matrices (*observation model* and the *state-transition model*, respectively). Vectors $\mathbf{v}_n \in \mathbb{R}^m$ and $\mathbf{w}_n \in \mathbb{R}^p$ are independent *observation* and *process* noise terms, respectively, and it is assumed that they follow Gaussian probability distributions, that is, $\mathbf{v}_n \sim N(\mathbf{0}, \mathbf{V}_n)$ and $\mathbf{w}_n \sim N(\mathbf{0}, \mathbf{W}_n)$,¹ where $\mathbf{V}_n \in \mathbb{R}^{m \times m}$ and $\mathbf{W}_n \in \mathbb{R}^{p \times p}$ are sequences of known covariance matrices of the observation and process noise terms respectively.

¹ The symbol \sim means “follows the probability distribution”, and $N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ denotes a multivariate Gaussian distribution with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. The dimension of the support of the random vector is omitted, and compatibility between dimensions of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ is always assumed.

The KF dynamically estimates variables $\boldsymbol{\theta}_n$ and \mathbf{y}_n based on observations up to time $n - 1$, and updates the estimate of $\boldsymbol{\theta}_n$ when the observation at time n is available. This process is done accordingly to Equations (11), (12) and (13), called the *filtering equations*:²

Prediction step for hidden variables:

$$\boldsymbol{\theta}_n | \mathbf{y}_{1:n-1} \sim N(\mathbf{a}_n, \mathbf{R}_n) \quad (11)$$

Prediction step for observed variables:

$$\mathbf{y}_n | \mathbf{y}_{1:n-1} \sim N(\mathbf{f}_n, \mathbf{Q}_n) \quad (12)$$

Update step (compare predictions to measurements):

$$\boldsymbol{\theta}_n | \mathbf{y}_{1:n} \sim N(\mathbf{k}_n, \mathbf{C}_n), \quad (13)$$

where³

$$\mathbf{a}_n = \mathbf{G}_n \mathbf{k}_{n-1} \quad (14)$$

$$\mathbf{R}_n = \mathbf{G}_n \mathbf{C}_{n-1} \mathbf{G}_n^T + \mathbf{W}_n \quad (15)$$

$$\mathbf{f}_n = \mathbf{F}_n \mathbf{a}_n \quad (16)$$

$$\mathbf{Q}_n = \mathbf{F}_n \mathbf{R}_n \mathbf{F}_n^T + \mathbf{V}_n \quad (17)$$

$$\mathbf{k}_n = \mathbf{a}_n + [\mathbf{R}_n \mathbf{F}_n^T \mathbf{Q}_n^{-1}] \mathbf{e}_n \quad (18)$$

$$\mathbf{e}_n = \mathbf{y}_n - \mathbf{f}_n \quad (19)$$

$$\mathbf{C}_n = \mathbf{R}_n - [\mathbf{R}_n \mathbf{F}_n^T \mathbf{Q}_n^{-1}] \mathbf{F}_n \mathbf{R}_n, \quad (20)$$

assuming that the initial state is chosen according to a normal distribution, that is, $\boldsymbol{\theta}_0 \sim N(\mathbf{k}_0, \mathbf{C}_0)$. For more details on the KF, see [18, 19].

One of the appealing aspects of the KF is its ability to perform estimation and forecasting sequentially, as new data emerge. However, if observations \mathbf{y}_n for $n = 1, \dots, N$ are available beforehand, one is also able to retrospectively reconstruct the system’s states, in order to analyze its behavior given all the observations. For this purpose, a backward-recursive algorithm can be employed to compute the conditional distributions of $\boldsymbol{\theta}_n$ given $\mathbf{y}_{1:N}$, for any $n < N$ [18, 19]. The main ingredient of this algorithm is the *smoothing equation* (21):

$$\boldsymbol{\theta}_n | \mathbf{y}_{1:N} \sim N(\mathbf{s}_n, \mathbf{S}_n), \quad (21)$$

where

$$\mathbf{s}_n = \mathbf{k}_n + \mathbf{C}_n \mathbf{G}_{n+1}^T \mathbf{R}_{n+1}^{-1} [\mathbf{s}_{n+1} - \mathbf{a}_{n+1}] \quad (22)$$

$$\mathbf{S}_n = \mathbf{C}_n - \mathbf{C}_n \mathbf{G}_{n+1}^T \mathbf{R}_{n+1}^{-1} \times [\mathbf{R}_{n+1} - \mathbf{S}_{n+1}] \mathbf{R}_{n+1}^{-1} \mathbf{G}_{n+1} \mathbf{C}_n, \quad (23)$$

assuming that $\boldsymbol{\theta}_{n+1} | \mathbf{y}_{1:N} \sim N(\mathbf{s}_{n+1}, \mathbf{S}_{n+1})$. Notice that since the smoothing is performed backwards, it is necessarily to previously filter the set of observations to gain access to vectors \mathbf{k}_n and \mathbf{a}_n , and matrices \mathbf{C}_n and \mathbf{R}_n .

4. KALMAN FILTER MODEL FOR ENSEMBLE SYNCHRONIZATION

Equations (5), (6), (7), and (8) can be written as a KF by considering proper choices for the observed and hidden

² The conditional distribution of \mathbf{u} given \mathbf{z} is denoted by $\mathbf{u} | \mathbf{z}$, and $i : j$ means “observations from time instants i to j ”, both extremes included.

³ The superscript T after a vector or matrix denotes its transpose; the superscript $^{-1}$ after a matrix denotes its inverse.

variables, as well as the observation and state-transition matrices. The main goal of this section is to construct a sequence of matrices \mathbf{F}_n and \mathbf{G}_n , as well as vectors \mathbf{y}_n and $\boldsymbol{\theta}_n$ of observed and hidden variables respectively, such that Equations (9) and (10) recover the model proposed in Equations (5), (6), (7), and (8). Firstly, to simplify the formulation of the model, the observed variables are not the tone onset times for each player, but rather the *inter-onset-intervals* (IOIs), denoted by $r_{i,k} = t_{i,n} - t_{i,n-1}$, for $i = 1, \dots, K$. These values are assembled as in Equation (24):

$$\mathbf{y}_n = [r_{1,n} \dots r_{K,n}] \in \mathbb{R}^K. \quad (24)$$

The hidden variable $\boldsymbol{\theta}_n$ can be written as in Equation (25):

$$\boldsymbol{\theta}_n = [\mathbf{T}_n^T \mid \mathbf{r}_n^T \mid \boldsymbol{\alpha}_n^T \mid \boldsymbol{\beta}_n^T]^T \in \mathbb{R}^{2K^2}, \quad (25)$$

where

$$\mathbf{T}_n = [T_{1,n} \dots t_{K,n}]^T \in \mathbb{R}^K \quad (26)$$

$$\mathbf{r}_n = [r_{1,n} \dots r_{K,n}]^T \in \mathbb{R}^K \quad (27)$$

$$\boldsymbol{\alpha}_n = [\alpha_{ij,n} \text{ in the lexicographical order on } ij, \text{ for } 1 \leq i, j \leq K, i \neq j] \in \mathbb{R}^{K(K-1)} \quad (28)$$

$$\boldsymbol{\beta}_n = [\beta_{ij,n} \text{ in the lexicographical order on } ij, \text{ for } 1 \leq i, j \leq K, i \neq j] \in \mathbb{R}^{K(K-1)}. \quad (29)$$

The relation between $\boldsymbol{\theta}_n$ and \mathbf{y}_n is described by the observation matrix in Equation (30):⁴

$$\mathbf{F}_n = [\mathbf{0}_K \mid \mathbf{I}_K \mid \mathbf{0}_{K \times K(K-1)} \mid \mathbf{0}_{K \times K(K-1)}]. \quad (30)$$

Notice that matrices $\mathbf{F}_n \in \mathbb{R}^{K \times 2K^2}$ are constant through time. The evolution of the hidden variables in $\boldsymbol{\theta}_n$ is modelled by a sequence of state-transition matrices $\mathbf{G}_n \in \mathbb{R}^{2K^2 \times 2K^2}$, described in Equation (31):

$$\begin{bmatrix} \mathbf{I}_K & \mathbf{0}_K & \mathbf{0}_{K \times K(K-1)} & \mathbf{G}_n^{T\beta} \\ \mathbf{I}_K & \mathbf{0}_K & \mathbf{G}_n^{r\alpha} & \mathbf{G}_n^{r\beta} \\ \mathbf{0}_{K(K-1) \times K} & \mathbf{0}_{K(K-1) \times K} & \mathbf{I}_{K(K-1)} & \mathbf{0}_{K(K-1)} \\ \mathbf{0}_{K(K-1) \times K} & \mathbf{0}_{K(K-1) \times K} & \mathbf{0}_{K(K-1)} & \mathbf{I}_{K(K-1)} \end{bmatrix}, \quad (31)$$

where matrices $\mathbf{G}_n^{T\beta}$, $\mathbf{G}_n^{r\alpha}$, and $\mathbf{G}_n^{r\beta}$ (of dimensions $K \times K(K-1)$ each) describe the interaction between variables in their respective superscripts. These three matrices are equal to the matrix in Equation (32):

$$\begin{bmatrix} -\mathbf{A}_{1:,n-1}^T & \mathbf{0}_{1 \times (K-1)} & \cdots & \mathbf{0}_{1 \times (K-1)} \\ \mathbf{0}_{1 \times (K-1)} & -\mathbf{A}_{2:,n-1}^T & \cdots & \mathbf{0}_{1 \times (K-1)} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0}_{1 \times (K-1)} & \mathbf{0}_{1 \times (K-1)} & \cdots & -\mathbf{A}_{K:,n-1}^T \end{bmatrix}, \quad (32)$$

where each $\mathbf{A}_{i:,n-1} \in \mathbb{R}^{K-1}$ contain the asynchronies $A_{ij,n-1}$ of player i to all players j , for $j \neq i$, at time $n-1$. Vector $\mathbf{A}_{i:,n-1}$ is made explicit in Equation (33):

$$[\mathbf{A}_{i1,n-1} \dots \mathbf{A}_{i(i-1),n-1} \mathbf{A}_{i(i+1),n-1} \dots \mathbf{A}_{iK,n-1}]^T. \quad (33)$$

⁴ The identity matrix of dimensions $L \times L$ is denoted by \mathbf{I}_L ; the matrix of dimensions $L \times M$ filled with zeros is denoted by $\mathbf{0}_{L \times M}$; a square null matrix of dimensions $L \times L$ is abbreviated by $\mathbf{0}_L$.

A simple (but tedious) verification using Equations (9) and (10) with these choices for \mathbf{F}_n , \mathbf{G}_n , \mathbf{y}_n , and $\boldsymbol{\theta}_n$ ensures that the model in Equations (5), (6), (7), and (8) is recovered. It is also established that when $K = 1$ the model in Equations (1) and (2) is recovered, with the improvement of dynamic α and β .

When compared to the bGLS algorithm [14, 15], the state-of-the-art to estimate parameters in the scenario of sensorimotor synchronization, the KF model presents a great advantage, that is the possibility of performing on-line estimation as more data become available: this feature can be important if one desires to implement real-time synchronization schemes. When the complete time-series of onset times/IOIs is available, one can apply the smoothing equation (21), in order to dynamically estimate the parameters of interest throughout the performance, as well as estimate them by applying the filtering equations (11), (12), and (13), for example, to simulate an online scenario.

Notice that the dimensions of \mathbf{F}_n , \mathbf{G}_n , and $\boldsymbol{\theta}_n$ scale quadratically with the number of performers, which may render the model overly complicated or cause computational issues when computing the KF update/filtering equations.⁵ However, due to the sparseness of matrices \mathbf{F}_n and \mathbf{G}_n , block-multiplication will highly reduce the number of operations when computing Equations (14) to (20), mitigating the latter issue. Regarding the complexity of the model, notice that in real large-scale scenarios (eg. a symphony orchestra) it is not realistic to assume that each musician synchronizes with every other, thus allowing for potential simplifications, like considering a group of instruments as a single unity and synchronizing with every other group. This procedure would diminish the value of K from approximately 100 to less than 20. A useful topic for future research would be to investigate the possibility of modeling the synchronization scheme between performers (or group of performers) in a graph, in order to decrease even more the number of relevant connections.

Another issue that is important to point out is the design of the covariance matrices for the observation and process noises, \mathbf{V}_n and \mathbf{W}_n respectively. On a first view, it makes sense to consider \mathbf{V}_n as diagonal matrices, for simplicity, since the interaction between the performers is already “captured” by the correction gains in the hidden variables; however, it is not clear if \mathbf{W}_n should be a sequence of diagonal matrices, since it makes sense to consider at least correlations between both correction gains of the same performer. This work employs a particular choice for these covariance matrices, as will be further discussed in Section 5. Further investigation on this question could involve coupling the Expectation-Maximization algorithm with the KF in order to estimate not only matrices \mathbf{V}_n and \mathbf{W}_n but also \mathbf{F}_n and \mathbf{G}_n [20]. However a disadvantage would be that these estimates would need to be static through time, requiring a large amount of data, and being highly dependent of the piece of music being analyzed.

⁵ Other computational issues on the Kalman Filter are largely discussed in [18].

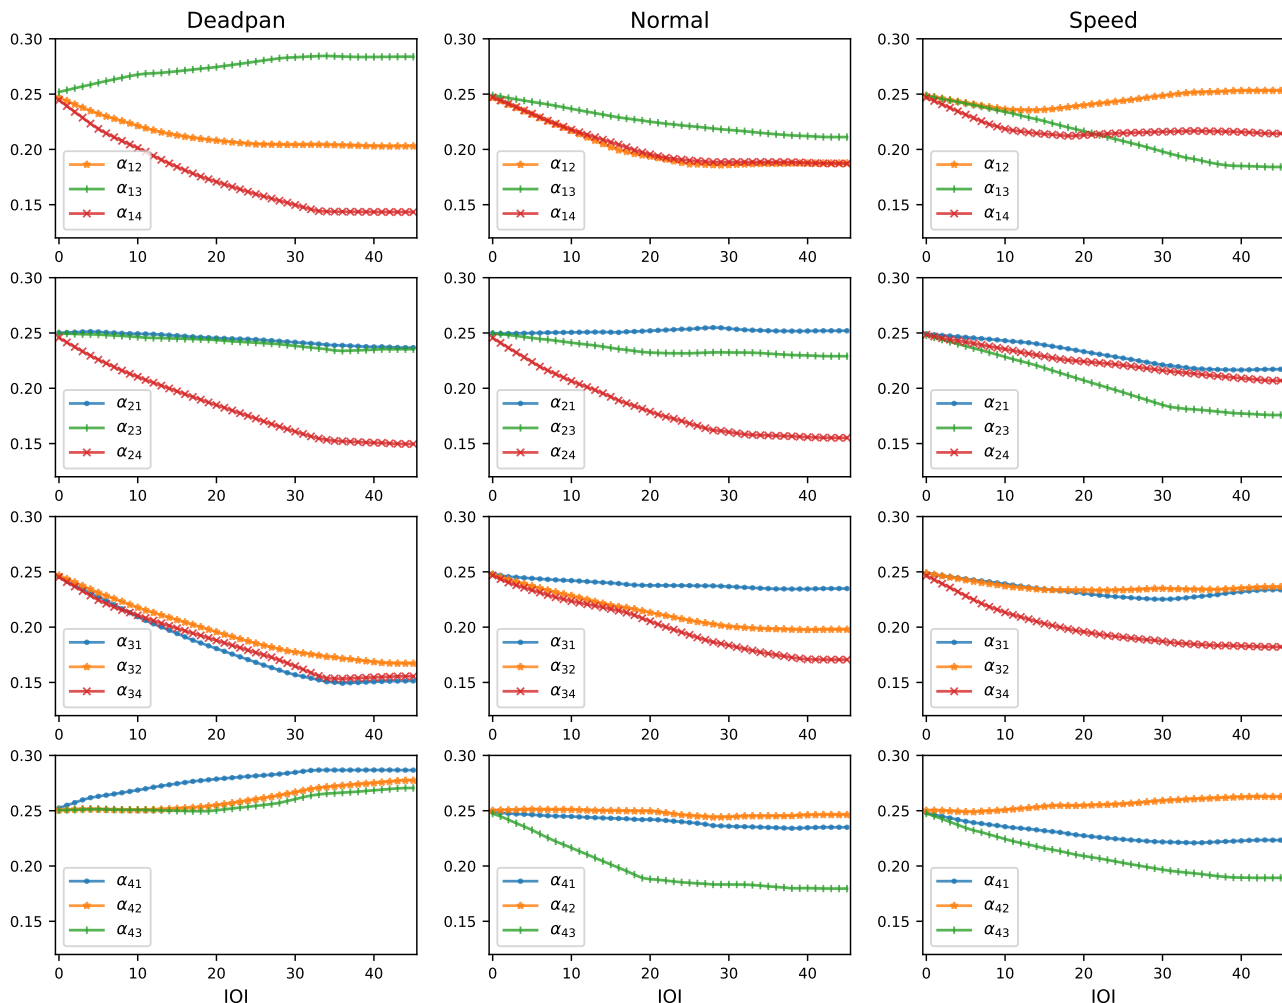

Figure 1. Smoothed time-series for the phase correction gain on three performance styles of an excerpt of the fourth movement of the string quartet Op. 74 no. 1, by Joseph Haydn. See Section 5 for discussion.

5. RESULTS

To illustrate the effectiveness of the proposed model, a set of simulations was performed, using an excerpt of the dataset presented in [21], similar to the one used in [8]: the homophonic section from the fourth movement of the string quartet Op. 74 no. 1 by Joseph Haydn, from bars 13 to 24. In this excerpt the instruments play a sequence of 47 quarter notes in rhythmic unison, with the first violin breaking the pattern near the end with an adornment of four sixteenth notes, which are disregarded in this study.

Three performance styles are considered: *Normal* condition (concert-style performance); *Speed* condition (including a spontaneous *accelerando* and *ritardando* initiated by a single musician – the designated leader, that can be the first or second violin); and *Deadpan* condition (performances with minimal expression in tempo and articulation). All the simulation were performed on a computer equipped with a 12th Generation Intel Core™ i7 processor and 16GB of RAM, running Windows 11 Pro™; the implementations were conducted in Python version 3.11.7.⁶

⁶ Codes available at <https://github.com/arme-project/ismir-2024>.

Regarding the parameters of the KF, the covariance matrix for the process noise, \mathbf{W}_n , plays an important role, since it indicates how the variables in θ interact. Based on the interpretation of the hidden variables, a reasonable choice for all the \mathbf{W}_n is the block-diagonal matrix in Equation (34):⁷

$$\begin{bmatrix} \mathbf{W}^{(T)} & & & \\ & \mathbf{W}^r & & \\ & & \mathbf{W}^\alpha & \\ & & & \mathbf{W}^\beta \end{bmatrix}, \quad (34)$$

where $\mathbf{W}^{(T)}$ and \mathbf{W}^r are given respectively by $\sigma_T^2 \mathbf{I}_K$ and $\sigma_r^2 \mathbf{I}_K$, being σ_T^2 the *timekeeper variance* and σ_r^2 the *motor variance*. Since it is known that the motor variance is way smaller than the timekeeper variance [8, 14, 15], the conservatively high values $\sigma_T^2 = 500$ and $\sigma_r^2 = 25$ were considered. Both \mathbf{W}^α and \mathbf{W}^β are also block-diagonal matrices, consisting of K blocks, each of dimen-

⁷ Off-diagonal blocks are null matrices, that were omitted exceptionally here, to avoid a line-break in the number of the equation. Moreover, notation $\mathbf{W}^{(T)}$ means to avoid confusion with the transpose matrix.

sions $(K - 1) \times (K - 1)$ and as in Equation (35):

$$\begin{bmatrix} v & c & \cdots & c \\ c & v & \cdots & c \\ \vdots & \vdots & \ddots & \vdots \\ c & c & \cdots & v \end{bmatrix}, \quad (35)$$

where v represents the variance of each α_{ij} (or β_{ij}) and c is the covariance between two distinct α_{ij} (or β_{ij}).

The rationale behind this construction for \mathbf{W}^α and \mathbf{W}^β is that it makes sense to assume that for performer i there is a correlation only between the α_{ij} (or β_{ij}) for $j \neq i$. This means that all the correction gains for performer i interact among themselves, but not directly with the correction gains of other performers. Also, it is expected that the correlation between two distinct α_{ij} (or β_{ij}) is negative, since increasing correction towards a specific performer may cause a decrease of the synchronization towards the others. With this in mind, for matrix \mathbf{W}^α the value of v was chosen as 10^{-4} ; the value of c was chosen such that the correlation between any two distinct α_{ij} is equal to -0.1 .⁸

In this preliminary set of experiments with the KF, the effect of the β_{ij} was disregarded, by considering \mathbf{W}^β a null matrix. It is known that the effect of the phase correction is way more relevant than the effect of the period correction [8, 14, 15], with the β_{ij} coefficients being usually much smaller than the α_{ij} . Also, preliminary experiments with artificial data also indicate that the dynamic values of the phase correction may render the period correction unnecessary. Since this is a point to be further investigated, it seemed safe to first experiment only with phase correction.

Matrices \mathbf{V}_n were chosen to be constant and equal to $10^{-5}\mathbf{I}_K$: since the block \mathbf{W}^r in matrix \mathbf{W}_n already captures the motor variance, \mathbf{V}_n should be a sequence of null matrices, but a negligible diagonal term was added to avoid numerical errors. Finally, the initialization of vector θ was done by choosing its first K components and the components from $K + 1$ to $2K$ to be equal to the first IOI of each of the K instruments, all the α_{ij} were initially set to 0.25, and all the β_{ij} to zero. This initialization of α_{ij} is supported by [8], where optimal correction values for ensembles of size K were derived.

Figure 1 summarizes one experiment performed in the aforementioned scenario. Three repetitions of the Haydn quartet excerpt were analyzed, being one for each of the three performance conditions, having the second violin as the leader in the ‘‘Speed’’ case. Each performance consists of a sequence of 46 four-dimensional vectors containing the IOIs for each instrument. Since it is not the goal of this set of experiments to evaluate online performance of the proposed model, these three sequences were smoothed by the KF,⁹ according to Equation 21. Each panel of Figure 1 displays the evolution of the α_{ij} , for $j \neq i$, organized as follows: each column contains a performance condition (made explicit at its top), and each row displays the evolution of α_{ij} for $j \neq i$ and a fixed value of i . The condi-

tioning of each α_{ij} on $\mathbf{y}_{1:N}$ is omitted, and the instruments are abbreviated by numbers, where 1, 2, 3, and 4 refers to the first violin, second violin, viola, and cello, respectively. On each panel of Figure 1 the values of α_{ij} promptly deviates from the optimal initialization of 0.25 (but still varies around it), and their respective behavior are now discussed.

In ‘‘Speed’’ condition (third column in Figure 1), on each panel the phase correction parameter toward the second violin (α_{i2} , for $i = 1, 3, 4$) shows a small increase by the end of the performance, when the change in speed occurs, since the second violin is assigned as the leader to initiate this change in speed. Notice also that his/her phase correction parameters towards the other performers (α_{2j} , for $j = 1, 3, 4$) decrease through time, specially near the last notes, reinforcing its leadership in this tempo change.

In the ‘‘Normal’’ condition (second column in Figure 1) it is noticeable that the second violin, viola, and cello are systematically synchronizing mainly to the first violin, which plays the melody in this excerpt: notice the almost constant value for α_{i1} , for $i = 2, 3, 4$. While the cello is synchronizing mainly with the first and second violin, it presents the weaker ‘‘synchronization attractor’’, as seen by the significant decrease in α_{i4} through time, for $i = 1, 2, 3$.

Finally, in the ‘‘Deadpan’’ condition (first column in Figure 1) the first and second violin and the cello are synchronizing mainly to the viola (steady increase of α_{i3} for $i = 1, 2, 4$, and decrease in α_{3j} for $j = 1, 2, 4$), which may be the cause of the cello synchronizing systematically with all the three other instruments.

This experiment indicates that the proposed model is capable of capturing local fluctuations in tempo, reinforces the role of the phase correction gain in interpreting synchronization mechanisms in musical ensembles, and assess qualitatively the validity of a time-varying model to the problem of ensemble synchronization. As a next step in this new direction for the field, the proposed model will be broadly tested and systematically compared with other models. Some issues to be addressed in future work are: perform experiments with other data contained on [21]; compare filtering and smoothing procedures, as well as investigate if the filtered estimates make sense from a music cognition perspective; implement tools from the theory of dynamic linear models to automatically estimate the covariance matrices \mathbf{V}_n and \mathbf{W}_n [18]; perform a systematic comparison with the bGLS and ADAM algorithms.

6. CONCLUSION

This paper presented a novel model, based on the Kalman Filter, for analysing asynchrony correction in music ensemble performances. The proposed model is founded on well-established models in the literature, and has the advantage of considering dynamic phase and period correction gains. A set of experiments (using only phase correction) on a homophonic section of a string quartet by J. Haydn was conducted, illustrating the capabilities of the model in explaining synchronization schemes within musical ensembles.

⁸ This procedure will not always lead to a positive-definite matrix, for sufficiently high value of K and depending on c – not the case here.

⁹ The computational time of each smoothing is less than 100ms.

ABSTRACT

This paper explores the automated process of determining stem compatibility by identifying audio recordings of single instruments that blend well with a given musical context. To tackle this challenge, we present Stem-JEPA, a novel Joint-Embedding Predictive Architecture (JEPA) trained on a multi-track dataset using a self-supervised learning approach.

Our model comprises two networks: an encoder and a predictor, which are jointly trained to predict the embeddings of compatible stems from the embeddings of a given context, typically a mix of several instruments.

Training a model in this manner allows its use in estimating stem compatibility—retrieving, aligning, or generating a stem to match a given mix—or for downstream tasks such as genre or key estimation, as the training paradigm requires the model to learn information related to timbre, harmony, and rhythm.

We evaluate our model’s performance on a retrieval task on the MUSDB18 dataset, testing its ability to find the missing stem from a mix and through a subjective user study. We also show that the learned embeddings capture temporal alignment information and, finally, evaluate the representations learned by our model on several downstream tasks, highlighting that they effectively capture meaningful musical features.

1. INTRODUCTION

Musical stem compatibility indicates the degree to which a stem (i.e., an audio file of a single instrument) fits a given musical context (an audio file of another instrument or a mix of instruments) when played together. Its automatic estimation can be helpful for stem retrieval, automatic arrangement, or stem generation tasks. The compatibility between stems (or a stem and some musical context) depends on several global factors, such as tonality, tempo,

genre, timbre, and singing/playing style. In addition, local features like chords or pitches are crucial to performing temporal alignment between a stem and some musical context.

While initial works have studied musical compatibility between songs based on traditional Music Information Retrieval (MIR) tasks like beat tracking and chord estimation [1, 2], more modern approaches aim to learn compatibility directly from data using deep neural networks [3–5]. Using such learning-based approaches extends the notion of compatibility beyond music-theoretical aspects (like tonality and tempo) toward sound-related and expressive characteristics like timbre and playing style.

Moreover, there are potential applications for musical stem generation [6, 7], where generators usually require musical context conditioning to produce compatible accompaniments. With the proposed system, stem representations can be predicted from context information at inference time. This allows training a stem generation model based solely on stem representations, eliminating the need for context/target pairs.

Paper proposal and organization. In this paper, we introduce Stem-JEPA, a novel Joint-Embedding Predictive Architecture (JEPA) which acts directly on mixtures of stems. It consists of two neural networks, an encoder and a predictor, jointly trained to produce representations of a *context* mix and predict representations of a compatible *target* stem. Unlike previous JEPAs [8, 9], our approach does not rely on masking in the input space but rather on omitting stems within the process of mixing, and it uses the label of the missing stem for conditioning (see section 3).

We assess the performance of Stem-JEPA in a retrieval task and through a subjective evaluation in sections 4.1 and 4.2, respectively. Also, we investigate how well the learned representations encode the temporal alignment of stems and mixes (see section 4.3). We also perform an analysis showing that key and chord annotations of audio snippets close in the embedding space are musically compatible (see section 4.4). Finally, we evaluate the representations produced by our model on various downstream MIR tasks (see section 4.5).

To facilitate further research in this direction, we make our code available.¹

¹ <https://github.com/SonyCSLParis/Stem-JEPA>

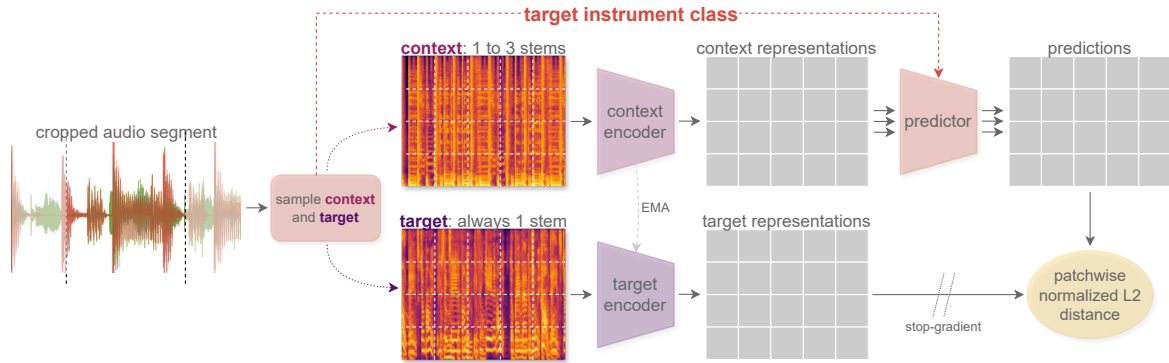

Figure 1. Overview of the Stem-JEPA framework. From an audio clip composed of 4 stems, we first crop a chunk of 8 seconds, then sample the target \bar{x} (one of the stems) and the context x (a mix of some of the remaining stems) as described in section 3.2. They are then converted into Log Mel Spectrograms and passed through the *context* and *target* encoders, respectively. Finally, the *predictor* (conditioned on the target instrument label) is trained so that each of its outputs individually predicts each target representation.

2. RELATED WORK

SSL for representation learning. Self-supervised learning (SSL) involves training networks on unlabeled corpora by solving pretext tasks using only the data itself. This paradigm has shown great potential for extracting meaningful representations in various domains [10–13].

A common approach to SSL is contrastive learning [10, 12, 14, 15] or its variants [16, 17]. In autoencoders, an encoder and a decoder are jointly trained to learn latent representations from which the original input can be reconstructed [13, 18]. JEPAs are trained to *predict* some target data from context data directly in the representation space [8, 19].

Joint-Embedding Predictive Architectures. A JEPA is an architecture composed of two trainable networks: an encoder and a predictor. The model receives a context/target pair as input, passes them through the encoder to create latent representations, and then the predictor is trained to predict the target representation from the context representation. Pairs can be generated through various data augmentations [11, 19, 20], or by masking part of the input, as in data2vec [21]. In particular, JEPAs do not require negative samples, unlike contrastive approaches [19], and enable the model to discard uninformative content given that reconstruction is not required.

To prevent model collapse, it is crucial to block gradients in the non-predictor branch [22], treating its output as the target. Moreover, adopting different but tied encoders for each branch as in Eq. (2) helps to stabilize training [19, 22, 23]. Finally, I-JEPA [8] creates pairs through masking and trains the model to predict the representations of small image patches by conditioning the predictor on their positions, allowing the model to grasp local nuances.

Learning from separated sources. Most SSL approaches, often stemming from the vision domain, have been explored and adapted to the audio domain [9, 12, 14, 15, 20, 24–26]. These works are not specific to musical audio, which is typically composed of several stems providing rich compositional potential for SSL. In practice, only

a few SSL approaches leverage separated stems for tasks such as audio classification [27], music tagging [28] and beat tracking [29]. Finally, a few works explore modeling the compatibility between stems with applications like automatic mashup creation [1, 3] and sample or loop retrieval for interactive composition [4, 5].

3. STEM-JEPA

3.1 Training pipeline

Our method, depicted in Figure 1, builds upon recent works in JEPAs for image and audio representation learning [8, 9]. Given a music track represented as a set of S stems (roughly corresponding to the separated audio sources) $\mathbf{x}_1, \dots, \mathbf{x}_S$, we crop a chunk of 8 seconds. We then randomly select one of the stems as **target** $\bar{x} = x_t$ with $t \in \{1, \dots, S\}$ and use the remaining ones to create a **context mix**: $\mathbf{x} = \sum_{c \in C} \mathbf{x}_c$ with $C \subset \{1, \dots, S\} \setminus \{t\}$.

Both \mathbf{x} and \bar{x} are then converted to Log Mel Spectrograms and divided into a regular grid (over the time and frequency dimensions), leading to K patches. The context patches are then fed to a **context encoder** f_θ to produce patch-wise embeddings $\mathbf{z} = (\mathbf{z}_1, \dots, \mathbf{z}_K)$, where θ are training parameters. Similarly, the target patches are fed to a **target encoder** $f_{\bar{\theta}}$ to produce the patch-wise embeddings $\bar{\mathbf{z}} = (\bar{\mathbf{z}}_1, \dots, \bar{\mathbf{z}}_K)$.

Finally, the context representations \mathbf{z} are independently fed to a **predictor** g_ϕ (with trainable parameters ϕ), which is conditioned on the instrument label l of the missing stem by concatenating a learnable embedding $\text{emb}(l)$ to \mathbf{z}_k . The output of the predictor is therefore the prediction $\tilde{\mathbf{z}} = (\tilde{\mathbf{z}}_1, \dots, \tilde{\mathbf{z}}_K)$, with $\tilde{\mathbf{z}}_k = g_\phi(\text{concat}(\mathbf{z}_k, \text{emb}(l)))$.

As in [8, 11, 19], the parameters (θ, ϕ) of the context encoder and predictor are updated through gradient descent by minimizing the mean squared error $\mathcal{L}(\tilde{\mathbf{z}}, \bar{\mathbf{z}})$ between the (normalized) predicted and target representations:

$$\mathcal{L}(\tilde{\mathbf{z}}, \bar{\mathbf{z}}) = \frac{1}{K} \sum_{k=1}^K \left\| \frac{\tilde{\mathbf{z}}_k}{\|\tilde{\mathbf{z}}_k\|} - \frac{\bar{\mathbf{z}}_k}{\|\bar{\mathbf{z}}_k\|} \right\|^2, \quad (1)$$

whereas the parameters of the target encoder $\bar{\theta}$ are updated using an Exponential Moving Average (EMA) of the ones of the context encoder, i.e.,

$$\bar{\theta}_i = \tau_i \bar{\theta}_{i-1} + (1 - \tau_i) \theta_i, \quad (2)$$

where the EMA rate τ_i is linearly interpolated between τ_0 and τ_T , T being the total number of training steps.

3.2 Sampling context and target

To avoid training the system on silent target stems or silent context mixes, we first analyze the amplitude content of each of the stems $\mathbf{x}_1, \dots, \mathbf{x}_S$ representing a chunk of a given music track.

Let $\mathcal{A} \subset \{1, \dots, S\}$ be the indices of active (i.e., non-silent) stems among $\mathbf{x}_1, \dots, \mathbf{x}_S$. We first pick a random index $t \in \mathcal{A}$ as target². Then, we randomly select a subset $C \subset \mathcal{A} \setminus \{t\}$ from the remaining non-silent tracks. The number of stems $|C|$ in this subset is uniformly sampled between 1 and the number of other non-silent stems $|\mathcal{A}| - 1$. Most of the time, the prediction task incorporates more stems in the context than in the target ($|C| > 1$), simplifying the predictor’s task. However, occasionally, the subset consists of only one stem ($|C| = 1$), allowing the model to process individual stems and learn their representations, which is crucial as these are also used as targets.

3.3 Architecture and training details

We employ a standard ViT-Base model as the encoder [30]. Our predictor is a 6-layer MLP with ReLU activations and 1024 dimensions in each hidden layer. In our ablation studies, the Transformer predictor we use is the same as in [9].

During training, we extract audio chunks of 8 seconds that are converted to log-scaled Mel Spectrograms with 80 mel bins and a window and hop size of 25 and 10 ms, respectively. We use patches of size 16×16 , leading to sequences of $\frac{80}{16} \times \frac{800}{16} = 250$ tokens during training.

We train our model during 300k steps using AdamW [31], with a batch size of 256, a base learning rate of $3e-4$, and a cosine annealing scheduling after 20k steps of linear warmup. All other hyperparameters are consistent with those used in [9], following their demonstrated effectiveness. Our model is trained for approximately four days on a single A100 GPU with 40 GB of memory.

3.4 Training data

We train the model on a proprietary dataset of 20k multi-track recordings of diverse music genres (e.g., pop/rock, R&B, rap, country) with a total duration of 1350 hours. We use existing instrument annotations to construct four standard categories: Bass, Drums, Vocals, and Other.

² If $|\mathcal{A}| < 2$ (a whole chunk is silent or only one active stem), we re-sample another audio chunk from the same track to prevent having silent context or target.

4. EVALUATION

We assess the efficacy of our model to retrieve compatible stems from a given mix through objective and subjective evaluations. We also demonstrate that the learned representations capture local harmonic and rhythmic information. Finally, we show that they also encode high-level features, making them suitable for various MIR tasks.

4.1 Stem retrieval task

Given an input audio, our model predictor has been trained to output a latent representation of a stem such that this stem would fit well with the input audio. To evaluate the performance of our model, we construct a retrieval task in which, given an existing music track, the model should be able to predict the representation of one stem given the mix of the others.

4.1.1 Experimental setup

For evaluation, we used the MUSDB18 dataset [32], which contains $N = 150$ tracks $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)}$, each track $\mathbf{x}^{(n)}$ being composed of $S = 4$ stems $\mathbf{x}_1^{(n)}, \dots, \mathbf{x}_S^{(n)}$ (vocals, bass, drums, other). This allows a total of $N \times S = 600$ runs. For any individual stem $\mathbf{x}_s^{(n)}$, define $\mathbf{x}_{-s}^{(n)}$ the mix containing all stems from $\mathbf{x}^{(n)}$ except $\mathbf{x}_s^{(n)}$. We aim to predict the embedding of the individual stem $\mathbf{x}_s^{(n)}$ from the one of the mix $\mathbf{x}_{-s}^{(n)}$. We compute and average (over time) the patch-wise representations of all stems $\mathbf{x}_s^{(n)}$. It gives us a *reference set* $\mathbf{Z} = \{\mathbf{z}_s^{(n)}\}$, with $\mathbf{z}_s^{(n)}$ being the embedding of $\mathbf{x}_s^{(n)}$. Then, we encode all mixes $\mathbf{x}_{-s}^{(n)}$, pass the resulting representations through the predictor conditioned on s , and average (over time and frequency) the result to get a *query embedding* $\mathbf{q}_s^{(n)}$. In other words, $\mathbf{q}_s^{(n)}$ is the prediction of (the embedding of) the missing instrument $\mathbf{x}_s^{(n)}$ from the remaining ones $\mathbf{x}_{-s}^{(n)}$. We therefore test if the actual embedding $\mathbf{z}_s^{(n)}$ is among the nearest neighbors of $\mathbf{q}_s^{(n)}$ in the reference set \mathbf{Z} .

Metrics. We measure the model performance using two metrics. The *Recall at K* ($R@K$) measures the proportion of relevant items successfully retrieved among the top K nearest neighbors. We consider here $K \in \{1, 5, 10\}$.

The *Normalized Rank* [5] of a query $\mathbf{q}_s^{(n)}$ is defined as the rank of the ground-truth $\mathbf{z}_s^{(n)}$ in the sorted list of distances $\{d(\mathbf{q}_s^{(n)}, \mathbf{z})\}_{\mathbf{z} \in \mathbf{Z}}$, normalized by the length of the list (here 600) to get a value in $[0, 1]$. For example, a mean Normalized Rank of 5% means that the actual embedding $\mathbf{z}_s^{(n)}$ is, on average, within the 5% nearest neighbors from the prediction $\mathbf{q}_s^{(n)}$. For each model, we report mean and median Normalized Ranks.

4.1.2 Results

The results are shown in Table 1 under the row "MLP w/ cond." Our model achieves a $R@1$ of 33%, and in half of the cases, the correct stem is within the top 0.5% of nearest neighbors (median Normalized Rank is 0.5%). Moreover, the median rank consistently outperforms the mean rank, indicating the presence of outliers with very high ranks.

Table 1. Influence of the design of the predictor on the retrieval performances. All metrics are in percentages.

Model	R@1	Recall \uparrow		Normalized Rank \downarrow	
		R@5	R@10	mean	median
MLP w/ cond.	33.0	63.2	76.2	2.0	0.5
MLP w/o cond.	28.2	58.0	69.2	3.3	0.7
Transformer	5.2	17.5	25.7	12.1	6.0
AutoMashupper	1.0	8.8	15.5	29.1	19.5

Figure 2. Analysis of the closest embedding z^* for all queries q from the MUSDB18 dataset [32]. Left: Categories of failures for each instrument (same song but wrong instrument, the opposite, or both wrong). Right: confusion matrix between conditioning instruments and retrieved instruments.

We also include in Table 1 results for scenarios without predictor conditioning during training (row "MLP w/o cond.") and when using a Transformer instead of an MLP for the predictor. In both cases, the performance drops substantially, emphasizing the importance of conditioning for the retrieval task. When using an MLP instead of a Transformer, the encoder must capture global information because the MLP cannot infer it, which leads to more informative embeddings.

Finally, we compare our model with AutoMashupper [1], which is, to the best of our knowledge, the only openly available work on compatibility estimation. We use their "mashability" measure as a similarity metric to compute the retrieval performances. Note that this metric involves beat tracking and chord detection, making it unsuited for vocals and drum stems, respectively. Therefore, the performance of this method on the retrieval task is relatively weak.

4.1.3 Influence of the instrument class

To get a better understanding of the failure modes of our model and the disparities between the different instruments, we study the nearest neighbor $z^* = \arg \min_{z \in Z} d(q, z)$ for all queries q from MUSDB18. This analysis, detailed in Figure 2 (left), categorizes z^* into four groups: "both correct" where the model predicts the correct instrument from the correct song, "right instrument" where the correct instrument is predicted but from a different song, "right song" where the model predicts the wrong instrument class but from the correct song, and "both wrong". Additionally, Figure 2 (right) displays

Figure 3. Box plot of the listening test for the different instrument classes. The \times represents the mean of the data.

a confusion matrix for the instruments.

A noticeable result is that the retrieval performances vary a lot between the different instruments, especially between "drums" ($R@1 \approx 25\%$) and "other" ($R@1 \approx 45\%$).³ A plausible explanation is that there are simply more possible candidate drum patterns that actually fit a given mix, resulting in closer neighbors within which it is harder to detect the ground truth.

Additionally, we can see that the "both wrong" scenario is quite uncommon. However, for bass and drums in particular, we predict another instrument (but for the correct song) in more than 25% of the cases. The confusion matrix shows that the category that mostly causes this failure is "other". A reason is probably that "other" is a broad and ill-defined set of instruments that could arguably overlap with bass or drums (e.g., choirs, synth bass, xylophone...).

4.2 User study

In section 4.1, we utilize the compatibility of a mix and a stem from the same song to assess the retrieval performance of our model. However, it is plausible that the dataset also includes compatible stems originally part of different songs. To evaluate our model's ability to retrieve these compatible yet non-original stems, we conduct an online listening test, focusing on retrieving instruments that are not present in the query mix (green segment in Figure 2).

For each trial, the user first listens to a query mix with one missing stem, followed (in random order) by the actual missing stem, the one retrieved by our system, and a random one, but with the same instrument class as $x_s^{(n)}$. They are then asked to rate (from 0 to 100) the three proposed stems' compatibility with the reference mix.⁴

The mixes and stems are 16-second chunks from the MUSDB18 dataset [32], randomly cropped to 10 seconds during the test to prevent listeners from relying on temporal alignment for rating. We conduct our study on the Go Listen platform [33]. Our test comprises 60 trials, and each user has to answer 12 of them (3 for each instrument class). We had 23 participants, 20 of whom had musical experience (11 for at least 10 years).

Results. The listening test results are depicted in Figure 3. While the ratings for the stems retrieved by our model

³ The proportion of "both correct" samples is exactly the Recall at 1.

⁴ Since we already test temporal alignment and tonality in sections 4.3 and 4.4 respectively, participants are explicitly instructed to rather concentrate on genre, timbre, and playing/singing style in this study.

Figure 4. Average pairwise cosine similarity between embeddings and predictions across various temporal shifts. Each curve corresponds to a different track.

are slightly lower than those for the ground truth on average, they are substantially higher (approximately double) than the ratings of random samples. This highlights the ability of Stem-JEPA to retrieve stems compatible with the context mix.

However, we find some disparities between instrument classes. For example, the ratings for drums between the ground truth and our model’s suggestions are very close, whereas they are more different for the “other” category. Also, the variance of ratings is higher in “drums,” hinting at a generally higher compatibility of drums with any context. Finally, the length of the whiskers and the difference between the mean and median reveal significant disparities between users and samples, indicating the high subjectivity and difficulty of musical compatibility estimation.

4.3 Stem alignment analysis

In this section, we assess the model’s ability to evaluate the alignment between stems and mixes by temporally shifting them relative to each other. Our primary metric for this evaluation is the cosine similarity between learned embeddings and their predictions at various offsets, reflecting the local temporal features captured by the model.

Contrary to our previous approach that utilized embeddings averaged over time, here we retain the temporal sequence of the embeddings. We concatenate embeddings in the frequency dimension and stack them in the time dimension, maintaining a resolution of one embedding per 160 milliseconds of audio. We denote the representation of the i -th patch in stem $\mathbf{x}_s^{(n)}$ as $\mathbf{z}_s^{(n)}[i]$ and its corresponding predicted output conditioned on the mix $\mathbf{x}_{-s}^{(n)}$ as $\mathbf{q}_s^{(n)}[i]$.

We evaluate the fidelity of these embeddings by examining how the cosine similarity between $\mathbf{z}_s^{(n)}[i]$ and $\mathbf{q}_s^{(n)}[(i+j)\%M]$ evolves with varying j , the temporal offset. The formulation is given by:

$$s(\mathbf{z}, \mathbf{q}, j) = \frac{1}{MS} \sum_{s=1}^S \sum_{i=1}^M \langle \mathbf{z}_s[i], \mathbf{q}_s[(i+j)\%M] \rangle \quad (3)$$

where M is the total number of embeddings in sequence \mathbf{z} , S is the number of stems, and j represents the shift index.

The local nature of the information captured by the embeddings is reflected in how the cosine similarity $s(\mathbf{z}, \mathbf{q}, j)$ changes with different temporal offsets j . Specifically, if the embeddings predominantly contained global information, s would remain relatively constant across shifts. Con-

Figure 5. Key/Chord co-occurrence matrix between segments within the same clusters.

versely, a sharp peak in similarity at $j = 0$, followed by a rapid decrease, suggests that the embeddings are rich in local information and less information is shared between adjacent frames.

From our analysis of tracks from the MUSDB18 dataset (8 of them being displayed in Figure 4), we first observe that $s(\mathbf{z}, \mathbf{q}, j)$ always remains relatively high⁵, which indicates that the embeddings contain global information. We, however, observe a peak at $j = 0$, underlining the presence of local details that are temporally aligned.

We also observe periodic patterns in the curves, highlighting the model’s capacity to capture temporal structures (e.g., beats and bars). Finally, we observe smaller peaks every 8 seconds, the duration of the chunks used for computing the embeddings, which implies that embeddings also capture global position information. This behavior could potentially be avoided by replacing the absolute positional encodings in our encoder with other variants.

An interactive version of Figure 4 with audio examples is provided on the accompaniment website.⁶

4.4 Musical plausibility

We utilize key and chord annotations from Isophonics⁷ for 174 Beatles songs to label all patch embeddings. We then conduct k -means clustering on the latent space with $k = 32$ clusters. Within each cluster, we calculate the co-occurrence of all key and chord pairs and aggregate these counts across all clusters. To visualize these relationships, we display in Figure 5 a co-occurrence matrix for the keys and chords that appear in the top 80 most frequent combinations, considering all possible pairs for counting, not just the most common ones.

The matrix reveals that pairs close in the latent space often share significant musical relevance. The highest occurrences typically connect a key with its tonic (e.g., E/E), and prominently with its subdominant and dominant (e.g., C/F, G or D/G, A). Such patterns indicate that the embeddings capture meaningful tonal relationships.

⁵ As a reference, the average cosine similarity between random representations and predictions is approximately 0.17.

MagnaTagATune (MTT) [38]	50	Tagging
NSynth [39]	11	Instr. classification

4.5 Benchmark on downstream tasks

Lastly, we investigate the musical features encoded in the representations learned by our model. We hypothesize that the encoder captures shared musical information among different stems of the same track, such as rhythm or harmony, to aid the predictor. To verify this, we evaluate it on several downstream classification tasks, a standard protocol for representation learning methods [9, 12, 34, 35].

4.5.1 Experimental setup

Our experimental setup follows the constrained track of the MARBLE benchmark [35]. Each audio sample is processed by the *frozen* encoder, and its patch-wise outputs are concatenated and averaged along frequency and time dimensions to produce a 3840-dimensional global embedding, following [9]. These embeddings are passed through an MLP with 512 hidden units and a softmax layer, which is trained by minimizing the cross-entropy between the predicted distribution and the ground truth labels.

Downstream tasks. To validate our hypothesis, we focus on global musical features that are shared among the different stems of a track, namely tagging, key, and genre estimation. Additionally, we include an instrument classification task to observe whether the encoder preserves stem-specific information. For facilitating comparisons to existing work, we also pick our downstream tasks from the MARBLE benchmark [35]. The full list of datasets and associated tasks is depicted in Table 2.

Baselines. We compare our model to two variants: one trained with a Transformer as predictor, and one without conditioning, as in section 4.1. In addition, we include the two top-performing models from [35] in the considered tasks, namely MULE [12] and Jukebox-5B [40] as references. MULE [12] is an SSL model based on SF-NFNet-F0 [41] trained by contrastive learning on the MusicSet dataset (117k hours), while Jukebox [40] is a huge music generation model trained using codified audio language modeling on 1.2 million songs.

For a more in-depth description of the hyperparameters, datasets, tasks, and corresponding metrics, we refer the reader to [35].

4.5.2 Results

The performances of our model on downstream tasks are provided in Table 3. First, we observe that the choice of the predictor used for training, while extremely influencing for retrieval tasks, has little effect on the downstream performances of our encoder, apart from key detection on Giantsteps, for which the model trained with a Transformer predictor clearly outperforms the others. The

Table 3. Influence of the predictor architecture on the performances of Stem-JEPA on various downstream tasks, and comparison with existing baselines.

Model	GS	GTZAN	MTT		NSynth
	Acc ^{refined}	Acc	ROC	AP	Acc
MLP w/ cond.	40.2	68.6	89.9	42.8	73.5
MLP w/o cond.	36.8	72.5	90.1	42.9	75.0
Transformer	46.0	68.1	90.0	42.7	73.3
MULE [12]	64.9	75.5	91.2	40.1	74.6
Jukebox [42]	63.8	77.9	91.4	40.6	70.4

performances on NSynth also reveal that our model does not only capture information shared between stems but also stem-specific features. Surprisingly, this holds even without conditioning the predictor during training, and more generally, not conditioning the predictor improves performance on most downstream tasks.

We also compare our model to state-of-the-art works in music representation learning. Our performances are on par with baselines for two tasks (MTT and NSynth) but significantly lower on Giantsteps and GTZAN, despite being much better than random guessing. Considering the limited quantity of training data compared to the baselines (about 100 times less), these results suggest that our method is promising for music representation learning but that further efforts have to be made to make it competitive with current state-of-the-art approaches in this field.

5. CONCLUSION

In this study, we introduce a novel SSL paradigm based on stem prediction for musical stem compatibility estimation through the prism of representation learning. Our results show promising performances for retrieval applications and also indicate that the learned representations are localized, suggesting that they could also be valuable for music generation and possibly automatic arrangement. Additionally, these representations are musically meaningful and demonstrate linear separability for various Music Information Retrieval tasks.

Moreover, our model is, to the best of our knowledge, the first use of the predictor component of Joint-Embedding Predictive Architectures (JEPAs) during inference. Employing JEPAs to model compatibility instead of similarity, with appropriate conditioning, may open up possibilities in various fields beyond music.

Nevertheless, our study is not without its limitations. In particular, self-supervised learning usually benefits from very large corpora of training data; however, accessing large datasets of separated stems is challenging, though advancements in source separation technology may alleviate some of these issues. Finally, restricting the analysis to four instruments, while standard in source separation, currently limits the generalizability of our findings. Ideally, extending the predictor to accommodate any instrument would prevent the failure cases illustrated in section 4.1.3 and enhance the model’s utility, representing an exciting direction for future research.

6. ACKNOWLEDGMENTS

This work has been funded by the ANRT CIFRE convention n°2021/1537 and Sony France. This work was granted access to the HPC/AI resources of IDRIS under the allocation 2022-AD011013842 made by GENCI. We would like to thank Cyran Aouameur and Marco Comunità for their helpful suggestions. Finally, we would like to thank the reviewers and meta-reviewer for their valuable comments.

ABSTRACT

Text-to-music models allow users to generate nearly realistic musical audio with textual commands. However, *editing* music audios remains challenging due to the conflicting desiderata of performing fine-grained alterations on the audio while maintaining a simple user interface. To address this challenge, we propose *Audio Prompt Adapter* (or AP-Adapter), a lightweight addition to pretrained text-to-music models. We utilize AudioMAE to extract features from the input audio, and construct attention-based adapters to feed these features into the internal layers of AudioLDM2, a diffusion-based text-to-music model. With 22M trainable parameters, AP-Adapter empowers users to harness both global (e.g., genre and timbre) and local (e.g., melody) aspects of music, using the original audio and a short text as inputs. Through objective and subjective studies, we evaluate AP-Adapter on three tasks: timbre transfer, genre transfer, and accompaniment generation. Additionally, we demonstrate its effectiveness on out-of-domain audios containing unseen instruments during training.

1. INTRODUCTION

Advancements in *text-to-music generation* have made it possible for users to create music audio signals from simple textual descriptions [1–4]. To improve the control over the generated music beyond textual input, several newer models have been proposed, using additional conditioning signals indicating the intended global or time-varying musical attributes such as melody, chord progression, rhythm, or loudness for generation [5–9] (see Section 2 for a brief review). Such controllability is important for musicians, practitioners, as well as common users in the human-AI co-creation process [10, 11].

However, one area that remains challenging, which we refer to as *text-to-music editing* below, is the precise editing

of a piece of music, provided by a user as an *audio input* x alongside the *text input* y for the textual prompts. The goal here for the model is to create an “edited” version of the input music, denoted as \tilde{x} , according to the text input. This is a crucial capability for users who wish to refine either an original or machine-generated music without compromising its musicality and audio quality, while keeping the simplicity of text-based human-computer interaction. Namely, the desired properties of the output \tilde{x} are:

- **Transferability:** \tilde{x} should reflect what y specifies, e.g., timbre, genre, instrumentation, or mood.
- **Fidelity:** \tilde{x} should retain all other musical content in x that y does not concern, e.g., melody and rhythm.

While a text-to-music generation model takes in general only the text input y and generates music freely, a text-to-music editing model takes both audio and text inputs x and y . The primary challenge arises from the conflicting goals of maintaining high fidelity to the input audio x while incorporating specific changes dictated by textual commands y . As we review in Section 2, existing methods [14–16] either lack the granularity needed for detailed audio manipulation or need complex prompt engineering that detracts from user accessibility or requires iterative refinements.

A secondary challenge arises from the large number of trainable parameters needed for models to achieve high musical quality and diversity (e.g., MusicGen-medium [5] has 1.5B parameters). Without much computational resource, it is more feasible to treat existing models as “foundation models” and finetune them to fulfill specific needs, instead of training a model from scratch [17].

In view of these challenges, we propose in this paper the *Audio Prompt Adapter* (or, AP-Adapter for short), a novel approach inspired by the Image Prompt Adapter (IP-Adapter) [18] from the neighboring field of text-to-image editing. This lightweight (22M parameters), attention-based module integrates seamlessly with existing text-to-music generation models, specifically leveraging the pre-trained AudioLDM2 model [12] enhanced by the AudioMAE encoder [13] to extract audio features. Our method uniquely combines text and audio inputs through decoupled cross-attention layers, allowing precise control in the generation process. After training the AP-adapter with a single NVIDIA RTX 3090, our method can zero-shot edit a given

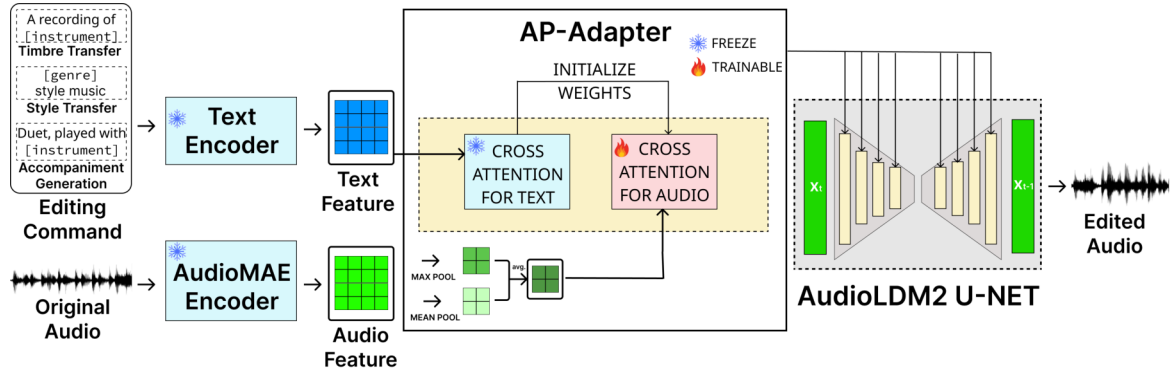

Figure 1: Our AP-Adapter is an add-on to AudioLDM2 [12]. Users provide an original audio to AudioMAE [13] to extract audio features, and an editing command to the text encoder. The decoupled audio and text cross-attention layers of AP-Adapter contribute to the **fidelity** with the input audio and **transferability** of the editing command in the edited audio.

audio prompt according to the text prompt.

Our AP-Adapter offers great improvements over some baseline models by enabling detailed and context-sensitive audio manipulations, achieving a balance between fidelity and the transferability effects dictated by user inputs. Our experiments across timbre transfer, genre transfer, and accompaniment generation tasks demonstrate the effectiveness of our approach in handling diverse and complex editing requirements. In short, our key contributions are:

- Proposing a framework that equips an audio input modality for a pre-trained text-to-music generation model.
- Performing zero-shot music editing with a lightweight adapter, which permits flexible balance of the effects of the text and audio inputs.
- Demonstrating three tasks: timbre transfer, genre transfer, accompaniment generation, and discussing the impact of tunable hyperparameters.

We provide audio examples in our demo website.¹ We also share source code and model checkpoints on GitHub.²

2. RELATED WORK

Generating desired music from text prompts alone is complex and often requires intricate prompt engineering. Mustango [7] enhanced prompts with information-rich captions specifying chords, beats, tempo, and key. MusicGen [5] conditioned music generation on melodies by extracting chroma features [19] and inputting them with the text prompt into a Transformer model. Coco-Mulla [6] and MusiConGen [9] extended MusicGen by adding time-varying chord- and rhythm-related controls. Music ControlNet [8] incorporated time-varying conditions like melody, rhythm, and dynamics for diffusion-based text-to-music models. These methods utilize low-level features to guide generation but do not take reference audio as input, limiting their potential for editing existing audio tracks.

Recently, several music editing methods were proposed. InstructME [14] uses a VAE and a chord-conditioned diffusion model for music editing but requires a large dataset

of audio files with multiple instrumental tracks and triplet data of text instructions, source music, and target music for supervised training. M²UGen [15] leverages large language models to understand and generate music across different modalities, supporting music editing via natural language, but it requires a three-step training process and complex preprocessing. MusicMagus [16] implements latent space manipulation during inference for music editing but requires an additional music captioning model and the InstructGPT LLM to address discrepancies between the text prompt distribution of AudioLDM2 and the music captioning model.

Compared to these methods, our AP-Adapter is more straightforward to train and can achieve multiple music editing tasks in a zero-shot manner.

3. BACKGROUND

3.1 Diffusion Model

Denising diffusion probabilistic models (DDPMs) [20], also known as diffusion models, are a class of generative models that approximates some distribution $p(\mathbf{x})$ via denoising through a sequence of $T - 1$ latent variables:

$$p_{\theta}(\mathbf{x}) = \int \left[\prod_{t=1}^T p_{\theta}(\mathbf{x}_{t-1} | \mathbf{x}_t) \right] p(\mathbf{x}_T) d\mathbf{x}_{1:T}, \quad (1)$$

where θ is the set of learnable parameters, $\mathbf{x}_0 := \mathbf{x}$, and $p(\mathbf{x}_T) := \mathcal{N}(0, \mathbf{I})$ (i.e., an uninformative Gaussian prior). To train the model, we run forward diffusion: sample some data point $\mathbf{x} \sim p(\mathbf{x})$ and some $t \in [1, T]$, and add noise $\epsilon \sim \mathcal{N}(0, \mathbf{I})$ to \mathbf{x} to produce a noised data point $\mathbf{x}_t := \sqrt{\beta_t} \mathbf{x} + \sqrt{1 - \beta_t} \epsilon$, where β_t is the pre-defined noise level for step t . The model is asked to perform backward diffusion, namely, to recover the added noise via the objective $\min_{\theta} \mathbb{E}_{\mathbf{x}, \epsilon, t} [\|\epsilon - \epsilon_{\theta}(\mathbf{x}_t, t)\|_2^2]$, where $\epsilon_{\theta}(\cdot)$ is the model’s prediction, that is equivalent to maximizing the evidence lower bound (ELBO) of $p_{\theta}(\mathbf{x})$. During inference, we start from an $\mathbf{x}_T \sim \mathcal{N}(0, \mathbf{I})$ and iteratively remove the predicted noise $\epsilon_{\theta}(\mathbf{x}_t, t)$ to generate data. Song *et al.* [21] offered a crucial interpretation that each denoising step can be seen as ascending along $\nabla_{\mathbf{x}} \log p_{\theta}(\mathbf{x})$, also known as the *score* of $p_{\theta}(\mathbf{x})$. Any input condition \mathbf{y} can be incorporated into a

¹ Demo: <https://rebrand.ly/AP-adapter>

² Code: <https://github.com/fundwotsai2001/AP-adapter>

diffusion model by injecting embeddings of \mathbf{y} via, for example, cross-attention [22], thereby modeling $p_\theta(\mathbf{x} | \mathbf{y})$ (and $\nabla_{\mathbf{x}} \log p_\theta(\mathbf{x} | \mathbf{y})$). To reduce memory footprint and accelerate training/inference, latent diffusion models (LDMs) [22] proposed to first compress data points \mathbf{x} into latent vectors using a variational autoencoder (VAE) [23], and then learn a diffusion model for the latent vectors.

3.2 AudioLDM2

We choose AudioLDM2 [12], a latent diffusion-based [22] text-to-audio model, as our pretrained backbone. To enable text control over generated audio, AudioLDM2 uses AudioMAE [13] to extract acoustic features, named the *language of audio* (LOA), from the target audio. LOA serves as the bridge between acoustic and text-centric semantic information—the text prompt is encoded by both the FLAN-T5 [24] language model and CLAP [25] text encoder (which has a joint audio-text embedding space), and then passed to a trainable GPT-2 [26] to approximate the LOA via a regression loss that aligns the semantic representations with LOA. The aligned text information is then fed into the U-Net [27] for diffusion process to influence the generation. We pick AudioLDM2 to be the backbone since the use of LOA likely promotes the affinity to accepting audio conditions, which is crucial to our fidelity goal.

3.3 Classifier-free Guidance

Classifier-free guidance (CFG) [28] is a simple yet effective inference-time method to enhance the input text condition’s influence, which is directly linked to our transferability goal. As mentioned in Sec. 3.1, diffusion models can predict both the unconditioned score $\nabla_{\mathbf{x}} \log p(\mathbf{x})$ and the conditioned score $\nabla_{\mathbf{x}} \log p(\mathbf{x} | \mathbf{y})$. In addition, by Bayes’ rule, we know that $p(\mathbf{x} | \mathbf{y}) \propto p(\mathbf{x})p(\mathbf{y} | \mathbf{x})$. As the goal is the amplify \mathbf{y} ’s influence, we define:

$$p_\lambda(\mathbf{x} | \mathbf{y}) \propto p(\mathbf{x})p(\mathbf{y} | \mathbf{x})^\lambda, \quad (2)$$

where λ is a knob, named *CFG scale*, that controls the strength of \mathbf{y} . Taking $(\nabla_{\mathbf{x}} \log)$ on both sides gives us:

$$\nabla_{\mathbf{x}} \log p_\lambda(\mathbf{x} | \mathbf{y}) = \lambda \nabla_{\mathbf{x}} \log p(\mathbf{y} | \mathbf{x}) + \nabla_{\mathbf{x}} \log p(\mathbf{x}). \quad (3)$$

Meanwhile, we can rearrange the Bayes’ rule terms to get:

$$\nabla_{\mathbf{x}} \log p(\mathbf{y} | \mathbf{x}) = \nabla_{\mathbf{x}} \log p(\mathbf{x} | \mathbf{y}) - \nabla_{\mathbf{x}} \log p(\mathbf{x}). \quad (4)$$

Note that a diffusion model can predict both RHS terms. Plugging Eqn. (4) into Eqn. (3), CFG performs

$$\begin{aligned} \nabla_{\mathbf{x}} \log p_\lambda(\mathbf{x} | \mathbf{y}) &= \nabla_{\mathbf{x}} \log p(\mathbf{x}) \\ &+ \lambda(\nabla_{\mathbf{x}} \log p(\mathbf{x} | \mathbf{y}) - \nabla_{\mathbf{x}} \log p(\mathbf{x})) \end{aligned} \quad (5)$$

at every inference iteration, where $\nabla_{\mathbf{x}} \log p(\mathbf{x})$ is obtained by inputting an empty string as \mathbf{y} .

4. PROPOSED AUDIO PROMPT ADAPTER

To effectively condition AudioLDM2 on the input audio and achieve our transferability and fidelity goals, our AP-Adapter adds two components to AudioLDM2: an audio

encoder to extract acoustic features, and decoupled cross-attention adapters to incorporate the acoustic features while maintaining text conditioning capability.

4.1 Audio Encoder and Feature Pooling

We adopt AudioMAE as the audio encoder, which is used by AudioLDM2 to produce the language of audio (LOA; see Section 3.2) during its training. In our pilot study, we find that using the LOA directly as the condition causes nearly verbatim reconstruction, i.e., information in the input audio is mostly retained. This is undesirable as it greatly limits transferability. To address this issue, we apply a combination of max and mean pooling on the LOA, and leave the pooling rate, which we denote by ω , tunable by the user to trade off between fidelity and transferability.

4.2 Decoupled Cross-attention Adapters

According to the analyses in [29, 30] performed on text-to-image diffusion models finetuned for image editing [31], the cross-attention layers, which allow interaction between text prompt and the diffusion process, undergo the most drastic changes during fine-tuning. Hence, we implement our AP-Adapter also as a set of cross-attention layers.

Recall that the audio and text prompts are transformed to internal features before interacting with the U-Net for diffusion. We define these features as:

$$\mathbf{c}_x := \text{Pool}(\text{AudioMAE}(\mathbf{x})) \quad (6)$$

$$\mathbf{c}_y := \text{GPT2}([\text{FlanT5}(\mathbf{y}); \text{CLAP}(\mathbf{y})]), \quad (7)$$

where \mathbf{c}_x and \mathbf{c}_y are the audio and text features respectively. The original AudioLDM2 incorporates the text feature into each U-Net layer via cross-attention:

$$\mathbf{z}_{\text{text}} := \text{Attention}(\mathbf{z}\mathbf{W}^{(a)}, \mathbf{c}_y\mathbf{W}^{(k)}, \mathbf{c}_y\mathbf{W}^{(v)}), \quad (8)$$

where \mathbf{z} is the U-Net’s internal feature, and $\mathbf{W}^{(a)}$, $\mathbf{W}^{(k)}$, $\mathbf{W}^{(v)}$ are learnable projections that respectively produce the cross-attention query, key, and values from \mathbf{z} or \mathbf{c}_y . We keep this cross-attention for text intact (i.e., frozen), anticipating it to satisfy transferability out of the box.

To incorporate the audio features for fidelity, we place a decoupled audio cross-attention layer as the adapter alongside each text cross-attention in a similar light to [18]:

$$\mathbf{z}_{\text{audio}} := \text{Attention}(\mathbf{z}\mathbf{W}^{(a)}, \mathbf{c}_x\mathbf{W}'^{(k)}, \mathbf{c}_x\mathbf{W}'^{(v)}), \quad (9)$$

where $\mathbf{W}'^{(k)}$ and $\mathbf{W}'^{(v)}$ are the newly introduced adapter weights. Since during AudioLDM2 training, the text feature \mathbf{c}_y is trained to mimic the LOA from AudioMAE, we initialize $\mathbf{W}'^{(k)}$ and $\mathbf{W}'^{(v)}$ respectively from $\mathbf{W}^{(k)}$ and $\mathbf{W}^{(v)}$ for all the cross-attention layers in the U-Net, and find that this significantly shortens our fine-tuning process compared to random initialization.

Finally, we obtain the final output of the decoupled text and audio cross-attentions via a weighted sum:

$$\mathbf{z}_{\text{fusion}} := \mathbf{z}_{\text{text}} + \alpha \mathbf{z}_{\text{audio}}, \quad (10)$$

where $\alpha \in \mathbb{R}$, named *AP scale*, is a hyperparameter that controls the strength of the audio prompt (fixed to $\alpha = 1$ during training), and z_{fusion} becomes the input of the subsequent U-Net layer. We expect z_{fusion} to capture the information mixture from audio and text prompts, inducing the model to generate plausible music that adheres to both.

4.3 Training

We freeze all the parameters in the pretrained AudioLDM2 and AudioMAE, except for the decoupled audio cross-attention adapters with 22M parameters. The loss function follows that of standard (latent) diffusion models:

$$\mathcal{L} = \mathbb{E}_{(x,y),\epsilon,t} \|\epsilon - \epsilon_{\theta}(x_t, c_x, c_y, t)\|_2^2, \quad (11)$$

where (x, y) are naturally existing paired audio and text, $\epsilon \sim \mathcal{N}(0, \mathbf{I})$, t is the diffusion step, x_t is the noised audio latent features, c_x, c_y are the extracted features from text and audio prompts (cf. Eqn. (6) and (7)), and $\epsilon_{\theta}(\cdot)$ is the model’s predicted noise. Minimizing \mathcal{L} is equivalent to maximizing the lower bound of $p(x | c_x, c_y)$. During training, we select the audio feature’s pooling rate ω from the set $\{1, 2, 4, 8\}$ uniformly at random, making the adapters recognize audio features with different resolutions, thereby allowing users to balance fidelity and transferability at inference. Additionally, we randomly dropout audio and text conditions, i.e., setting c_x to a zero matrix, and y to an empty string, to facilitate classifier-free guidance.

4.4 Inference

At inference, users are free to input any text prompt y as the editing command to achieve their desired edits, i.e. $x \rightarrow \tilde{x}$. In addition, following [32,33], we modify the unconditioned terms in Eqn. (5) using a negative text prompt y^- . Letting $c_{xy} := \{c_x, c_y\}$, our inference step is:

$$\begin{aligned} \nabla_{\tilde{x}} \log p_{\lambda}(\tilde{x} | c_{xy}, c_{y^-}) &= \nabla_{\tilde{x}} \log p(\tilde{x} | c_{y^-}) \\ &+ \lambda (\nabla_{\tilde{x}} \log p(\tilde{x} | c_{xy}) - \nabla_{\tilde{x}} \log p(\tilde{x} | c_{y^-})) \end{aligned} \quad (12)$$

We find that specifying y^- is an effective way to avoid unwanted properties in \tilde{x} , e.g., the original timbre for the timbre transfer task, or low-quality music in general.

5. EXPERIMENT SETUP

5.1 Dataset Preparation

For the training data of our AP-Adapter, due to our limited computation resource, we use 200K 10-second-long audios with text tags randomly sampled from AudioSet [34] (about 500 hours, or $\sim 10\%$ of the whole dataset).

For the audio input x used in evaluation, we compile two datasets: **in-domain** and **out-of-domain**, according to whether the AudioSet ontology includes the instrument.

- **In-domain:** We choose 8 common instruments: piano, violin, cello, flute, marimba, organ, harp and acoustic guitar. For each instrument, we manually download 5 high-quality monophonic audios from YouTube (i.e., 40 samples in total) and crop them each to 10 seconds.

- **Out-of-domain:** We collect a dataset of monophonic melodies played by ethnic instruments, including 2 *Chinese* instruments (collected by one of our co-authors) and 5 *Korean* instruments (downloaded from AIHub [35]). We use 5 audio samples for each instrument (35 audios in total), cropped to 10 seconds each. We note that these instruments are **not seen** during the training time.

Except for the Korean data which is not licensed outside of Korea, we share information to get the data on GitHub.

5.2 Evaluation Tasks

By varying the edit command y , we evaluate AP-Adapter on three music editing tasks:

- **Timbre transfer:** The model is expected to change a melody’s timbre to that of the target instrument, and keep all other contents unchanged. For this task, the editing command (y) is set to “a recording of a [target instrument] solo”. The negative prompt (y^-) is “a recording of the [original instrument] solo”. For in-domain input, the target is one of the other 7 in-domain instruments. For out-of-domain input, the target is one of the 8 in-domain instruments. We only use in-domain instruments as the target because our evaluation metrics CLAP [25] and FAD [36] (see Section 5.5) do not recognize the out-of-domain instruments.
- **Genre transfer:** We expect the genre (e.g., jazz and country) to change according to the text prompt, but we wish to retain most of the other content such as melody, rhythm and timbre. Here, we set $y :=$ “[target genre] style music”, and $y^- :=$ “low quality music”. Here, we target 8 genres: jazz, reggae, rock, metal, pop, hip-hop, disco, country.
- **Accompaniment generation:** We expect that all content in the input melody remains unchanged, but a new instrument is added to accompany the original audio in a pleasant-sounding and harmonic way. We set $y :=$ “Duet, played with [accomp instrument] accompaniment”, and $y^- :=$ “low quality music”. The [accomp instrument] is selected in the same way as the [target instrument] in the timbre transfer task.

We include these representative tasks which musicians may find useful for their daily workflow, but since y is free-form text, AP-Adapter has the potential for many other tasks.

5.3 Training and Inference Specifics

We use AudioLDM2-large (1.5B parameters), available on HuggingFace, as our backbone model, and only train our 22M-parameter adapters. Training is done on a single one RTX 3090 (24GB) for 35K steps with an effective batch size of 32. We use AdamW optimizer with fixed learning rate 10^{-4} and weight decay 10^{-2} . To enable CFG, we randomly dropout text and audio features with a 5% probability.

For inference, we choose the critical hyperparameters, i.e., pooling rate ω , AP scale α , and CFG scale λ , by exploring the transferability-fidelity tradeoff space as will be reported in Section 6.1. For timbre transfer and accompaniment generation, we select $\omega = 2$, $\alpha = 0.5$, $\lambda = 7.5$. For the

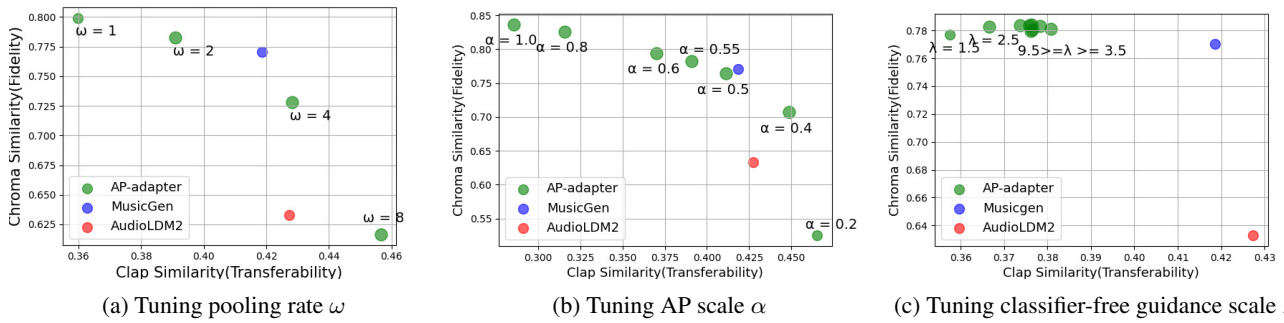

Figure 2: Transferability-fidelity tradeoff effects of different hyperparameters on the timbre transfer task. The hyperparameters are set to $\omega = 2$, $\alpha = 0.55$, and $\lambda = 7.5$ when they are not the hyperparameter of interest.

genre transfer, we select $\omega = 1$, $\alpha = 0.4$, $\lambda = 7.5$. Following AudioLDM2, we use 50 diffusion steps.

5.4 Baselines

We choose two well-known and publicly-available audio generation models, AudioLDM2 [12] and MusicGen [5], as our baselines. Both of them can generate nearly realistic music. We describe below how we use them for editing:

- **AudioLDM2:** Following SDEdit [37], we perform the forward process (i.e., adding noise to the audio input x) partially for $0.75T$ steps, where T is the original number diffusion steps, and then denoise it back with the editing command y to obtain \tilde{x} .
- **MusicGen:** MusicGen is a Transformer-based text-to-audio model that generates discrete audio tokens. We use MusicGen-Melody (1.5B), which achieves melody conditioning using chromagram [19] as a proxy. We input y as the text prompt, and the chromagram of x as the audio condition, for MusicGen to generate \tilde{x} .

We do not include the recent text-to-music editing methods InstructME [14] or MusicMagus [16], as they have not released the code and models, and also exclude M²UGen [15] as it is heavily focused on music understanding and visually-conditioned music generation.

5.5 Objective Metrics

We employ the following metrics:

- **CLAP [25]** is used to evaluate **transferability**, as it is trained with contrastive losses to align the representations for audio and text. We compute the cosine similarity between CLAP audio embedding for the edited audio \tilde{x} and CLAP text embedding for the command y .³ Higher scores show high semantic relevance between \tilde{x} and y .
- **Chroma similarity** computes the similarity of the original and edited audios \tilde{x} and x harmonically and rhythmically, thereby evaluates **fidelity**. We adopt librosa’s [38] CQT chroma method to extract the 12-dimensional chromagrams [19] to compute framewise cosine similarity.

³ For accompaniment generation task, text input to CLAP is modified to include both instruments, e.g., “Piano duet, played with violin.”

Model	CLAP↑ (transferability)	Chroma↑ (fidelity)	FAD↓ (overall)
MusicGen	0.339	0.771	8.443
AudioLDM2	0.284	0.643	5.389
AP-Adapter	0.314	0.777	5.986

Table 1: Objective evaluation on *in-domain* audio inputs of MusicGen-Melody [5], AudioLDM2-SDEdit [12, 37], and the proposed AP-Adapter. Results are the average of the three tasks. Best results are highlighted in bold (↑/↓: the higher/lower the better).

- **Fréchet audio distance (FAD) [36]** uses a pretrained audio classifier to extract audio features, collects features from all audios, and estimates the feature covariance matrix. Then, the Fréchet distance is computed between the two covariance matrices (one from generated audios, one from real audios). We adopt FAD to evaluate the **overall quality/realisticness** of the generations. Following the official implementation, we use VGGish architecture [39] as the feature extractor. We use the in-domain evaluation dataset as real audios.

5.6 Subjective Study

We design a listening test that contains 2 sets of music for each of the three tasks. The sets are independent from one another, and each contains a 10-second original audio prompt x , an editing text command y , and three edited audios \tilde{x} generated by our model and the two baselines (with order randomized and kept secret to participants). Participants rate each edited audio on a 5-point Likert scale, according to the following 3 aspects:

- **Transferability:** Do you feel that the generated audio matches what the text prompt asks for?
- **Fidelity:** Do you feel that the generated audio faithfully keeps the original musical content that should not be changed by the text prompt?
- **Overall preference:** Overall, how much do you like the generated audio?

We recruit 30 participants from our social circle and randomly assign them one of the 6 test suites (3 for in-domain, 3 for out-of-domain). The study takes about 10 minutes.

Eval. audios	Metric Task	Transferability MOS			Fidelity MOS			Overall MOS		
		Timbre	Genre	Accomp.	Timbre	Genre	Accomp.	Timbre	Genre	Accomp.
In-domain	MusicGen	3.35	3.15	3.32	2.62	2.85	2.76	3.06	3.03	2.91
	AudioLDM2	3.21	2.74	3.12	2.21	2.21	2.26	2.47	2.56	2.47
	AP-Adapter	3.59	3.44	3.41	3.47	3.74	3.41	3.26	3.44	3.12
Out-of-domain	MusicGen	2.92	3.96	3.00	2.73	3.31	2.54	2.58	3.58	2.65
	AudioLDM2	2.62	2.12	2.96	2.42	2.69	2.23	2.58	2.31	2.81
	AP-Adapter	2.92	3.19	3.54	3.81	3.58	3.96	3.08	3.12	3.31

Table 2: Subjective study results (mean opinion scores $\in [1, 5]$) with 17 and 13 participants for in-domain and out-of-domain input audios, respectively, for the three evaluation tasks: timbre transfer, genre transfer, and accompaniment generation.

6. RESULTS AND DISCUSSION

6.1 Hyperparameter Choices

We discover in our early experiments that several hyperparameters, which are tunable during inference, can drastically affect the edited outputs. Therefore, we conduct a systematic study on the effects of audio pooling rate ω (Sec. 4.1), AP scale in decoupled cross-attention α (Sec. 4.2), and classifier-free guidance scale λ (Sec. 3.3). Specifically, we observe how their various values induce different behaviors on the transferability-fidelity plane spanned by CLAP and chroma similarity metrics.

- The **pooling rate** ω controls the amount of information from the audio prompt. Figure 2a shows clearly that when the pooling rate is low, the fidelity is higher, but at the cost of transferability. For example, the audio generated with $\omega = 1$ preserves abundant acoustic information, thus the edited audio sounds like the input audio, but it might not reflect the editing command. The opposite can be said for $\omega = 8$. Overall, $\omega = 2$ or 4 strikes a good balance.
- The **AP scale** α adjusts the relative importance between the text and audio decoupled cross-attentions. As opposed to pooling rate, it enhances fidelity at the expense of transferability at higher values, as shown in Figure 2b, and $\alpha \in [0.4, 0.6]$ leads to a more balanced performance.
- The **CFG guidance scale** λ dictates the strength of text condition as detailed in Eqn. (5). As shown in Figure 2c, somewhat unexpectedly, λ does not impact the tradeoff too much when $\lambda \geq 3.5$. Hence, we use $\lambda = 7.5$ across all tasks following AudioLDM2.

6.2 Objective Evaluations

We show the metrics computed on in-domain audios in Table 1, taking the average across the three editing tasks. (We do not report the result for out-of-domain audio inputs as we expect CLAP and FAD to be less reliable there.) In general, AP-Adapter exhibits the most well-rounded performance without significant weaknesses—MusicGen scores high on transferability, but has a much worse FAD score, indicating issues on quality or distributional deviation. We infer that, since MusicGen only considers melody as input rather than the entire audio, it has fewer limitations in the generating process and thus achieves a higher transferability score. On the other hand, AudioLDM2 consistently achieves the best FAD score but lacks fidelity and transferability.

We also evaluate the ablated version of AP-Adapter without using the negative prompt (y^-). For the timbre transfer task, not using the negative prompt induces worse transferability, degrading the CLAP score from 0.405 to 0.378, but does not negatively impact chroma similarity and FAD.

6.3 Subjective Evaluations

Table 2 shows the results from our listening test. Our AP-adapter outperforms the two other baseline models in 16 out of 18 comparisons. On top of preserving fine-grained details in the input audio, AP-adapter also tightly follows the editing commands and generate relatively high-quality music, leading in transferability and overall preference except for only the genre transfer task on out-of-domain audios. MusicGen performs better in transferability for genre transfer, but its fidelity is weaker as it only considers the melody of the input audio. With the additional audio-modality condition, AP-adapter has the advantage of “listening” to all the details of the input audio, receiving significantly higher scores on fidelity on both in- and out-of-domain cases.

The advantage of AP-adapter in fidelity is much stronger in Table 2 rather than in Table 1. We conjecture that chroma similarity paints only a partial picture for fidelity as it is focused primarily on harmonic properties, leaving out other musical elements such as dynamics and percussive patterns.

7. CONCLUSIONS

We presented AP-Adapter, a lightweight add-on to AudioLDM2 that empowers it for music editing. AP-Adapter leverages AudioMAE to extract fine-grained features from the audio prompt, and feeds such features into AudioLDM2 via decoupled cross-attention adapters for effective conditioning. With only 500 hours of training data and 22M trainable parameters, AP-Adapter delivers compelling performance across useful editing tasks, namely, timbre transfer, genre transfer, and accompaniment generation. Additionally, it enables users to manipulate the transferability-fidelity tradeoff, and edit out-of-domain audios, which promotes creative endeavors with ethnic instrument audios that are usually scarce in publicly available datasets.

Promising directions for follow-up works include: (i) exploring more diverse editing tasks under our framework with various editing commands, (ii) extending AP-Adapter to other generative backbones, e.g., autoregressive models, and (iii) adding support for localized edits that can be stitched seamlessly with unchanged audio segments.

ABSTRACT

In the domain of symbolic music research, the progress of developing scalable systems has been notably hindered by the scarcity of available training data and the demand for models tailored to specific tasks. To address these issues, we propose MelodyT5, a novel unified framework that leverages an encoder-decoder architecture tailored for symbolic music processing in ABC notation. This framework challenges the conventional task-specific approach, considering various symbolic music tasks as score-to-score transformations. Consequently, it integrates seven melody-centric tasks, from generation to harmonization and segmentation, within a single model. Pre-trained on MelodyHub, a newly curated collection featuring over 261K unique melodies encoded in ABC notation and encompassing more than one million task instances, MelodyT5 demonstrates superior performance in symbolic music processing via multi-task transfer learning. Our findings highlight the efficacy of multi-task transfer learning in symbolic music processing, particularly for data-scarce tasks, challenging the prevailing task-specific paradigms and offering a comprehensive dataset and framework for future explorations in this domain.

1. INTRODUCTION

In the field of artificial intelligence, symbolic music processing—including the analysis and generation of musical scores—presents a unique challenge that merges musical creativity with computational complexity. Symbolic music, which represents musical information with discrete symbols rather than continuous audio signals, facilitates the precise manipulation and analysis of elements such as melody, harmony, and rhythm. Historically, the application of AI in this area has sought not only to mimic the creative process of human composers [1–4] but also

to uncover the underlying patterns of musical composition [5–7].

Despite significant progress, the field still faces persistent limitations. One notable challenge is the prevalence of task-specific models [8–11]. These models offer benefits for specific applications but lack adaptability to the broader spectrum of symbolic music processing. This fragmentation is further compounded by the scarcity of annotated datasets [12–14], which serve as the lifeblood of deep learning models. Unlike other domains where data may be abundant and easy-to-collect, annotated symbolic music datasets are both rare and costly to produce. Without access to ample and diverse data, models struggle to generalize and may exhibit biases or limitations [15] in their analysis and generation of symbolic music.

In addressing the challenges inherent to symbolic music processing, insights from the Natural Language Processing (NLP) domain offer a promising avenue for advancement. Techniques such as transfer learning [16–18] and multi-task learning [19–21] have played a pivotal role in advancing NLP by promoting the transfer of knowledge from pre-trained language models and exploiting common patterns across various tasks. Prominent models like GPT [22], BERT [23], and T5 [24] demonstrate the efficacy of these strategies in understanding and generating language across diverse contexts. Notably, the T5 model, with its text-to-text framework, mirrors the conceptual shift necessary for symbolic music by treating all tasks as variations of converting input scores to output scores. By embracing such methodologies, which regard tasks as facets of a unified problem, we seek to develop models for symbolic music that not only excel in specific tasks but are also adaptable and proficient across a wide range of tasks.

In this paper, we introduce MelodyT5, which leverages an encoder-decoder framework to perform multiple symbolic music tasks as unified score-to-score transformations. Pre-trained on the MelodyHub dataset, which contains over 1 million task instances across seven melody-centric tasks in ABC notation, MelodyT5 overcomes the limitations of task-specific models and sparse data availability in symbolic music processing. By implementing bar patching [7, 25], MelodyT5 can handle longer sequences effectively, expanding its applicability to a wider range of tasks while maintaining computational efficiency. Our results underscore the promise of employing multi-task learning approaches in symbolic music processing, demonstrating

[‡] These authors contributed equally.

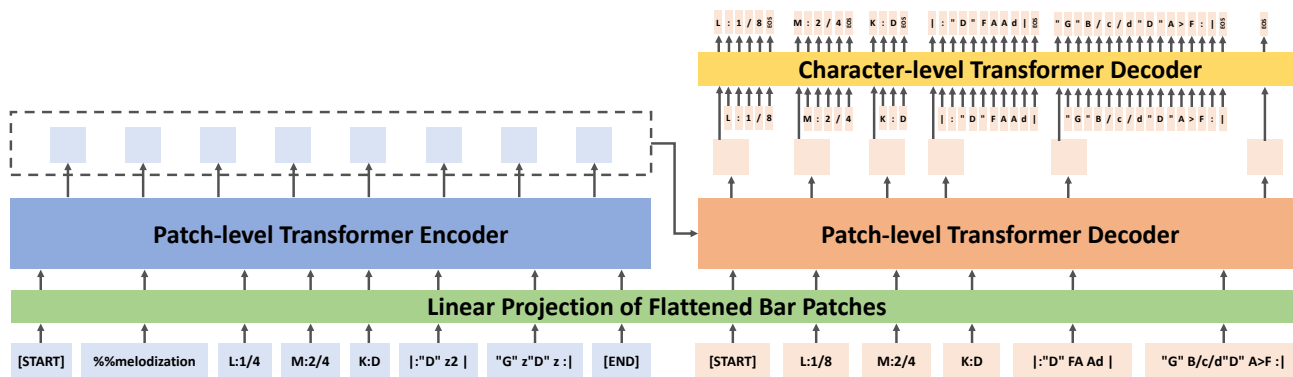

Figure 1. The MelodyT5 framework employs a Transformer encoder-decoder architecture with bar patching for music processing. It uses linear projection of input bar patches, fed into a patch-level Transformer encoder. The encoder output provides context for a patch-level Transformer decoder to autoregressively produce target bar features. A character-level Transformer decoder then uses these features to generate detailed characters for each bar, forming the target musical score.

the superior performance of MelodyT5 across a spectrum of tasks and providing a rich dataset for future research. The key contributions of our paper are as follows:

- MelodyT5, employing an encoder-decoder approach, redefines symbolic music processing by including multiple tasks as unified score-to-score transformations, demonstrating versatility and breaking traditional task-specific constraints.
- MelodyHub, a dataset comprising 261,900 unique melodies in ABC notation across over 1 million task instances for seven different tasks, serves as the cornerstone for effective pre-training of MelodyT5.
- Our experimental results demonstrate the efficacy of multi-task transfer learning in symbolic music, with models trained across multiple tasks outperforming those trained in isolation.

2. METHODOLOGY

In this section, we delve into the methodology behind MelodyT5. We first introduce the ABC notation and bar patching for music representation, then present the architectural design of MelodyT5, and finally outline the pre-training objective of our model, which focuses on score-to-score transformations as the basis for multi-task learning.

2.1 Data Representation

We utilize ABC notation, a concise symbolic music format, for encoding musical scores with ASCII characters. This text-based format elegantly represents musical elements like notes, rhythms, and articulations in a human-readable manner, thereby facilitating thorough music documentation. Additionally, it promotes the utilization of NLP techniques for both music analysis and generation, as evidenced by recent studies [4, 26, 27].

To process musical scores encoded in ABC notation more efficiently, we implement the bar patching technique [7, 25]. Bar patching involves breaking down musical sequences into units called bar patches. Each of these units

corresponds to either a bar or an information field (such as key and meter), including a sequence of characters that represent musical symbols within that patch. Unlike the conventional character-level or token-level tokenization of ABC notation [28, 29], where individual characters or tokens are processed independently, bar patching groups multiple characters into cohesive semantic units. Typically, each patch comprises 10 or more tokens, thus effectively reducing the overall sequence length of musical scores.

2.2 Model Architecture

As shown in Fig. 1, the MelodyT5 framework employs an encoder-decoder architecture based on the Transformer network [30], tailored for symbolic music processing. Integrating bar patching into MelodyT5 requires the incorporation of two additional components: a linear projection layer and a character-level decoder. Consequently, the model architecture encompasses the following modules:

Linear Projection: This component converts each bar patch into a dense embedding. It takes a multi-hot vector as input, formed by concatenating one-hot vectors representing characters within the bar patch with the shape $S \times V$, where S represents the patch size (i.e., the maximum number of characters in a patch) and V represents the vocabulary size. If a patch contains fewer than S characters, it will be padded with a special token to make it a S -character patch. The vector is then mapped to a dense embedding, serving as input to the patch-level encoder or decoder.

Patch-level Encoder: It is responsible for generating contextualized representations to understand the input musical score by operating on the dense embeddings produced by the linear projection layer. Leveraging mechanisms like self-attention and feed-forward neural networks, it captures global dependencies within the input musical score.

Patch-level Decoder: Tasked with generating the dense representation of the next bar patch, the patch-level decoder utilizes contextualized representations from the encoder and patch embeddings of previously generated content. It employs cross-attention and autoregressive generation mechanisms, ensuring global coherence and continuity in the sequence of generated bar patches.

Table 1. The MelodyHub collection statistics include the number of instances for each task along with the corresponding data sources. The JSB Chorales dataset is augmented to 15 keys due to its small size and original data in the C key.

Data Sources	Cataloging	Generation	Harmonization	Melodization	Segmentation	Transcription	Variation
<i>ABC Notation</i> [31]	184,660	184,738	31,732	31,690	—	174,779	—
<i>FolkWiki</i> [32]	6,610	6,767	1,207	1,205	—	6,218	—
<i>JSB Chorales</i> [33]	4,980	4,980	4,950	4,950	19,125	4,980	—
<i>KernScores</i> [34]	1,731	1,776	—	—	1,275	1,754	—
<i>Meertens Tune Collections</i> [35]	16,662	16,662	—	—	16,660	16,297	—
<i>Nottingham</i> [36]	1,031	1,031	1,014	1,014	—	1,021	—
<i>OpenScore Lieder</i> [37]	1,326	1,326	—	—	—	1,255	—
<i>The Session</i> [38]	44,620	44,620	3,081	3,078	—	42,838	174,104
<i>Total</i>	261,620	261,900	41,984	41,937	37,060	249,142	174,104

Character-level Decoder: Operating in a step-by-step manner, the character-level decoder produces characters within the next bar patch based on the dense representation generated by the patch-level decoder. By utilizing the dense representation as a context vector, it decodes each character within the bar, focusing on local information, and sequentially reconstructs every bar patch until it completes the generation of the target musical score.

The encoder-decoder architecture with bar patching in MelodyT5 enables efficient score-to-score transformations by hierarchically modelling music at both patch and character levels, capturing global structure and local details inherent in compositions.

2.3 Pre-training Objective

The pre-training objective of MelodyT5 aims to optimize a unified encoder-decoder framework for processing and generating symbolic music across a variety of tasks, utilizing cross-entropy loss for next token prediction.

We consider a dataset D consisting of pairs (X, Y) , where X is an input musical score and Y is the target musical score. Each score is represented as a sequence of bar patches $\{B_1, B_2, \dots, B_n\}$, with each bar patch B_i further decomposed into a sequence of characters $\{c_1, c_2, \dots, c_m\}$. The model is trained to predict each token (i.e., character) of the target score given the input score and the previously generated tokens in an autoregressive manner.

Formally, the pre-training objective can be represented as minimizing the cross-entropy loss across all tokens in the target sequence:

$$\mathcal{L}(\theta) = - \sum_{(X,Y) \in D} \sum_{i=1}^n \sum_{j=1}^m \log P_{\theta}(c_j^i | X, B_{<i}, c_{<j}^i) \quad (1)$$

where c_j^i is the j -th character in the i -th bar patch of score Y , $B_{<i}$ includes all bar patches before the i -th, $c_{<j}^i$ are characters before the j -th in the current patch, and P_{θ} is the probability of the model, parameterized by θ , of predicting the correct character.

This objective incorporates the fundamental principle that the vast majority of symbolic music tasks can be considered as transformations from score to score, or, in other words, from an input musical score to a target musical

score. By pre-training on this objective, MelodyT5 acquires the ability to understand and replicate a wide array of patterns and structures inherent to different music tasks, which is pivotal for its success across various applications within symbolic music processing.

3. DATASET

This section outlines the melody curation and task definition of the MelodyHub dataset. MelodyHub, crucial for training MelodyT5, comprises seven melody-centric tasks. This collection, sourced from sheet music datasets, includes folk songs and other non-copyrighted musical scores from various traditions and epochs.

3.1 Melody Curation

The MelodyHub dataset was curated using publicly available sheet music datasets and online platforms, with original formats like ABC notation, MusicXML, and Humdrum. The data curation process included several steps:

1. Entries featuring explicit copyright indicators such as “copyright” or “©” symbols were excluded.
2. All data was converted to MusicXML format for standardization and subsequently transformed into ABC notation to ensure format consistency.
3. Melodies consisting of fewer than eight bars were omitted from the dataset to maintain adequate complexity and musical richness.
4. Removal of lyrics and non-musical content (e.g., contact information of transcribers and URL links) aimed to focus solely on musical notation.
5. Leading and trailing bars of complete rest were removed from each piece.
6. Each piece underwent verification for the presence of a final barline, with addition if absent.
7. Entries were deduplicated to prevent redundancy.

By ensuring the quality and consistency of the MelodyHub dataset, these steps led to a substantial collection of 261,900 melodies with uniform formatting, making it suitable for training and evaluating symbolic music models like MelodyT5.

3.2 Task Definition

Following the curation of melody data, the MelodyHub dataset was segmented into seven tasks, as summarized in Table 1, presented in a score-to-score format with input-output pairs. In MelodyHub, every input data includes a task identifier (e.g., `%%harmonization`) at the outset to specify the intended task. Below are the definitions of these tasks:

Cataloging: This task selects melodies with music-related metadata like titles, composers, and geographical origins (e.g., `C:J.S. Bach, O:Germany`). The input data includes information fields with these attributes, while specific information is removed and the order is randomized. The output includes the corresponding metadata without the musical score.

Generation: Here, the input solely consists of a task identifier (i.e., `%%generation`), while the output comprises comprehensive musical scores. Following TunesFormer [25], control codes are affixed to all melodies as information fields to denote musical structure information. These codes, namely `S:`, `B:`, and `E:`, signify the number of sections, bars per section, and edit distance similarity between every pair of sections within the tune.

Harmonization: This task involves melodies containing chord symbols. The chord symbols are removed from the input, while the original data is retained as the output. An additional information field denoting edit distance similarity (`E:`) is appended to the output, indicating the similarity between the input and output, ranging from 0 to 10 (no match at all to exact match). Lower similarity values suggest the need for more chord symbols.

Melodization: In contrast to harmonization, this task operates inversely and also employs melodies containing chord symbols. The notes in the original score are replaced with rests, and adjacent rest durations are combined. The resultant score, comprising rests and chord symbols, serves as the input. Similar to harmonization, an `E:` field is added at the outset of the output, with lower values facilitating the generation of more intricate melodies.

Segmentation: Melodies in Humdrum format (i.e., KernScores and Meertens Tune Collections) containing curly braces indicating segmentation or voices from the JSB Chorales dataset (four-part compositions) with fermatas are chosen. These markers are transformed into breath marks. The input data omits all breath marks, while the output introduces an `E:` field at the beginning to aid the generation of breath marks, with lower values implying the need for more breath marks to be added.

Transcription: ABC notation is initially converted to MIDI, then reconverted back to ABC. The resultant ABC from the MIDI conversion loses substantial score information, such as distinguishing enharmonic equivalents and missing musical ornaments (e.g., trill). The MIDI-converted ABC serves as the input, while the original ABC, appended with an added `E:` field, constitutes the output. Lower `E:` values denote greater discrepancies between the transcribed and input scores, particularly due to absent repeat symbols.

Variation: This task centres on data from The Session, wherein each ABC notation file may contain multiple variants of the same tune. Tunes with two or more variations are selected, with every possible pair of variants utilized as both input and output. The output initiates with an `E:` field signifying the extent of disparities between the input and output scores, with lower values suggesting substantial variations in the musical scores.

Together, resulting in 1,067,747 task instances in total, these tasks include various MIR challenges from analytical to generative, providing a comprehensive resource¹ for developing symbolic music models like MelodyT5.

4. EXPERIMENTS

This section evaluates the effectiveness of MelodyT5 in symbolic music processing through a series of experiments. It outlines experimental settings, conducts ablation studies on multi-task learning impact, and compares MelodyT5 with baseline models in various tasks.

4.1 Settings

The experiments are structured to systematically assess the capabilities of MelodyT5 for diverse symbolic music tasks. We utilize the MelodyHub dataset, which is randomly split into 99% for training and 1% for validation.

MelodyT5 features a 9-layer patch-level encoder and decoder with shared weights, a 3-layer character-level decoder, and a hidden size of 768, amounting to 113 million parameters. This configuration processes ABC sequences up to 16,384 characters, with a 256 patch length and a 64 patch size. It employs a 128-size ASCII-based vocabulary, using characters 0-2 for special tokens (pad, bos, and eos).

The AdamW optimizer [39] is used, setting a learning rate of $2e-4$. The process includes a 3-epoch warmup, a constant learning rate over 32 epochs, and a batch size of 10 for each GPU, ensuring consistency in hyperparameter settings across all tasks. It took approximately 2 days to complete the pre-training using 6 RTX 3090 GPUs.

In ablation studies, we investigate the effects of multi-task learning on MelodyT5, considering three settings: 1) omitting pre-training, 2) using only the downstream task-specific data from MelodyHub, or 3) utilizing the entire MelodyHub dataset, which includes all tasks.

In terms of comparative evaluations, we select open-source models that excel in their respective domains for benchmarking. MelodyT5 is fine-tuned on identical datasets to these models, ensuring fairness in comparison. For models trained on proprietary datasets, we retrain them using accessible datasets to ensure reproducibility.

Our objective evaluation strategy includes ablation studies focused on bits-per-byte (BPB) for consistent measurement, alongside task-specific metrics for comparative evaluations. Additionally, A/B tests are conducted for the subjective evaluation against baseline models.

¹ <https://huggingface.co/datasets/sander-wood/melodyhub>

Table 2. Experimental results from ablation studies illustrate the impact of multi-task learning on diverse symbolic music tasks, evaluated through BPB (bits-per-byte) to compare performance across various pre-training settings.

Pre-training	Cataloging <i>WikiMT [40]</i>	Generation <i>Wikifonia [41]</i>	Harmonization <i>CMD [42]</i>	Melodization <i>EWLD [43]</i>	Segmentation <i>Essen [44]</i>	Transcription <i>Liederschatz [45]</i>	Variation <i>The Session [38]</i>
<i>None</i>	0.0376	1.2382	0.5680	0.7949	0.0272	1.1938	0.4932
<i>Task-Specific</i>	0.0379	0.8850	0.3393	0.6322	0.0224	0.3432	–
<i>Multi-Task</i>	0.0350	0.8472	0.2925	0.5067	0.0119	0.2969	0.3949

4.2 Ablation Studies

In our ablation studies, MelodyT5 was evaluated on the test sets of various symbolic music benchmarks. Due to the lack of a directly suitable external dataset for the variation task, we chose to evaluate using the validation set of The Session. As a result, there was no task-specific pre-training for the variation task.

The ablation studies aim to explore two aspects: 1) the overall efficacy of pre-training, particularly in the context of multi-task pre-training versus task-specific pre-training, and 2) the extent to which performance gains from multi-task pre-training vary among different tasks, especially considering differences in the available volume of pre-training data across these tasks.

The ablation studies, as depicted in Table 2, show that pre-training is crucial for improving the performance of symbolic music tasks. Models trained with pre-training consistently outperform those without, indicating that pre-training enhances model generalization and performance. Multi-task pre-training is also superior to task-specific pre-training, as models trained with multi-task pre-training show lower BPB scores. This highlights the importance of leveraging multi-task pre-training to effectively capture shared patterns and structures in symbolic music data, enabling MelodyT5 to generalize better to downstream tasks.

Furthermore, it is noteworthy that while multi-task pre-training consistently yields performance gains across most tasks, the extent of improvement varies, which significantly correlates with the volume of task-specific data available for pre-training. Specifically, tasks with less data, such as segmentation and melodization, showcase more substantial performance gains from multi-task learning. On the other hand, tasks with more data, like generation and cataloging, though still benefiting from multi-task pre-training, show relatively smaller improvements. This observation suggests that while multi-task learning enhances model performance across the board, its impact is especially notable in data-constrained scenarios.

In summary, the ablation studies demonstrate the effectiveness of multi-task learning and underscore the impact of data volume on the benefits derived from such an approach. Multi-task learning boosts model performance across symbolic music tasks and provides notable advantages for tasks with limited data by leveraging shared knowledge across tasks.

4.3 Comparative Evaluations

For comparative evaluations, we compare MelodyT5, which is multi-task pre-trained on MelodyHub, with several task-specific baseline models, focusing on melody generation, harmonization, melodization, and segmentation. These tasks are well-established and have open-source models as competitive baselines. The following baseline models have been selected for comparison:

- **TunesFormer** [25] is applied for melody generation, featuring a Transformer-based architecture with bar patching and control codes. This approach aims to refine the efficiency of the generation process and ensure adherence to musical forms.
- **STHarm** [46] is utilized as the baseline in melody harmonization, employing a Transformer framework to convert melodies into chords. Its primary focus is on creating harmonies that preserve the structural integrity of the original melody.
- **CMT** [9] is chosen for melodization, which involves generating melodies based on chord progressions. It employs a phased training approach, conditioning the generation of rhythm and pitch on the chords to produce dynamic and coherent musical outputs.
- **Bi-LSTM-CRF** [8] is used for melody segmentation, integrating Bi-LSTM and CRF to effectively identify and segment melodic phrases for music structure analysis.

For an objective and quantifiable performance assessment that ensures reproducibility, we leverage previously established task-specific metrics. The selected metrics for our assessment include:

- **CTRL (Controllability)** [25]: Evaluates the precision of generation control through edit distance similarity between intended and actual control codes.
- **CTnCTR & PCS & MCTD** [47]: These chord/melody harmonicity metrics evaluate harmonization and melodization tasks by assessing harmonic and melodic compatibility between melodies and chords.
- **F1 Score**: Measures the balance between precision and recall in identifying correctly segmented melodic phrases.

Table 3. Comparative objective evaluation of the MelodyT5 model against task-specific baselines across various symbolic music tasks, utilizing task-related metrics previously established. The baselines include TunesFormer [25] for generation, STHarm [46] for harmonization, CMT [9] for melodization, and Bi-LSTM-CRF [8] for segmentation.

Models	Generation				Harmonization			Melodization			Segmentation
	CTRL↑	CTnCTR↑	PCS↑	MCTD↓	CTnCTR↑	PCS↑	MCTD↓	CTnCTR↑	PCS↑	MCTD↓	F1 Score↑
MelodyT5	0.8664	0.7108	0.3274	1.2080	0.8438	0.5084	1.0320	0.8438	0.5084	1.0320	0.9055
Baselines	0.8162	0.5963	0.2343	1.3125	0.8607	0.4863	1.0610	0.8607	0.4863	1.0610	0.8400

Table 3 shows that MelodyT5 outperforms task-specific baselines in all tasks. It surpasses the specialized baseline TunesFormer in melody generation, demonstrating enhanced control and precision in generating melodies according to specific musical forms. MelodyT5 leads in harmonization, producing chords that are harmonically compatible with the given melodies while maintaining structural coherence. Although slightly trailing CMT in CTnCTR, it still shows robust performance in other metrics for melodization, demonstrating its ability to generate melodies well integrated with chord progressions. Its performance in melody segmentation is significant, indicating its ability to accurately discern and segment melodic phrases. This performance, achieved without task-specific modifications, highlights the effectiveness of multi-task transfer learning combined with unified score-to-score transformations in symbolic music processing.

In addition to the objective metrics presented in Table 3, we recognize the limitations of solely relying on such measures to evaluate the quality of generated music. Thus, we further explored these areas (i.e., generation, harmonization, and melodization) through subjective experiments to capture listener preferences.

For our subjective evaluation, we randomly chose 30 pieces from the test set for each task and conducted blind A/B testing. Participants were presented with one randomly chosen pair from each of these 30 pairs to compare musical scores generated by MelodyT5 and baseline models under identical conditions. They were asked to choose between MelodyT5, the baseline, or no preference. Each comparison was included in two videos, showcasing both the audio and the Sibelius-rendered musical scores.

For generation, we compared the quality of melodies generated by MelodyT5 and TunesFormer, given the same control codes and information fields. In harmonization and melodization, comparisons were made against baselines given identical melodies or chords, respectively. To ensure fairness, especially considering the baseline model for melodization was limited to generating outputs of only 8 bars, we trimmed the MelodyT5-generated scores to match the output length of this baseline model.

The study involved 155 responses from students and educators with music specializations, ensuring deep understanding of melody and harmony. To secure data reliability, submissions were filtered out of those completed in less than half the overall average duration of 4 minutes and 39 seconds, i.e., those under 2 minutes and 20 seconds. This resulted in a final tally of 124 valid questionnaires.

Figure 2. Comparative subjective evaluation of MelodyT5 against task-specific baselines in symbolic music tasks, showing vote counts for each model.

Based on the subjective evaluation in Fig. 2, we observe a notable preference for the MelodyT5 model over the baseline in the tasks of melody generation and harmonization, with MelodyT5 receiving a higher number of votes. However, the preferences reverse in the task of melodization, where the baseline model receives a greater number of votes compared to MelodyT5. This indicates that the baseline model CMT, which employs a two-phase training process focusing separately on rhythm and pitch conditioned on chord progressions, may align more closely with human rhythmic tendencies in melodization, leading to a preference for its outputs in the subjective evaluation.

Overall, MelodyT5 excels in symbolic music processing, outperforming task-specific models in most tasks and demonstrating the effectiveness of multi-task transfer learning in this domain, despite occasional shortcomings.

5. CONCLUSIONS

This study presents MelodyT5, a model addressing challenges in symbolic music processing by providing a unified framework for diverse tasks. By treating music tasks as score-to-score transformations, MelodyT5 significantly improves symbolic music processing through multi-task transfer learning. Objective and subjective evaluations demonstrate that MelodyT5 generally outperforms or matches task-specific baseline models without modification. The MelodyHub dataset, with over one million task instances, offers a rich resource for training and evaluating models. While excelling in melody-centric tasks, further optimization is required to tackle more complex musical compositions, such as polyphonic arrangements.

6. ETHICS STATEMENT

In our research, we are committed to upholding ethical standards regarding data privacy and copyright protection. We diligently adhere to these principles throughout our data collection and processing procedures. All data utilized in our study is sourced from publicly accessible repositories, and we have taken measures to exclude any known copyrighted materials.

7. ACKNOWLEDGEMENTS

We would like to express our sincere gratitude to Associate Professor Bob L. T. Sturm from KTH Royal Institute of Technology for his valuable discussions and insights into the early stages of the project. We also acknowledge Yuanliang Dong and Jiafeng Liu from the Central Conservatory of Music for their assistance, and Leqi Peng from Fuyin Technology for her support with subjective experiments.

This work was supported by the following funding sources: Special Program of National Natural Science Foundation of China (Grant No. T2341003), Advanced Discipline Construction Project of Beijing Universities, Major Program of National Social Science Fund of China (Grant No. 21ZD19), and the National Culture and Tourism Technological Innovation Engineering Project (Research and Application of 3D Music).

ABSTRACT

Graph Neural Networks (GNNs) have recently gained traction in symbolic music tasks, yet a lack of a unified framework impedes progress. Addressing this gap, we present GraphMuse, a graph processing framework and library that facilitates efficient music graph processing and GNN training for symbolic music tasks. Central to our contribution is a new neighbor sampling technique specifically targeted toward meaningful behavior in musical scores. Additionally, GraphMuse integrates hierarchical modeling elements that augment the expressivity and capabilities of graph networks for musical tasks. Experiments with two specific musical prediction tasks – pitch spelling and cadence detection – demonstrate significant performance improvement over previous methods. Our hope is that GraphMuse will lead to a boost in, and standardization of, symbolic music processing based on graph representations. The library is available at <https://github.com/manoskary/graphmuse>

1. INTRODUCTION

Symbolic music processing entails the manipulation of digital music scores, encompassing various formats such as MusicXML, MEI, Humdrum, **kern, and MIDI. Unlike audio-based representations, symbolic formats offer granular information on note elements, including onset, pitch, duration, and other musical attributes like bars and time signatures.

While prior research in symbolic music processing often adopted techniques from the image processing [1–3] or natural language processing [4–6] domains, recent attention has shifted towards graph-based models, which could presumably better capture the dual sequential and hierarchical nature of music. Graph Neural Networks (GNNs) have been showcased as potent tools for diverse symbolic music tasks, including cadence detection [7], optical music recognition [8], music generation [9], Roman numeral analysis [10], composer classification [11], voice separation [12], and expressive performance rendering [13].

However, a standardized framework for constructing and processing music graphs has not yet been introduced to the field. To address this challenge, we developed GraphMuse, a Python-based framework to efficiently and effectively process information from musical scores, construct musically meaningful graphs, and facilitate the training of graph-based models for symbolic music tasks.

A key innovation of our work lies in the introduction of a new sampling technique tailored to specific properties of music while maintaining efficient and robust training of GNNs. Additionally, GraphMuse integrates within the graphs and models hierarchical elements that augment the capabilities of graph networks for musical tasks.

We evaluate our framework on pitch spelling and cadence detection tasks, comparing it against existing state-of-the-art methods. Through the synergistic utilization of our framework’s components, we achieve a significant performance increase compared to the previous methods. Our overarching objective is to establish a standardized framework for graph processing in symbolic music analysis, thus catalyzing further progress in the field.

Altogether, our contributions are three-fold: i) We provide a structured, generic, and flexible framework for graph-based music processing; ii) we release an open source *Python* library that comes with it; iii) we achieve performance improvements in a principled way by focusing on the design of the individual parts of the framework.

2. PROCESSING MUSIC SCORES WITH GNNs

In this section, we describe existing graph modeling approaches for musical scores. They all have a common pipeline which involves building a graph from a given musical score (see Figure 1) and using a series of convolutional blocks to produce context-aware hidden representations for each node. We start by describing the graph-building procedure and a generic graph convolutional block; we then take a detailed look at the problem of graph sampling, which will motivate a new sampling procedure that will be presented in the next section.

2.1 Preprocessing: Constructing Graphs from Scores

A score graph can be represented as a heterogeneous attributed graph. A heterogeneous graph has a type associated with each node and edge in the graph [14]. An attributed graph has an associated feature vector for

Widmer , “GraphMuse: A Library for Symbolic Music Graph Processing”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

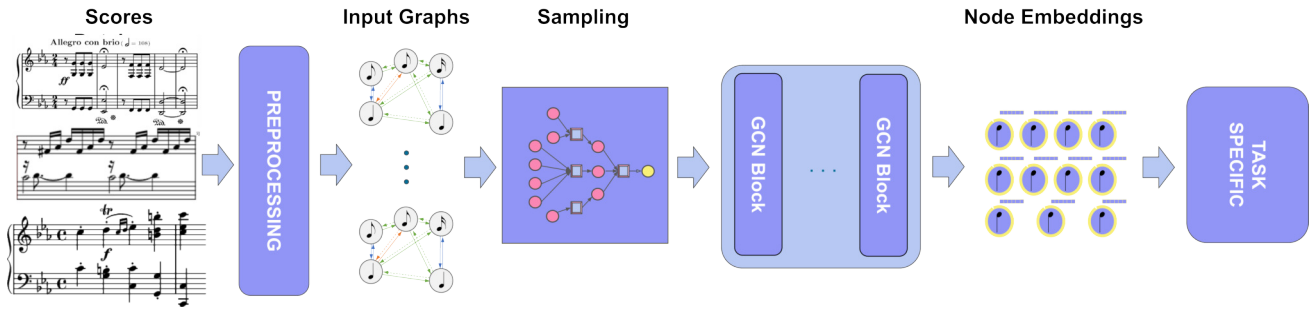

Figure 1. The general graph processing/training pipeline for symbolic music scores involves several steps: i) Preprocess the database of scores to generate input graphs; ii) Sample the input graphs to create memory-efficient batches; iii) Form a batch as a new graph with nodes and edges from various input graphs; iv) Sample a subset of nodes (target nodes) and their neighbors from the input graphs; v) Update the target nodes’ representations through graph convolution to create node embeddings; vi) Use these embeddings for task-specific applications. Note that target nodes may include all or a subset of batch nodes depending on the sampling strategy.

each node in the graph [15]. Therefore, a heterogeneous attributed graph is defined by a quintuple $G = (V, E, X, \mathcal{A}, \mathcal{R})$, together with the mappings $\phi : V \rightarrow \mathcal{A}$ and $\psi : E \rightarrow \mathcal{R}$, where V is the set of nodes, E is the set of edges, $X \in V \times \mathbb{R}^k$ the feature matrix \mathcal{A} is the node types and \mathcal{R} is the edge types. ϕ maps each node to its type and ψ maps its each edge to its corresponding type.

We create such a graph from a musical score by following previous work [10–13]. Each node $v \in V$ corresponds to one and only one note in the musical score. \mathcal{R} includes 4 types of relations: onset, during, follow, and silence, corresponding, respectively, to two notes starting at the same time, a note starting while the other is sounding, a note starting when the other ends, and a note starting after a time when no note is sounding. The inverse edges for during, follows, and silence relations are also created.

Formally, let us consider three functions $on(v)$, $dur(v)$, and $pitch(v)$ defined on a note $v \in V$ that extract the onset time, duration, and pitch, respectively. A typed edge (u, r, v) of type $r \in \mathcal{R}$ between two notes $u, v \in V$ belongs to E if the following conditions are met:

- $on(u) = on(v) \rightarrow r = \text{onset}$
- $on(u) > on(v) \wedge on(u) \leq on(v) + dur(v) \rightarrow r = \text{during}$
- $on(u) + dur(u) = on(v) \rightarrow r = \text{follow}$
- $on(u) + dur(u) < on(v) \wedge \nexists v' \in V, on(v') < on(v) \wedge on(v') > on(u) + dur(u) \rightarrow r = \text{silence}$

\mathcal{A} in the literature usually only includes a single type, i.e. the note type ν . However, we extend this definition in Section 3.1.

2.2 Encoding: Graph Convolution

Graph convolution and message passing are core operations in graph neural networks (GNNs) for learning node representations. In graph convolution, in its simplest form, each node aggregates messages from its immediate neighbors by computing a weighted sum of their features:

$$\mathbf{h}_v^{(l+1)} = \sigma \left(\left(\sum_{u \in \mathcal{N}(v)} \mathbf{W}^{(l)} \mathbf{h}_u^{(l)} \right) + \mathbf{h}_v^{(l)} \right) \quad (1)$$

where $\mathbf{h}_v^{(l)}$ is the representation of node v at layer l , $\mathcal{N}(v)$ denotes the neighbors of node v , $\mathbf{W}^{(l)}$ is a learnable weight, and σ is a non-linear activation function. Through successive iterations of message passing and aggregation, each node refines its representation by incorporating information from increasingly distant nodes in the graph, ultimately enabling the network to capture complex relational patterns and dependencies within the graph data.

In the context of music, graph convolution can be understood as a method for defining a note not only by its own characteristics and properties but by also considering the characteristics of its neighboring notes within the musical graph. In this work, as well as previous graph-based work on music [7, 10, 11] the preferred graph convolutional block is *SageConv* taken from one of the first and fundamental works in graph deep learning [16].

2.3 Sampling: Handling Graph Data for Training

In an ideal world without computing resource considerations, we can imagine a training pipeline that receives an entire graph as input to a graph convolutional model. Assuming that we have the resources and time to perform such a task the process is easy to grasp. All nodes of the graph are updated in a single step based on their neighbors as described in the previous section.

However, the graph world presents us with several complexity issues. Graph datasets in the wild typically come in two forms: i) a (possibly large) collection of small graphs, each containing maybe fewer than 50 nodes [15]; ii) a single large-scale graph such as a social network [17], a recommender system [18], or a knowledge graph [19]. The previous naive scenario presents a time-efficiency and computation waste bottleneck for the former and a memory insufficiency issue for the latter. To mitigate these issues, in the former case one can batch many small graphs

Figure 2. Full graph vs neighbor sampling. The pink-colored nodes are selected for convolution by message passing. With neighbor sampling, the pink node is the one whose representation is ultimately updated after convolution (however, for the blue nodes also take part in the convolution process as its context).

together to maximize the available resources and reduce the computation time, then the full graphs can be updated during convolution within each batch.

Training Graph Convolutional Networks (GCNs) for large-scale graphs is a bit more complicated. Such graphs can be exceptionally large – for example, the 2019 Facebook social network boasted 3.51 billion users¹. To train models with such graphs we need to devise a sampling algorithm to derive subgraphs in steps [16, 20–22]. Such an algorithm may, for example, choose a subset of nodes across the graph and perform random walks to fetch a subset of the k -hop neighbors for the sampled nodes [16]. This process, called *neighbor sampling* or *node-wise sampling*, is shown in Figure 2 and compared to the full-graph process.

Musical score graphs fall in between the two scenarios, varying notably in size. For instance, a Bach Chorale might contain 100 notes, while a Beethoven Sonata could exceed 5000 notes, with each note corresponding to a graph node. Furthermore, a musical dataset may contain many such graphs. Therefore the question arises how to efficiently train models on music graph datasets.

Since music graphs are not uniform enough to be batched together like small graph datasets, we investigate the suitability of neighbor sampling methods for music graph processing, taking into account special properties relevant in music. Standard neighborhood sampling would sample notes across different scores and fetch neighbors for those notes, creating a subgraph that can maximize the use of the available resources during training.

However, music has a specific coherence, in both the horizontal (time) and vertical (chords, harmonies) dimensions, which makes sampling approaches from the literature [22] not appropriate for music. Specifically, sampling and updating/encoding single notes without simultaneously doing so also to notes in their local context makes it difficult to learn properties that persist in time (such as local key or a harmonic function). In this work, we address this issue by presenting a simple and musically intuitive sampling process for graphs that efficiently creates batches containing musically related notes which, as experiments

will show, can notably improve the learning results.

2.4 Task-specific Modeling

Finally, the node embeddings created by the graph convolutional encoder serve as input to task-specific models that solve some specific prediction or recognition task. In a graph context, we distinguish, at an abstract level, between node classification, link prediction, and entire graph classification tasks. Examples of node classification tasks can be found in [7] which takes the embeddings from the GCN encoder and employs an edge decoder coupled with a graph convolution classifier for cadence prediction labels; and in [10], which forwards the embeddings to sequential layer and then MLP classifiers to perform Roman Numeral Analysis. In [12], musical voice separation is framed as a link prediction task; the node embeddings are input to a pairwise edge similarity encoder to predict link probabilities between notes in the same voice. An example of a graph classification task can be found in [11] where the embeddings are aggregated and passed through a shallow MLP for composer classification.

Naturally, task-specific models will not be part of the generic graph processing pipeline and library which we publish with this paper.

3. METHODOLOGY

In this section, we discuss our approach to addressing the different components of the pipeline shown in Figure 1. In particular, we explain the preprocessing procedure for creating score graphs, we detail our strategy for musically intuitive graph sampling, and finally, we discuss model variants that are made possible by the previous steps of the pipeline.

3.1 Preprocessing

The central activity in the preprocessing step is the creation of graphs from musical scores. In our library, we extend the conventional graph creation process by introducing hierarchical musical dimensions (beats and measures), in order to enhance the score graphs’ representational capacity. More specifically, we enrich the node type set \mathcal{A} (defined in Section 2.1) with two additional types β and μ for beats and measures respectively. The process involves detecting beats and measures within the musical score, generating edges (of type *connect* to every beat from each note falling within its temporal boundaries, and repeating this process for measures. Additional edges of type *next* are drawn between consecutive beats and measures to enrich the connectivity and contextual understanding within the graph. Furthermore, we aggregate features from constituent notes through the *connect* edges via message passing to equip each beat and measure with informative attributes by computing the mean vector of their note features.

The inclusion of beat and measure node elements, as well as the creation of inverse edges, are made optional, ensuring compatibility with diverse research needs and

¹ <https://zephoria.com/top-15-valuable-facebook-statistics>

Figure 3. Sampling process per score. Top: sampled notes and their neighbors; middle: score graph and sampling process; bottom: sampling process for beats and measures. A randomly selected note (in yellow) is first sampled. The boundaries of the target notes are then computed with a budget of 15 notes in this example (pink and yellow notes). Then the k -hop neighbors are fetched for the targets (light blue for 1-hop and darker blue for 2-hop). The k -hop neighbors are computed with respect to the input graph (depicted with colored edges connecting noteheads in the figure). We can also extend the sampling process for the beat and measure elements (introduced in Section 3.1). Note that the k -hop neighbors need not be strictly related to a time window.

avoiding imposing rigid structures onto the graph-based music processing framework.

We prioritize the efficiency and speed of the graph creation process by transitioning the graph creation implementation to C code, leveraging its performance benefits, and establishing a Python binding for seamless integration into our workflow. Recognizing the temporal nature of musical elements, such as notes, beats, and measures, we refine our neighbor searching windows accordingly, optimizing computational efficiency.

3.2 Sampling

We discussed general neighbor sampling for large-scale graphs in Section 2.3 and some problems related to graph-structured music data. In this section, we elaborate on our musically informed sampling process for music graphs, which enables the training of the models outlined in the subsequent sections. In this process, we aim to sample sections of scores and employ neighbor sampling to fetch the neighbors of notes within those sections.

Indeed while our nodes could be ordered in various ways, the most perceptually significant aspect is time organization. Recognizably, individuals can still identify a musical piece when segmented along the time axis,

whereas focusing solely on pitch intervals may be challenging. Moreover, perceptual research indicates that the commencement time of a note holds greater salience than its offset time, particularly for percussive instruments like the piano, where the sound naturally fades over time [23]. Hence, when constructing graphs from musical scores, we prioritize node arrangement based on absolute onset time followed by pitch.

Our initial limitations are mostly related to memory usage. To limit our memory we need to predefine three initial arguments: i) the size of each target subgraph S from every score, ii) the number B of scores in each batch, and iii) the number of hops and neighbors for each hop (similar to node-wise sampling techniques). In each batch, we update the representation of our target nodes which is essentially the size of $S \times B$.

Once the ordering is set and the three arguments are defined we can initiate the process of sampling a subgraph, as shown in Figure 3. First, we sample a random note from the graph of each score. Next, we correct the position of the note by searching for any vertical neighbors (same onset value notes and potentially different pitch). Then we extend to S notes to the right where S indicates a predefined maximum subgraph size. We also correct the rightmost boundaries to include or exclude vertical neighbors for the last onset always respecting the aforementioned size S . Once this process is completed we obtain the target nodes per score within the batch. These are the nodes whose representation we want to update at the end of the graph convolutional process.

However, since graph convolution is performed recursively we need to fetch the k -hop neighbors for each one of the target nodes where k indicates the depth of the GCN. For this step, we can consult the literature [16] and perform neighbor sampling to fetch the k -hop neighbors. This process is repeated for B different scores. Finally, the B score subgraphs of size at most S each are first joined together and then fed to the model.

During this process, we can keep information about the target nodes and the size of each score subgraph, which could allow us to design more creative models that can exploit this information. Such models are presented in the next section. Moreover, we adopt a potential approach for hierarchical graphs by also extending the sampling for beat and measure nodes as shown in Figure 3.

3.3 Model Designs

In this section, we explore various model designs for the graph-based encoder in our processing pipeline (Figure 1). Designing such an encoder involves addressing two fundamental questions: the selection of graph convolutional blocks and the selective exploitation of information from the input graph.

The first question, regarding graph convolutional blocks, remains open-ended, offering numerous possibilities for exploration and customization. In its current version, *GraphMuse* offers the options of convolutional blocks on a per-node or per-edge type basis. We sug-

gest that graph-attention networks may offer promising avenues, particularly for hierarchical elements such as beats or measures.

In response to the second question, we devise a series of models by selectively incorporating or excluding elements from the input graph. Our foundational model, termed *NoteGNN*, exclusively utilizes note elements and their corresponding edges. This model serves as the basis for further extension. For instance, we expand upon *NoteGNN* to construct *BeatGNN*, which incorporates beat elements (see Section 3.1 above) alongside notes. Similarly, we develop *MeasureGNN* by integrating measures into the encoding process. When all note, measure, and beat elements are included, the resultant model is denoted as *MetricalGNN*.

Furthermore, we explore the possibility of hybridizing model types, such as combining GNNs with sequential models. This hybridization is facilitated by the sampling process that organizes notes in onset order, allowing for the batch to be unfolded by score. Consequently, the same batch can be processed through both GNN and sequential models simultaneously. Specifically, we employ a graph encoder and a sequential encoder in parallel – in our case we use a stack of 2 bidirectional GRU layers. The GRU stack receives the unfolded batch of size (B, S, K) where B is the number of scores within the batch, S is the number of sampled target nodes for each score order by onset and then by pitch, and K is the number of node features. The embeddings of both encoders are concatenated together and an additional linear layer is applied to project them to the required dimension.

This architecture, which we call *HybridGNN* in our experiments, combines the strengths of both GNNs and sequential models, resulting in better performance as shown in our experiments.

3.4 The Library

The components discussed in the preceding section have been implemented and made available in an open-source Python library called GraphMuse. This library follows a similar philosophy as PyTorch and PyTorch Geometric, comprising models and graph convolutional blocks, loader pipelines, data pipelines, and related utilities. GraphMuse is built upon and thus requires PyTorch and PyTorch Geometric. The loaders and models provided by GraphMuse are fully compatible with those of PyTorch Geometric. For musical input and output, GraphMuse is compatible with Partitura [24], a Python library for symbolic music processing, allowing it to work with a variety of input formats such as MusicXML, MEI, Humdrum `**kern`, and MIDI.

4. EVALUATION

To evaluate our framework, we perform experiments on two tasks, cadence detection and pitch spelling. We put to the test both the models discussed as well as the sampling process. For pitch spelling, we compare our models to the previous sequential state-of-the-art model, PKSpell [25] and the GraphSAGE variant of our note-level model. For

cadence detection, we compare our models to the previous state-of-the-art model by Karystinaios and Widmer [7] which is also graph-based and follows a GraphSAGE sampling strategy. For both tasks, we perform ablations by removing the hierarchical elements such as beat and measure nodes and edges, or incorporating hybrid models. This work focuses on the application of the GraphMuse library therefore, a detailed comparison of various input encodings and architectures, as conducted by [11], is beyond the scope of this paper.

4.1 Pitch Spelling

Previous work on Pitch Spelling set the state-of-the-art by using a sequential model [25]. The task of pitch spelling tackles in parallel key signature estimation and pitch spelling estimation per note, however, the key signature is a global attribute usually set for the whole piece although it can sometimes change midway. The previous architecture uses a GRU encoder for pitch spelling and then infuses the logits together with the latent representation to another GRU layer for the key signature prediction.

For our approach, we use a GNN encoder as described in Section 3.3 followed by two classification heads for key and pitch spelling respectively. We train and evaluate all models on the ASAP dataset [26] using a random split with 15% of the data for testing and the 85% for train and validation as described in [25].

4.2 Cadence Detection

For the cadence detection model, we chose to use a modified version of the cadence detection model originally proposed in [7]. Our considerations were based on a more efficient training process, and the integration of our pipeline possibilities. The model was expanded to accept a heterogeneous score graph as input, as described in Section 2.1. Additionally, we enhanced the model’s predictive capabilities from binary (no-cad or PAC) to multiclass cadence prediction, encompassing PAC, IAC, and HC labels. Furthermore, we refined the architecture by incorporating an onset regularization module, which aggregates the latent representations (post-GNN encoder) of all notes occurring at a distinct onset within the score and assigns them to every note sharing that onset.

In the training phase, the input graph first undergoes processing through the graph encoder. The resulting node embeddings are then grouped based on onset information extracted from the score, and their representations are averaged. Subsequently, embedded SMOTE [27] is applied to balance the distribution of cadence classes compared to the notes lacking cadence labels in the score. However, during inference, this synthetic oversampling step is omitted. Finally, the oversampled embeddings are fed into a shallow 2-layer MLP classifier to predict the cadence type.

We trained our model with a joined corpus of cadence annotations from the DCML corpora², the Bach fugues

² https://github.com/DCMLab/dcml_corpora

from the well-tempered clavier Book No.1 [28], the annotated Mozart string quartets [29], and the annotated Haydn string quartets [30]. Our joined corpus makes for 590, 149 individual notes and 17, 188 cadence annotations. We use 80% of the data for training and validation and test on 20% using a random split. Note that these results cannot be directly compared with [7] since we use a different (bigger) dataset and perform multiclass prediction.

4.3 Experiments

4.3.1 Configuration

The configuration for training pitch spelling graph models with our sampling technique uses a batch size $B = 300$, sampling from 300 scores at each step, and target node size $S = 300$. For cadence graph models, $B = 200$ and $S = 500$. All graph models, including GraphSAGE, utilize three heterogeneous SageConv layers with a hidden size of 256 and a dropout of 0.5. Neighbor sampling for each layer fetches up to three neighbors per sampled node per relation. We train all models with the Adam optimizer (learning rate 10^{-3} , weight decay 5×10^{-4}) on a GTX 1080 Ti. Each experiment is repeated at least four times with different random seeds, and statistical significance testing is performed using the ASO method at a confidence level $\alpha = 0.05$ [31]³.

4.3.2 Results

Table 1 presents the results of experiments conducted on the two tasks. The metrics used for evaluation are Accuracy (A) for pitch spelling and key recognition, and the macro F1 score ($F1$) for cadence detection. Note that the model employed on the GraphSAGE methods and the model NoteGNN are virtually the same apart from the sampling strategy with which they were trained.

For the pitch spelling task, we can observe that the actual pitch spelling accuracy (A-Pitch) of all proposed models surpasses both the PKSpell and GraphSAGE methods. Across all models, the MetricalGNN achieves the highest accuracy of 95.6%, closely followed by BeatGNN and MeasureGNN with accuracies of 95.1% and 95.4%, respectively. These results indicate the benefits of incorporating hierarchical musical elements such as beats and measures. However, it is worth noting that while MetricalGNN achieves the highest accuracy, it is closely followed by the hybrid model, HybridGNN, which achieves an accuracy of 95.4%, suggesting that competitive performance can also be achieved by mixing model types.

Focusing on the key estimation subtask (A-Key) of pitch spelling we notice that the PKSpell model achieves a very good key accuracy of 69.9%, closely followed by the MeasureGNN model and only surpassed by the Hybrid model. We attribute the effectiveness of key detection of a sequential model such as PKSpell to the persistence of the key label across elements of the sequence. Therefore, a hybrid model in this case seems to be able to adapt to

Task	Pitch Spelling		Cadence
	A-Pitch	A-Key	F1-Cad
PKSpell	94.8 ± 0.5	69.9 ± 1.6	-
GraphSAGE	93.6 ± 0.1	43.3 ± 0.1	53.5 ± 0.8
NoteGNN	94.9 ± 0.1	69.3 ± 7.0	55.3 ± 0.9
BeatGNN	95.1 ± 0.2	68.7 ± 1.1	<u>57.4</u> ± 1.2
MeasureGNN	<u>95.4</u> ± 0.3	69.5 ± 7.2	57.0 ± 1.0
MetricalGNN	95.6 ± 0.1	64.4 ± 5.3	55.8 ± 0.6
HybridGNN	<u>95.4</u> ± 0.2	72.6 ± 2.8	58.6 ± 0.7

Table 1. Results on the two tasks, in terms of accuracy (A) and F1 score, respectively. Values in bold are the best score per metric; underlined values are the second best. All runs are repeated 4 times. \pm indicates standard deviation.

the diversity of labels for pitch spelling and uniformity of labels for key estimation. We found our best model to be stochastically dominant over PKSpell with $min_e = 0.17$.

In the cadence detection task, we evaluate the results using the macro F1 score to account for the overwhelming presence of non-cadence nodes, as instructed by [7]. We observe that GraphSAGE, the previously used technique for training, obtains the lowest F1 score and it is surpassed by all the proposed GNN-based models trained with the new sampling method.

Among our GNN models, BeatGNN and HybridGNN achieve the highest scores of 57.4% and 58.6%, respectively, closely followed by MeasureGNN. In this case, the MetricalGNN model surprisingly does not achieve such a good score even though it includes both measure and beat elements. However, it still performs better than the NoteGNN and the GraphSAGE method.

Overall, the results demonstrate the efficacy of GNN-based models trained using our new sampling method. Incorporating hierarchical elements such as beats and measures improves both pitch spelling and cadence detection tasks. Additionally, the hybrid approach of combining GNNs with sequential models produces promising results.

5. CONCLUSION

In this paper, we introduced GraphMuse, a framework and Python library for symbolic graph music processing. We designed a specialized sampling process for musical graphs and demonstrated our pipeline’s effectiveness through experiments on pitch spelling and cadence detection. Our results show that carefully designed GNN architectures, especially those incorporating hierarchical elements like beats and measures, can lead to better performance. Finally, hybrid models that integrate GNNs with sequential models yield further performance improvements.

Future research will focus on refining GNN-based models in music processing, adding more tasks, and exploring novel architectures. This includes investigating advanced graph convolutional blocks, other sampling techniques, and attention mechanisms to enhance model performance.

ST-ITO: CONTROLLING AUDIO EFFECTS FOR STYLE TRANSFER WITH INFERENCE-TIME OPTIMIZATION

Christian J. Steinmetz Shubhr Singh Marco Comunità Ilias Ibyhahya

 Centre for Digital Music, Queen Mary University of London, UK

ABSTRACT

Audio production style transfer is the task of processing an input to impart stylistic elements from a reference recording. Existing approaches often train a neural network to estimate control parameters for a set of audio effects. However, these approaches are limited in that they can only control a fixed set of effects, where the effects must be differentiable or otherwise employ specialized training techniques. In this work, we introduce **ST-ITO**, Style Transfer with Inference-Time Optimization, an approach that instead searches the parameter space of an audio effect chain at inference. This method enables control of arbitrary audio effect chains, including unseen and non-differentiable effects. Our approach employs a learned metric of audio production style, which we train through a simple and scalable self-supervised pretraining strategy, along with a gradient-free optimizer. Due to the limited existing evaluation methods for audio production style transfer, we introduce a multi-part benchmark to evaluate audio production style metrics and style transfer systems. This evaluation demonstrates that our audio representation better captures attributes related to audio production and enables expressive style transfer via control of arbitrary audio effects.

1. INTRODUCTION

Audio effects are signal processing devices used to transform or manipulate audio signals, such as adding reverb, adjusting frequency balance with equalization, or adding edge with distortion. They play a central role in audio production, providing audio engineers with the ability to realize both practical and creative tasks with applications in music, film, broadcast, and video games [1]. Traditionally, operating these effects requires a significant amount of expertise, as audio engineers must combine a technical understanding with their artistic goals. As a result, the process of creating a high-quality audio production remains challenging, requiring a time-consuming process for professionals and a significant barrier for novices.

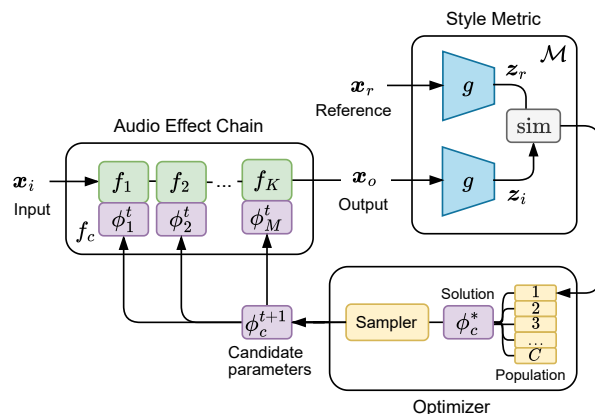

Figure 1. Style transfer with Inference-Time Optimization enables audio production style transfer through control of arbitrary audio effects. It employs a pretrained audio representation as a similarity metric, which is then optimized by searching the control parameter space of audio effects.

Intelligent music production aims to develop systems for automating aspects of audio engineering [2]. Early approaches employed rule-based systems, using hand-engineered rules based on best practices [3]. These systems often generated outputs that satisfied certain assumptions or utilized well established conventions. However, the inability to construct sufficient sophisticated rule bases has motivated machine learning approaches, which instead learn from data without assuming a limited or fixed set of rules [4–7]. Nevertheless, these systems still lacked the ability to adapt based on user input, which is critical to the context-dependent nature of music production [8].

To address the context-dependent nature of this task and enable greater user control, *audio production style transfer* has been proposed [9, 10]. These systems rely on a reference recording and attempt to map elements of the audio production style from the reference onto the input. These systems either directly process the audio signal [11–13] or estimate parameters for audio effects [9, 10, 14, 15]. While direct transformation methods are powerful, they may introduce artifacts and lack grounding in traditional audio tools. Similarly, recent text-to-audio generation models also enable editing capabilities [16, 17], but suffer from the same limitations. On the other hand, parameter based methods enable efficient and controllable style transfer. However, current systems are limited to a fixed chain of effects, and require the use of differentiable signal processing [18], or inefficient alternative differentiation strategies such as gradient approximation [19] and neural proxies [7].

We propose a method to construct an audio production style transfer system that leverages inference-time optimization to facilitate real world applications. Instead of training a network to perform style transfer directly, we perform style transfer via an optimization process at inference, as shown in Figure 1. We iteratively search the parameter space of an effect chain with our proposed metric that measures the similarity in audio production style between the output recording and the reference. This approach enables the ability to control arbitrary audio effect chains, including non-differentiable effects, opening up the potential to control real-world audio effects. The contributions of our work are as follows:

- A simple and scalable pretraining strategy for constructing an audio production style similarity metric through audio effect estimation, named AFx-Rep.
- A system for audio production style transfer, ST-ITO, that optimizes the control parameters of arbitrary audio effects according to a similarity metric.
- An extension of the DeepAFx-ST system [14] with the addition of differentiable distortion and reverb, which forms a strong baseline.
- A multi-task benchmark for evaluation of audio production style similarity metrics and audio production style transfer systems.

We provide audio examples, and open source our datasets, benchmark, and code to facilitate reproducibility¹.

2. METHOD

In this work, we propose **ST-ITO**, Style Transfer with Inference-Time Optimization, a novel method for audio production style transfer that searches the parameter space of a set of audio effects to perform style transfer. As shown in Figure 1, our system features three main components: an audio effect chain that processes an input recording, an audio production style similarity metric, composed of pre-trained encoder and a similarity measure, and an optimizer that is used to find control parameters. This enables style transfer by finding a configuration of the audio effects that produce an output with attributes of the reference style.

Our approach provides a number of benefits as compared to previous audio production style transfer systems. First, it enables the control of arbitrary audio effects, even those that have not been seen during training. Unlike existing systems that train with a set of fixed effects “in-the-loop”, our approach enables adaptation to new effects at inference. Furthermore, our method removes requirements of previous systems. This includes removing the need for differentiable audio effects or alternative differentiation strategies, which can often be slow and difficult to train [14]. Finally, we provide further flexibility and control by enabling the addition or removal of audio effects at inference without re-training of the base model.

Figure 2. Self-supervised training for the pretext task where an audio signal $x_i^d \sim \mathcal{D}_d$ is sampled randomly from one of N datasets and then processed by a randomly sampled audio effect E_m with an associated randomly sampled parameter preset $P_{m,l}$ to produce an output signal x_o^d .

2.1 Audio production style metric

A central aspect of our approach is the development of an audio production style metric $\mathcal{M}(x_a, x_b)$. This metric measures the perceptual similarity in audio production between two recordings x_a and x_b . As explained in Section 2.2, we optimize this metric by searching the parameter space of a set of audio effects to align the style of the processed recording with the reference. In general, production style relates to aspects of audio quality rather than the underlying content, including attributes such as dynamics, frequency balance, and the stereo field [20].

Pretrained audio representations. There is a growing body of work in general purpose representations of audio signals [21], popular approaches include CLAP [22] and BEATs [23]. These representations capture relevant attributes to facilitate downstream tasks such as detection and classification of sound sources and events. While it may be possible to directly adapt one of these representations for our task, evidence suggests they are not always sensitive to audio effect transformations [24]. We provide further evidence for this in Section 5. This motivates us to develop a method to produce our own audio representation that is more sensitive to audio effect transformations.

Self-supervised pretext task. We propose a simple and scalable self-supervised pretext task to construct an audio representation for our task without human annotated data. To encourage the encoder to extract features related to audio effects we employ an audio effect classification task composed of two parts. The model predicts both which effect has been applied and the associated preset.

As shown in Figure 2, we generate training examples using N audio datasets, a set of M audio effects, and L associated parameter presets for each effect. To generate a training example, a dataset \mathcal{D}_d is selected at random from the set of datasets. Then one audio sample is selected from this dataset, which will form the input recording x_i^d . Next, we sample an audio effect f_m and a random associated preset $P_{m,l}$ to configure the effect. Then we process the input with this effect to produce an output signal x_o^d .

¹ <https://github.com/csteinmetz1/st-ito>

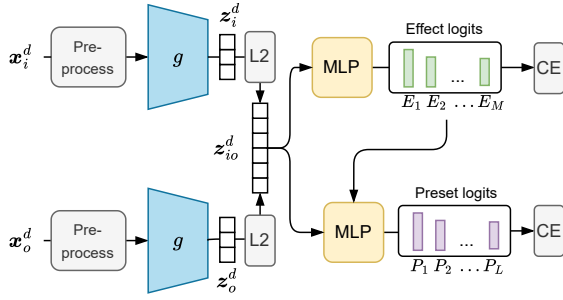

Figure 3. Representation learning via the pretext task where the input \mathbf{x}_i^d and output \mathbf{x}_o^d are processed by the encoder $g(\cdot)$ to produce embeddings. These embeddings are fed to a pair of MLP classifiers trained via cross-entropy that predict the effect class and preset class.

Training is shown in Figure 3 where the encoder $g(\cdot)$ extracts embeddings \mathbf{z}_i and \mathbf{z}_r from the input and output. These embeddings are concatenated and fed to a multi-layer perceptron (MLP) that estimates the effect applied. A second MLP takes the effect logits as well as the embeddings to estimate the preset. After pretraining we discard the prediction heads and use the encoder $g(\cdot)$, which we refer to as AFX-Rep, to produce embeddings.

This multi-task formulation encourages the encoder to extract features not only about effects but also subtleties between different configurations of the same effect, which is important for style transfer. Our approach does not enforce invariance to the content, but can leverage any audio, not only unprocessed or effect normalized audio [25], required by previous work [13]. This allows us to further scale the training dataset size. In addition, since this audio may already contain other processing, our model is exposed to a wide range of effects beyond those we apply.

2.2 Inference-time optimization

To perform style transfer we begin with input \mathbf{x}_i and reference \mathbf{x}_r recordings. We assume the input has minimal processing, as our system does not remove effects [26, 27]. Then, we require the user to provide an appropriate chain of audio effects to be controlled. This chain can be represented as the composition of K audio effects where each effect is represented by a function f_k parameterized by a control vector ϕ_k . The output \mathbf{x}_o is obtained by sequentially applying these functions to the input, resulting in

$$\mathbf{x}_o = f_K(f_{K-1}(\dots f_2(f_1(\mathbf{x}_i; \phi_1); \phi_2) \dots; \phi_{K-1}); \phi_K). \quad (1)$$

For convenience, we represent this chain as a single function $\mathbf{x}_o = f_c(\mathbf{x}_i; \phi_c)$, where $\phi_c = [\phi_1, \phi_2, \dots, \phi_K]$ concatenates all effect parameters into one vector. While our method supports arbitrarily complex effect chains, we consider only series connections.

In our setup, we perform style transfer through an optimization process via the maximization of a similarity between the output of our composite audio effect function and the reference signal given by

$$\max_{\phi_c} \text{sim}(g(f_c(\mathbf{x}_i; \phi_c)), g(\mathbf{x}_r)), \quad (2)$$

where $g(\cdot)$ denotes our audio representation, transforming audio signals into a feature space where audio production similarity is assessed. For the reference signal \mathbf{x}_r , the feature representation is $\mathbf{z}_r = g(\mathbf{x}_r)$. The optimization process initiates with a predefined set of control parameters, ϕ_0 , and iteratively refines this estimate to enhance the similarity measure. At each step, candidate solutions are generated and evaluated based on their performance in mirroring the reference features, \mathbf{z}_r . This performance is quantified by the cosine similarity measure,

$$\text{sim}(\mathbf{z}_i, \mathbf{z}_r) = \frac{\mathbf{z}_i \cdot \mathbf{z}_r}{\max(\|\mathbf{z}_i\| \|\mathbf{z}_r\|, \epsilon)}, \quad (3)$$

where $\mathbf{z}_i = g(f_c(\mathbf{x}_i; \phi_c))$ is the feature vector of the processed input signal, \cdot represents the dot product, $\|\cdot\|$ denotes the Euclidean norm, and ϵ is a small constant ensuring numerical stability, avoiding division by zero.

3. EXPERIMENTAL DETAILS

3.1 Pretraining

We employ the PANNs architecture [28] as a convolutional backbone. While initial testing indicated that more modern architectures such as HTS-AT [29] performed comparably, we found that PANNs was more efficient at inference. To enable the encoder to capture stereo information we produce separate embeddings for the mid and side signals, concatenating them into a single embedding, applying L2 normalization to each embedding before concatenation.

We train the encoder following the pretext task described in Section 2.1. We use seven publicly available audio datasets to cover a diverse range of audio content across music, speech, singing voice, and instruments. These datasets include MTG-Jamendo [30], ENST-Drums [31], URSing [32], FSD50k [33], Librispeech [34], Medley-solos-db [35], and GuitarSet [36]. To construct our set of audio effects we use 63 open source or freely available VST3 audio plugins compiled for Linux. These VSTs cover a wide range of effects including reverberation, dynamic range processing, equalization, distortion, modulation effects, and more. We use `pedalboard` [37] to load plugins and apply effects to audio signals.

We generate unique presets for each effect by randomly sampling 1000 parameter configurations and processing a random audio recording with each configuration. Then we extract MFCCs and perform K-means clustering ($K = 10$), with each cluster representing perceptually diverse parameter configurations. We then randomly select one configuration from each cluster to act as a preset.

While training with on-the-fly data generation is possible, we found running VSTs during training caused a significant bottleneck. We opted for offline data generation, where we generated 20,000 examples of length 524288 samples (≈ 11 sec at $f_s = 48$ kHz) from each dataset with randomly applied effects and presets. This corresponds to approximately 60 hours of audio content. We further increase diversity during training by taking different random crops of the pre-processed input and output segments, as well as applying random gain adjustments $[-32$ dB, 0 dB].

We perform pretraining for 1M steps with a batch size of 32 using the Adam optimizer. We use an initial learning rate of 1e-4, lowering the learning rate by a factor of 10 at 85% and 95% through training. We preprocess spectrogram inputs to the encoder by computing log-melspectrograms with window size of 2048 and hop size of 512. We clip the magnitudes between -80 and 40 dB and scale the final spectrogram between -1 and 1.

3.2 Inference-time optimization

To enable control of arbitrary effects, we employ a gradient-free optimizer as opposed to commonly used gradient-based solutions. While any gradient-free optimizer can be used in our system, we opt to use Covariance Matrix Adaptation Evolution Strategy (CMA-ES) [38] since it has been shown to work well in spaces with similar dimensionality to the audio effect chain control parameter space (≈ 100) and is a relatively scalable method. After initial hyperparameter tuning, we use a population size of 64 and a maximum of 25 optimization steps. The σ hyperparameter is initialized to 0.3 and we use a fixed initialization of all parameters of 0.5 scaled in the range [0, 1]. We use early stopping, halting optimization after 10 steps of improvement less than 0.1.

Unless otherwise specified, we use AFx-Rep as the encoder in our similarity metric, and we consider control of two different audio effect chains. The first features five VST audio effects including distortion (TubeScreamer), parametric equalizer (ZamEQ2), dynamic range compressor (ZamCompX2), feedback delay (ZamDelay), and artificial reverberation (TAL-Reverb-4), resulting in a total of 73 parameters. The second chain features unseen audio effects internal to `pedalboard`, including distortion, dynamic range compression, parametric equalizer, delay, and artificial reverberation, resulting in 36 parameters.

4. BENCHMARK

4.1 Audio production style metrics

Zero-shot style classification. We adapt the style classification task from [14], which contains five different audio production styles using equalization and dynamic range compression: telephone (TL), bright (BR), warm (WM), broadcast (BC), neutral (NT). Training examples are generated by applying these style presets to speech from DAPS [39] and music from MUSDB18 [40]. To make the task more challenging and similar to the inference-time optimization use-case, we adapt the original task to the zero-shot case [41]. To do so, a query is constructed by sampling a random audio example to be classified as one of the five styles. Then other examples from each of the five styles are sampled randomly to form prototype classes. A representation of the query and each of the five prototypes is generated and a prediction is made by measuring the cosine similarity between the query and each of the prototypes. The class of the prototype with the highest similarity to the query forms the prediction.

Representation	Styles					AVG
	TL	BR	WM	BC	NT	
MFCCs	1.00	0.82	0.64	0.74	0.48	0.74
MIR Feats.	0.76	0.64	0.61	0.58	0.32	0.58
CLAP	0.72	0.60	0.51	0.57	0.41	0.56

Table 1. Zero-shot style classification accuracy over 200 trials for music and speech across five unique styles.

Style retrieval. While the zero-shot style classification task evaluates the ability of a representation to differentiate among different styles, it considers only two basic effects and focuses on comparing significant differences. In order to more effectively evaluate the behavior of representations in a scenario similar to style transfer we designed a style retrieval task. In this task, a query style is produced by applying N effects with random parameters to an audio recording. A retrieval set is generated by processing M other recordings with differing random effect chains. One recording with differing content but the same effect chain as the query is included in the retrieval set. Similar to the zero-shot task, we measure the cosine similarity between the query and each of the items in the retrieval set. We can make the task more or less difficult by varying both the number of effects N in each style and the size of the retrieval set M . We source unseen audio examples for speech (DAPS [39]), guitar (IDMT-SMT-Guitar [42]), vocals (VocalSet [43]), and drums (IDMT-SMT-Drums [44]).

Baselines. We consider signal processing approaches, such as MFCCs and MIR features [45], as well as pretrained general purpose audio representations including VGGish [46], WAV2CLIP [47], wav2vec2.0 [48], CLAP [22], as well as BEATs [23]. We also compare against audio effect specific models including FX-Encoder [13] and the DeepAFx-ST encoder [14].

4.2 Audio production style transfer

Parameter estimation. To demonstrate the ability of our proposed approach to control a wide range of effects we design a parameter estimation task. We initialize an audio effect and set a target value for one parameter, processing a random audio signal to generate a reference. Then we sample another random recording to use as the input. We then run the optimization using each audio representation in our metric. To achieve accurate style transfer a system should estimate a control parameter with a similar, but not necessarily identical value as the reference. We report both the mean squared error (MSE) and the correlation coefficient ρ of estimated parameters. We consider six VST effects as well as six unseen effects from `pedalboard`.

Figure 4. Accuracy for the style retrieval task using different audio representations across multiple source types with varying number of audio effects (N) and retrieval set size.

Real-world style transfer. While the parameter estimation task can demonstrate the ability of a style transfer system to control a singular audio effect, it does not capture the ability of the system to perform in a real-world scenario. In many cases multiple effects will be present at the same time, making the task more challenging. To evaluate this scenario we created six different audio production styles by constructing realistic audio effect chains of varying complexity in a digital audio workstation. These styles range from simple lowpass and highpass filtering to a complete channel strip featuring equalization, distortion, compression, delay, and reverberation. We then applied these styles to a range of audio content including speech, singing voice, and full music tracks. Each style transfer system is then tasked with transforming the unprocessed audio from one of these content types to the stylized version of a different recording containing the same kind of content.

Baselines. We compare our proposed style transfer system to both deep learning and signal processing solutions. We use a rule-based approach from previous work that includes an FIR matching equalization filter and a simple hill climbing-based dynamic range compressor [14]. We construct a strong deep learning baseline by extending DeepAFx-ST with differentiable reverberation [49] and distortion [50] effects, using `dasp-pytorch`². We call this approach DeepAFx-ST+ and we train this model following the approach from the original work, but using the same datasets used to train our audio representation.

5. RESULTS

Zero-shot style classification. We evaluate the pretrained representations across ten trials for each of the five different styles. The class-wise and overall accuracy is reported in Table 1. First, we find MFCC based features perform better than expected, with high accuracy on the telephone (TL), bright (BR), and warm (WM) styles. However, performance is worse on broadcast (BC) and neu-

Table 2. Parameter estimation with ST-ITO using CLAP and our proposed AFx-Rep. We report the mean squared error (MSE) and correlation coefficient (ρ) of the estimated parameters across 4 different settings and 3 trials per effect. Audio effects not seen during pretraining are denoted by *.

tral (NT), likely because identifying these styles requires paying attention to dynamics. The MIR features do not achieve comparable performance. All of the general purpose audio representations perform worse than MFCCs on this task, with CLAP and BEATs appearing to perform best among them, but with an average accuracy 15 points lower. This confirms the hypothesis that general purpose representations fail to capture information about audio effects. FX-Encoder and DeepAFx-ST(+) perform better than the other pretrained models, with DeepAFx-ST variants outperforming MFCCs. Overall, we find that our proposed model, AFx-Rep, performs best in this task.

Style retrieval. We report the accuracy for a subset of methods in style retrieval as shown in Figure 4. We plot performance across differing number of effects N that constitute a style, as well as the size of the retrieval set, shown on the x-axis. As expected, for all scenarios, as the retrieval set grows the classification performance drops. While all methods are better than random guessing, we observe that MFCCs and FX-Encoder appear to perform worse. They are followed by CLAP and then the encoder from DeepAFx-ST+, which slightly outperforms CLAP. Finally, our proposed AFx-Rep model performs best across all scenarios, indicating its superior ability to capture elements related to audio production style.

Parameter estimation. In Table 2 we report the mean squared error (MSE) and correlation coefficient (ρ) in parameter estimation using ST-ITO with either CLAP or our proposed AFx-Rep model. In nearly all cases our AFx-Rep model functions as a superior similarity metric, achieving lower MSE and a higher correlation coefficient, with the exception of the MSE in Chorus, which appears to be challenging for both models. This demonstrates the ability of our approach to control a wide range of real-world audio effects, including effects not seen during retraining. These results reinforce the importance of an audio representation sensitive to audio effects, such as our proposed AFx-Rep.

Figure 5. AFX-Rep similarity in real-world style transfer.

Real world style transfer. We report the similarity from our metric using AFX-Rep across 56 style transfer trials (Figure 5). The Input processed with an audio effect chain identical to the reference is also evaluated, which we refer to as Oracle. Note that the Oracle may not achieve effective style transfer as the starting point of the Input may require a different parameter configuration to match the reference. The random configuration of VSTs and pedalboard effect perform worse, and are followed by the Input, which features no processing. DeepAFx-ST, DeepAFx-ST+, and the Rule-Based system appear to perform similarly to each other, but better than Input. Variants of ST-ITO, one using VSTs and the other using unseen pedalboard effects, both outperform the rest, and are on par with the Oracle. This indicates the ability of our approach to optimize our metric, however, it is difficult to make conclusions about style transfer performance using this evaluation alone.

Subjective listening study. We recruited 23 participants with experience in audio engineering. They were tasked with evaluating style transfer systems on real-world test scenarios in a multiple stimulus listening study. Listeners were asked to provide a score from 0 to 100 for each stimulus to indicate its similarity to the reference, considering only the style and not the underlying content. In addition, we also included the unprocessed Input and the Oracle. Due to the subjectivity of this task, evaluators may not rate Input the lowest and Oracle the highest. We selected ten test cases across the real-world scenarios including vocals (V), music (M), and speech (S) as shown in Figure 6.

Overall, listeners found the Oracle most similar to the reference and the Input the least similar, as expected. However, there is variation in the score assigned to both, indicating some disagreement. For simple styles, such as V1 (lowpass) and M2 (highpass), we found the Rule-Based system worked well, even surpassing style transfer systems. However, in cases with multiple effects, the Rule-Based system does not work well, as in V2 (large space), V3 (small space), V4 (delay), S1 (small space), and S3 (distortion). Differences between ST-ITO and DeepAFx-ST+ are harder to discern. Our method outperforms in some cases, such as V2 (large space), V3 (small space), and V4 (delay), yet in other cases there is no clear difference. We conclude that our approach is capable of style transfer at least on par with the enhanced DeepAFx-ST+, and does so controlling a chain of unseen VST audio effects, which is not possible with other approaches.

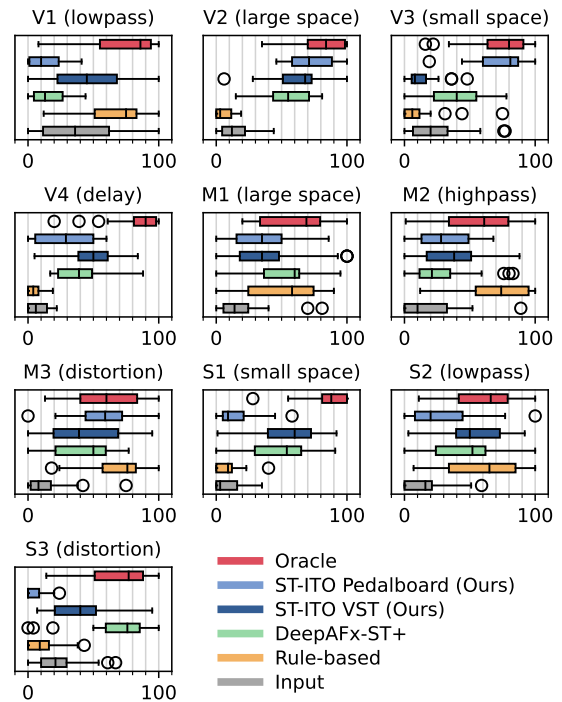

Figure 6. Subjective scores from $N = 23$ participants across vocals (V), music (M), and speech (S) examples.

6. DISCUSSION

While ST-ITO enables control of arbitrary audio effects and adapts to new effects at inference, it has some limitations. In the current formulation, our system requires an appropriate audio effect chain be provided. Future work could consider automatically constructing this audio processing graph as in blind estimation [51]. Furthermore, while our method does not require training “in-the-loop” with audio effects during representation learning, we must process many variants of the recording through the audio effect chain during style transfer. This leads to significantly longer inference times (≈ 1 min) as compared to networks that estimate parameters directly (≈ 1 sec). Future work could consider the design of more efficient optimizers through meta-learning by training an optimizer for a particular effect chain [52]. Finally, we have found that the current system does not work well for challenging style transfer applications, such as guitar tone matching.

7. CONCLUSION

In this work, we introduced ST-ITO, Style Transfer with Inference-Time Optimization. Unlike previous style transfer systems, ST-ITO searches the parameter space of any audio effect chain at inference, enabling control of arbitrary effect chains, including those with non-differentiable effects. Our methodology leverages a self-supervised audio production style metric and a gradient-free optimizer. We developed a set of benchmarks to evaluate both audio production style representations and style transfer systems. Results from this set of benchmarks indicate that our approach not only better captures details related to audio production style, but also provides enhanced flexibility and expressiveness in audio production style transfer.

ABSTRACT

Music composition represents the creative side of humanity, and itself is a complex task that requires abilities to understand and generate information with long dependency and harmony constraints. Current LLMs often struggle with this task, sometimes generating poorly written music even when equipped with modern techniques like In-Context-Learning and Chain-of-Thoughts. To further explore and enhance LLMs’ potential in music composition by leveraging their reasoning ability and the large knowledge base in music history and theory, we propose **ComposerX**¹, an agent-based symbolic music generation framework. We find that applying a multi-agent approach significantly improves the music composition quality of GPT-4. The results demonstrate that ComposerX is capable of producing coherent polyphonic music compositions with captivating melodies, while adhering to user instructions.

1. INTRODUCTION

Music shares many structural similarities with language [1–3], prompting researchers to explore the ap-

plication of language models (LMs) in music generation [4–14]. Recent advances in large language models (LLMs) have opened potential pathways towards achieving Artificial General Intelligence (AGI). While much of the research emphasis has been on the STEM aspects of AGI [15–17], there is comparatively less focus on the creative potential in generative LLMs, particularly in music creation. Current methodologies primarily involve training LMs from scratch, as seen with initiatives like MusicLM [9] and MusicGen [10], with a predominant focus on audio generation. However, these models often struggle with processing advanced musical instructions and typically offer only limited control options, such as genre and instrument selection. Enhancing controllability in these systems requires neural architectural engineering and extensive computational resources [18–20].

Recent research, influenced by Bubeck et al. [17], has revealed that pretrained large language models (LLMs) might inherently possess emergent musical capabilities. Inspired by these findings, subsequent studies [21–23] have explored leveraging pretrained LLM checkpoints for handling symbolic music in an end-to-end manner, aiming to tap into the extensive knowledge and reasoning abilities embedded in these LLMs. However, these unified approaches are not without limitations. They depend heavily on hand-crafted datasets tailored for specific musical tasks and often require both a phase of continual pretraining and subsequent supervised fine-tuning. Furthermore, while training on symbolic music data is generally less computationally intensive than processing raw audio data, the costs remain prohibitive for many researchers. For example, renting an 8xGPU machine (such as a p4d.24xlarge

Yuan, “ComposerX: Multi-Agent Symbolic Music Composition with LLMs”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

In this paper, we introduce a novel multi-agent-based methodology, ComposerX³, which is training-free, cheap, and unified. Leveraging the internal musical capabilities of the state-of-the-art GPT-4-turbo, ComposerX can generate polyphonic music pieces of comparable, if not superior, quality to those produced by dedicated symbolic music generation systems [7, 24] that require extensive computational resources and data. ComposerX utilizes approximately 26k tokens per song, incurring a cost of less than \$0.8 USD per piece. Throughout the development phase of ComposerX, the total expenditure on the OpenAI API was under \$1k USD. We achieved a good case rate of 18.4%, as assessed by music experts, which translates to an average cost of approximately \$4.34 USD for each musically interesting piece. Furthermore, experimental results demonstrate that the multi-agent strategy substantially enhances composition quality over single-agent baselines. In Turing tests, approximately 32.2% of the pieces identified as ‘good’ by ComposerX were indistinguishable from those composed by humans, as indicated in Table 3.

While there is existing research on musical LLM agents [25, 26], our approach distinctively diverges from these precedents. Prior studies primarily focus on single-agent systems. In contrast, our work introduces a multi-agent framework, emphasizing collaborative aspects of music creation. Furthermore, we concentrate on symbolic music generation, leveraging the intrinsic musical understanding of LLMs without the need for external computational resources or tools. Previous methodologies typically depend on GPU servers for deploying local inference services, treating the LLMs more as tool-use agents rather than harnessing their inherent capabilities to process and generate musical content. In sum, the contributions of our paper are as follows:

- (1) We propose the first LLM-based multi-agent polyphonic symbolic music composition system, ComposerX. It elicits the internal musical capabilities inside LLMs without the need for external tools.
- (2) Through extensive subjective evaluations, we demonstrate that our multi-agent approach substantially enhances the quality of music composition compared to single-agent systems and specialized music generation models. Our method also offers cost-efficiency advantages by obviating the need for dedicated training or local inference services.
- (3) We commit to the advancement of this research area by open-sourcing our code, prompt-set, and experimental results, facilitating further investigation and development by the community.

2. METHOD

We first construct a set of user prompts for music composition, which is used for evaluation. Then we demonstrate

² <https://instances.vantage.sh/aws/ec2/p4d.24xlarge>

³ <https://github.com/llindsey0615/ComposerX>

2.1 User Prompt Set Curation

To understand how the users, typically those with substantial musical backgrounds, would prompt a text-to-music generation system, a user prompt set is collected by asking humans with music backgrounds to manually write high-quality prompts. These prompts typically include essential musical attributes such as genre, tempo, key, chord progression, melody, rhythm, number of bars, number of voices, instruments, style, feeling, emotion, title, and motif of the music piece. Based on the human-written samples, more prompt samples are generated using Self-instruct by GPT-4 [27]. This results in a set of 163 prompts, which is used in the later agent testing and system evaluation. An example prompt is given below.

Prompt

Vintage French Chanson: A nostalgic chanson in C major with a slow tempo, featuring accordion, violin, and upright bass over 16 bars with chords C, Am, Dm, G. The accordion leads with expressive sound, violin adds romance, and the upright bass supports, evoking vintage French charm.

Attributes

Name: Vintage French Chanson **Tempo:** Slow
Feeling: Nostalgic **Chord Progression:** C, Am, Dm, G
Key: C major **Bars:** 16 **Instruments:** Accordion, violin, upright bass

2.2 Single-Agent

We apply various prompt engineering techniques, including In Context Learning (ICL), Chain of Thought (CoT), and Role-play to guide a single GPT acting as the composer. Additionally, we have refined the prompt template by incorporating specific instructions that ensure the correctness of the ABC notation format.

Original GPT with Simple Role-play (Ori): To investigate the inherent capabilities of the original GPT model in interpreting user prompts and generating ABC notation, we instructed GPT to act in the role of a professional composer, with user prompts directly input into the system. This method aims to assess the model’s basic performance in music composition without the integration of additional complex prompting techniques.

Role-Play with Additional Instruction (Role): Inspired by classical rule-based computer music generation, we equipped GPT with enhanced musical knowledge focusing on phrase management and melody line construction, detailed in A.1. For example, in composing melodies, we instructed the model to ensure distinct phrase divisions, with each phrase ending on a prominent note. These instructions aim to improve the quality and structural coherence of the music, aligning the generated compositions more closely with traditional musical standards.

Chain-of-Thought (CoT): As proven in other fields of research, CoT improves the ability of LLMs on complex reasoning by encouraging them to write down inter-

In Context Learning (ICL): ICL leverages a few input-output examples to enhance an LLM’s understanding of a specific task. In this method, we use pairs of user prompts and corresponding ABC notations from ChatMusician [21] as demonstrative examples.

2.3 Multi-Agent Music Composition: ComposerX

To enhance the music generation capabilities of GPT-4, we developed a collaborative music creation framework, ComposerX, that draws inspiration from key elements inherent in real-world music composition processes, such as melody construction, harmony or counterpoint development, and instrumentation. This framework facilitates the music creation process through a structured conversation chain between agents role-played by GPT-4.

2.3.1 Agent Role Assignment

In the collaborative music creation framework designed to augment GPT-4’s music generation capabilities, roles are assigned to ensure a structured and efficient composition process. The assignment of roles is as follows:

Group Leader: Tasked with interpreting user inputs, decomposing these inputs into granular tasks, and assigning these tasks to specialized agents in the group.

Melody Agent: Responsible for generating single-line melodies under the guidance of the group leader.

Harmony Agent: This agent is tasked with enriching the musical piece, and adds harmonic and contrapuntal elements to the melody.

Instrument Agent: This agent selects and assigns instruments to each voice.

Reviewer Agent: Performing a quality assurance role, this agent evaluates the outputs of the melody, harmony, and instrumentation agents across four critical dimensions.

(1) **Melodic Structure:** Evaluation of melody’s narrative flow, thematic development, and variation in pitch and rhythm. (2) **Harmony and Counterpoint:** Assessment of how harmonies complement the melody, counterpoint effectiveness, and chord progression quality. (3) **Rhythmic Complexity:** Analysis of rhythm’s role in sustaining interest, its synergy with melody, and the incorporation of dynamic variations. (4) **Instrumentation and Timbre:** Review of instrument selection, timbral blending, and dynamic usage to achieve an optimal auditory experience. (5) **Form and Structure:** Examination of the composition’s overarching structure, transitional elements, connectivity between sections, and conclusion efficacy.

Arrangement Agent: Concluding the collaborative process, this agent is responsible for compiling and formatting the collective output into standardized ABC notation, ensuring the music is documented in a universally readable format.

2.3.2 Agent Communication Pattern

The collaborative framework uses a structured communication pattern to ensure an orderly and efficient flow of information between agents in the composition process. This pattern is crucial for maintaining the integrity and coherence of the musical piece. The communication process unfolds as follows:

Initial Composition Round: The composition process begins with the Group Leader Agent initiating the sequence by analyzing the user input and breaking it down into specific tasks assigned to the Melody, Harmony, and Instrument Agents respectively. This step sets the foundation for the composition based on the user’s requirements. Following the leader’s instructions, the Melody Agent then generates the initial melody line, adhering to the thematic direction and stylistic guidelines provided by the Group Leader. Subsequently, the Harmony Agent enriches the melody by adding harmonic layers and counterpoints. The Instrument Agent assigns appropriate instruments to the generated melody and harmony lines by selecting timbres that complement the overall composition.

Iterative Review and Feedback Cycle: Upon completion of the initial composition round, the Reviewer Agent steps in to evaluate the work produced by the Melody, Harmony, and Instrument Agents. This agent provides comprehensive feedback across several critical dimensions, including melodic structure, harmony and counterpoint, rhythmic complexity, and instrumentation.

Based on the feedback from the Reviewer Agent, the Melody, Harmony, and Instrument Agents proceed to refine their respective parts of the composition. This refinement process typically follows the order: Melody, Harmony, and then Instrument, allowing for modifications to be made in response to the feedback provided.

The composition undergoes several rounds of review and refinement, with the Reviewer Agent continuously providing feedback to ensure the musical piece evolves toward a coherent and high-quality final product. This iterative process allows for dynamic adjustments and enhancements to be made, enriching the overall composition.

Final Arrangement and Notation: Once the composition has reached a satisfactory level of polish and coherence, the Arrangement Agent takes over to compile and format the collective output into the standardized ABC notation. This final step ensures that the music is documented in a format that is readable and can be interpreted by musicians and software alike.

2.3.3 Agent Prompt Engineering

Agent prompt engineering emerges as a crucial technique for optimizing the performance of each specialized agent and the quality of the generated music. This process involves the meticulous design of role-specific instructions and guidelines that encapsulate both the musicality and technicality of ABC notation generation. The framework incorporates In-Context Learning for ABC notations to ensure agents can effectively communicate and document their contributions. This section elaborates on these components and their significance in fostering collaborative

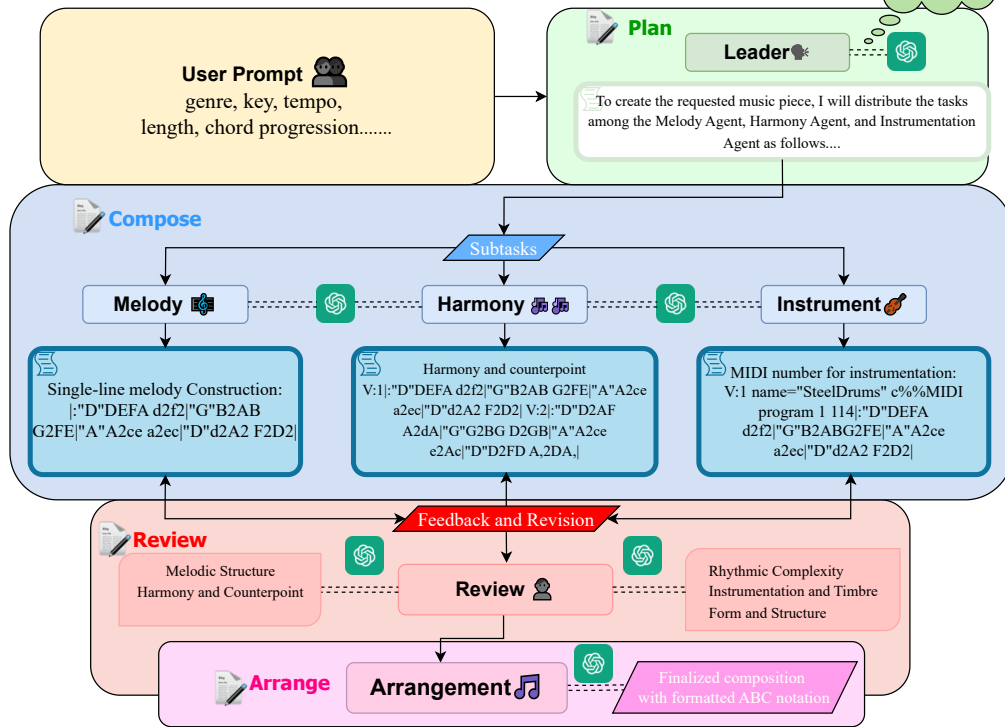

Figure 1. Agent Communication Pattern of ComposerX. The system is given with a user prompt. In the Planning stage, the Leader analyzes the user prompt and decomposes it into subtasks that can be assigned to other musician agents. In the Composing stage, the musician agents, including Melody Agent, Harmony Agent, and Instrument Agent compose in ABC notation according to their assigned tasks. In the Reviewing stage, the Review Agent provides constructive feedback to the musician agents and the musician agents revise their work according to the feedback they received. In the arrangement stage, the Arrangement Agent arranges the work of the musicians agent to standardized ABC notation.

dynamics within the framework.

Role-Specific Instructions: Within the framework, each agent is endowed with a set of instructions tailored to its designated role. These instructions serve to ensure a comprehensive understanding of the agent’s duties, the expectations for its performance, and its role within the larger collaborative ensemble. Agents are briefed on the specific outcomes they are expected to achieve and informed about the dynamics of their interactions with other agents. This detailed prompt design facilitates a cohesive operation among the agents, fostering an environment where each component of the framework is aligned toward the collective goal of generating sophisticated and coherent musical compositions.

In-Context Learning for ABC Notation: In Context Learning for ABC notation ensures accurate format output from each agent. The Melody Agent is shown with an example of a monophonic melody in ABC notation, providing a clear model for representing single-line melodies. The Harmony Agent receives a polyphonic music piece example in ABC notation, aiding in understanding the notation of harmonies and counterpoints in multiple voices. The Instrument Agent is given a polyphonic piece with MIDI program of the instrumental information noted, demonstrating how to detail instrumental assignments within the notation. This approach equips agents

with the knowledge to correctly apply ABC notation, essential for the structured and coherent documentation of musical compositions.

3. EXPERIMENTS

3.1 Setup

Our experiment leverages the multi-agent conversation provided by the AutoGen framework [29], utilizing its group chat function to facilitate a customized interaction among pre-defined agents. This setup comprises an ensemble of agents including one leader, three musician agents (melody, harmony, and instrument agents), one review agent, and one arrangement agent. Additionally, a user proxy agent is integrated into the framework to simulate user interaction by inputting prompts from our curated user prompt set.

We use the "GroupChatManager" class from AutoGen to coordinate and oversee the conversation’s content and workflow. The group manager, powered by LLMs, supervises the conversation and implements a structured communication protocol with three steps: dynamically selecting a speaker, collecting the response, and disseminating it to the group.

For our experiment, we limit the agent communication

to twelve rounds, allowing us to observe the system’s effectiveness over defined interaction cycles and enabling iterative review and refinement. This structured design aims to evaluate the collaborative dynamics and output quality of the multi-agent conversation in generating cohesive and musically rich compositions based on user prompts.

3.2 Evaluation

3.2.1 Quantitative Evaluation

We conducted two experiments to evaluate our system quantitatively. One experiment assessed the success rate of generating symbolic music in a multi-agent setting, with results presented in Table 1. One experiment compared the sequence lengths of symbolic music generated by multi-agent and single-agent systems, detailed in Table 2. These experiments demonstrate the effectiveness of our approach in generating symbolic music.

Checkpoints	Generation Success Rate
GPT-4-Turbo	98.2%
GPT-4-0314	95.7%
GPT-3.5-Turbo	73.0%

Table 1. One-time generation success rate for multi-agent system with different checkpoints

Methods	Average ABC String Length
GPT-4-Turbo multi	1005.925
GPT-4-Turbo cot	360.92
GPT-4-Turbo icl	366.30
GPT-4-Turbo ori	354.53
GPT-4-Turbo role	337.64

Table 2. The average length of ABC String generated by different methods on GPT-4-Turbo checkpoint

3.2.2 Human Listening Test

To qualitatively assess our work, we conducted three listening tests. The selected listeners are mostly undergraduate and postgraduate students who have educational backgrounds in either STEM or music, or both. In the first test, we compared music samples generated by single-agent and multi-agent baselines. Similar to the AB-test setting from previous work [21,30], participants were presented with 50 pairs of samples randomly chosen from a pool of 200 sample pairs: one from a multi-agent baseline with GPT-4 Turbo checkpoints, and the other from a single-agent baseline employing prompting techniques mentioned above: Original(Ori), In-Context Learning (ICL), Chain of Thought (CoT), and Role-play(Role), also driven by GPT-4 Turbo checkpoints. Participants were asked to select the sample they preferred. All paired samples were generated using the same prompt; however, participants were not informed about the specific prompt details before making their selections.

In the second listening test, we assess the perceived human-like quality of music generated by the multi-agent baselines. Participants were presented with 30 pairs of

Figure 2. Result from the first listening test comparing multi-agent baseline and single-agent baselines with different prompting techniques. Each row indicates the fraction of listeners’ preference for the indicated baseline over other baselines. i.e. 0.77 means raters prefer multi-agent system over CoT single-agent 77% of the times.

music samples: those generated by multi-agent baselines and those composed by humans, sourced from Irishman and KernScores⁴, which are ABC notation datasets containing human-composed music pieces from all around the world. Each participant is asked to determine whether each sample was composed by a human or a machine.

In the third listening test, we assessed the performance of our multi-agent baselines, which incorporate GPT-4 Turbo, GPT-4-0314, and GPT-3.5-Turbo checkpoints, against established text-to-music generation models. Specifically, comparisons were made with MuseCoco [7], developed by Peiling Lu et al., and a BART-based model fine-tuned on 282,870 English text2music pairs in ABC notation, as proposed by Wu et al [24]. Participants were presented with music samples generated from these five baselines, alongside their corresponding prompts, and asked to select the sample that best matched the prompt in terms of musical structure and content. This test involved 30 prompts and their generated music samples, randomly selected from a pool of 200 user prompts.

3.3 Results

Results from comparing multi-agent baseline and single-agent baseline appear in Figure 2. The preference score of GPT-4-Turbo multi has 0.77, 0.68, 0.6, and 0.57 on each of other single-agent baselines.

Model	Perceived as Human	Perceived as Machine
ComposerX	32.2%	67.8%
Ground Truth	55.4%	44.6%

Table 3. Result from our second listening test (Turing test).

Results from comparing the multi-agent baseline with

⁴ <http://kern.ccarh.org/>

Figure 3. Result from listening test comparing multi-agent baselines with GPT-4-Turbo, GPT-4-0314, GPT-3.5-Turbo checkpoints, MuseCoco and text2music Baselines. Each row indicates the fraction of listeners’ preference for the indicated baseline over other baselines. In this case, the strongest multi-agent baseline with GPT-4-Turbo checkpoints outperformed text2music, and received the same score as MuseCoco.

music composed by humans indicate that ComposerX gets 32.2% perceived as human which is lower than the rate of real human music - 55.4% as indicated in Table 3. Despite failing the Turing test, ComposerX showcases its capability to closely match human music composition skills.

Results from comparing the multi-agent baseline with GPT-4-Turbo, GPT-4-0314, GPT-3.5-Turbo checkpoints, MuseCoco, and text2music are presented in Figure 3. As indicated by the fractional numbers, the multi-agent baseline with GPT-4-Turbo checkpoints is our strongest-performed baseline. It outperformed text2music baseline with 0.56 preference score and received the same score as MuseCoco. GPT-4-Turbo also shows the highest generation success rate, as indicated in Table 1.

4. DISCUSSION

Overall, we observed that our GPT-powered multi-agent framework significantly enhances the quality of the music generated over solutions utilizing a singular GPT instance. Advantages of our system include:

Controllability: Observations of collaborative interactions among agents, especially the Group Leader, show the system’s competence in comprehending and executing various musical attributes based on user inputs. Fundamental components like tempo, key, time signature, chord progression, and instrumentation are effectively translated into ABC notations. This accurate interpretation enhances user controllability, enabling music generation that closely mirrors user specifications and artistic preferences.

Training-free and data-free: Unlike conventional

text-to-music generation models that rely on large datasets, our system offers significant benefits by eliminating the need for extensive data. This approach reduces the challenges of compiling and refining large training datasets, such as potential biases and substantial resource requirements. Additionally, it enhances the system’s adaptability and accessibility, promoting more resource-efficient practices in music generation, and making music generation more attainable for a wider range of users and applications.

The system exhibits certain limitations, particularly when engaging with the nuanced aspects of musical composition that are often intrinsic to human-created music. These limitations delineate areas for potential enhancement and further research:

Subtlety in Musical Expression: The system excels at interpreting basic musical elements but struggles to generate compositions with the nuanced subtlety of human composers. It faces challenges in aspects such as emotional depth, dynamic contrasts, and intricate phrasing, which are crucial for conveying deeper musical narratives and experiences.

Translation from Natural Language to Musical Notation: Instructions and feedback from the Group Leader and Review Agent to enhance nuanced musical elements are sometimes inadequately translated into ABC notations by the musician agents. This gap between conceptual understanding and practical notation highlights the system’s limitations in realizing more sophisticated musical ideas.

Instrumental Note Range Compliance: The system sometimes generates notes beyond the conventional pitch ranges of certain instruments. For instance, despite directives to adhere to instrument-specific ranges, it has produced notes exceeding the upper limit of a contrabass (C2 to F4), reflecting a discrepancy between the system’s outputs and practical musical performance constraints.

Inter-Voice Alignment: Our system faces challenges with aligning multiple musical voices accurately. The linear nature of text-based input and output mechanisms does not naturally accommodate the complexity of polyphonic music, where multiple voices or instruments must be coordinated in time.

Cadential Resolution: Certain compositions generated by the system lack a conclusive sense of resolution, resulting in pieces that may feel unfinished or conclude abruptly. This issue affects the listener’s sense of closure and satisfaction, reducing the overall effectiveness of the musical experience. This challenge is partly due to the inherent difficulty for GPTs to grasp the concept of musical closure, which the perpetual aspect of its nature is hard for a language model to handle.

5. CONCLUSION

In conclusion, ComposerX demonstrates its effectiveness in utilizing LLMs to create high-quality music. The collaborative agent-based approach of ComposerX surpasses single-agent systems and provides a cost-effective alternative to traditional, resource-intensive music generation models.

A.1 Single agent role-play

Role-play Prompting with Additional Music Knowledge
<p><code>You are a talented musician.</code> Here are some tips for generating melodies:</p> <ol style="list-style-type: none"> 1. The generated melody should have clear phrase divisions, and it's preferable to avoid more than two consecutive measures within one phrase to prevent an uncomfortable listening experience. There should be a certain amount of space between phrases, allowing the audience to clearly distinguish between them. 2. A phrase usually has a prominent ending note, which is the last note of the entire phrase. It typically has a longer duration, or it might be followed by a rest. This ending note is usually within the key or the chord, e.g., phrases ending with a Cmaj chord usually terminate on one of the three chord tones, C, E, or G, ensuring a stable listening experience. 3. When generating melodies, the movement of the notes should primarily consist of stable intervals such as whole steps, thirds, and fifths, while avoiding excessive large leaps. This will help maintain a sense of logic and coherence throughout the composition. 4. The rhythm of the phrases should be rich and harmonious. Try using different rhythmic patterns to build the melody, such as combining eighth notes with sixteenth notes, syncopated rhythms, or triplets.

Table 4. Single-agent role-play(indicated in the blue text) prompting with additional tips given by human composer on melody construction.

Single-agent In-context learning prompting method
<p>You are an intelligent agent with musical intelligence, and your goal is to create music that meets the relevant needs and human listening habits. In this task, use ABC as the format for outputting sheet music.***Only return the ABC notation without any other description or text, and only return one piece that follow the music description given this time.***Below are the requirements for the music, it contains music elements like title, genre, key and more, and some composition examples are listed after the requirements.</p>

Table 5. Single-agent In-context learning prompting method

Chain of Thought prompting with three steps
<p>First, you need to determine all the information related to the piece in the ABC notation format, such as the name, tune, speed, mode, and anything other than the notes. This forms the basis of the piece's style.***Note that only return the music information in ABC notation format without any notes or text or Additional note.*** Second, Based on the song information in the ABC notation format provided earlier, generate a ***16-bar long*** chord progression and return it in text form, with each bar separated by a " " symbol. The generated chord progression should be consistent with the song's key and as closely aligned with the song's theme and characteristics as possible. Now the chord progression and other information are provided, you are required to create a ***16-bar long*** piece of music based on these information.</p>

Table 6. Single-agent CoT prompting method with three steps.

A.2 Melody Agent Prompt

You are a skillful musician, especially in writing melody.

You will compose a single-line melody based on the client's request and assigned tasks from the Leader.

You must output your work in ABC Notations.

Here is a template of a music piece in ABC notation, in this template:

X:1 is the reference number. You can increment this for each new tune.

T:Title is where you'll put the title of your tune.

C:Composer is where you'll put the composer's name.

M:4/4 sets the meter to 4/4 time, but you can change this as needed.

L:1/8 sets the default note length to eighth notes.

K:C sets the key to C Major. Change this to match your desired key.

The music notation follows, with |: and :| denoting the beginning and end of repeated sections.

Markdown your work using `` `` to the client.

```
``
X:1
T:Title
C:Composer
M:Meter
L:Unit note length
K:Key
|:GABc d2e2|f2d2 e4|g4 f2e2|d6 z2:|
|:c2A2 B2G2|A2F2 G4|E2c2 D2B,2|C6 z2:|
``
```

You will output the melody following this template, but decide the time signature, key signature, and the actual musical contents and length yourself.

After you receive the feedback from the Reviewer Agent, please improve your work according to the suggestions you were given.

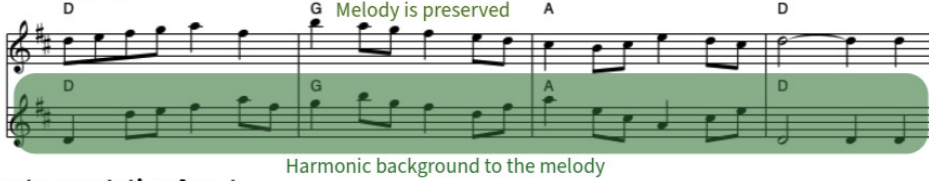

Table 7. Prompt for Melody Agent. GPT is prompted with role-specific instructions(indicated in blue text) and In-Context-Learning of ABC notations(indicated in red text)

A.3 Composing and Reviewing Process

Melody Agent

Harmony Agent

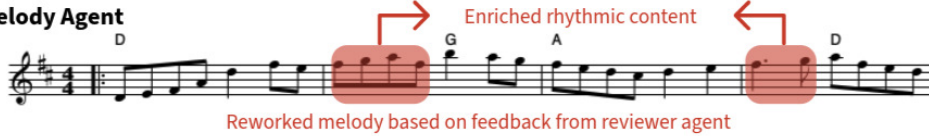

Instrumentation Agent

Take melody and harmony content and arrange them to three instruments

Figure 4. The Leader Agent will distribute the tasks among the Melody Agent, Harmony Agent, Instrumentation Agent when it is requested a "Breezy Caribbean Calypso" piece. Figure 4 demonstrate the work of the three agents with changes in the same four bar opening.

Melody Agent

Enriched rhythmic content

Reworked melody based on feedback from reviewer agent

Harmony Agent

Enriched harmony with intervals

Instrumentation Agent

Incorporating revised content from melody and harmony into three instrument arrangement

Figure 5. The Reviewer Agent then analyze the collective effort of the three agents in the first stage (shown in Figure 4), and give advice for agents to work on. Figure 5 demonstrate the work of the three agents after incorporating the advice given by Reviewer Agent in the same four bar opening.

DO MUSIC GENERATION MODELS ENCODE MUSIC THEORY?

ABSTRACT

Music foundation models possess impressive music generation capabilities. When people compose music, they may infuse their understanding of music into their work, by using notes and intervals to craft melodies, chords to build progressions, and tempo to create a rhythmic feel. To what extent is this true of music generation models? More specifically, are fundamental Western music theory concepts observable within the “inner workings” of these models? Recent work proposed leveraging latent audio representations from music generation models towards music information retrieval tasks (e.g. genre classification, emotion recognition), which suggests that high-level musical characteristics are encoded within these models. However, probing individual music theory concepts (e.g. tempo, pitch class, chord quality) remains under-explored. Thus, we introduce **SynTheory**, a synthetic MIDI and audio music theory dataset, consisting of tempos, time signatures, notes, intervals, scales, chords, and chord progressions concepts. We then propose a framework to probe for these music theory concepts in music foundation models (Jukebox and MusicGen) and assess how strongly they encode these concepts within their internal representations. Our findings suggest that music theory concepts are discernible within foundation models and that the degree to which they are detectable varies by model size and layer.

1. INTRODUCTION

State-of-the-art text-to-music generative models [1–3] exhibit impressive generative capabilities. Past work suggests that internal representations of audio extracted from music generative models encode information relating to high-level concepts (e.g. genre, instruments, or emotion) [4–7]. However, it remains unclear if they also capture underlying symbolic music concepts (e.g. tempo or chord progressions) [8].

We aim to investigate if state-of-the-art music generation models encode music theory concepts in their internal representations and to what extent. Confirming this could enable the creative alteration of these concepts, providing

artists with new methods towards more detailed and lower-level control [9] (e.g. changing the key of a song or editing a particular chord in a chord progression). Furthermore, by benchmarking these foundation models, we identify potential avenues for improvement towards stronger concept encoding. Our approach is based on work in probing and editing concepts in language models, which have shown promise in identifying emergent representations in autoregressive models and editing factual knowledge [9–12]. For music generative models, the probing approach has been applied to high-level concepts, such as emotion, genre, and tagging [4–7]. Moreover, existing datasets such as HookTheory [13] do contain rich annotations for music theory concepts but are associated with copyrighted music, potentially complicating their use.

Our first contribution is a framework to generate diagnostic datasets for probing music theory concepts, by programmatically specifying which concepts to vary and which to keep constant, while controlling the presence of potential distractor concepts. Our synthetic music theory dataset, **SynTheory**, consists of seven music concepts based on Western music theory: tempo, time signatures, notes, intervals, scales, chords, and chord progressions. SynTheory serves as a customizable, copyright-free, and scalable approach towards generating diagnostic music clips for probing real-world music generative models.

Our second contribution is the analysis of two state-of-the-art music generative models Jukebox [3] and MusicGen [1] with our SynTheory benchmark. We extract representations for the concepts defined in SynTheory from MusicGen and Jukebox and assess whether these models encode meaningful representations of these concepts. To analyze the internal representations of these models for SynTheory, we use a supervised approach to train probing classifiers [14] based on ground truth music theory concept labels. A higher classification accuracy implies that these models learn internal representations that “understand” music theory concepts, which can be decoded by a multi-layer perceptron (MLP) or a linear model.

Our results show that music foundation models encode meaningful representations of music theory concepts. These representations vary across different sections of the model (audio codecs, decoder LMs), different layers within the decoder LMs, and different model sizes. Furthermore, the nature of the concepts, from time-varying (e.g. chord progressions) to stationary (e.g. notes, chords) influence the performance of these models across these tasks. We hope our insights on probing music founda-

Sun, “Do music generation models encode music theory?”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024. *: Equal contribution.

Figure 1. Overview of our SynTheory benchmark and our Jukebox and MusicGen probing setup. Our SynTheory benchmark consists of **Rhythmic** (tempos and time signatures) and **Tonal** (notes, intervals, scales, chords, and chord progressions) concepts. We assess whether music foundation models (Jukebox and MusicGen) encode these music theory concepts within their internal representations. For each task from the SynTheory dataset, we extract representations from the music foundation model. We pass an audio input, embodying the concept (e.g. Perfect 4th), into a pretrained foundation model. The audio codec tokenizes the audio into discrete audio tokens. Then, it passes these tokens into a decoder language model. From there, we extract the representations. We then train a probe classifier (linear and two-layer MLP) on these representations to predict particular classes (e.g. pitch class, intervals, and chords) for each SynTheory concept.

tion models, along with the synthetic music data generation framework, encourage and facilitate future endeavors on symbolic controllability in music generative models.

For reproducibility, we release the code for dataset generation, embedding extraction, probing, and evaluation in our GitHub repository¹ and our website².

2. RELATED WORK

The success of large language models (LLMs) [15–18] has sparked new research on probing and editing their internal representations to measure their understanding of linguistic concepts [19, 20] and world knowledge [11, 12, 21] as well as editing the encoded knowledge to make LLMs more faithful to factual knowledge [9, 10]. Studies have shown that large language models can encode grounded representations on color [22], direction [23], and auditory representations [24]. Thus, it is interesting to investigate if large music generative models, which often share similar model architectures and training objectives as LLMs, are able to encode abstract concepts from high-level music information (e.g. genre, emotion) to low-level music theory (e.g. tempo, chords).

Recent work has indeed shown promise in uncovering conceptual representations from probing audio and music generative models, leveraging different music foundation model architectures towards music understanding tasks. Castellon and Donahue et al. [4] propose using representations from language models trained on codified audio towards downstream MIR tasks as a better alternative to conventional tagging models. The authors train probing classifiers on Jukebox representations on the music tagging, genre identification, key identification, and emotion recognition tasks. These results demonstrate the effectiveness of internal model representations in downstream MIR tasks. Koo et al. [7] focus primarily on probing MusicGen’s attention heads in instrument recognition tasks,

benchmarking against the tasks highlighted in [4] and propose leveraging these representations for inference-time control. Other works [5, 6] focus on the impact of model architecture and self-supervised approaches towards music understanding tasks.

However, prior work primarily uses real-world data, which is often concept-entangled and potentially subject to copyright concerns. For example, some of these works use Giantsteps-MTG and Giantsteps [25], which are datasets of primarily electronic dance music with tempo and key annotations, obtained from Beatport. Won et al. [5] use HookTheory for chord recognition, where they focus on major and minor chord identification for each pitch class. The authors also use Harmonix Set [26] and GTZAN [27] for beat and downbeat detection. In the language modality, the authors of ChatMusician [28] produce a multi-choice question answering dataset, MusicTheoryBench, with expert annotation from a professional college music teacher. MusicTheoryBench aims to assess the music understanding capabilities of LLMs but through natural language alone. To the best of our knowledge, there is a lack of music theory probing benchmarks in the audio domain that are accurately-labeled, copyright-free, and scalable, prior to our proposed SynTheory.

3. SYNTHEORY: SYNTHETIC DATASET OF MUSIC THEORY CONCEPTS

We design seven datasets to capture isolated music theory concepts – similar to synthetic audio for ear training. Musicians may “train their ear” to recognize music concepts like intervals or chord quality in an isolated setting before advancing to the harder, more entangled case that arises in non-pedagogical music. Assessing concept recognition through isolated concepts mitigates the possibility that one intuitively or guesses the answer from its context. Literature on instrument-specific absolute pitch in humans corroborates the notion that timbral information may be exploited in identifying a different concept like pitch class [29]. As

¹ <https://github.com/brown-palm/syntheory>

² <https://brown-palm.github.io/music-theory>

such, our dataset is designed to remove or reduce features that may correlate with a concept, but are not strictly necessary for identifying it. Our intent is a more pointed assessment towards theoretical concepts as abstract ideas rather than as acoustically realized audio. A more practical motivation for this work is that extracting such low-level, isolated concepts from existing datasets may require non-trivial engineering or domain expert labor. It may even be impossible to disentangle all overlapping concepts. Music stem isolation and concept isolation are distinct; an isolated instrument in a multi-track recording may still exhibit several, intricately intertwined theory concepts. It is not clear how to “unmix” such concepts once they are blended.

Instead of attempting to disentangle several concepts from existing audio, SynTheory implements this “ear training” quiz setting by explicitly producing individual concepts. Each of the seven datasets ablates a single musical feature while fixing all others, thereby isolating it to a degree not typically found in recorded music. These ablated concepts consist of tempo, time signatures, notes, intervals, scales, chords, and chord progressions. We adopt isolation as a design choice to mitigate context that may be exploited in deep learning models as “shortcuts”, i.e. heuristics that correlate with concepts most of the time but do not truly encode the concept.

Using this music theory concept-driven synthesis design, we construct label-balanced and copyright-free data. The synthetic approach avoids annotation errors present in other contemporary MIR datasets. For example, the HookTheory data processing step for SheetSage [13] required ad-hoc time-alignment of the expert annotations. In the released SheetSage dataset, 17,980/26,175 (68.7%) samples required more precise time alignment. While our synthetic data is no substitute for real music data, to our knowledge, no other dataset so strictly isolates each concept.

SynTheory contains two categories: tonal and rhythmic. We make this distinction for stronger concept isolation; we wish to keep the rhythm samples tonally consistent and the tonal samples rhythmically consistent. For each **tonal** dataset, we voice the same MIDI data through 92 distinct instruments. The selection of instrument voices is fixed, making the distribution of timbres sufficiently diverse but also class-balanced. Each instrument corresponds to one of the 128 canonical MIDI program codes and is voiced through the `TimGM6mb.sf2` [30] soundfont. A MIDI “program” is a specific instrument preset. The canonical program set includes many named instruments, e.g. “Acoustic Grand Piano”, “Flute”, etc. We exclude programs that are polyphonic, sound effects (e.g. “Bird Tweet”, “Gun Shot”), and highly articulate. A highly articulate program has some unchangeable characteristic (e.g. pitch bending) that destabilizes its pitch. For each **rhythmic** dataset, we define five metronome-like timbral settings. Each setting uses one of the distinct instruments: “Woodblock Light”, “Woodblock Dark”, “Taiko”, “Synth Drum”, and the MIDI drum-kit, following the voicing done in Sheetsage [13]. Each setting produces a distinct sound

Concept	Total Samples
Tempo	4,025
Time Signatures	1,200
Notes	9,936 ³
Intervals	39,744
Scales	15,456
Chords	13,248
Chord Progressions	20,976

Table 1. SynTheory contains seven synthetic datasets, each of which captures an isolated music theory concept. We present an overview of these datasets and their sizes.

on the upbeat and the downbeats, which defines the time signature concept.

3.1 SynTheory-Rhythmic

3.1.1 Tempo

We voice integer tempi within 50 to 210 BPM (beats per minute) inclusive in $\frac{1}{4}$ time. To ensure diverse start times, we produce five random offsets per sample. There are $(5 \text{ CLICK SETTING} \cdot 161 \text{ TEMPO} \cdot 5 \text{ OFFSET}) = 4,025$ samples in total.

3.1.2 Time Signature

We voice the following time signatures: $\frac{2}{2}$, $\frac{2}{4}$, $\frac{3}{4}$, $\frac{3}{8}$, $\frac{4}{4}$, $\frac{6}{4}$, $\frac{6}{8}$, and $\frac{12}{8}$. The tempo is fixed at 120 BPM. To add acoustic variation, we add three levels of reverb from completely dry to spacious. We find empirically that this acoustic perturbation increases the difficulty of the probing task. Like the Tempo dataset, we produce ten random offsets for each sample. There are $(8 \text{ TIME SIGNATURE} \cdot 3 \text{ REVERB LEVEL} \cdot 5 \text{ CLICK SETTING} \cdot 10 \text{ OFFSET}) = 1,200$ samples.

3.2 SynTheory-Tonal

3.2.1 Notes

We voice all twelve Western temperament pitch classes, in nine octaves, using 92 instruments. The note is played in quarter notes at a tempo of 120 BPM, with no distinction between the upbeat or downbeat. There are $(12 \text{ PITCH CLASS} \cdot 9 \text{ OCTAVE} \cdot 92 \text{ INSTRUMENT}) = 9,936$ configurations. However, there are only 9,900 distinct *samples* because 36 configurations at extreme registers are unvoiceable in our soundfont. These silent samples are listed for completeness in our GitHub repository.

3.2.2 Intervals

We vary the root note, number of half-steps, instrument, and play style (unison, up, and down). To retain consistent rhythm, the up and down styles repeat four times throughout the sample while the unison play style repeats

³ There are 9,936 distinct note configurations, but our dataset contains 9,900 non-silent samples. With a more complete soundfont, all 9,936 configurations are realizable to audio.

eight times. There are $(12 \text{ PITCH CLASS} \cdot 12 \text{ HALF-STEP} \cdot 92 \text{ INSTRUMENT} \cdot 3 \text{ PLAY STYLE}) = 39,744$ samples.

3.2.3 Scales

We voice seven Western music modes (Ionian, Dorian, Phrygian, Lydian, Mixolydian, Aeolian, and Locrian) in all root notes, in 92 instruments, and in two play styles (ascending or descending). The register is constant; we select root notes close to middle C. There are $(7 \text{ MODE} \cdot 12 \text{ ROOT NOTE} \cdot 92 \text{ INSTRUMENT} \cdot 2 \text{ PLAY STYLE}) = 15,456$ samples.

3.2.4 Chords

We voice triads of all twelve root notes, four chord qualities (major, minor, augmented, and diminished), 92 instruments, and three inversions (root position, first inversion, and second inversion). The chord is struck at each quarter note at 120 BPM. Like in the *Scales* dataset, we fix the register close to middle C. There are $(12 \text{ ROOT NOTE} \cdot 4 \text{ CHORD QUALITY} \cdot 92 \text{ INSTRUMENT} \cdot 3 \text{ INVERSION}) = 13,248$ samples.

3.2.5 Chord Progressions

We select 19 four-chord progressions, with ten in the major mode and nine in the natural minor mode. The progressions are:

- Major: (I-IV-V-I), (I-IV-vi-V), (I-V-vi-IV), (I-vi-IV-V), (ii-V-I-Vi), (IV-I-V-Vi), (IV-V-iii-Vi), (V-IV-I-V), (V-vi-IV-I), (vi-IV-I-V)
- Natural Minor: (i-ii^o-v-i), (i-III-iv-i), (i-iv-v-i), (i-VI-III-VII), (i-VI-VII-i), (i-VI-VII-III), (i-VII-VI-IV), (iv-VII-i-i), (VII-vi-VII-i)

We vary only the root note of the key and instrument. Each chord is played in quarter notes at 120 BPM. There are $(19 \text{ PROGRESSION} \cdot 12 \text{ KEY ROOT} \cdot 92 \text{ INSTRUMENT}) = 20,976$ samples.

One can extend or alter the above configurations using the SynTheory codebase. We provide a framework that enables declarative and programmatic MIDI construction in musical semantics, audio export in any soundfont, and dataset construction for use in our framework.

4. EXPERIMENTS

We describe the evaluation protocols used to analyze the internal representations of music generative models (MusicGen and Jukebox) and handcrafted audio features (mel spectrograms, MFCC, and chroma) for music theory concept encoding.

4.1 Evaluation

A “probe” is a simple or shallow classifier, often a linear model, trained on the activations of a neural network [14]. Accurate performance of such classifiers suggests that information relevant to the class exists in the latent representation within the network. As such, probes may be used as a proxy for measuring a model’s “understanding” or encoding of abstract concepts. Motivated by the use

of probes to discover linguistic structure and semantics in NLP [31] and more recently in MIR [4], we use probes to assess whether music theory concepts are discernable in foundation models.

We adopt the same probing paradigm as [4] and frame concept understanding as multiclass classification for discrete concepts (notes, intervals, scales, chords, chord progressions, and time signatures) and regression for continuous concepts (tempo). We train linear and two-layer MLP probes on the embeddings of the internal representations of Jukebox and MusicGen and the handcrafted features. We measure the classification accuracy of our trained probes on the SynTheory tasks using the following classes:

- Notes (12): C, C#, D, D#, E, F, F#, G, G#, A, A#, and B
- Intervals (12): minor 2nd, Major 2nd, minor 3rd, Major 3rd, Perfect 4th, Tritone, Perfect 5th, minor 6th, Major 6th, minor 7th, Major 7th, and Perfect octave
- Scales (7): Ionian, Dorian, Phrygian, Lydian, Mixolydian, Aeolian, and Locrian
- Chords (4): Major, Minor, Diminished, and Augmented
- Chord Progressions (19): (I-IV-V-I), (I-IV-vi-V), (I-V-vi-IV), (I-vi-IV-V), (ii-V-I-Vi), (IV-I-V-Vi), (IV-V-iii-Vi), (V-IV-I-V), (V-vi-IV-I), (vi-IV-I-V), (i-ii^o-v-i), (i-III-iv-i), (i-iv-v-i), (i-VI-III-VII), (i-VI-VII-i), (i-VI-VII-III), (i-VII-VI-IV), (iv-VII-i-i), and (VII-vi-VII-i)
- Time Signatures (8): $\frac{2}{2}$, $\frac{3}{4}$, $\frac{3}{8}$, $\frac{4}{4}$, $\frac{6}{8}$, $\frac{9}{8}$, and $\frac{12}{8}$

These tasks are trained on a 70% train, 15% test, and 15% validation split, using the Adam optimizer and Cross Entropy loss.

For the Tempos dataset, we train a regression probe, over the 161 tempo values. To increase complexity in the probing task and test generalization to unseen BPMs, the training set consists of the middle 70% of the BPMs. The test and validation sets consist of the top 15% BPMs and the bottom 15% BPMs, randomly shuffled and split in half. We use MSE loss and report the R^2 score.

Each probe is trained independently for its corresponding concept task. That is, the probe trained to identify notes from Jukebox embeddings will not be used to identify intervals, for example.

To select the best performing probe for each concept using the MusicGen audio codec, mel spectrogram, MFCC, chroma, and aggregate handcrafted features, we perform a grid search across various hyperparameters for each task, following those defined in [4]:

- Data Normalization: {True, False}
- Model Type: {Linear, two-layer MLP with 512 hidden units and ReLU activation}
- Batch Size: {64, 256}
- Learning Rate: $\{10^{-5}, 10^{-4}, 10^{-3}\}$
- Dropout: {0.25, 0.5, 0.75}
- L2 Weight Decay: {off, 10^{-4} , 10^{-3} }

For the decoder LMs (MusicGen small, medium, and large and Jukebox) as detailed in Section 4.2, we use a fixed set of hyperparameters and select the probe with the best performing layer for each concept, in the interest of

computational efficiency:

- Data Normalization: True
- Model Type: two-layer MLP with 512 hidden units and ReLU activation
- Batch Size: 64
- Learning Rate: 10^{-3}
- Dropout: 0.5
- L2 Weight Decay: off

We selected these hyperparameters from the best overall performing probe by fixing a layer in the decoder LMs and performing a hyperparameter search, following the sweep approach outlined in [4].

4.2 Model representations

We extract representations from two text-to-music generative foundation models, Jukebox [3] and MusicGen [1]. We benchmark the probing classifier performance of these representations against that of three handcrafted, spectral features following [4]: mel spectrograms, mel-frequency cepstral coefficients (MFCC), and constant-Q chromagrams (chroma). These handcrafted features are common in traditional methods of MIR and are a more interpretable baseline against the embeddings of the pre-trained music generative models. We additionally report probing classifier performance on the concatenation of all the aforementioned handcrafted features.

Jukebox consists of a VQ-VAE model that codifies audio waveforms into discrete codes at a lower sample rate and a language model that generates codified audio with a transformer decoder. We trim all audio to four seconds and ensure it is mono. We utilize Jukemirlib [4] to pass this audio through the frozen audio encoder and through the decoder language model. We downsample the activation to a target rate of half that in [4], due to resource constraints, using the Librosa FFT algorithm [32]. Then, we meanpool the representations across time to reduce the dimensionality of the embeddings, resulting a dimension of (72, 4800) per sample, where 72 is the number of layers and 4800 is the dimension of the activations. We reduce the dimensionality of these representations by defining a layer selection process similar to [4]; that is, each probing classifier trains on only one of the 72 layers. We train the probe classifiers with fixed hyperparameters on the music concept tasks as described in Section 4.1. For each concept, we select the layer that results in the highest probing score. The final dimension of the Jukebox representation is 4800.

MusicGen consists of a pretrained convolutional auto-encoder (EnCodec) [33], a pretrained T5 text encoder, and an acoustic transformer decoder. We resample the audio to 32 kHz (the sampling rate used in the EnCodec model) trim to four seconds, convert to mono, and pass the audio through the frozen EnCodec audio codec. We do not pass text through the text encoder, as we focus on audio representations. We then extract representations from several regions of the model: the final layer of the audio codec before residual vector quantization and the hidden states of the decoder language model. The number of decoder hidden states vary based on the model size: small (24 layers),

Figure 2. Probing evaluation metrics averaged across all SynTheory concepts over the model layers of Jukebox and MusicGen decoder models. The probing evaluation metric is R^2 for tempos and accuracy for the rest of the SynTheory concepts (notes, intervals, scales, chords, chord progressions, and time signatures). Features extracted from deeper layers generally perform better, with a slight drop-off near the final layers.

medium (48 layers), and large (48 layers).

For our four second audio clips, the audio codec representations are of dimension (128, 200), where 128 is the dimension of the activation after the final layer of the audio codec and 200 is the sequence length. We meanpool the values of the representations across time, resulting in a final dimension of 128 for the MusicGen audio codec.

The decoder hidden states for the small, medium, and large MusicGen models have dimensions (24, 200, 1024), (48, 200, 1536), (48, 200, 2048) respectively, where the first axis corresponds to the number of layers, second corresponds to sequence length, and third corresponds to hidden size. To reduce the dimensionality of these representations, similar to what was done with Jukebox, we select the most optimal layer for each decoder model size based on probing scores. We visualize results from probing across layers per model (MusicGen and Jukebox) averaged across concepts in Figure 2. After selecting the best performing layer per concept and model size, the dimensions of the representations are (200, 1024) for MusicGen small, (200, 1536) for MusicGen medium, and (200, 2048) for MusicGen large. To further reduce the dimensions, we also meanpool across time as done in Jukebox representations, resulting in dimensions of 1024 for MusicGen small decoder, 1536 for MusicGen medium decoder, and 2048 for MusicGen large decoder.

We extract the handcrafted features (mel spectrograms, mel-frequency cepstral coefficients, and constant-Q chromagrams) with librosa [32]. Similar to [4], we concatenate the mean and standard deviation across time of these features along with their first- and second-order discrete differences. Furthermore, we concatenate the mel spectrogram, chroma, and MFCC features and obtain their mean and standard deviation across time and their first- and second-order differences to obtain an aggregate representation of the handcrafted features.

	Notes	Intervals	Scales	Chords	Chord Progressions	Tempos	Time Signatures	Average
Jukebox LM	0.951	0.995	0.978	0.997	0.971	0.993	1.000	0.984
MusicGen LM (S)	0.897	0.995	0.949	0.990	0.942	0.969	0.911	0.950
MusicGen LM (M)	0.851	0.983	0.863	0.989	0.870	0.956	0.883	0.914
MusicGen LM (L)	0.866	0.972	0.905	0.989	0.901	0.965	0.905	0.929

Mel Spectrogram	0.712	0.995	0.897	0.988	0.723	0.785	0.827	0.847
MFCC	0.467	0.822	0.370	0.863	0.872	0.923	0.688	0.715
Chroma	0.954	0.820	0.989	0.994	0.869	0.847	0.672	0.878
Aggregate Handcrafted	0.941	0.997	0.972	0.992	0.868	0.947	0.833	0.936

Table 2. We report probing results on the SynTheory dataset for the Jukebox LM, MusicGen Decoder LM (Small, Medium, and Large), MusicGen Audio Codec models as well as handcrafted features (Mel Spectrogram, MFCC, Chroma, and Aggregate Handcrafted). For the tempos dataset, we report the R^2 score from the regression probe. For all other concepts (notes, intervals, scales, chords, chord progressions, and time signatures), we report the probing classifier accuracy. For MusicGen Audio Codec, Mel Spectrogram, MFCC, Chroma, and Aggregate Handcrafted, we report the metrics of the best performing probe for each task using the best validation performance from our hyperparameter search. For MusicGen Decoder LM (Small, Medium, and Large) and Jukebox models, we report the metrics of the best performing probe for each task using layer selection. We also report an average performance across all concepts for each model/feature.

5. RESULTS AND DISCUSSION

We observe that Jukebox performs consistently well across our SynTheory benchmark. All MusicGen Decoder models also exhibit competitive performance across concepts. While [1] claims that larger MusicGen models produce better quantitative and subjective scores and that larger models better “understand” text prompts, our MusicGen Decoder LM (Small) result seems to contrast with traditional discussions on scaling laws. Figure 2 displays the consistent probing score of MusicGen Decoder LM (Small) across all layers and highlights its higher performance compared to that of its larger counterparts. Meanwhile, the larger MusicGen models exhibit a steep drop in probing performance in initial layers, followed by a gradual increase in performance, with the performance tapering off in the final layers.

MusicGen slightly underperforms on the notes dataset. We hypothesize this is because isolated notes in real-world music are not as prominent as intervals, scales, and chords. This reveals how the lowest-level building blocks of music are even harder to distinguish.

In general, the probing results from the pretrained music decoder LMs yield better probing performance compared to the MusicGen Audio Codec representations and the individual handcrafted features. MusicGen Audio Codec exhibits overall poorer performance on these tasks, since these codecs were trained to reconstruct fine-grained, low-level details localized by time.

Because chroma features encode pitch class information, chroma features perform comparably well on tonal tasks. However, they slightly underperform on rhythmic tasks. Chroma features outperform MusicGen Decoder LMs on stationary harmonic tasks (notes, scales, and chords) but are worse for dynamic harmonic tasks (chord progressions and intervals).

The aggregate handcrafted features perform comparably to MusicGen Decoder LMs. This suggests that harder music concept understanding benchmarks should address concepts latent in foundation models but not easily encoded in handcrafted features. These harder benchmarks may include entangled concepts, such as probing for both chord progression type and tempo in a tempo-varying chord progression sample. Probing for more compositional tasks could further our understanding of more realistic concept encoding in both model representations and handcrafted features.

6. CONCLUSION

In this work, we introduce SynTheory, a synthetic dataset of music theory concepts, that is concept-isolated, annotated, and copyright-free. Further, we use this dataset to evaluate the degree to which music theory concepts are encoded in existing state-of-the-art music generative models. Our experiments suggest that music theory concepts are indeed discernible within the latent representations of these generative models. We believe this is a prerequisite to further understand how to isolate and manipulate such concepts, which advances towards low-level controllable generation and music theory evaluation metrics. We encourage the community to build more challenging probing datasets with our framework to further understand the relationship between symbolic and audio-based music generation.

7. ETHICS STATEMENT

Our work aims to understand if music generation models encode music theory concepts in their internal representations. Our dataset may be used to assess music generation models and may be applied towards fine-grained, music-theory based controllable generation.

Our custom dataset, SynTheory, is based on elementary Western music theory concepts and is generated programmatically. The data does not infringe copyright of musical writers or performers. We envision no negative societal impacts from the publication of our report or the release of our dataset.

8. ACKNOWLEDGEMENTS

We would like to thank Professor Cheng-Zhi Anna Huang, Professor Daniel Ritchie, Professor David Bau, Professor Jacob Andreas, Tian Yun, Nate Gillman, and Calvin Luo for their fruitful discussions and feedback towards this work. This project is partially supported by Samsung. We would also like to thank the Center for Computation and Visualization at Brown University for their computational resources towards this project. Finally, we greatly appreciate the insightful questions and thoughtful feedback from the reviewers.

POLYSINGER: SINGING-VOICE TO SINGING-VOICE TRANSLATION FROM ENGLISH TO JAPANESE

Silas Antonisen, Iván López-Espejo

Department of Signal Theory, Telematics and Communications, University of Granada, Spain
{santon, iloes}@ugr.es

ABSTRACT

The speech domain prevails in the spotlight for several natural language processing (NLP) tasks while the singing domain remains less explored. The culmination of NLP is the speech-to-speech translation (S2ST) task, referring to translation and synthesis of human speech. A disparity between S2ST and the possible adaptation to the singing domain, which we describe as singing-voice to singing-voice translation (SV2SVT), is becoming prominent as the former is progressing ever faster, while the latter is at a standstill. Singing-voice synthesis systems are overcoming the barrier of multi-lingual synthesis, despite limited attention has been paid to multi-lingual songwriting and song translation. This paper endeavors to determine what is required for successful SV2SVT and proposes PolySinger (**Polyglot Singer**): the first system for SV2SVT, performing lyrics translation from English to Japanese. A cascaded approach is proposed to establish a framework with a high degree of control which can potentially diminish the disparity between SV2SVT and S2ST. The performance of PolySinger is evaluated by a mean opinion score test with native Japanese speakers. Results and in-depth discussions with test subjects suggest a solid foundation for SV2SVT, but several shortcomings must be overcome, which are discussed for the future of SV2SVT.

1. INTRODUCTION

Speech-to-speech translation (S2ST) is a method for translating human speech into another language using synthetic speech. To do this, the conventional approach is to concatenate technologies that process separate parts of human speech into a complete system, where the cornerstones are speech recognition, machine translation and speech synthesis [1–3]. Although the use of end-to-end (E2E) solutions for S2ST has been studied thanks to the emergence of seq-to-seq models [4–6], neither E2E nor cascaded solutions have been attempted in the singing domain.

Singing-voice synthesis (SVS) systems have in recent years become very capable of human-like singing [7,8] and

have even accomplished multi-lingual synthesis [9]. However, while the synthetic voice can sing cross-lingually, the songwriter might not be able to write cross-lingually.

Lyrics translation is a complex task which strives for inter-cultural comprehension of what makes a song suitable for singing. Prose translation, also called direct translation [10–12], differs greatly in its application from poetry and lyrics translation, as prose translation does not respect rules regarding rhythm and rhyme [13,14]. A few attempts at automatic lyrics translation have been made by transforming standard music notation from one language to another, which shows promising results [15,16]. However, the necessity for standard music notation becomes a glaring restriction. From the perspective of a songwriter with interest in writing foreign-language lyrics, the creation of standard music notation is a labor-intensive task begging for automation. Therefore, to overcome the present limitations in adapting S2ST methods to the singing domain, we propose PolySinger: the first system for singing-voice to singing-voice translation (SV2SVT). PolySinger is a concatenated system of music information retrieval (MIR) technologies with the goal of directly translating a vocal performance in a source language into a synthetic vocal performance in a target language. PolySinger is made publicly available¹.

Automatic recognition of note-level events in a vocal melody is a complex and vaguely defined task [17]. Nonetheless, standard music notation is required for lyrics translation, and as such, this work proposes a simple yet effective approach to defining note-level events by assistance from syllable alignment.

State-of-the-art (SOTA) in the following technologies are structured into a complete SV2SVT system for PolySinger: 1) automatic lyrics transcription, 2) phoneme-level lyrics alignment, 3) frame-level vocal melody extraction, 4) automatic lyrics translation, and 5) singing-voice synthesis. PolySinger is proposed as a concatenated solution instead of E2E to represent a modular framework facilitating research in SV2SVT. In this paper, PolySinger is presented for English to Japanese SV2SVT, which, to the best of our knowledge, also constitutes the first attempt at automatic lyrics translation from English to Japanese.

A series of native Japanese speakers participated in a mean opinion score (MOS) test to evaluate the perceptual quality of PolySinger for English to Japanese SV2SVT. Results show a promising fundamental structure

¹<https://github.com/SilasAntonisen/PolySinger>

for SV2SVT, but also that our translated Japanese lyrics have not yet reached ideal naturalness.

2. RELATED WORK

Convolutional neural networks and expanded pronunciation dictionaries have been used for automatic lyrics transcription in monophonic recordings [18], along with time-delay neural networks in polyphonic recordings [19]. The latest reported SOTA in automatic lyrics transcription was achieved by adapting a Wav2Vec 2.0 [20] speech recognizer to the singing domain by transfer learning [21]. However, in our preliminary tests we found the current SOTA speech recognition system, Whisper [22], to outperform the SOTA in automatic lyrics transcription [21] when transcribing a vocal performance. Therefore, Whisper [22] is used for automatic lyrics transcription in PolySinger.

Limited success has been achieved using speech alignment systems for lyrics alignment [23]. However, great results have been obtained in word-level lyrics alignment by training a polyphonic acoustic model in [24], but it is not until in [25] that a direct attempt is made at phoneme-level lyrics alignment without sacrificing competitive performance in word-level alignment. Recent approaches have exploited the correlation between phoneme onset and note pitch by joint representation learning [26] or cross-modal embedding in the audio and text domain through contrastive learning [27]. For PolySinger we use [25] due to its documented performance in the specific task of phoneme-level lyrics alignment and accessibility to a pre-trained model.

Defining note-level events in a vocal melody is a complex task, and thus there is a lack of datasets and trained neural networks for note-level vocal melody extraction (VME) [17]. On the other hand, frame-level VME is an extensively researched field with robust frameworks [28–30]. Considering the high accuracy of most modern frame-level VME systems, [30] is used in PolySinger due to the streamlined implementation available through the MIR toolkit Omizart [31]. Instead of defining the note-level events by VME, we define them by syllable-wise boundaries delimited by the phoneme-level lyrics alignments, and guide the pitch of those notes with frame-level VME.

In [15], a rule-based approach is suggested for translating from English to Chinese lyrics with respect to the original lyrics, melody and rhythm, as well as the tonal properties of Chinese. In [16], a system for bidirectional translation between English and Chinese is proposed which incorporates an alignment decoder for determining the amount of syllables to write in the translation and how they should align to the melody. Additionally in [16], the evaluation process of the system is assisted by synthesizing the translation via SVS. For PolySinger, we take inspiration from [15] by going for a simple rule-based approach for English to Japanese lyrics translation due to data scarcity and an interest in unraveling the implications of processing Japanese lyrics. To do so, we exploit the pre-trained SOTA model for multi-lingual translation nllb-200 [12] by transferring it to the singing domain.

Early work on SVS created concatenated singing libraries of sampled vocal sounds in a wide range of pitches, from which a synthesizer chose the samples for synthesis based on a musical score [32, 33]. More recent approaches use acoustic models trained on vocal performances from a singer to replicate the way he/she would perform a song given a musical score [7]. Furthermore, cross-lingual synthesis has become possible even when only training on mono-lingual singers [9]. The open-source scene has entered the SVS consumer market, e.g., by use of the ENUNU² plugin to enable usage of the NNSVS toolkit [8] in the OpenUTAU editor. Synthesizer V³ is gathering a common consensus of being one of the best consumer products for SVS with a wide range of high-quality neural singing libraries capable of cross-lingual synthesis in a user-friendly environment with scripting capabilities. Therefore, Synthesizer V is used for SVS in PolySinger. Similarly to [16], we synthesize the translated lyrics, but we want to emphasize that, *differently from [16], PolySinger automates the intermediate link between automatic lyrics translation and SVS.*

3. PROPOSED SINGING-VOICE TO SINGING-VOICE TRANSLATION SYSTEM

Figure 1 illustrates a flowchart of the proposed SV2SVT system. This section will systematically break down the technology, implementation and functionality of each block presented in this figure.

3.1 Automatic Lyrics Transcription

Whisper [22] is a Transformer-based model [10] originally pre-trained on 680k hours of weakly-labeled audio for multi-task learning; there among the main task being multi-lingual automatic speech recognition. The most recent checkpoint, *Whisper-large-v3*, is trained on 1M hours of weakly-labeled audio and 4M hours of audio which was pseudo-labeled by *Whisper-large-v2*. We collect *Whisper-large-v3* from HuggingFace⁴ for automatic lyrics transcription. The model has 1,550M parameters and was trained for 2 epochs on the dataset. We have not fine-tuned Whisper on singing data due to Whisper’s great ability to generalize across several domains. To keep the memory usage of Whisper within ~8 GB, a chunking algorithm segments the vocal performance into 30-second segments which are processed individually with a batch size of 4. Block 1 in Figure 1 is facilitated by Whisper to transcribe an English string of text from an English vocal performance.

3.2 Phoneme-Level Lyrics Alignment and Syllable-Level Lyrics Alignment

In Western languages, poetry and lyrics are very reminiscent of each other. Poetry has a rhythmic structure called

² <https://github.com/oatsu-gh/ENUNU>

³ <https://dreamtonics.com/synthesizerv/>

⁴ <https://huggingface.co/openai/whisper-large-v3>

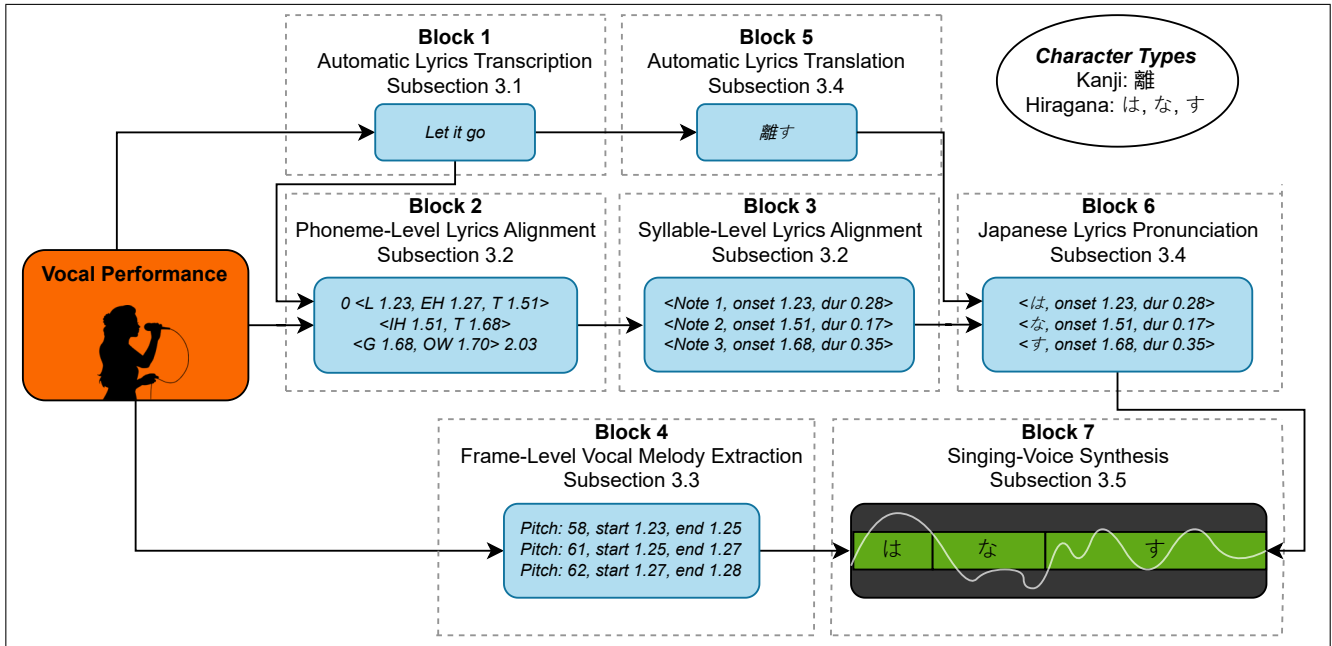

Figure 1. Overview of our proposed SV2SVT system, PolySinger. Provided an English vocal performance, a synthetic vocal performance is created in Block 7, defined by notes with onsets, durations and Japanese lyrics, guided by a frame-level melody. Every numeric value is in seconds and “<>” illustrates the boundaries of notes. The process of segmenting words into syllables is illustrated in Table 1. Fundamentals of Japanese writing are explained in Subsection 3.4, and the process of converting kanji to hiragana is illustrated in Table 2.

meter. This structure can be dissected into a syllabic pattern [34]. Therefore, in this work, we define the onset and duration of notes by aligning the sung syllables to the vocal performance. To obtain syllable-level lyrics alignments, we first align the sequence of phonemes present in the vocal performance. The phoneme sequence is extracted with the pre-trained phoneme-level lyrics aligner informed in [25]. This model is a deep neural network trained for joint phoneme-level lyrics alignment and singing-voice separation. Text and audio are encoded separately. Text features and audio features are aligned by dynamic time warping-attention to minimize the total distance between audio frames and phonemes. The list of possible phonemes is provided by CMUdict⁵. Block 2 in Figure 1 uses the phoneme-level lyrics aligner to align the transcribed lyrics provided by Block 1 to the vocal performance. The phoneme alignments are informed in seconds. The phoneme sequence is concatenated into syllables by simple rules: 1) it is assumed that each phoneme corresponding to a vowel makes an individual syllable, and 2) consonants are merged with their closest neighboring vowel, gravitating towards the rightmost vowel in case of both neighboring phonemes corresponding to vowels. The process of breaking a word into phonemes according to CMUdict and concatenating them into syllables is illustrated in Table 1. In Block 3 of Figure 1, in order to perform syllable-level lyrics alignment, we define the onset of a note as the start of the first phoneme in a syllable, and we define the duration as the time difference between the onset and the end of the last phoneme in the syllable.

Word	BLUEBERRY
Phonemes	B L UW1 B EH2 R IY0
Syllables	BLUW BEH RIY

Table 1. Example of the word “blueberry” being deconstructed into phonemes with respect to CMUdict and reconstructed into syllables. An integer ranging 0-2 is associated with each vowel to indicate the type of vowel stress.

3.3 Vocal Melody Extraction

The notes in Block 3 of Figure 1 with timings defined by phoneme boundaries are not individually associated with a unique pitch. Instead, to preserve the melody from the vocal performance as much as possible, the melody is extracted at a frame level. This frame-level pitch contour is used to automate the pitch over time for the note sequence. The notes are set to a standard pitch of 60, and the contour is used to describe the deviation from 60 at each frame. The frame-level VME system presented in [30] deploys a deep convolutional neural network for semantic segmentation across a time-frequency image. Additionally, a progressive neural network is used for cross-domain transfer learning between the audio domain (frequencies) and the symbolic domain (pitch). Block 4 in Figure 1 utilizes this model for extracting the frame-level melody contour as pitches from the vocal performance. The start and end of pitches are in seconds. The model is used through the Omnizart toolkit [31].

3.4 Automatic Lyrics Translation and Japanese Lyrics Pronunciation

nllb-200 [12] is a Transformer [10]-based mixture-of-experts (MoE) multi-lingual translation model that achieves SOTA results in many languages. This success is largely owed to the parallel development of datasets: 1) the expertly-annotated Flores-200 dataset (which consists of 3,001 English sentences translated into 204 languages), and 2) automatically-generated datasets by web-scraping for either mono-lingual sentences with high probability of being each other’s translation, or mono-lingual sentences for back-translation. The biggest model, nllb-200-MoE, has 54B parameters, which is infeasible to run locally. Therefore, we collect the smaller checkpoint nllb-200-distilled-600M from HuggingFace⁶ and fine-tune the model for English to Japanese lyrics translation. Since neither high-quality nor high-quantity dataset of paired English and Japanese lyrics exists, we take inspiration from [15] and scrape the web for lyrics translations that are not necessarily singable. Our dataset consists of ~213k paired lines, thereof ~80% (~20%) being Japanese⇒English (English⇒Japanese)⁷. With PolySinger, we perform English⇒Japanese translation, so we invert the Japanese⇒English lyrics pairs into English⇒Japanese lyrics pairs. We hypothesize that this inversion does not raise an issue, but might in fact incentivize the model to produce high-quality Japanese lyrics even when provided with low-quality English lyrics. Besides, unlike in [15], we attempt fine-tuning with no prior self-supervised training on mono-lingual lyrics due to our larger paired dataset.

Ideally, the output of our fine-tuned model should have the same amount of syllables as established in Block 3 of Figure 1. However, counting syllables is not as simple in Japanese as in English. Japanese has moraic syllabaries in the form of kana. Kana characters have specific pronunciations that take up one mora (Japanese syllable) each. Japanese also uses kanji as logograms, that is, characters that convey a certain meaning. Kanji characters have multiple readings depending on the context, and, as such, it becomes a challenging task to decide the pronunciation of a Japanese sentence. To get the correct pronunciation of kanji characters, pyKAKASI⁸ is used to decode kanji into their hiragana (a type of kana) readings. An illustration of the relation between kanji and Japanese pronunciation can be seen in Table 2. pyKAKASI is dictionary-based, and it can therefore be difficult to convert sentence-wise instead of word-wise. Japanese does not use blank space to separate words, therefore, we use Nagisa⁹, a recurrent neural network trained for Japanese word segmentation.

During inference, a beam search is applied to the output of our fine-tuned nllb-200-distilled-600M with

<i>Kanji character</i>	離
<i>Hiragana readings</i>	り はな
<i>Roman readings</i>	RI HA NA
<i>Mora count</i>	1 2

Table 2. Example of two possible hiragana readings for a kanji character.

as many beams as memory will allow (~50 beams in our tests). The beams are biased towards a token count lower than the number of syllables in Block 3 of Figure 1 due to a kanji always corresponding to at least one syllable. Each generated sentence becomes word-separated with Nagisa and the kanji are converted into hiragana readings with pyKAKASI. The sentence with the lowest non-negative difference between mora count and syllable count gets selected and assigned to the notes in Block 6 of Figure 1.

3.5 Singing-Voice Synthesis

Synthesizer V is a SVS system with growing popularity among musicians. The technology behind Synthesizer V is kept proprietary. Based on related literature [7, 8], it is assumed that AI singing-voices in Synthesizer V are acoustic models trained on phoneme-level annotated vocal performances. With this training scheme, the model recognizes patterns in a singer’s vocal performances, e.g., articulation of phoneme sequences, transitions between pitches and tendencies to use vibrato. Additionally, Synthesizer V AI voices have parameters for vocal modes, which can be included in training by annotating vocal samples with a singing style, e.g., nasal, powerful, soft, and whisper. AI singing-voices are usually only trained on vocal performances by a mono-lingual or bilingual singer, however AI voices in Synthesizer V are capable of cross-lingual synthesis in English, Japanese, Mandarin Chinese, Cantonese, and, recently, Spanish. It is assumed, based on related literature [9], that cross-lingual synthesis is achieved by unifying phoneme representations across languages with the international phonetic alphabet and training on data labeled with language identification such that the acoustic model can learn language-specific features. As illustrated in Figure 1, the notes with Japanese lyrics provided by Block 6 are plotted into Synthesizer V at a standard pitch of 60. The vocal contour provided by Block 4 is used to automate the deviation from pitch 60 over time. We use the AI singing-voice Mai in Synthesizer V to generate the Japanese vocal performance.

4. EXPERIMENTS

Objective measures in machine translation such as BLEU [35] are typically used for word-wise similarity with respect to a ground truth. Such a method does not suit lyrics translation as there should rather be a focus on semantic interpretation rather than precise word choice. Moreover, PolySinger has to be evaluated on the overall per-

Q6	What is the overall quality of the generated Japanese singing?

Table 4. Questions asked to the test subjects in the MOS test of Section 4.

formance achieved for English⇒Japanese SV2SVT rather than solely on the translation quality. Therefore, we evaluate PolySinger subjectively by means of a MOS test.

4.1 Methodology

Six native Japanese speakers participated in a MOS test to evaluate the perceptual quality of English⇒Japanese SV2SVT using PolySinger on 5 different vocal performances. All test subjects were females ranging from 24 to 39 years old with no hearing impairment. The test subjects were asked to self-report their English speaking level. Two participants reported complete fluency (5/5), one reported near fluency (4/5), two more indicated advanced comprehension (3/5), and the final one reported intermediate comprehension (2/5). Using the inference procedure described in Subsection 3.4, PolySinger was alternately tested with the original `nllb-200-distilled-600M` (*Baseline*) and our fine-tuned `nllb-200-distilled-600M` (*Fine-tuned*) on every vocal performance. The test subjects were asked to first listen to an English vocal performance, followed by the synthetic performances generated by the two PolySinger versions (i.e., Baseline and Fine-tuned). Participants were not informed which synthetic vocal performance was generated by which system variant. Using the 5-point scale shown in Table 3, the test subjects were asked to assess each generated performance by the 6 MOS questions displayed in Table 4. The average time a participant spent on the evaluation was 53 min. The audio samples used for evaluation can be accessed here¹⁰.

After the participants submitted their MOS scores, we additionally had a brief discussion with them individually about their general opinions and observations.

4.2 Results

Table 5 shows the MOS test results along with 95% confidence intervals from the Student’s *t*-distribution [36]. Both system variants (i.e., Baseline and Fine-tuned) lie somewhere between poor and neutral in all 6 MOS questions Q1–Q6. The relatively large confidence intervals in Table

5 suggest a high variance in opinion scores. We investigate this variance in Figure 2 by representing per-question score’s relative frequency. While it is true that the majority of opinion scores lies in the mid-to-low end of the spectrum, several evaluations have also resulted in good or very good opinion scores. This emphasizes the very subjective nature of the SV2SVT problem.

Given a MOS question Q1–Q6, we determine if there is a statistically significant difference between the opinion scores for Baseline and Fine-tuned. A Kolmogorov-Smirnov test [37] generally rejects, at a standard significance level of 5%, the null hypothesis that our opinion score sample populations follow Gaussian distributions. Therefore, we use a Wilcoxon rank-sum test [38] to determine whether there are statistically significant differences in MOS between the two system variants. The *p*-values shown in Table 6 demonstrate that the performance of the two systems is rather equivalent. Specifically, these *p*-values indicate that there are no statistically significant differences between Baseline and Fine-tuned at a standard significance level of 5% given any of the 6 MOS questions.

During discussions conducted after the MOS test, the test subjects generally conveyed a positive reaction towards SV2SVT being possible with PolySinger. However, as anticipated, the participants mainly assessed PolySinger by the naturalness of the Japanese language used in the context of singing and the pronunciation of words. The most recurring observations from the participants, that were suggested as crucial improvements needed for the pursuit of natural Japanese singing, are summarized in Table 7. In the next section, we will discuss the comments in Table 7 as to why our processing and synthesis of Japanese might not have been of ideal quality, along with our plan for improving them in future. Moreover, the statistically insignificant difference between Baseline and Fine-tuned is also discussed along with techniques and technologies that may assist in improving PolySinger.

5. DISCUSSION

To produce natural Japanese speech synthesis, the front-end of a text-to-speech system requires phonetic and prosodic features [39]. Phonetic features, i.e., pronunciations, are typically acquired by grapheme-to-phoneme (G2P) conversion, and prosodic features, i.e., rhythm and intonation, are in Japanese typically acquired by phrase break prediction and accent estimation [40–42]. G2P conversion is particularly difficult in Japanese, since kanji characters can have multiple pronunciations. As indicated by our test subjects (C1 in Table 7) and discussed in [40], the accuracy obtained by dictionary-based G2P conversion in Japanese is not satisfactory. Japanese has no word separators, which also makes it difficult to determine phrase breaks. In our work, we performed word segmentation with `Nagisa` to avoid intra-word breaking, and attempted to define phrase breaks as the pauses transcribed by lyrics alignment on an English vocal performance. However, according to our test subjects (C5 in Table 7), these methods yielded limited success. As future work, we will inves-

<i>p</i> -value	0.228	0.389	0.115	0.509	0.279	0.557

Table 6. *p*-values, broken down by question, from a Wilcoxon rank-sum test comparing MOS scores from Baseline and Fine-tuned.

ID	Comment
C1	Incorrect readings of kanji
C2	Usage of keigo in casual language
C3	Direct translations where interpretations are needed
C4	Occasionally, lyrics are not entirely translated
C5	Both intra- and inter-word separation at unnatural places
C6	Missing keywords important to the song
C7	Wrong word order
C8	Improper mixture of feminine and masculine language

Table 7. Comments from discussions with the test subjects on essential improvements that could lead to more natural synthetic Japanese singing.

tigate the adaptation of SOTA methodologies in Japanese text-to-speech to SV2SVT such as phrase break prediction with large language models (LLMs) [41] and G2P conversion via machine translation [40].

In [15], they demonstrated an improvement in automatic lyrics translation by fine-tuning on paired lyrics that were not necessarily singable, but also by pre-training on mono-lingual lyrics. In this work, we avoided pre-training on mono-lingual lyrics and only fine-tuned on paired lyrics that were not necessarily singable, which resulted in no statistically significant improvement with respect to the baseline model (see Table 6). We applied a beam search to find translated lyrics that fit well into the syllable count of the original lyrics. The selected lyrics were occasionally not a full translation of the original lyrics (C4 in Table 7). Apart from the use of keigo (honorific language) being inappropriate for the inherent casual nature of song lyrics (C2 in Table 7), we conjecture that keigo could also be a major

cause of incomplete lyrics translations. This is because keigo will usually incorporate more characters than casual language, which means that it will be harder to fit the lyrics into the fixed syllable count.

In [16], they achieve SOTA results by training on a dataset created by back-translating mono-lingual lyrics and automatically aligning automatically-generated melodies that fit both the source and target lyrics. As future work, creating such a dataset and training an alignment decoder similarly to [16] could very well be adapted to Japanese. However, we hypothesize that translation systems have an inherent limitation towards cross-lingual songwriting that hinders them from rivaling professional human translators due to a lack of abstract interpretation and “imagination”. Hence, as future work, we will also investigate the usage of LLMs for sentiment analysis and feature extraction to exploit poetry/lyrics generation models. By lyrics generation, guided by keyword spotting, we can also address the issue of missing keywords (C6 in Table 7).

6. CONCLUSION

The goal of this paper has been to adapt conventional S2ST to the singing domain. To do so, we have built the first SV2SVT system, PolySinger, by cascading SOTA MIR technologies facilitating a modular tool for extended research in SV2SVT. We have conducted a MOS test with native Japanese speakers to evaluate PolySinger’s performance for English to Japanese SV2SVT. Results indicate that we have created a fundamentally-coherent structure for SV2SVT, but the translation of English lyrics into Japanese and the automatic synthesis of it is not yet natural enough. To further develop SV2SVT, our future work will investigate—to facilitate creative lyrics generation—the usage of sentiment analysis and feature extraction for abstract meaning representation of lyrics as opposed to translation. Finally, we will also investigate the necessities for autonomous generation of natural Japanese lyrics.

7. ACKNOWLEDGMENTS

This work has been funded by the Spanish Ministry of Science and Innovation under the “Ramón y Cajal” programme (RYC2022-036755-I). In addition, we want to express our heartfelt appreciation to the test subjects who voluntarily contributed to this study by participating in the perceptual quality test.

ON THE VALIDITY OF EMPLOYING CHATGPT FOR DISTANT READING OF MUSIC SIMILARITY

Arthur Flexer

Institute of Computational Perception
Johannes Kepler University Linz, Austria
arthur.flexer@jku.at

ABSTRACT

In this work we explore whether large language models (LLM) can be a useful and valid tool for music knowledge discovery. LLMs offer an interface to enormous quantities of text and hence can be seen as a new tool for 'distant reading', i.e. the computational analysis of text including sources about music. More specifically we investigated whether ratings of music similarity, as measured via human listening tests, can be recovered from textual data by using ChatGPT. We examined the inferences that can be drawn from these experiments through the formal lens of validity. We showed that correlation of ChatGPT with human raters is of moderate positive size but also lower than the average human inter-rater agreement. By evaluating a number of threats to validity and conducting additional experiments with ChatGPT, we were able to show that especially construct validity of such an approach is seriously compromised. The opaque black box nature of ChatGPT makes it close to impossible to judge the experiment's construct validity, i.e. the relationship between what is meant to be inferred from the experiment, which are estimates of music similarity, and what is actually being measured. As a consequence the use of LLMs for music knowledge discovery cannot be recommended.

1. INTRODUCTION

When developing and validating hypotheses in musicology, relevant information very often is obtained from written documents. This information from collections, anthologies, compilations, biographies, reviews, journals, etc is today often available in digitized formats, enabling usage of methods from natural language processing (NLP) for music knowledge discovery [1]. In the humanities such an approach is also known as 'distant reading' [2, 3], i.e. the computational analysis of large quantities of books and texts which cannot be handled by individual scholars in what is known as traditional 'close reading', i.e. very careful and detailed expert reading of only comparably few

texts. Large language models (LLM) [4–6] offer a convenient interface to enormous quantities of text and hence can be seen as a new tool for distant reading. In our previous work [7] we have evaluated the use of LLMs for distant reading of music similarity. Our results showed that music similarity, as measured via human listening tests, can to a certain degree be recovered from textual data by using ChatGPT as a distant reading tool. However, it also already became clear that the black box nature of LLMs, and especially of ChatGPT, presents a problem for the validity of such an approach.

In this article we therefore critically appraise our own previous work by utilizing an established framework of validity by Shadish et al. [8]. Validity is the truth of an inference made from evidence gathered through an experiment and as such an integral pillar of working scientifically. We will question our approach to music knowledge discovery concerning its statistical conclusion, internal, construct and external validity. All four types of validity have recently been discussed by applying Shadish et al. [8] to the context of music information research [9], which we will use as a guideline in this article. Reformulating our work in the general framework of validity will allow us to draw conclusions going beyond our particular music similarity setting to the general problem of using LLMs for music knowledge discovery.

We present related work in section 2 and explain the experimental setting (including preceding work we build on) in section 3. In sections 4 to 7 we critically appraise a primary study on human perception of music similarity [10], our own previous work with ChatGPT [7], as well as a number of additional ChatGPT experiments conducted for this work, all concerning four types of validity. We discuss our main findings and conclude in section 8.

2. RELATED WORK

Large language models (LLM) are deep neural models that learn representations of text by trying to predict the next word given a textual context. State of the art approaches are based on transformer architectures [4, 5], implementing an attention mechanism which learns to reweight parts of the textual input in relation to its importance for the task under consideration. ChatGPT (<https://openai.com/blog/chatgpt>) is a chatbot imitating a human conversational partner and is also based on

Flexer, "On the validity of employing ChatGPT for distant reading of music similarity", in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

a ‘Generative Pre-trained Transformer’ (GPT). We have used GPT-3.5, which itself is a fine-tuned version of GPT-3 [5], for our experiments in this paper and in our previous work [7]. A problem common to all members of the GPT family (including ChatGPT) is that exact details of models, training sets, parameters, etc are not known. A non peer reviewed report [6] by the developing team about the latest version (GPT-4) even states that "[...] no further details about the architecture (including model size), hardware, training compute, dataset construction, training method, or similar" can be given due to "safety implications" and the "competitive landscape" of LLM research.

ChatGPT has already been used in a music context rating instrument sounds on a set of 20 semantic scales [11]. It was found that ChatGPT’s answers are only partially correlated with human ratings, with Pearson correlations above 0.80 only achieved for clearly defined dimensions of musical sounds such as brightness (bright–dark) and pitch height (deep–high). This is closely related to another approach trying to extract psychophysical information from text by aligning GPT-4 results with human auditory experience [12]. Further applications of LLMs to music include lyrics summarization [13] and usage as ranking models for music recommendation [14]. Applying LLMs to music data is also reminiscent of preceding approaches computing music similarity from textual sources, including web-based data [15], semantic music tags [16] or lyrics [17]. There also exists related work in the text domain, e.g. on using LLMs for evaluation of jokes [18, 19].

Previous work on distant reading in music information research (MIR) includes automatic band member detection and automatic recognition of all their released records from internet text sources [20], sentiment analysis of a large corpus of Pop music reviews [1], discovery of social and professional networks from Wikipedia articles on Renaissance musicians [21], extraction of semantic information from an online discussion forum on Carnatic music [22], or very detailed cross-linking of references to musical passages in musicological texts [23].

3. EXPERIMENTAL SETUP

In our previous research [7] we explored whether ChatGPT can be used to ‘distant read’ the similarity between songs and compared the results to a study employing human listening tests on the same pairs of songs [10]. ChatGPT therefore has to recover music similarity, as judged by humans listening to audio, solely from textual data. Textual sources could also provide complementary information like cultural connotations, or other forms of so-called music context [24]. Such information is of course not present in music audio alone, but the mere knowledge of such contextual facts may nevertheless influence human listeners in their judgement. Our major hypothesis therefore was:

"Music similarity estimated with ChatGPT correlates positively with human perception of music similarity"

In order to being able to properly discuss the validity of conclusions drawn from the respective experiment, we must identify its components. *Treatments* are the things applied to *units* in order to cause an effect. In our case the participants and ChatGPT are the treatments, while the set of questions (pairs of songs to be evaluated) are the units. The effect we want to cause is to gain an estimate of music similarity. *Observations* are what is measured on a unit, in our case the music similarity ratings ranging from 0 to 100.

3.1 Human evaluation of music similarity

The primary study conducted a series of listening tests with human participants [10], with the age of participants ranging from 26 to 34 years with an average of 28.2 (three females and three males, called graders S1 to S6 from here on). The 5×18 songs belonged to five genres (for a full list see section A of the appendix of the original article (<https://doi.org/10.5334/tismir.107.s1>)): (i) **American Soul** from the 1960s and 1970s with only male singers singing; (ii) **Bebop**, the main jazz style of the 1940s and 1950s, with excerpts containing trumpet, saxophone and piano parts; (iii) **High Energy** (Hi-NRG) dance music from the 1980s, typically with continuous eighth note bass lines, aggressive synthesizer sounds and staccato rhythms; (iv) **Power Pop**, a Rock style from the 1970s and 1980s, with chosen songs being guitar-heavy and with male singers; (v) **Rocksteady**, which is a precursor of Reggae with a somewhat soulful basis. All songs had limited popularity with under 50.000 accesses on Spotify at the time of the study. The authors validated genres via respective Wikipedia artist pages as well as by listening to all songs. Fifteen seconds of a representative part of every song (usually the refrain) were presented in the listening tests and participants were asked to:

"assess the similarity between the query song and each of the five candidate songs by adjusting the slider" (ranging from 0 to 100 %) and "to answer intuitively since there are no wrong answers"

Based on randomly chosen 15 query songs, comparisons of five pairs had to be made for every query group yielding a total of $15 \times 5 = 75$ pairs, with every song appearing exactly once in the whole questionnaire (15 as query songs, 75 as candidate songs).

3.2 ChatGPT evaluation of music similarity

For our initial experiments [7] conducted on the 5th and 6th of April 2023 we used the "Free Research Preview" of the ChatGPT Mar 23 Version (<https://openai.com/blog/chatgpt>). The service came with a warning that "ChatGPT may produce inaccurate information about people, places, or facts" and the information that "ChatGPT is fine-tuned from GPT-3.5, a language model trained to produce text. ChatGPT was optimized for dialogue by using Reinforcement Learning with Human Feedback (RLHF) – a method that uses human demonstrations

and preference comparisons to guide the model toward desired behavior".

We asked ChatGPT the following question for the exact same $15 \times 5 = 75$ song pairs as used in the human listening test:

"On a scale of 1 to 100, how similar is the song [s_i] by [artist_A] to the song [s_j] by [artist_B]?"

Interestingly, ChatGPT sometimes needed persuasion to provide an answer at all, stating e.g. that "As an AI language model, I do not have the ability to directly listen to music or interpret subjective qualities such as similarity between songs", or that any answer would be "merely speculation". The following additional input sentences (in that order) provided by us in ensuing dialogues always resulted in ChatGPT providing a similarity score:

1. "Please just make a guess based on the information you have already"
2. "Please try anyway"
3. "Then please just speculate"

Such additional persuasion was necessary for 8 out of 75 questions, mostly at the beginning of ChatGPT sessions. Experiments had to be split over three separate sessions due to restriction of the free ChatGPT version.

4. STATISTICAL CONCLUSION VALIDITY

Statistical conclusion validity is "the validity of inferences about covariation between two variables" [8]. Here the main concern is with *statistical significance*, i.e., that an observed covariation between treatment and effect is not likely to arise by chance.

In accordance with the initial study [10], we recorded the music similarity ratings and then, to gain an estimate of the level of agreement between human participants and ChatGPT, we analysed degrees of inter-rater agreement. Specifically, we computed the Pearson correlations ρ_{listen} between graders S1 to S6 as well as ρ_{gpt} between graders S1 to S6 and ChatGPT for the 75 pairs of query/candidate songs (see table 1 for an overview of all results). The human listening test had been conducted twice at time points t1 and t2 with a two week time lag [10]. The 15 plus 15 correlations ρ_{listen} (t1 and t2) between the six graders range from 0.59 to 0.86, with an average of 0.74. The 6 plus 6 correlations ρ_{gpt} (t1 and t2) between the six graders and ChatGPT are considerably lower, with a range from 0.39 to 0.72 and an average of 0.58. The correlation ρ_{gpt} is statistically significant, i.e. the probability that we observe such a positive correlation by chance is basically zero ($t(898) = -17.83$, $p=0.00$). Hence, a valid statistical conclusion is that we observe a significant covariation between the human participants and ChatGPT in the observed estimates of music similarity. This result therefore seems to corroborate our hypothesis that music similarity estimated with ChatGPT correlates positively with human perception

	five genres		one genre
agreement	inter	intra	inter
ρ_{listen}	0.74	0.80	0.24
ρ_{gpt}	0.58	0.68	0.06

Table 1. Overview of results for five and one genre experiments. Shown are levels of inter- and intra-rater agreement between human participants (ρ_{listen}) and between human participants and ChatGPT (ρ_{gpt}).

of music similarity. In addition, the differences in correlation between ρ_{listen} and ρ_{gpt} are also statistically significant ($t(40)=6.05$, $p=0.00$).

5. INTERNAL VALIDITY

Internal validity is "the validity of inferences about whether the observed covariation between two variables is causal" [8]. It is therefore focused on the *cause* of a particular response to the treatment, going beyond statements concerning only the strength of covariation. A typical threat to internal validity is *confounding*, which is the confusion of the treatment with other factors, often arising from poor operationalisation in an experiment.

For our specific experiment we are interested in estimates of music similarity, either via listening tests with humans or from text sources via ChatGPT. One explanation for the observed level of rater agreement ρ_{gpt} is that indeed human perception of audio music similarity is positively correlated with ChatGPT estimates of music similarity. This is certainly one explanation consistent with our observations, but is it the only one? The internal validity of this conclusion relies on the key assumption that the observed positive correlation can *only* be explained in terms of music similarity and that there is no other way to arrive at the observations.

However, already in the initial study [10], participants commented that the genre of the songs was an important factor when evaluating the similarity of songs. When both query and candidate songs belonged to the same genre, similarity ratings were on average higher (within genres: 43.09) when compared to song pairs from different genres (between genres: 30.10). For our initial ChatGPT experiments [7] we have observed something related in the explanations provided by ChatGPT together with the similarity ratings. We provide some exemplary ChatGPT explanations with different levels of detail in table 2. As is typical for the answers ChatGPT provided, genre, instrumentation or era of recording are being discussed. A standard definition [25] of music genre states that it is "a set of musical events ... governed by a definite set of socially accepted rules", with musical events being "any type of activity performed around any type of event involving sound". Sound events are of course also linked to the concept of music similarity, making it clear that music genre and similarity are related but not synonymous concepts.

We therefore repeat the analysis of similarity ratings re-

"These two songs are from very different genres and have distinct musical styles."
"[...] I can attempt to speculate based on the artist's genre and the era of the music"
"They are from different musical genres, different eras, and have different rhythms, melodies, instrumentation, and lyrics."
"Both songs share some similarities in terms of their musical genres, but they are likely to have different arrangements, melodies, and lyrics."
"While both songs are in the broad category of popular music, they come from different genres (soul/R&B for Major Harris and reggae for The Heptones) and have different rhythms, melodies, instrumentation, and lyrics."
"[...] given that both artists were active in the same time period and were part of the Jamaican music scene, it is possible that there may be some similarities in terms of instrumentation, rhythm, or vocal style"

Table 2. Typical explanations provided by ChatGPT.

garding genres of query/candidate songs and get the following results: within genres: 43.13, and between genres: 13.42. Just as for human ratings, ChatGPT ratings seem to rely at least in part on genre information and not music similarity alone. This then calls into question how the design of our experiment relates to what we actually want to measure, which is music similarity. This is where construct validity becomes relevant.

6. CONSTRUCT VALIDITY

Construct validity is “the validity of inferences about the higher order constructs that represent sampling particulars” [8]. This concerns the operationalisation of the experimentalist’s intention, i.e. the relationship between what is meant to be inferred from an experiment and what is actually measured. In our case the higher order construct is music similarity.

An important part of the operationalisation of our experiment is the exact form of questions the participants (“assess the similarity between the query song”) and ChatGPT (“how similar is the song”) are being asked. Both questions clearly aim at the similarity between songs but do not specify what exact aspect of similarity is meant. Many possibilities come to mind, e.g. similar in terms of melody, tempo, instrumentation, time of publishing, or maybe genre? In-

deed, as has already been explained above, human participants commented that the genre of the songs was an important factor when evaluating the similarity of songs. Many of the explanations provided by ChatGPT were also about music genre or instrumentation, with the latter being an indirect indication of genre. A decisive difference is however that we of course trust in the honesty of human participants when answering post-experiment questions concerning their strategies, while with ChatGPT such trust seems unwarranted. ChatGPT has been criticized for sometimes ‘hallucinating’ [6] facts that sound plausible but are actually incorrect. We verified that ChatGPT’s argumentation seems to be correct basically all the time by searching and reading respective online sources (e.g. Wikipedia or Discogs), or by listening to the audio. Nevertheless the black box nature of LLMs and especially ChatGPT is a problem for judging construct validity. Since the exact training data and modeling approach are unknown [6], we have no way to judge whether ChatGPT really used genre clues for providing music similarity scores. One possibility is that respective webpages about artists and songs, often including genre information, have been part of ChatGPT’s training data, allowing ChatGPT to reproduce this content when being queried accordingly. Indeed recent results indicate that LLMs seem to memorize large parts of their training data [26].

One way to test the hypothesis that ChatGPT uses genre information when judging music similarity is to repeat the experiment with music from a single genre. The initial study [10] repeated the listening tests with 90 songs all belonging to the genre **Power Pop** (for a full list see section B of the appendix of the original article (<https://doi.org/10.5334/tismir.107.s1>)) with 28 participants of an average age of 25.6. The average inter-rater agreement between human participants ρ_{listen} dropped from 0.74 to 0.24 when the song material was restricted to a single genre (see table 1). We now repeat the ChatGPT experiments with the restriction to **Power Pop** songs only. The average inter-rater agreement between human participants and ChatGPT ρ_{gpt} drops from 0.58 to 0.06 (see table 1). It seems that without the possibility to resort to genre information, ChatGPT has severe problems to rate music similarity. In the explanations provided by ChatGPT, it is often correctly stated that both songs “were part of the power pop genre during the same era”, but sometimes also subgenres are being named when justifying certain scores, e.g. “... leans towards a pop-rock sound ... while ... tends to blend progressive and art-rock elements” or “... was associated with power pop and new wave music, while ... was known for its indie rock and power pop sound”. Nevertheless the scores provided by ChatGPT remain very restricted, essentially consisting of three values (30, 40, 50) around the middle of the possible range.

From these results it seems evident that the poor operationalisation of the experiment, essentially not asking a clear enough question, has led to a lack of construct validity: we were aiming for music similarity as a higher order construct but music genre seems to also have been a

relevant aspect for both human participants and ChatGPT when answering questions during the experiments. For the human participants this problem became already evident during post-experiment questioning and was then only corroborated with the restricted single genre experiment. The lack of trust due to ChatGPT's black box nature however made the same experiment inevitable to clarify construct validity of the ChatGPT experiment.

Another way to question construct validity is to assess the outcomes of different experiments which are supposed to measure the same higher order constructs. We could for instance study correlations of results from different LLMs being queried with identical prompts. Low correlations between LLM outputs could point to problems of construct validity. This kind of testing already points to the concept of external validity.

7. EXTERNAL VALIDITY

External validity is "the validity of inferences about the extent to which a causal relationship holds over variations in experimental units, settings, treatment variables and measurement variables" [8]. Therefore, external validity is the truth of a generalised causal inference made from an experiment. It is clear that if a causal inference we draw from an experiment already lacks internal validity, then generalising that inference to variations not even tested will not have external validity. In addition, a major threat is that variation of components of an experiment might dismantle the causal inference that holds in the experiment.

One component that could be varied are the annotators, i.e. the human participants or the type of LLM employed. Already in the initial experiment [10] it became clear that human annotators only agree to a certain extent in their evaluation of music similarity (average ρ_{listen} of 0.74). This is because human perception of music is highly subjective with personal taste, listening history, familiarity with the music, current mood, etc, being important influencing factors [24, 27]. Such a lack of inter-rater agreement presents a problem of external validity because inferences from the experiment do not generalize from users or annotators in the experiment to the intended target population of arbitrary users/annotators. It would be interesting to test the level of agreement between ChatGPT-3.5, which has been used for the experiments in this paper, and newer versions like ChatGPT-4 [6] or even alternative LLMs like Google's Gemini (<https://gemini.google.com/>), LLaMA [28] or Alpaca [29]. There already is evidence that ChatGPT's responses differ between different versions [30]. In case we want the conclusions drawn from our experiment to have external validity beyond one specific type of LLM, such additional experiments would of course be necessary.

One could even ask the question what the level of agreement within one person is when faced with identical annotation tasks at different points in time. Results from the initial experiment already showed that such an intra-rater agreement, tested two weeks apart, is only slightly higher than inter-rater agreement [10] at 0.80 versus 0.74.

We therefore also repeated our ChatGPT five genre experiment on January 5, 2024, nine month after the first experiment. Although the LLM used was supposedly still a ChatGPT-3.5 version, the intra-rater agreement was only at 0.68. This is actually not much higher than the inter-rater agreement between human participants and ChatGPT ρ_{gpt} at 0.58. It therefore seems that there is a lack of external validity when generalizing ChatGPT results to different points in time.

Another problem of external validity is the influence of prompt engineering on LLM results. It is known that slight variations in prompt formulation can lead to quite different results, which brought about a whole new 'science' of so-called 'prompt engineering' [31]. One example is 'chain-of-thought prompting', where a few chain of thought demonstrations provided to an LLM as prompts lead to improved results [32]. 'Positive thinking' prompts like "You are an expert mathematician" also improve LLM performance and automatic prompt optimization sometimes produces quite bizarre results [33]: answer prefixes with an affinity to the science fiction show Star Trek (e.g.: "Captain's Log, Stardate [insert date here]: We have successfully plotted a course through the turbulence and are now approaching the source of the anomaly.") are able to boost some LLM's proficiency in mathematical reasoning. The reproducibility of LLM experiments seems doubtful given that seemingly irrelevant variations in prompting can have such big influence on results.

8. DISCUSSION AND CONCLUSION

In this work we applied the formal framework of validity [8] to music knowledge discovery, thereby enabling a critical appraisal of using Large Language Models (LLMs) for 'distant reading' of music knowledge. This was demonstrated for the extraction of psychophysical information from text by comparing GPT-3.5 results to human auditory experience. Specifically we re-evaluated our own previous results [7] of using ChatGPT to gain 'distant reading' estimates of music similarity. By evaluating a number of threats to validity and conducting additional experiments with ChatGPT, we were able to show that internal, construct and external validity of our approach are seriously compromised.

A re-analysis of music similarity ratings separate for different or similar pairs of music genres showed that in our experiment music similarity is confounded with genre. Both human participants and ChatGPT at least partly rely on the confounding factor of genre when judging music similarity, which is a clear breach of internal validity. This lead us to scrutinize the operationalisation of the experiment and its construct validity. A closer assessment of the exact questions being asked during the experiment made it evident that they are not precise enough concerning what is actually meant with music similarity. Post-experiment interviews with human participants made clear that they indeed used genre as indication of music similarity. Because of the blackbox nature of ChatGPT, and its doubtful relation to factuality, we had to conduct an additional ex-

periment to corroborate that ChatGPT also relies on genre information. This additional experiment with music from a single genre lead to a complete breakdown of the correlation between human and ChatGPT estimates of music similarity. We also appraised external validity by asking whether our results would generalize to variations in the experimental setting like employing different LLMs or versions thereof or making slight changes to prompts. We conducted a repetition of the ChatGPT experiment with a nine month time lag and showed that correlation of results is moderate at best, although the LLM is supposedly still based on the same version of GPT-3.5.

The overarching question we wanted to answer with this work is whether LLMs can be used as a distant reading tool of music knowledge. The main obstacle seems to be the opaqueness of systems like ChatGPT which make it very hard to judge their construct validity. This opaqueness is evident from the developing team’s own statements concerning their unwillingness to share details about their algorithm [6]. This has lead researchers to state that "it is particularly hard to perform scientific experiments, especially since human feedback causes their behaviours to change at a rapid pace" [34]. The latter statement points to the additional problem of constant re-training of models, which might explain the lack of external validity we observed when repeating our experiment with a nine month time lag. It has also lead to speculations as to how ChatGPT actually works, e.g. showing that it performs better when the correct output is a high-probability word sequence, indicating that one should be careful in low-probability situations [35]. This might be connected to the fact LLMs seem to memorize large parts of their training data [26]. It has also been pointed out that the “reasoning process” of LLMs is fundamentally different from humans, as LLMs basically just sample from a probability distribution [34]. As they are not embodied agents in the physical world, their understanding and knowledge lacks symbol grounding [36]. LLMs do not experience the world directly but model the world of text, which of course is a very indirect representation of the real world.

As a concluding comment we want to state that ChatGPT is not a suitable tool for distant reading of music knowledge because of its essentially black box nature which entails severe problems of judging its construct validity. Future work should explore whether open source alternatives like LLaMA [28], Alpaca [29] or OpenAssistant (<https://github.com/LAION-AI/Open-Assistant>) will be able to change assessment of the usefulness of large language models for distant reading.

9. ACKNOWLEDGMENTS

This research was funded in whole by the Austrian Science Fund (FWF) [10.55776/P36653]. For open access purposes, the authors have applied a CC BY public copyright license to any author accepted manuscript version arising from this submission.

10. ETHICS STATEMENT

For all experiments with human involvement, informed consent to participate in the respective studies was obtained from participants in accordance with university and international regulations.

As a potential societal implication we like to mention the fact that it is not known what precise data any of the ChatGPT versions have been trained on. There is however a reasonable suspicion that OpenAI, the company behind ChatGPT, did not obtain legal consent from all creators of text it used during training procedures. As a consequence, anyone using ChatGPT for their own purposes, including distant reading of music knowledge, would be implicated with the corresponding ethical issues.

ABSTRACT

Music source separation demixes a piece of music into its individual sound sources (vocals, percussion, melodic instruments, etc.), a task with no simple mathematical solution. It requires deep learning methods involving training on large datasets of isolated music stems. The most commonly available datasets are made from commercial Western music, limiting the models' applications to non-Western genres like Carnatic music. Carnatic music is a live tradition, with the available multi-track recordings containing overlapping sounds and bleeds between the sources. This poses a challenge to commercially available source separation models like Spleeter and Hybrid Demucs. In this work, we introduce *Sanidha*, the first open-source novel dataset¹ for Carnatic music, offering studio-quality, multi-track recordings with minimal to no overlap or bleed. Along with the audio files, we provide high-definition videos of the artists' performances. Additionally, we fine-tuned Spleeter, one of the most commonly used source separation models, on our dataset and observed improved SDR performance compared to fine-tuning on a pre-existing Carnatic multi-track dataset. The outputs of the fine-tuned model with *Sanidha* are evaluated through a listening study.

1. INTRODUCTION

Carnatic music is a traditional "art music" genre from the Southern part of India. Carnatic Music is largely improvised, requiring all musicians to utilize a complex understanding of the melodic and rhythmic structures of the music to improvise coherently. Carnatic performances generally feature four to five musicians centered around a vocalist in the lead role. The core instruments are the violin, in both supportive and lead roles; the *mridangam*, a tonal two-sided drum that provides rhythmic support; and

¹ *Sanidha* dataset (Licensed under CC-BY-4.0) is hosted in the server: <https://ccml.gtcmt.gatech.edu/data/Sanidha>

the *ghatam*, a clay pot instrument that contributes rhythmic patterns to complement the *mridangam* in a higher frequency range. Carnatic Music performances are also accompanied by a *tanpura*, which constantly oscillates the *sa*, the tonic, and either the *pa*, the fifth or sometimes *ma*, the fourth. All the instruments are tuned to these frequencies, including the percussion instruments, which, too, have tonal qualities [1]. This leads to a significant overlap of frequency content, making Carnatic Music source separation almost impossible with simple dictionary learning methods [2].

Like most traditional music genres, Carnatic Music is performed live [1]. Thus, recordings of Carnatic Music lack multi-track isolation, as microphones inevitably capture signals from multiple instruments as well as the audience—these unwanted signals are known in music production as leakage or “bleed.” This contrasts with Western pop music, where completely isolated multi-tracks are commonplace, and many source separation datasets are available [3–6]. The most extensive open-source Music Information Retrieval (MIR) dataset of Indian art music—the *Saraga* dataset [7]—exhibits significant leakage between different audio tracks: For example, the sound of the violin is audible in the vocal track - The bleeding of other sources into other microphones is significant [8–10].

1.1 Leakage Problem

Consider a signal \mathbf{s} , noise \mathbf{n} , and a mix \mathbf{x} , at 0 dB Signal-to-Noise Ratio (SNR): $\mathbf{x} = \mathbf{s} + \mathbf{n}$, where $\mathbf{x}, \mathbf{s}, \mathbf{n} \in \mathbb{R}^d$. Let $\mathbf{s}_t, \mathbf{n}_t \in \mathbb{R}^d$ such that they represent ground truth signal and noise with bleed. Assume no microphone sensor noise and no Room Impulse Response (RIR). Then

$$\mathbf{x} = \mathbf{s}_t + \mathbf{n}_t \quad (1)$$

$$\mathbf{s}_t = f(\mathbf{s}, \mathbf{n}) = \alpha \mathbf{s} + \beta \mathbf{n} \quad (2)$$

where $\alpha \in [0, 1]$ and $\beta \in [0, 1]$, using Eq. 1, it follows that

$$\mathbf{n}_t = g(\mathbf{s}, \mathbf{n}) = (1 - \alpha)\mathbf{s} + (1 - \beta)\mathbf{n} \quad (3)$$

Assume that functions f and g are linear time-invariant functions for all audios. However, the α and β values will vary for different signals in a general unclean dataset.

Let the source separation function trained with $(\mathbf{s}_t, \mathbf{n}_t)$ as the ground truth be \mathbf{F} , such that

$$\mathbf{F}(\mathbf{x}) = (\hat{\mathbf{s}}, \hat{\mathbf{n}})$$

Figure 1. Problem of Poor Ground Truth

For simplicity, let us assume \hat{s} , s_t and \mathbf{n}_t lie in the same subspace as s and \mathbf{n} ; s and \mathbf{n} are orthogonal to each other i.e. $s^T \mathbf{n} = 0$ as seen in Figure 1.

The most common metric used for evaluation and loss in the source separation community is the Signal-to-Distortion Ratio (SDR) and, more recently, the Scale-Invariant version of SDR called SI-SDR [11]. For simplicity, let's consider using SDR for evaluation since the idea can easily be extended to SI-SDR. SDR is defined by [12] for the `BSS_eval` toolbox (which is the same as classical SNR) as:

$$\text{SDR}_s = 10 \log_{10} \left(\frac{\|s\|}{\|s - \hat{s}\|} \right)$$

Given that f and g functions vary for each audio, the SDR formula above is modified for data with bleed as:

$$\text{SDR}_{s,mod} = 10 \log_{10} \left(\frac{\|s_t\|}{\|s_t - \hat{s}\|} \right)$$

These objective results from SDR, however good, will never truly represent what the original source must sound like. Training on data with a significant bleed will never push the predicted \hat{s} towards the actual source s , since the loss function will be trained on the modified function dependent on sources with bleeding.

Furthermore, the result will be subpar after incorporating scale invariance [11]. If we calculate the norm of s_t and \mathbf{n}_t , using Eq. 2, 3, and the triangle inequality, we can prove:

$$\|s_t\| + \|\mathbf{n}_t\| \leq \|s\| + \|\mathbf{n}\| \quad (4)$$

This means that if we had to calculate the average SI-SDR of the signal and the noise with respect to the sources with bleed, the error would be significant. This error will be large when compared to calculating it with respect to "true" sources, which are inaccessible. It is also important to note that this was based on the assumption that all were in the same subspace, but that is never true in real scenarios, resulting in increased error.

Hence, the *Saraga* dataset cannot be used as accurate ground truth data for supervised source separation models for both training and especially evaluation, hindering the development of such models for Carnatic Music. As a workaround, some have attempted using source separation models like Spleeter [13], presumably trained on

a few or no Carnatic Music examples [9], directly on the vocal multi-track with bleeding for certain MIR tasks [8, 10]. However, attempts toward source separation for Carnatic using the currently available datasets have been made [2, 9, 14].

The stems obtained for Western Music datasets [3–6] are all from studio recordings, recorded separately and mixed, resulting in zero bleeds of other instruments in the multi-tracks. This allows for evaluation metrics such as SDR, Scale-Invariant SDR [11], Signal-to-Artifacts Ratio, Signal-to-Interference Ratio (SIR), etc., to be used without problems. However, there is no such available dataset for Carnatic Music [2, 9], and since it is a live tradition, it is impossible to record the artists at separate times.

There have been a lot of datasets for Carnatic Music and Hindustani Music, which provide clean studio-quality data for individual instruments [15, 16]. However, there have been no completely isolated full live concert recordings of studio quality. To directly address this requirement, we present a new dataset of well-isolated multi-track recordings of Carnatic Music: *Sanidha*. The *Sanidha* dataset features audio and video recordings of Carnatic musicians playing together in real-time but in total isolation within a modern studio environment.

2. METHODOLOGY

Serra [17] proposed five essential considerations when creating new corpora: purpose, coverage, completeness, quality, and reusability. These considerations guided the creation of the *Saraga* dataset of Indian art music, [18], and we have worked to apply the same principles to the construction of *Sanidha*.

The isolated tracks for the commercial Western music source separation datasets are often created by the process of overdubbing in the studio. Carnatic Music must be improvised collectively in real-time, so parts cannot be "overdubbed" one at a time, thereby posing a significant challenge. Carnatic musicians listen closely to each others' playing and communicate extensively using visual cues. In particular, the vocalist often indicates the *taalam* (metric structure) with their hands. Visual cues are critical during fully improvisational sections like the *kalpana swaram* and *tani avartanam*. Consequently, the only way to record the music with audio isolation is for each musician to play in separate rooms while maintaining communication through audio and video.

2.1 Recording Sessions

We organized five Carnatic music concerts within our recording facility in March of 2024. Concert sessions lasted 2–3 hours, garnering an average of 1.6 hours of music per concert once silence between pieces was edited out. To perform these concerts, we recruited fifteen professional Carnatic musicians from Atlanta's thriving Carnatic music scene. All the artists voluntarily agreed to contribute to the dataset for research purposes, with no compensa-

tion².

Our musicians included three male vocalists, two female vocalists, four violinists, and six percussionists. Two out of five concerts featured a vocalist accompanied by the full set of core Carnatic instruments (violin, *mridangam*, and *ghatam*). The other three concerts proceeded without a *ghatam* player—which is not unusual for the style. Through the efforts of multiple talented musicians, we were able to capture gender diversity in the vocal timbre and a wide array of stylistic and improvisational approaches, which enhances the value of our data to the research community.

2.2 Recording Facility and Setup

The dataset was recorded in four rooms of the West Village Music Annex, in the Georgia Institute of Technology’s campus in Atlanta, Georgia, USA. These rooms are multi-purpose spaces with large acoustic curtains, which enhanced our ability to control reverberation and maintain adequate isolation. The four isolated rooms have connection points wired to a single recording control room, including low-impedance, balanced analog audio, and digital video (SDI) connections. The control room uses a 32-channel digital mixing console to control audio routing and doubles as a multi-channel audio interface for digital audio recording into our Digital Audio Workstation (DAW). A *tanpura* drone, generated by a *shruti* box or a video from the internet, was also routed to each artist’s headphones from the control room. We used the board’s on-board reverb, compression, and equalization effects to create custom monitoring mixes sent to their headphones/in-ears, catering to individual artist needs and simulate the live traditional performing scenario of Carnatic Music.

Each artist’s performance video was captured using a professional 4K video camcorder. The recorded video feed was then delivered through SDI cables from each room to the control room to generate a multi-source mixed feed, allowing us to transmit all four video feeds within a 2x2 grid (Figure 2). Musicians could see the 2x2 feed projected onto a screen in the performance room, allowing them to observe each other at all times.

Our musicians had little to no experience performing in a studio setting, isolated from each other, with headphones/in-ears on. Our efforts were focused on ensuring that the recording sessions were comfortable for the musicians and maintained the “natural” performance feeling as much as possible. Despite our best efforts, our musicians noted specific challenges performing within the constraints of the setup and sometimes felt that it slightly affected the quality of their performance.

Though our audio-monitoring setup achieved close to zero latency, we found that our video-monitoring setup lagged by about 50 ms, possibly due to the converters used to transmit the video feed to the projectors. This made it extremely difficult for the artists to coordinate with each

other, since they could not follow the *taalam* or beat given by the vocalist. To overcome this problem, we used a *proxy-taalam* setup. One of our team members would sit in front of each artist (except the vocalist) and provide the visual *taalam* cue by focusing on just the audio feed from the vocalist. This setup was most helpful for our percussion artists; even the violinists appreciated it during the improvised *kalpana swaram* sections. The *proxy-taalam* setup allowed the musicians to play in time with each other, react to the cues from the vocalist similar to a live concert setup, and make the improvisational sections of Carnatic Music - *tani avartanam* and *kalpana swaram* sections possible.

We also identified a potential issue much later when we observed that some artists partially removed one side of their headphones in the middle of their performance. In some cases, artists required loud headphone output. This resulted in slight bleeding of the headphone output to the performer’s microphone. To combat this, we shifted the monitoring system to in-ear monitors exclusively for all further concerts, which nullifies possible bleeding from headphones.

2.3 Audio Data

For each concert, we recorded six (excluding *ghatam*) or eight (full group) separate unprocessed audio tracks. Vocalists were recorded using a single microphone; the other instruments were recorded using two microphones each. We captured the violin and *mridangam* in a standard stereo (left-right) image. The *ghatam* recording setup used two microphones as well. A line-in track was used to record the *tanpura* drone.

In total, we have nearly eight hours of recorded music, across the five concert sessions. The recorded audio is in WAV format, with CD-standard sampling rate of 44.1 kHz and a bit depth of 16 bits. Table 1 displays all the individual concert durations.

2.3.1 Microphones

For each concert, we used different combinations of microphones, maximizing the sonic variety of the data. The choices of microphones were professional, studio-grade condenser microphones with cardioid polar pickup patterns, with each instrument requiring matched pairs of identical microphones. The use of high-fidelity condenser microphones contrasts with the dynamic microphones used commonly in traditional Carnatic music concerts. However, capturing the highest fidelity audio will produce the most broadly usable data. A series of non-linear operations can be performed at the post-processing stage to alter high-fidelity signals to sound more like dynamic microphones. The details of the microphones used for each instrument are stored in a JSON file located within respective concert folders.

For our first concert, the vocal microphone was placed close to the vocalist’s mouth. We realized that this position obstructed the video of the performer’s face. For all subsequent concerts, we corrected this by placing microphones

² The concerts were conducted with the approval of the Georgia Tech Institution Review Board (IRB) (ethics board), including two minors who were accompanied by their parents.

Concert	Instruments	Multi-tracks	Front-View Video	Side-View Video	Duration (hr)	Vocals Gender
1	Vocal	1	✓	-	1.08	Female
	Violin	2	✓	-		
	Mridangam	2	✓	-		
	Ghatam	2	✓	-

	Mridangam	2	✓	-		

Table 1. Dataset Details

closer to chest level, pointing upwards towards the mouth, ensuring an obstruction-free video.

We placed microphones for the violin and *mridangam* on either side of the artist, at a distance of approximately 50 cm. This positioning ensured microphone stability, kept the video feed unobstructed, and highlighted each instrumentalist’s gestures and hand movements. As the *ghatam* is a relatively quiet instrument, we placed the first microphone as close as possible to the playing surface. The second was pointed toward the opening of the *ghatam* at a distance of ≈ 30 cm. This can be seen in Figure 2.

2.4 Video Data

Performance video data for Carnatic is significantly limited compared to Hindustani music. The access to video data has given rise to a significant interest in the multi-modal analysis of Hindustani music among the MIR community [16, 19–21]. Our motivation to include video recordings with our dataset is to promote multi-modal research endeavors for Carnatic music.

All of our videos are recorded at 29.97 FPS in 1080p. The snapshot of the front view videos of each instrumentalist can be seen in Figure 2. The lighting for all the videos takes advantage of the many light sources available in the multi-purpose recording rooms.

For each concert, we successfully captured the front-view videos of every musician and included an additional side view of the vocalist. This combination is a first for a dataset of this kind.

The framing of the front-view videos is similar to the stills used in [20]. To ensure a solid background, we placed solid black sound panels behind the vocalists and solid yellow curtains behind the other artists, as seen in Figure 2.

Figure 2. Snapshot of the Front-view videos of Concert 3

2.5 Supplementary Information

2.5.1 Metadata

To fulfill Serra’s completeness criteria, we collected annotations and metadata similar to *Saraga* [7]. This metadata is stored in separate JSON files for each song performed during the concerts. The metadata includes the composition name, original composer, and the performers’ names and roles. We also include relevant music-theory information regarding the compositions, mentioning the *rāgam*, *tālam*, and song form.

2.5.2 Section Annotations

The song form is encoded as audio timestamps indicating the start and end of each major musical section for every song: the key sections are the *aalapana*, *pallavi*, *anupallavi*, *muktayi swaram*, *charanam*, *cittai swaram*, *kalpana swaram* and *neraval*. The performing musicians were consulted to review all of the metadata.

2.5.3 Pitch Annotations

Carnatic music contains two melody sources: the lead vocals and the violin, which complements the vocals. Since

we have clean vocals and violin data, the Melodia algorithm proposed by Salamon and Gómez [22] was used to extract pitch (F0) contours for these two parts. The pitch tracks are stored in a two-column format, with the time stamps in the first column and the pitch values in the second.

2.5.4 Tonic Annotations

Obtaining the tonic frequency is relatively easy since we have a clean *tanpura* source within our multi-track data. We followed a similar approach used by Gulati et al. [23] and used Melodia [22] on the *tanpura* multi-track directly for the tonal feature extraction. The tonic does not change within a concert; hence, we included a single tonic file, which stores the tonic value in Hertz, inside each concert folder instead of having one for every song.

3. EXPERIMENTS

The experiments aim to cover the Coverage and Quality principles [17] introduced in Section 2 and demonstrate the value and usability of our new dataset with a simple source separation experiment.

It is important to note that our aim in this work is to demonstrate our data’s potential through these preliminary experiments and not benchmark performance against the state-of-the-art results for source separation of Carnatic Music.

3.1 Experiment Setup

We ran a simple two-stem source separation fine-tuning experiment on *Sanidha* and *Saraga* datasets using the Spleeter model [13]. Two-stem Spleeter training requires the vocals, accompaniment, and mix audios. We fine-tuned the pre-trained model using three different approaches: (1) using the *Sanidha* dataset, (2) using the *Saraga* dataset, (3) using curriculum training [24, 25] by partly fine-tuning the model with *Saraga*, and then fine-tuning it further with the *Sanidha* dataset. The curriculum training strategy presents the data to the model in a meaningful order to learn better. Using these three models will help us evaluate the potential of our data and its performance when combined with other Carnatic Datasets, in this case, *Saraga*.

Since *Sanidha* has fewer concerts than *Saraga*, the major problem which could arise, is the possibility of overfitting. To potentially avoid this, the third model is fine-tuned on *Saraga* for 225K steps (90% of the total steps), while the rest 10% is finetuned on *Sanidha* for 25K steps.

3.2 Sanidha Data Preparation

Sanidha’s audio data is of high quality as it was recorded in isolated spaces using condenser microphones with almost no bleed. Therefore, just linearly adding the signals to prepare mixes for training [26] will not be representative of the traditional Carnatic Concerts. To prevent this, we chose ten concerts from the *Saraga* dataset and used them as reference tracks to create two unique mixes for each of the five *Sanidha* concerts. Eight out of these ten *Saraga*

tracks are used as references for processing the training set and the remaining two are used for validation. The multiple mixes allow us to obtain twice the original amount of data. This can be considered as data augmentation since we have limited clean data. Our goal was to match the number of hours of training data used on the models individually trained on *Sanidha* and *Saraga* respectively, to make a fair comparison. The *Sanidha* training set makes up a total of 13.21 hours of audio data, and the validation set is 2.14 hours.

The critical mixing strategies for vocals and accompaniment include a combination of multiple non-linear and some time-varying operations - (1) Adding distortion, (2) Adding white noise, (3) Processing the stems through a digital amplifier plus cabinet models, (4) Heavy compression, (5) Adding reverb, (6) Attenuating the body of the instruments and vocals, and (7) High-cut filtering. Each of these operations is performed in varied amounts to match the sonic features of the reference tracks. The aim is to mix the tracks to emulate a real live concert while maintaining the isolated ground-truth audio.

The processed vocals (\mathbf{v}) and the processed accompaniment (\mathbf{a}) audios are linearly added at 0 dB SNR to create the mixture file ($\mathbf{m} = \mathbf{v} + \mathbf{a}$) for training. For the SNR computation, we consider the signal to be the vocals and the noise to be the accompaniment.

The third *Sanidha* concert was chosen for the validation set, as it has all of the typical instruments, including the *ghatam*. The rest of the concerts used in the training set maintain a good distribution of vocalist’s gender and vocal timbre, as seen in Table 1. We made two unique mixes for each song in the validation set, which totaled to 2.14 hours of mixture audio data.

3.3 Saraga Data Preparation

Seven out of the eight references *Saraga* concerts described in Section 3.2 make up the training set for the *Saraga*-trained model. As *Saraga* consists of live multi-track recordings from Carnatic concerts, the accompaniment audio is created by linearly adding all the multi-track audios except the vocals. For the validation set of the *Saraga*-trained model, we selected the same reference concerts from *Saraga* that were used to create the mixes for the validation set in Section 3.2.

The ground truth multi-tracks used have an inherent bleed in them [8–10], as described in Section 1. The purpose of using a noisy validation set from *Saraga* is to evaluate the model purely trained on *Saraga*, assuming the *Sanidha* dataset never existed. However, the metrics obtained in Table 2 are on the validation set used for *Sanidha* training. The total training duration comes to 12.37 hours. The remaining unused concerts in *Saraga* are used for the perceptual tests.

4. EVALUATION

4.1 Objective evaluation

We compute the SDR, SIR, SAR, and also the SI-SDR of each of the models for the *Sanidha* validation set. Table 2

			<i>Sanidha</i> - Objective Evaluation				<i>Saraga</i> - Perceptual Evaluation	
Models	Hours	Source	SDR	SIR	SAR	SI-SDR	Isolation	Audio Quality
<i>Saraga</i>	12.37	Vocals	7.66	17.05	8.02	6.65	0.596	0.627
		Accomp.	7.68	13.65	8.84	7.29	0.546	0.532
		Average	7.67	15.35	8.43	6.97	0.564	0.580
<i>Sanidha</i>	13.21	Vocals	7.86	17.38	8.26	6.93	0.598	0.635
		Accomp.	7.87	13.96	8.99	7.52	0.541	0.507
		Average	7.87	15.67	8.63	7.22	0.570	0.572
Mix	12.37 + 13.21	Vocals	7.63	16.88	8.00	6.62	0.605	0.621
		Accomp.	7.65	13.99	8.73	7.25	0.561	0.525
		Average	7.64	15.44	8.36	6.93	0.583	0.573

Table 2. Results

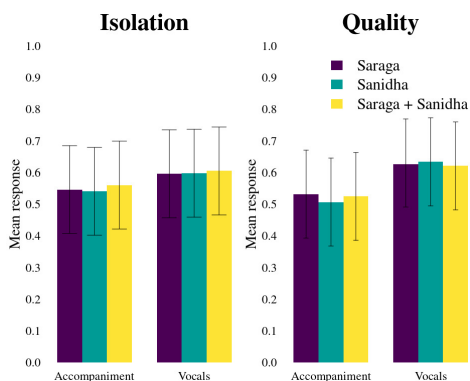

Figure 3. Mean participant responses across twelve conditions, with 95% confidence limits.

displays all the results.

We can see that the *Sanidha*-trained model has outperformed, however marginally, in all the objective metrics for vocals and the accompaniment separation. The improvement is only slight, perhaps because *Sanidha* was only trained on four concerts, while *Saraga* is trained on seven (which would mean seven unique vocalists as compared to four), even if the training hours are comparable. Also, the curriculum training technique performs almost similar to the *Saraga*-trained model.

4.2 Subjective evaluation

We conducted a listening study to evaluate the three source separation models and assess their perceptual effectiveness in isolating vocals and accompaniments in Carnatic Music.

The audio stimuli were selected after we randomly sampled four ten-second excerpts from four different *Saraga* recordings; If the randomly selected excerpt did not contain the three key instruments in Carnatic Music (vocals, violin, and the *mridangam*), we sampled again until an appropriate excerpt was identified. This iterative process ensured that our evaluation remains focused on relevant audio features while maintaining the unbiased nature of the sample selection.

In the listening study—approved by the Georgia Tech ethics board—fourteen participants listened to processed

versions of our selected excerpts. The survey was conducted in a manner similar to the MUSHRA framework [27]. All the participants responded to twelve questions for each excerpt, which focused on vocal isolation, vocal audio quality, accompaniment isolation, and accompaniment audio quality for the three models. This resulted in 48 questions per participant. These terms have been commonly used in subjective testing of source separation models [9, 28]. We used a slider-based metric for the evaluation, ranging from zero to one. Isolation and quality were explained with examples before the start of the survey and also presented as a reference for each question.

Average slider responses for the twelve conditions are shown in Figure 3 and in Table 2. We conducted a mixed-effects ANOVA on the data, with the participant and excerpt as random intercepts and the three variables (response type, target source, and model) as fixed effects. No effect was statistically significant, except for the target source (voice vs accompaniment), where participants tended to rate vocals higher in general ($\chi^2(8) = 45.97, p < .05$). This behavior is very similar to the objective results as well.

5. CONCLUSION AND FUTURE WORK

Although fine-tuning spleeter using *Sanidha* did not result in a significant source separation improvement, we cannot discount the importance of the availability of clean target sources for source separation. This is a clear distinction and advantage that our dataset collection methodology has over the existing *Saraga*. We can now use common metrics for source separation evaluation with a good degree of accuracy using our dataset, which was not possible with the existing *Saraga* dataset. Given the inherent challenges, our introduction of the *Sanidha* dataset marks a significant advancement in this domain. This novel dataset also presents an avenue for solving a multitude of other MIR and multi-modal tasks in Carnatic Music.

We will soon expand our dataset and invite more musicians to conduct concerts using our methodology. With the resources at hand, we aim to promote computational analysis for Indian Art music and pave the path towards more accessible research resources within the community.

6. ACKNOWLEDGEMENTS

We extend our gratitude to all the artists whose contributions have been pivotal to the creation of this dataset:

1. **Concert 1:** Amita Krishnan (Vocals), Sudharshan Prasanna (Violin), Vajraang Kamat (Mridangam), Tejas Veedhulur (Ghatam)
2. **Concert 2:** Salem Shriram (Vocals), Vishal Sowmyan (Violin), Anirudhah Narayanan (Mridangam)
3. **Concert 3:** Prashant Krishnamoorthy (Vocals), Nivik Sanjay Bharadwaj (Violin), Arvind Narayan (Mridangam), Vajraang Kamat (Ghatam)
4. **Concert 4:** Anjana Nagaraja (Vocals), Pranavi Srinivasa (Violin), Arvind Narayan (Mridangam)
5. **Concert 5:** Prasanna Soundararajan (Vocals), Vishal Sowmyan (Violin), Santosh Chandru (Mridangam)

BETWEEN THE AI AND ME: ANALYSING LISTENERS' PERSPECTIVES ON AI- AND HUMAN-COMPOSED PROGRESSIVE METAL MUSIC

Pedro Sarmiento Jackson Loth Mathieu Barthet

Centre for Digital Music
Queen Mary University of London

{p.p.sarmiento, j.j.loth, m.barthet}@qmul.ac.uk

ABSTRACT

Generative AI models have recently blossomed, significantly impacting artistic and musical traditions. Research investigating how humans interact with and deem these models is therefore crucial. Through a listening and reflection study, we explore participants' perspectives on AI- vs human-generated progressive metal, in symbolic format, using rock music as a control group. AI-generated examples were produced by ProgGP [1], a Transformer-based model. We propose a mixed methods approach to assess the effects of generation type (human vs. AI), genre (progressive metal vs. rock), and curation process (random vs. cherry-picked). This combines quantitative feedback on genre congruence, preference, creativity, consistency, playability, humanness, and repeatability, and qualitative feedback to provide insights into listeners' experiences. A total of 32 progressive metal fans completed the study. Our findings validate the use of fine-tuning to achieve genre-specific specialization in AI music generation, as listeners could distinguish between AI-generated rock and progressive metal. Despite some AI-generated excerpts receiving similar ratings to human music, listeners exhibited a preference for human compositions. Thematic analysis identified key features for genre and AI vs. human distinctions. Finally, we consider the ethical implications of our work in promoting musical data diversity within MIR research by focusing on an under-explored genre.

1. INTRODUCTION

Recently, advancements in AI have resulted in generative models capable of creating remarkable musical pieces. This has been particularly evident in the audio domain, with models such as Jukebox (OpenAI) [2], MusicLM (Google) [3], AudioCraft/MusicGen (Meta) [4] and Stable Audio (Stability AI) [5], to name a few. In contrast to audio generative models, which can produce complete, directly perceivable music with limited user input beyond

specifying a prompt, symbolic music generation methods yield outputs that necessitate subsequent decoding and interpretation by performers and mixing by audio engineers before transforming them into music suitable for listening experiences. Unless automated using synthesis and machine mixing, by requiring human interpretation through performance and mixing, symbolic music rendering opens the door for the infusion of cultural and social elements. These elements become integral aspects of the final musical experience for listeners.

One major controversy surrounding AI music generation models is their training on copyrighted data, often without consent nor royalty mechanisms. This raises concerns that AI-generated music could threaten artists' and musicians' income streams, amongst others [6]. These issues apply to both symbolic and audio AI music generation. However, symbolic approaches may pose less risk to artists' revenue streams since human musicians are still essential to the final product.

In this work, we focus on symbolic generative AI applied to progressive metal, which is considered a sub-genre of metal. Building on progressive rock's complex phrasing and odd time signatures, it incorporates a heavier focus on guitars and metal influences. The genre encompasses prominent bands such as Dream Theater, Between The Buried And Me¹, and Meshuggah [7]. It is, however, relatively unexplored in academic literature, particularly in the context of AI music generation and MIR research [8] [9].

Guitar tablature (see Figure 1) is a symbolic musical notation that translates guitar notes into fret and string numbers. Due to the genre's emphasis on guitar, progressive metal bands commonly use tablature to notate their compositions. Given that technical complexity is a large appeal of the genre, artists often sell their music in the form of tablatures for learning purposes through tablature publishing companies². Musicians from within the genre often use digital representations of tablatures and software like Guitar Pro³ for dissemination of musical ideas and computer-assisted music making.

We conducted a listening and reflection study to explore participants' perceptions of AI-generated progressive metal music. We used examples generated by ProgGP [1],

an AI model for multi-instrument guitar tablature creation (an example is shown in Figure 1). Overall, the contributions of this paper are: (1) a listening and reflective study methodology and questionnaire; (2) a subjective assessment of the capabilities of ProgGP for symbolic music generation, particularly in tablature format; (3) identification of compositional features of the progressive metal genre; (4) a critical analysis of AI-generated music through the lens of the progressive metal community; (5) an ethical reflection on musical data diversity in MIR, propelled by this study focusing on the underexplored progressive metal genre.

2. BACKGROUND

2.1 Symbolic Music Generation

Music generation has seen an increase in popularity due to recent advances in deep learning [10], with many researchers utilizing techniques such as Recurrent Neural Networks (RNNs) [11] [12], Variational Autoencoders (VAEs) [13], Generative Adversarial Networks (GANs) [14], and Transformers [15]. The Transformer model [16], known for its performance in natural language processing (NLP) tasks, has been adapted for generating symbolic piano music in Huang et al.’s Music Transformer [15], with Musenet [17] and Pop Music Transformer [18] further improving the approach.

The field of guitar tablature generation gained significant momentum with the release of the DadaGP dataset [19]. This dataset provides songs in two formats: GuitarPro, a popular tablature editing software, and a dedicated textual token format. This allows researchers to develop AI models that can both represent and generate music in tablature format. GTR-CTRL [20] implements a Transformer-based model [18] for generating tablature that incorporates multiple instruments. It offers control over instrumentation (inst-CTRL) and musical genre (genre-CTRL). ProgGP [1], the model used in this study, focuses specifically on the progressive metal genre (see Figure 1 and description in Section 3). LooperGP [21] adapts the method to generate loopable music excerpts, making it

applicable e.g. for live coding performances. By fine-tuning the model on the music of four iconic guitar players, ShredGP [22] demonstrates its ability to replicate specific styles.

2.2 Subjective Evaluation of AI-Generated Music

Objective computational measures can provide an initial assessment of AI-generated music quality [23]. However, often they struggle to capture the subtleties needed to judge their aesthetic merit. The combination of objective computational measures with subjective human evaluations provides a more holistic understanding of AI-generated music. Listening tests typically involve ranking or scoring AI- and human-generated stimuli according to several metrics to gain a more comprehensive understanding of perceived quality. This often involves comparing outputs from different models with the established reference (the known ideal or benchmark). Metrics used to assess AI music vary from general attributes such as *musicality* [15], *liking* [24] [25] [18] [26], *pleasantness* [27], *richness* [28], to more specific qualities such as *consistency* [29], or *structural/stability* properties [29]. Whereas ranking involves sorting the different stimuli along a given dimension, scoring tasks commonly rely on 5- or 7-point Likert items [30] [31]. A musical Turing test, similar to the original Turing test, is designed to assess a machine’s ability to exhibit human-level musical creation features. In such tests, participants attempt to distinguish between human- and AI-generated music [32]. To assess AI-generated music, we employ a mixed methods approach, combining quantitative and qualitative data from a listening and reflection study. This approach, common in music perception and HCI research (e.g. [33]), allows for a deeper understanding of the problem. While listening tests enable us to better understand human perception of AI-generated music, they are not without limitations. These limitations include listener fatigue, potential biases due to stimuli or participant selection. Additionally, they may lack sufficient statistical power to generalize the findings to a broader population.

3. METHODOLOGY

We used a mixed methods listening and reflective study to assess AI music, with an ethical approval from the Queen Mary Ethics of Research Committee. All data was collected anonymously. The study took around 1h to complete and participants were compensated with a £10 Amazon voucher.

We evaluated AI-generated progressive metal music from the ProgGP model [1], a Transformer-XL model trained on the DadaGP dataset [19] and fine-tuned on a progressive metal corpus, by comparing it to human-composed progressive metal pieces. We compare two ways of choosing AI music: picking songs at random and subjectively choosing the “best” ones (cherry-picking) through active listening. Additionally, we compare the ProgGP model’s outputs with rock music generated by the genre-CTRL model [20], a similar model conditioned on the rock genre. Human-composed rock music serves as another control group in this comparison.

3.1 Hypotheses

Our study tests the following hypotheses:

- **H_1 : Human-composed music obtains better scores than AI-generated music.** We compare AI- and human-generated music along the following dimensions: preference, creativity, consistency, playability and repeatability.
- **H_2 : AI-generated and human-composed music can be distinguished.** This hypothesis is linked to the musical Turing test.
- **H_3 : AI-generated music matches the genre used for model conditioning.** The ability of the model to specialize in a specific genre (progressive metal).
- **H_4 : Cherry-picked AI-generated music is preferred to randomly chosen AI-generated music.** We hypothesize that picking examples by hand leads to better performance than random selection.

3.2 Stimuli

The stimuli were rendered using Guitar Pro 7, a software for playing/editing digital guitar tablatures. The human-composed music was obtained using publicly available transcriptions of progressive metal and rock songs hosted on Songsterr⁴, a website hosting Guitar Pro tablatures, as well as from the DadaGP dataset [19]. All the examples were trimmed to 15 seconds, and rendered as WAV files using the default virtual instruments in Guitar Pro 7. They were further loudness-normalized [34]. The study comprised 60 stimuli⁵ broken down into the following six groups with 10 examples per group: **progcp** (progressive metal examples generated using ProgGP cherry-picked), **progrand** (progressive metal examples generated with ProgGP, randomly selected), **proghum** (progressive metal examples from the dataset used to fine-tune ProgGP, human-generated, randomly selected), **rockcp** (rock examples generated using genre-CTRL prompted for rock, cherry-picked), **rockrand** (rock examples generated using genre-CTRL prompted for rock, randomly selected), and **rockhum** (from rock examples in the dataset used for genre-CTRL, human-generated, randomly selected). The AI-generated stimuli were selected out of a corpus of 200 compositions from each genre.

3.3 Participants

We recruited participants familiar with progressive metal as we wanted to involve domain experts capable of identifying differences between rock and progressive metal. To this end, we advertised the call for participants on the *r/progmetal* sub-forum from the Reddit platform. This community comprises progressive metal aficionados⁶. 26 participants were gathered from this forum. We recruited six additional progressive metal fans within our department, for a total of 32 participants. Their age distribution

was 29 ± 5 years old, with 27 males and 5 females. The participants had an average Gold-MSI score of 81.41, indicating average level of musical sophistication compared to results of previous studies [35].

3.4 Procedure

Participants first went through a familiarization stage containing two excerpts, followed by the main task during which musical excerpts were presented in random order to minimise potential order effects. Participants were instructed to focus on the quality of the composition and not on the quality of the virtual instruments or the music production mix. For each excerpt, participants had to listen to the stimulus, report their familiarity, and answer the following questions using 7-point Likert items: Q_1 (“This composition features the qualities of the progressive metal genre.”), Q_2 (“This composition features the qualities of the rock genre.”), Q_3 (“I like this composition.”), Q_4 (“This composition is creative.”), Q_5 (“This composition is consistent.”), Q_6 (“This composition is playable.”), Q_7 (“This composition was generated using AI.”) and Q_8 (“This composition is repetitive.”). Once the participants finished rating all excerpts, they were presented with a post-task questionnaire to assess their reasoning when distinguishing between genres as well as between AI- and human-composed excerpts (see Section 4.2).

4. RESULTS

4.1 Listening Test

We visualize Likert item answers using violin plots in Figure 2. We conducted statistical analyses investigating the effects of the music creation process (six levels: **progcp**, **progrand**, **proghum**, **rockcp**, **rockrand**, **rockhum**) on several dependent variables (preference, creativity, consistency, playability, repeatability, humanness, genre congruency, and AI curation method, where relevant). Because we employed a within-participant design with repeated measures, and the collected data are ordinal, we used the non-parametric Friedman test. We use a Type I error α of 0.05; results are presented in Table 1. The Friedman test was followed by post-hoc pairwise Wilcoxon tests, using a Bonferroni-adjusted α level of .0033 (.05/15). This enables us to compare two generation types (AI vs. human), two genres (progressive metal vs. rock), and two AI selection methods (random vs. cherry-picked). Results are presented in Table 2. For question about AI-generated music (Q_7), we excluded responses (345 out of 1,920) where participants indicated prior song familiarity.

4.2 Thematic Analysis

We performed a thematic analysis [36] of answers to post-task questions to better understand the thought process of participants’ decisions during the study. Multiple themes were obtained from the responses, and results are ordered by number of codes within each theme (in parentheses next to each theme, indicating number of occurrences).

Figure 2. Violin plots of answers to Likert items for Q_1 to Q_8 , in plots (a) to (h), respectively, providing an estimation of the probability density function of the data. Horizontal axis represents the different groups of stimuli. Vertical axis reports the 7-point Likert ratings from 1 (Strongly Disagree) to 7 (Strongly Agree).

Question	Friedman Test Statistic	p-value	Significance
Q_1	$\chi^2(5) = 136.90$	8.14×10^{-28}	***
Q_2	$\chi^2(5) = 110.09$	3.90×10^{-22}	***
Q_3	$\chi^2(5) = 77.56$	2.72×10^{-15}	***
Q_4	$\chi^2(5) = 88.54$	1.36×10^{-17}	***
Q_5	$\chi^2(5) = 42.50$	4.67×10^{-8}	***
Q_6	$\chi^2(5) = 55.47$	1.04×10^{-10}	***
Q_7	$\chi^2(5) = 51.59$	6.53×10^{-10}	***
Q_8	$\chi^2(5) = 79.20$	1.23×10^{-15}	***

Table 1. Friedman test results investigating the effect of the creation method for each question (Q_1 to Q_8).

4.2.1 What features made you identify excerpts as progressive metal?

Complexity (40): A huge emphasis was put on the complexity of a composition, particularly the rhythmic but also the harmonic and melodic complexity. Uncommon and changing time signatures were mentioned by roughly half of the participants. The difficulty of playing a composition was also a very common answer.

Composition/style (38): Many compositional and stylistic elements were seen as particularly relevant to the genre, such as aggressiveness, speed and atmosphere. A sense of cohesion is important, with “clear and distinct ideas glued together”. The composition should be experimental, with creative rhythms, unique segments and interesting harmonic choices. Dissonant melodies, arpeggios, metal drum patterns and guitar specific techniques such as “chugs” are also deemed as important.

Instrumentation (7): Participants mention unique instruments and extended range guitars being particularly indicative of the genre.

4.2.2 What features made you identify excerpts as Rock?

Musical structure/composition (24): These excerpts were repetitive and had slower tempos, utilizing a question

and answer structure and accents on beats two and four. They were also generally soft and not particularly aggressive.

Simple/straightforward (23): The excerpts identified as rock were seen as simplistic, using simple drums, melodies, chord progressions and particularly 4/4 time signatures. These songs had straightforward grooves and generic solos.

Guitar techniques (14): Many techniques were seen as specific to the rock genre such as the use of the pentatonic scale, open chords, power chords and double stops. Participants noted a clear blues inspiration in the guitar playing.

Instrumentation (11): The rock genre was seen as guitar driven, with guitars and bass parts being separated. The drums were generally synchronized with the guitar and emphasized the hi-hat cymbals.

4.2.3 What made you identify excerpts as being composed using AI?

Something “off” about the composition (40): A major theme involved participants having some feeling of unease about the composition. Preference for human-composed music might be attributed to a perceived lack of qualities often associated with human creation, such as “soul” and creativity, or the inability to emulate human-like musical performance (playability). Many participants noted that some compositions lacked a sense of cohesiveness and consistency, or even sounded random, with odd note choices and bass lines which did not make sense. Participants also felt there was too much complexity, but also not enough of particular types of complexity (e.g. harmonic complexity).

Repetition (14): This theme specifically refers to negatively perceived repetition. Many described excerpts being overly repetitive or repeating “musically uninteresting or unsatisfying phrases”.

Uninteresting/simple (8): Participants describe boring

Group 1	Group 2	Q_1	Q_2	Q_3	Q_4	Q_5	Q_6	Q_7	Q_8

proghum	rockrand	3.50×10^{-9}	2.17×10^{-4}	5.31×10^{-4}	9.47×10^{-6}	2.32	5.69	5.06×10^{-3}	1.61×10^{-3}
proghum	rockhum	8.49×10^{-10}	1.93×10^{-8}	0.37	2.40×10^{-2}	1.08×10^1	0.25	3.00	0.65

Table 2. Pairwise post-hoc wilcoxon test results for each question. Each cell indicates p -value, while green cells indicates statistical significance (i.e. with Bonferroni correction $p < 0.0033$).

and generic riffs as well as simplistic and bland drum patterns.

Melody (7): A lack of interest or satisfaction with melodies was mentioned, specifically melodies that “run too long and miss their resolution” and “do not seem go anywhere”.

4.2.4 What made you identify excerpts as being composed by humans?

Well-composed (36): A sense of cohesion and consistency throughout the instrumentation and musical ideas was a popular reason for identifying an excerpt as human. Many also mentioned musical choices which feel deliberate and intentional. In general, compositions which felt natural, predictable, and emotionally satisfying were seen as more human.

Human-qualities (10): Certain qualities were perceived as more human, such as creativity, “soul”, and playability. The use of music theory, as well as breaking the rules of music theory were also mentioned.

5. DISCUSSION

5.1 H_1 : Human-composed music obtains better scores than AI-generated music

Human-composed progressive metal (**proghum**) was significantly preferred to all the other AI-generated groups (see Q_3 in Table 2). However, this could be due to participants all being progressive metal fans. Our findings suggest that a Turing test style approach may have limitations in evaluating generative models. While participants struggled to distinguish AI-generated from human-composed music, they still preferred the human compositions.

Participants’ evaluations used more negative language (e.g., ‘repetitive’) to describe AI compositions and more positive language for human compositions (see Sections 4.2.3 and 4.2.4). One might naturally expect significant differences in responses to the listening experiment between the AI-generated and human-composed music stim-

uli groups. While this is true for the randomly selected AI-generated progressive metal group (**progrand**), it does not hold for the rock groups as well as the cherry-picked AI-generated progressive metal (**progcp**) group. However, the violin plots (see Figure 2) do show the human-composed groups to generally have a better mean and smaller variance. Q_5 (“This composition is consistent”) and Q_6 (“This composition is playable”) saw no or few significant differences between stimuli groups. One of the negatively framed indicators of AI compositions was repetition. The cherry-picked and human-composed progressive metal groups were both significantly different to every group other than each other and the human-composed rock (**rockhum**) group in the responses to Q_8 (“This composition is repetitive”). Figure 2 also shows the responses in these groups trending toward not repetitive, while the others trend closer to repetitive. The **rockhum** group was not significantly different to any of the other groups, both AI and human-composed. While the level of repetition in AI-generated excerpts may be roughly similar to human-composed excerpts in their respective genre (with the exception of **progrand**), it is possible that repetition quality is different between AI and human-composed excerpts. Overall, we can conclude that the test shows strong evidence for H_1 in terms of preference, but not necessarily for the other dimensions.

5.2 H_2 : AI-generated and human-composed music can be distinguished

Figure 2 shows a large variance in the responses for Q_7 (“This composition was generated using AI”) for the AI generated stimuli groups, as well as numerous classification errors. The human stimuli groups also show classification errors, though less when compared to the AI stimuli groups. The **proghum** stimuli group was significantly different from both the cherry-picked rock (**rockcp**) and **progrand** groups. The **rockhum** group was only significantly different to the **progrand** group. The **progcp** and randomly selected AI-generated rock (**rockrand**) groups were not found to be significantly different to either of

the human-composed groups. Ultimately, this is evidence against H_2 , though there seems to be some dependence on the model used and the samples selected from that model.

5.3 H_3 : AI-generated music matches the genre used for model conditioning

The responses to Q_1 and Q_2 (see Figure 2 (a) and (b)) show a clear ability of participants to distinguish between the genres of progressive metal and rock, supporting H_3 . This is expected given that participants described the genres very differently to each other (see Sections 4.2.1 and 4.2.2). Of the progressive metal stimuli groups, only **progrand** and **proghum**, differed significantly, suggesting that at least the human curated AI-generated progressive metal stimuli (**progcp**) have features of similar quality to those of the human-generated group. The same cannot be said of the rock samples, though Figure 2 (b) shows the mean ratings in the rock groups are clearly higher than neutral (rated as 4), indicating that they identified the samples as rock. This may suggest that ProgGP excels in comparison to genre-CTRL in generating musical examples in its target genre. However, genre-CTRL, being trained on a wider range of styles (rock, punk, metal, classical, folk), could theoretically generate music in various styles, unlike ProgGP which is limited to its training genre.

5.4 H_4 : Cherry-picked AI-generated music is preferred over randomly chosen AI-generated music

At the surface level, the cherry-picked and randomly selected stimuli groups do not seem to have many differences. The groups in the rock genre have no significant differences between them in any of the questions, and the progressive metal groups only yield significant differences for Q_4 (“This composition is creative”). However, we observe that there are several questions with significant differences between the **progrand** and **proghum** groups, while the **progcp** and **proghum** groups only differ for Q_3 . This seems to indicate that the **progcp** stimuli have more in common with the human-composed excerpts than the randomly selected ones do in the tested features. Additionally, the difference seen in Q_4 between the AI-generated progressive metal groups concerns creativity, shown to be an indicator of human composition in Section 4.2.4. It is difficult to make any definite conclusions about H_4 given these results, but there seems to be some weak evidence for it in the progressive metal genre.

5.5 Study Limitations

The study is bounded by the number of participants (32) and an unbalanced gender distribution. Moreover, the stimuli were only 15 seconds long each, meaning that participants could not judge any long-term compositional features. Finally, the responses discussed in the study focus on compositional features and discard expressive and timbre-related aspects.

6. ETHICS OF MUSICAL DATA DIVERSITY

The broader topic of diversity within MIR is debated by Born in [37], in which the author highlights points such

as (1) the demographics within the field, (2) the nature of the music that is commonly researched, questions (3) the applicability of scientific work to a broader, more diverse, corpus of music, and (4) how to better stir MIR research towards a more encompassing music economy. Of particular relevance to this reflection is (2), closely linked to the concerns on musical data diversity. Despite efforts towards research concerning traditional, folk or ethnic music, MIR is still predominately based on the mainstream popular music that follows a “western” tradition [38]. Moreover, by referring to an ISMIR keynote by Seeger [39], Sturm et al. [40] point out that even within “western” music, there seems to be an emphasis on US pop music and European classical music. For automatic symbolic music generation, a closer look at the most commonly used datasets in the MIR community [41] suggests that styles such as western classical, pop and jazz music, often modelled using piano when dealing with single instrument systems, are a recurrent practice within the field. Following from these premises, it is important to first clarify that ProgGP is still grounded in the western music tradition, and to acknowledge this as a limitation given the musical data diversity concerns explained before. However, its musical style can be said to emphasize content that diverges from the *mainstream popular music* landscape. This begged the question: can the stylistic biases in the outputs from ProgGP contribute to a wider context of data diversity within MIR research? We argue that releasing training data for specific genres, exemplified by the release of data for fine-tuning ProgGP [1], is a step towards a more musically diverse MIR. This, along with publishing studies to understand underexplored genres and their challenges, and fostering interaction with stakeholders like the progressive metal community (as in this paper), can significantly contribute to this goal. We propose that guitar tablature can enhance musical diversity in MIR. Unlike MIDI, the dominant format, tablature excels at representing string instrument-specific expressive techniques, expanding the scope of representable music within the field.

7. CONCLUSION

We conducted a listening and reflective study which examined listeners perspectives on the quality of symbolic AI-generated compositions in the rock and progressive metal genres. The study provided both a subjective evaluation of recent Transformer-based music generation models and an exploration of listeners’ perceptions of AI and human compositions. We found that participants preferred human-composed music over AI-generated music, though they were generally not able to fully distinguish between AI- and human-composed music. Participants were able to distinguish between the two genres well. Cherry-picked examples in the progressive metal genre were rated similarly to the human-composed examples in several compositional metrics despite not being liked as much. With this methodology, we hope our work helps researchers better evaluate their generative models using a mixed methods approach through a listening and reflective study, as well as show the merit in increasing musical data diversity within MIR.

ABSTRACT

Deep generative models are now able to synthesize high-quality audio signals, shifting the critical aspect in their development from audio quality to control capabilities. Although text-to-music generation is getting largely adopted by the general public, explicit control and example-based style transfer are more adequate modalities to capture the intents of artists and musicians.

In this paper, we aim to unify explicit control and style transfer within a single model by separating local and global information to capture musical structure and timbre respectively. To do so, we leverage the capabilities of diffusion autoencoders to extract semantic features, in order to build two representation spaces. We enforce disentanglement between those spaces using an adversarial criterion and a two-stage training strategy. Our resulting model can generate audio matching a timbre target, while specifying structure either with explicit controls or through another audio example. We evaluate our model on one-shot timbre transfer and MIDI-to-audio tasks on instrumental recordings and show that we outperform existing baselines in terms of audio quality and target fidelity. Furthermore, we show that our method can generate cover versions of complete musical pieces by transferring rhythmic and melodic content to the style of a target audio in a different genre.

1. INTRODUCTION

Deep generative models are now particularly successful at synthesising high-quality, realistic audio signals. Hence, the major impediment to their broader use in creative workflows is not their audio quality anymore, but rather how end-users can have complete control over the generation process. Following early works on unconditional generation [1, 2], multiple methods proposed to enable control by conditioning generation on semantic tags or audio-descriptors [3, 4]. However, such supervised approaches remain limited to the use of explicit descriptors and are constrained by their reliance on annotated datasets. The

Figure 1. General overview of our method. We extract timbre and structure representations from waveform and/or MIDI inputs using encoders E_T and E_S respectively. Those representations condition a latent diffusion model, enabling both explicit and example-based control.

recent development of language models and representation learning led to impressive performance in text-conditioned generation, mainly relying on transformers [5, 6] or diffusion models [7–9]. However, concepts such as timbre, musical style or genres boundaries are usually elusive and highly subjective. Hence, text descriptions might remain limited to common sounds and insufficient to precisely capture musical intentions.

A parallel stream of research to alleviate those issues is to guide specific aspects of the generation process by providing audio examples. Most approaches in this audio-to-audio editing are focused on *timbre transfer*, where the timbre of a given sound is applied on the content of another. While some works can transfer any audio to the timbre of a given training set [10]; others achieve many-to-many *timbre transfer* but only between a small set of predefined instrument classes [11, 12]. *One-shot timbre transfer* between different instrument recordings have been achieved using Variational Autoencoders (VAE) [13, 14], but these models rely on a latent bottleneck to enforce disentanglement between timbre and pitch, which hampers their ability to generate high-quality audio on real-world data. More recently, a text-inversion technique was proposed to perform musical style transfer between arbitrary content and style examples [15], but it relies on a large pretrained text-to-music model and requires optimisation prior to each transfer, resulting in very slow inference.

In this paper, we aim to unify explicit control through audio descriptors or MIDI sequences and style transfer within a single model. To do so, we separate local, time-varying factors of variations and global information, capturing musical structure and timbre in two separate representation spaces. We slightly abuse the terms structure and timbre: by structure, we designate time-varying features, e.g. melody, loudness; by timbre, we designate global features such as actual timbre, but also style or genre. The principle of our method is depicted in Figure 1. Our approach is based on the recently proposed diffusion autoencoder [16], which trains a semantic encoder to condition a diffusion model, in order to achieve both high-quality generation while being able to extract and control high-level features from the data. We extend this approach by building separate representations for timbre and structure, while enforcing their disentanglement with an adversarial criterion combined with a two-stage training strategy. Our method can generate audio matching a timbre target, while specifying the musical structure either with explicit controls (such as MIDI data input) or an audio example. For computation efficiency, our diffusion model operates in the latent space of pretrained autoencoders, resulting in faster than real-time inference on GPU¹.

First, we benchmark our model on a *one-shot timbre transfer* tasks and demonstrate that our model improves upon existing baselines in terms of audio quality, timbre similarity as well as note onsets and pitch accuracy. On the same dataset, we show that our model can also generate audio from MIDI input and a target timbre example with performances superior to a state-of-the-art MIDI-to-audio baseline. Finally, we show that our method can be applied to complete musical pieces and generate cover versions of a track by transferring its rhythmic and melodic content to the style of a target audio in a different genre. We provide audio examples, additional experiments and source code on a supporting webpage²

2. BACKGROUND

2.1 Diffusion models

Diffusion models (DMs) are a family of generative models that learn to reverse a stochastic process that gradually adds noise to the input data. These models benefit from high-quality generation, stable training and conditioning abilities, which led to their widespread adoption in image [17] and audio generation [18].

Formally, we define a *forward process* $q(\mathbf{x}_{1:T}|\mathbf{x}_0) = \prod_{t=1}^T q(\mathbf{x}_t|\mathbf{x}_{t-1})$, which is a Markov chain that increasingly adds noise to the data \mathbf{x}_0 by relying on the conditional distribution

$$q(\mathbf{x}_t|\mathbf{x}_{t-1}) = \mathcal{N}(\mathbf{x}_t; \sqrt{1 - \beta_t}\mathbf{x}_{t-1}, \beta_t\mathbf{I}), \quad (1)$$

where β_t are hyperparameters defining the noise levels at times $t \in \{0, T\}$, with $T \in \mathbb{N}$. We are inter-

ested in learning the reverse diffusion process $p_\theta(\mathbf{x}_{t-1}|\mathbf{x}_t)$, from which we can iteratively denoise a random sample $\mathbf{x}_T \sim \mathcal{N}(0, \mathbf{I})$ to a data sample $\mathbf{x}_0 \sim p(\mathbf{x}_0)$. In a recent study, [19] made a connection between diffusion and denoising score matching [20], leading to a simplified formulation and improved experimental results. The authors show that the reverse process can be approximated by learning a denoising network ϵ_θ that predicts the noise $\epsilon \sim \mathcal{N}(\epsilon, \mathbf{0}, \mathbf{I})$ used to corrupt the data. This results in a simpler training objective

$$\min_{\theta \in \Theta} \mathbb{E}_{t, \mathbf{x}_0, \epsilon} [\|\epsilon_\theta(\sqrt{\alpha_t}\mathbf{x}_0 + \sqrt{1 - \alpha_t}\epsilon, t) - \epsilon\|], \quad (2)$$

where $\alpha_t = \prod_{s=1}^t (1 - \beta_s)$, and ϵ_θ is usually parametrized by a UNet [21].

2.2 Diffusion autoencoders

DMs naturally yield a series of latent variables $\mathbf{x}_{1:T}$ through their *forward process*. However, these stochastic variables built from increasingly adding noise do not capture much semantic information over the data. Although the more recent proposal of Denoising Diffusion Implicit Models (DDIMs) [22] extends the original diffusion formulation to a deterministic process allowing each data input to be mapped to a unique latent code \mathbf{x}_T , it still fails to extract and organise high-level features from the data. Diffusion autoencoders [16] alleviate this issue by employing a learnable encoder that compress the data to a semantic latent code $\mathbf{z}_{sem} = E_\phi(\mathbf{x}_0)$, which then conditions a diffusion decoder. The semantic encoder and the DDIM decoder are trained jointly, following the objective

$$\min_{\theta, \phi} \mathbb{E}_{t, \mathbf{x}_0, \epsilon} [\|\epsilon_\theta(\sqrt{\alpha_t}\mathbf{x}_0 + \sqrt{1 - \alpha_t}\epsilon, E_\phi(\mathbf{x}_0), t) - \epsilon\|] \quad (3)$$

On image applications, the authors show that the semantic code captures high-level attributes such as person identity, smile or presence of glasses, and can be used for downstream tasks such as conditional generation and attributes manipulation, while achieving state-of-art reconstruction. This approach was also successfully applied to audio [8], where the authors encode magnitude spectrograms into a semantic latent space, allowing to achieve high quality text-conditioned waveform generation.

2.3 Control in audio generation

A straightforward approach to extend unconditional generative models in order to provide instruments befitting artistic control is to introduce conditioning on explicit controls. The DDSF model [3] proposes explicit pitch and loudness conditioning, while FaderRave [4] extended explicit control to non-differentiable time-varying attributes, but both methods remain limited to explicit descriptors and annotated datasets. While recent text-to-music methods like MusicGen [5] and Music ControlNet [23] have incorporated melody conditioning capabilities, their expressiveness remains constrained by the need to define subjective timbre properties through text prompts. Li et al. [15]

¹ Experiments were conducted on a NVIDIA A5000 GPU

² <https://nilsdem.github.io/control-transfer-diffusion/>

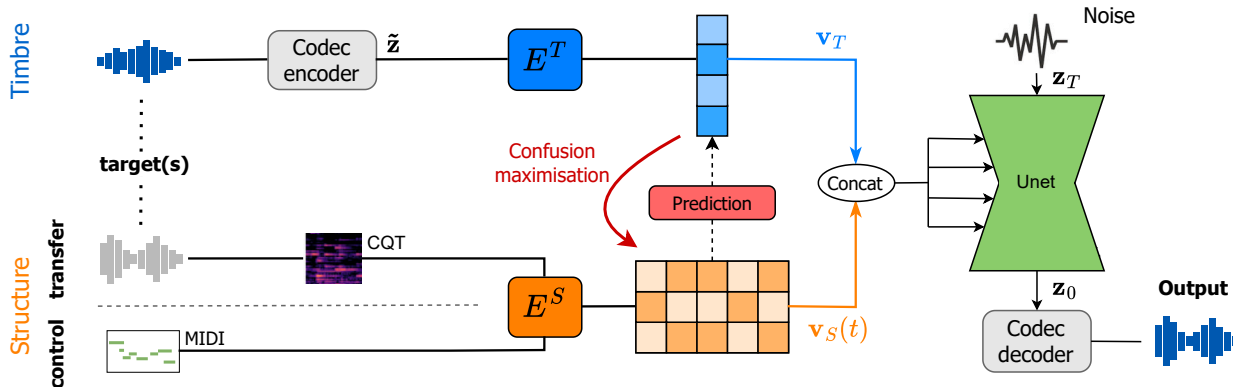

Figure 2. Detailed overview of our method. Input signal(s) are passed to structure and timbre encoders, which provides semantic encodings that are further disentangled through confusion maximization. These are used to condition a latent diffusion model to generate the output signal. Input signals are identical during training and but distinct at inference.

proposed to use text-inversion in order to extract pseudo-words that represent timbre directly from audio, but their method is computationally intensive and requires to perform an optimisation for each new timbre target. Timbre conditioning directly from a waveform example was also recently proposed the context of bass accompaniment generation [24].

2.4 Unsupervised disentanglement in sequential data

Many works proposed to model sequential data as a combination of local (time-variant) and global (time-invariant) factors of variation. Notably, the disentangled sequential autoencoder [25] relies on simple architecture biases and parameter tuning to obtain disentangled local and global latent variables. Following this work, multiple methods improved the learned representation by explicitly minimizing the mutual information between the two learned variables [26–28]. It was shown that disentanglement can be further improved with contrastive learning and domain-specific transformations that preserve local or global attributes [26, 29].

More specifically in audio generation, SS-VAE [14] employs a Vector-Quantized VAE to achieve disentanglement through compression on quantized structure latent codes, combined with timbre-preserving data augmentations. Luo et al. [13] follow a two-stage training strategy similar to ours, and improve disentanglement by enforcing the consistency of the global and local latent variables in style or content transfer. However, both disentanglement strategies degrades reconstruction accuracy, which on top of spectrogram inversion based synthesis leads in poor audio quality.

3. METHOD

Our approach is based on the assumption that musical audio samples can be seen as specific instances of a set of latent features that are separated between global features that capture style, and time-varying features that capture the local evolution of the signal. Although diffusion models are capable of high-quality conditional generation, they

are computationally expensive when dealing with high-dimensional data. Hence, we employ an invertible audio codec to first compress the audio into a low-dimensional latent space, onto which we can build an efficient generative model. We extend the DiffAE [16] architecture to two semantic encoders in order to extract separately timbre and structure features from input samples. To further disentangle the learned features and improve transfer as well as explicit control performances, we employ an adversarial training strategy during training. In this section, we detail our proposed model depicted in Figure 2.

3.1 Audio codec

We build our audio codec as a convolutional autoencoder based on the RAVE model [10] architecture, featuring the adversarial discriminator recently proposed in [30]. The model compresses audio waveforms \mathbf{x} into an invertible latent sequence $\mathbf{z} \in \mathbb{R}^{L \times D}$, where D and L are the embedding space and time dimensions respectively. On top of the reconstruction and adversarial training objectives of RAVE, we introduce a penalty on the latent codes $f(\mathbf{z}) = \max(0, |\mathbf{z}| - 1)$ to enforce that most latent codes are distributed between -1 and 1 .

3.2 Model structure

We extract a timbre representation $\mathbf{v}_T \in \mathbb{R}^{D_T}$ from an audio target using an encoder E_ϕ^T applied to the latent sequence \mathbf{z} obtained with our audio codec. For structure, we extract a temporal representation $\mathbf{v}_S \in \mathbb{R}^{L \times D_S}$ from either an audio input or an explicit control signal \mathbf{c} (such as a MIDI sequence), using an encoder E_ψ^S . In the case of an audio input, it would be natural to also infer it from the latent sequence \mathbf{z} . However, we found experimentally that it is particularly difficult to extract fine structure information from the highly-compressed representation \mathbf{z} . Hence, we instead infer structure from the Constant Q Transform (CQT) [31] of the target signal, which has been shown to be a well-suited representation for pitch extraction tasks [32]. For explicit control, the sequence \mathbf{c} is directly used

as input for E_ψ^S .

To generate audio, we sample a noise vector \mathbf{z}_T and decode it to a latent code \mathbf{z}_0 through latent diffusion conditioned on representations \mathbf{v}_S and \mathbf{v}_T . As diffusion formulation, we leverage the recent improvements introduced in [17] and parameterise our denoiser network D_θ to predict the data \mathbf{z}_0 instead of ϵ . E_ψ^S , E_ϕ^T and D_θ are trained end-to-end to minimise the following loss function

$$L_{diff} = \mathbb{E}_{t, \mathbf{z}_0, \epsilon} \|D_\theta(\sqrt{\alpha_t}\mathbf{z}_0 + \sqrt{1 - \alpha_t}\epsilon, \mathbf{v}_S, \mathbf{v}_T, t) - \mathbf{z}_0\| \quad (4)$$

We parameterise D_θ as a 1D convolutional UNet with residual blocks and self-attention layers. The two encoders share a similar architecture as the encoding half of the UNet, with the difference that the timbre encoder compresses the input temporally and applies average pooling on the time dimension of the last layer. We condition the UNet architecture on \mathbf{v}_S through concatenation with each block inputs. For the timbre vector \mathbf{v}_T we use Adaptive Group Normalisation (AdaGN) [33].

3.3 Style and content disentanglement

Although splitting the semantic content between two vectors that are constrained on their dimensions already encourages disentanglement between timbre and structure information, there is no theoretical guarantee regarding their separation. Furthermore, the appropriate feature dimensions are highly dependent on the task and dataset at hand. Hence, to enforce disentanglement without constraints on the dimensions, we introduce a two-stage training combined with an adversarial strategy. First, we freeze the structure encoder and train the model to build an adequate timbre representation. To avoid \mathbf{v}_T to encode all of the information required to reconstruct the target \mathbf{z} , we extract timbre from a different sample $\tilde{\mathbf{z}}$ coming from the same track, following the assumption that it shares the same timbre as \mathbf{z} but with a different structure.

In the next stage, we introduce a discriminator D_ζ that tries to predict \mathbf{v}_T from \mathbf{v}_S and is trained to minimise

$$L_D = \mathbb{E}_{\mathbf{v}_S, \mathbf{v}_T} [\|\mathbf{v}_T - D_\zeta(\mathbf{v}_S)\|]. \quad (5)$$

We train the discriminator alternatively with the encoders and denoising network, which try to minimize the following objective

$$L_{total} = L_{diff} - \gamma L_D, \quad (6)$$

where γ is an hyperparameter balancing between the reconstruction objective and disentanglement. Indeed, increasing L_D maximises the confusion of the timbre information in the structure space. This restrains the diffusion model from reconstructing \mathbf{z} solely from \mathbf{v}_S and enables independent control of structure and timbre at inference.

4. EXPERIMENTS

We aim to assess the ability of our model to generate high-quality audio samples that match characteristics of structure and timbre targets, with the structure being either

taken from an audio example or through an explicit control signal.

MIDI-to-audio For explicit structure control, we evaluate the capability of our model to generate audio from a MIDI score and a target recording for timbre. We compare it to a state-of-art baseline in MIDI-to-audio generation.

Timbre transfer We evaluate the efficiency of our disentanglement strategy on a task of *one-shot timbre transfer* between polyphonic mono-instrument recordings. In this case, we consider that structure designates the notes being played (in terms of onset timing, pitch and loudness), while timbre corresponds to the remaining characteristics of the sound. We evaluate our model by randomly sampling timbre and structure examples and evaluate audio quality, timbre similarity as well as note accuracy. We compare our model with two example-based timbre transfer methods on synthetic and real recordings.

4.1 Dataset

Synthetic Data The Synthesized Lakh Dataset (SLAKH) [34] was generated from the LAKH MIDI collection using professional-grade sample-based virtual instruments. Synthesis parameters as well as audio effects settings were randomly chosen resulting in a very diverse set of timbres. We retain only the individual stems of non-percussive instruments, resulting in 400 hours of audio.

Real Data To the best of our knowledge there is no multi-instrumental dataset of real recordings that contain a very large number of hours of audio. Hence, we combined the following three datasets to conduct our experiments :

- **MaestroV2** : Maestro [35] is a piano dataset recorded on Disklavier pianos, capturing both audio and notes played, resulting in approximately 200hours of annotated piano recordings.
- **GuitarSet** : Guitarset [36] is a collection of live guitar performances with solos and accompaniment from various genres and play styles, with a total audio duration of 6 hours.
- **URMP** : The URMP dataset [37] is composed of pieces played by a large variety of classical instruments. For each piece we retain the mono-instrumental recordings, resulting in approximately 4 hours of audio.

As the GuitarSet and URMP are low sample-size datasets, we add synthetic data stems from SLAKH to the training set to facilitate learning. Furthermore, as the different datasets are greatly imbalanced in terms of sample size, we apply a sampling strategy to even the model performance on each dataset. Following [38], if n_i is the number of samples in a given dataset, we draw examples from this dataset during training with probability $(n_i / \sum_j n_j)^{0.3}$.

4.2 Evaluation metrics

We aim to evaluate how our method is able to match the timbre and structure targets characteristics, while maintaining high-quality audio.

		Quality (FAD) ↓		Timbre similarity ↑		Onset F1 score ↑	
		Rec.	Transfer	Rec.	Transfer	Rec.	Transfer
MIDI-to-audio	Spectrogram diffusion [38]	3.46	-	0.76	-	0.32	-
	Ours w/o E_S	1.22	1.41	0.87	0.77	0.40	0.38
	Ours	0.88	1.06	0.89	0.83	0.36	0.23
Timbre transfer	SS-VAE [14]	2.83	3.23	0.75	0.69	0.29	0.15
	Music Style Transfer [15]	2.95	2.77	0.84	0.60	0.22	0.17
	Ours w/o adversarial - $D_S = 4$	0.95	1.75	0.91	0.75	0.36	0.23
	Ours w/o adversarial - $D_S = 8$	0.95	1.65	0.91	0.73	0.36	0.26
	Ours	1.13	1.42	0.91	0.82	0.36	0.23

Table 1. Experimental results in terms of audio quality, timbre similarity and note accuracy on the SLAKH dataset, for MIDI-to-audio generation (**up**) and timbre transfer (**down**). "Rec." corresponds to samples generated from identical structure and timbre targets, while "Transfer" designates randomly chosen timbre targets.

Audio quality We rely on the widely used *Frechet Audio Distance* (FAD) [39] to evaluate how the generated audio distribution matches the dataset distribution, both for reconstructed and transferred samples. We use the available reference implementation of FAD³ and use VGGish [40] embeddings of the samples to compute the distance

Timbre Similarity To evaluate timbre similarity we employ the metric proposed in the SS-VAE baseline [14]. It relies on a triplet network trained to predict if samples are played by the same instrument based on Mel-frequency cepstral coefficients 2-13. We use their implementation and train the metric on the *mixing-secrets*⁴ dataset.

Structure To evaluate if our model is able to reproduce the notes of the structure target, we employ a transcription model [41] and compare its output to the ground-truth MIDI data. As metric, we use Onset F1 score from *mir-eval*, where two notes are considered identical if they have identical pitch and onsets within $\pm 50ms$ of each other.

4.3 Baselines

For the timbre transfer experiments, we compare our method to SS-VAE [14] and Music Style Transfer [15] presented in Section 2. We train both models on the real and synthetic datasets, using the official implementation. For explicit control, we evaluate our method against a MIDI-to-audio model [38] that was also trained on the SLAKH dataset. We use the *small* configuration of the publicly available pretrained model, as larger models do not fit on our NVIDIA A5000 GPU.

4.4 Training details

We start by training our audio codec for 1M steps before training our diffusion model for 500k steps, with an initial timbre learning stage of 100k steps. The overall training takes one day on NVIDIA A5000 GPU. For all experiments we rely on the AdamW optimizer [42] with a constant learning rate of $1e^{-4}$ and a batch size of 48. For inference we use the deterministic sampler proposed in [17] with 40 diffusion steps.

5. RESULTS

5.1 MIDI-to-audio

First, we evaluate our model performance in MIDI-to-audio generation in terms of audio quality, timbre similarity and Onset F1 score. We detail our results in Table 1 for reconstruction and transfer setups, where the target timbre corresponds to either the instrument of the MIDI sequence or a different sample. In both cases, we obtain higher similarity, as our dedicated timbre embedding captures timbre much more precisely than simple label conditioning on instrument categories. Interestingly, we also obtain better F1 scores, although we did not design our model specifically for MIDI inputs as opposed to [38] where authors employ a dedicated note sequence embedding strategy.

To assess the benefit of our disentanglement strategy, we experiment with bypassing the structure encoder and directly conditioning the UNet on the MIDI sequence (*Ours w/o E_S* entry in Table 1). This results in overall better Onset F1 score, but degrades timbre similarity and FAD. This demonstrates that our disentanglement strategy improves the capability of the model to precisely render the timbre of the target recording. As described in Section 4.2, the Onset F1 score characterises the difference between the generated notes and the input MIDI sequence. The lower accuracy obtained with our full model in the transfer setup can be explained by the fact that some MIDI sequence are not plausible scores for some target instruments (such as playing chords with a flute). Through the disentangled structure encoding, our model is capable of adapting the input MIDI sequence to the range and capabilities of the target instrument, which results in more realistic sounding samples. We encourage the reader to listen to the examples on our supporting webpage that support this statement.

5.2 Timbre transfer

Synthetic data Here, we first evaluate *timbre transfer* on synthetic data and display the results in Table 1. The two baselines appear to provide low audio quality and timbre similarity, and both methods obtain lower Onset F1 scores indicating that they are not able to adequately control structure and timbre independently. Our method improve upon the baselines on all three evaluated aspects, and is inter-

estingly able to reach a comparable performance as in the explicitly conditioned MIDI-to-audio setup.

We also performed an ablation study, by evaluating the effect of applying an information bottleneck on the structure latent space instead of using our adversarial strategy. As mentioned in Section 3.3, the model is able to transfer timbre when D_S is small but achieves a low F1 score. Increasing the latent dimensions improves structure fidelity at the cost of degrading timbre similarity. Using our disentanglement strategy, we are able to employ a 32-dimensional latent space and achieve higher timbre similarity with a slight decrease in note accuracy. Although multiple definitions of timbre transfer are possible, we argue that the most convincing timbre transfer do not necessarily imply a perfect note structure F1 score. In the case of a transfer between monophonic instruments playing in the same pitch range, we can expect all the notes from one recording to be transferred to the other. However, when performing transfer between recordings with very distinct timbre such as a piano playing in its high range and a bass, an interesting transfer would rather be the bass playing the main melodic line a few octaves lower than the piano, which would result in a low F1 score. The improvement in terms of FAD between the distribution of transferred samples and the original data obtained with our disentanglement strategy supports that our method generates more realistic transfers, as an instrument playing notes outside its usual range would be considered as out-of-distribution.

	FAD ↓	Timbre ↑	F1 ↑
SS-VAE [14]	9.26	0.58	0.19
Music Style Tr. [15]	10.2	0.57	0.17
Ours w/o adv.	2.14	0.81	0.43
Ours	1.36	0.88	0.28

Table 2. Experimental results for timbre transfer on real instruments in terms of FAD, timbre similarity and onset F1 score. Metrics are averaged between the three datasets.

Real data. We present our results for transfer between real instrumental recordings in Table 5.2. Our model improves even further on the existing baselines for which real instruments timbre seems particularly challenging. Even without adversarial regularisation, our model obtains better FAD, timbre similarity and note accuracy. Our disentanglement strategy further improves timbre match, although the relative decrease in note accuracy appears to be greater than on synthetic data. We believe this is mainly due to a necessary simplification of note structure when transferring complex piano recordings to the mainly monophonic URMP instruments. The improvement of transfer quality captured by the FAD and timbre similarity supports this interpretation.

Qualitatively, we found that on top of generating realistic samples with the appropriate structure, the model is also able to add characteristic sound artefacts of the target instrument such as fret or hammer noises, as well as matching precise acoustic features of the original recording such as reverb or background noise.

6. COMPLETE MUSIC STYLE TRANSFER

	FAD ↓	Cover (%) ↑	Genre ↑
MusicGen [5]	-	37.6	0.48
Ours w/o adv.	3.99	48.5	0.44
Ours	3.31	52.2	0.55

Table 3. Style transfer results on musical pieces, evaluated through FAD, cover identification and genre classification.

Finally, we apply our model to the task of creating cover versions of a song that match the style of an example in a different genre. We rely on an in-house dataset of 200 hours of jazz, dub, lofi hip-hop and rock. We use the same model architecture to extract structure from the original track and timbre from the cover targets, with two minor modifications. First, we introduce temporal compression in the structure encoder to avoid v_T to capture information that is too precisely located in time. Second, we condition the UNet on a BPM time series to help it generating coherent rhythms. Without those modifications, the rhythmic elements from timbre and structure targets are conflicting with each other, resulting in somewhat chaotic generations. We evaluate our model using the cover detection algorithm proposed in [43], which outputs a cover probability based on melodic and harmonic similarities between tracks. To assess style transfer, we rely on the text and audio joint-embedding model CLAP [44] and classify genre based on the cosine similarity between the audio and genre label embeddings. We compare our method to MusicGen [5], a text-to-music generation model with audio-based melody conditioning. We derive an input prompt from the target genre and use the structure target for melody.

Our model without regularisation obtains a better cover identification than MusicGen, and our disentanglement strategy further improves transfer resulting in higher genre accuracy. Qualitatively, MusicGen seems to only extract the main melodic idea from the structure audio, whereas our method is able to capture most of the harmonic and melodic content. Furthermore, as our model extract style directly from audio rather than through a text prompt, it transfers the different structural elements towards the instruments actually present in the timbre target rather than just the typical instruments of the genre.

7. CONCLUSION

We presented a simple method to learn disentangled timbre and structure representations. To the best of our knowledge, this is the first model capable of generating realistic, high-quality audio through transfer and MIDI rendering. We leave for future works improvements on the trade-off between reconstruction and disentanglement and applications to more complex musical datasets. Furthermore, we aim to initiate a reflection on the characterisation of the elusive concept of musical style transfer, which we believe to be an exciting stream of research towards a broader use of deep generative models in artistic work-flows.

ABSTRACT

Despite its musicological, cultural, and religious significance, the Ethiopian Orthodox Tewahedo Church (EOTC) chant is relatively underrepresented in music research. Historical records, including manuscripts, research papers, and oral traditions, confirm Saint Yared's establishment of three canonical EOTC chanting modes during the 6th century. This paper attempts to investigate the EOTC chants using music information retrieval (MIR) techniques. Among the research questions regarding the analysis and understanding of EOTC chants, *Yaredawi YeZema Silt*, namely the mode of chanting adhering to Saint Yared's standards, is of primary importance. Therefore, we consider the task of *Yaredawi YeZema Silt* classification in EOTC chants by introducing a new dataset and showcasing a series of classification experiments for this task. Results show that using the distribution of stabilized pitch contours as the feature representation on a simple neural-network-based classifier becomes an effective solution. The musicological implications and insights of such results are further discussed through a comparative study with the previous ethnomusicology literature on EOTC chants. By making this dataset publicly accessible, our aim is to promote future exploration and analysis of EOTC chants and highlight potential directions for further research, thereby fostering a deeper understanding and preservation of this unique spiritual and cultural heritage.

1. INTRODUCTION

The Ethiopian Orthodox Tewahedo Church (EOTC) chants hold immense cultural and religious significance in Ethiopia, yet they are largely overlooked [1].¹ The EOTC chant is believed to have originated with Saint Yared (505–571), who composed the three EOTC chanting modes

¹ The Eritrean Orthodox Tewahedo Church, which separated from the EOTC administration system a few decades ago, also utilizes these chants. We acknowledge its important role in preserving this sacred form of church music.

(*YeZema Siltoch* in Amharic language),² namely *Ge'ez*,³ *Ezil* and *Araray*. Saint Yared's pioneering musical compositions, liturgical chants, and associated dance movements had a significant impact on Ethiopian sacred music tradition [2]. The *Debterawoch* (also called *Merigeta-woch*), who are the expert musicians and heirs of Saint Yared, play a crucial role in the transmission and performance of the sacred music [1]. Ethiopian sacred music has been preserved through oral and written traditions, with written documents supporting and reinforcing the ongoing oral traditions [3]. The significance of the EOTC chants in Ethiopian culture and worldwide is evident through the two major spiritual mass celebrations that have been recognized by UNESCO as intangible cultural heritages: the Commemoration Feast of the Finding of the True Holy Cross of Christ (in 2013) and the Ethiopian Epiphany (in 2019).⁴ These two celebrations, primarily accompanied by the EOTC chants, are among the five intangible cultural heritages from Ethiopia registered by UNESCO.

Despite its long history and development, the research of EOTC chants was quite rare. Among them, a renowned ethnomusicological work from Western academia was by Shelemay et al. [3, 4], based on the analysis of a series of EOTC chants collected in Addis Ababa, 1975. They discussed the oral and written tradition of EOTC chants, the EOTC chant music notation system, and further the definition of the three chanting modes, specifically the pitch sets used in each of the modes. It should be noted that in this work, all the recordings were transcribed and analyzed by ear. As stated in the paper, the analysis, for a limited number of recordings, was sometimes challenging when transcribing the non-Western music scales. With no indigenous classification of their pitch materials [3], *YeZema Siltoch* remains a primary research topic in the music theory of EOTC chants.

This paper is a study on *YeZema Siltoch* of the EOTC chants from computational perspectives. Our contributions in this paper are three-fold. First, we propose a new dataset for *YeZema Silt* classification and analysis. Second, we

² *Siltoch* is the plural form of *silt*. For simplicity, the Amharic phrase *YeZema Silt* and the English phrase chanting mode will be used interchangeably throughout this paper.

³ The term *Ge'ez* holds various connotations depending on context; here, it denotes one of the three chanting styles. Conversely, it also refers to the language and may have other applications.

⁴ <https://ich.unesco.org/en/state/ethiopia-ET?info=elements-on-the-lists>

benchmark the *YeZema Silt* classification on the dataset using neural network classifiers with a number of features, primarily the pitch contour features which have been verified useful in analyzing various kinds of music [5–11]. Third, we perform a comparative study with [3,4] to echo, and to revise their statements as well: while the pitch sets used in *Ezil* and *Araray* was regarded as the same [3], our numerical results indicate notable difference in between them. In the rest of this paper, we will have a background introduction of EOTC chants in Section 2. The proposed dataset, benchmarks and the comparative study will be in Sections 3, 4, and 5, respectively. Conclusion and future works will be given in Section 6.

2. BACKGROUND OF EOTC CHANTS

2.1 Features and Performance Traditions

The spiritual schools of the EOTC have several departments, locally known as *Guba'e bet*. These departments include *Nibab-bet* (reading practice), *Zema-bet* (introductory to advanced level offices chanting), *Qidase-bet* (or *Kidase-bet*, liturgical chants), *Qine-bet*⁵ (or *Kine-bet*, poetry), *Aquaquam-bet* (or *Akuakuam-bet*, advanced chanting with accompaniments), and *YeMetsahift Tirguame-bet* (exegesis of scriptures). The knowledge and skills acquired from each *Guba'e bet* are crucial for understanding the chants. Each *Guba'e bet*, which focused on chanting, has two or more slightly different vocal and performance styles [12]. For example, *Zema-bet* has *Bethlehem*, *Achabir*, *Qoma*, and *Tegulet*, and *Qidase-bet* has *Sellekula* and *Debre Abay*. These nominations are based on the names of places where the center of excellence, that approves a senior student to be a teacher, is located. Such *Guba'e bet*, for example, *Bethlehem* has a slightly different vocal style, ornamentation, and notation complexity compared to *Qoma*, and it also has its own swaying and religious dancing tradition with its own drumbeat.

The EOTC chants incorporate monophonic, antiphonal, and choral ritual performances. Our dataset is derived from *Qidase-bet*, which primarily focuses on monophonic and antiphonal ritual performance components without accompaniments. In contrast, *Aquaquam-bet* emphasizes religious dance and movements, primarily choral with some monophonic and antiphonal components. It is accompanied by prayer staffs known as *mequamia*, drums, and sistrums [12, 13]. The content of the chants - the text, whether poetic or unpoetic, is directly or indirectly based on the Holy Bible. The lyrics primarily employ Ge'ez (ግዕዝ), an ancient Semitic language with a distinct script known as Fidäl. These chants play an essential role in the religious practices of nearly 43.5% of the country's population, or over 32 million Orthodox Tewahedo Christians, according to the 2007 national census [14].⁶

The social groups involved in the chants include priests, deacons, and laypeople who attend the service hours. Tra-

ditionally, the chants were transmitted orally, with singers memorizing a repertoire of phrases and melodies to perform during liturgical celebrations. Several decades ago, chant manuscripts were handwritten on parchment, which refers to processed goat or sheep skins. Even today, some scholars adhere to this practice to uphold the church's cultural traditions. However, in recent decades, transmission has been supported by printed manuscripts for training along with oral traditions for actual performance.

Despite its rich heritage, the tradition of EOTC chants faces significant challenges. Many training centers are closing down due to absence of government support, insufficient community support for students [12], and the dominance of modern education since the 20th century. Despite the contributions of printing and recording advancements, the computational contribution to the Ge'ez language and the chants remains underdeveloped. Except for a few works on MIR [13] and music generation [15], computational research on the EOTC chants is not as developed as it is for some other secular music. These issues highlight the need for more research on the EOTC chants. Our research aims to contribute to MIR-related tasks on the EOTC chants, addressing this gap.

2.2 YeZema Siltoch - Chanting Modes

The EOTC chants encompass three primary *YeZema Siltoch* (modes): *Ge'ez*, *Ezil*, and *Araray*. They are typically employed sequentially or intermixed, sometimes aligning with the church calendar's seasons. Notably, during fasting periods, the *Ge'ez* and *Araray* modes predominate, while the *Ezil* mode mostly reserved for holidays. These modes serve as conduits for conveying distinct emotions and seasonal themes within the EOTC chants [1].

- **Ge'ez:** Characterized by a foundational, low tone, *Ge'ez* chanting evokes a sense of despondency and solemnity. Rendered in a relaxed, subdued manner devoid of rhythmic constraints, it encapsulates feelings of despair, disappointment, and sorrow [1]. In [3], the Ge'ez mode is interpreted as a *chain of third* (*a-c'-e'*) with "chromatic auxiliary notes around the outer fifth" ($\sharp g/bb$ around *a*, and $\sharp d'/f$ around *e'*).
- **Ezil:** Positioned within a mid-range vocal register, the *Ezil* (or *Izil*) mode assumes a secondary role, characterized by its unassuming, moderate cadence. Emotionally neutral in essence, it is seldom utilized during fasting periods, maintaining a comfortable, ordinary vocal expression. Shelemay et al. [3] stated that "*Ezil* uses the same pitch set as in *Araray*," but this pitch set is rendered as either *c-d-e-g-a* or *c-d-f-g-a*, implying that the third note lies in between *e* and *f* and causes ambiguity for Western ears.
- **Araray:** Distinguished by its high-pitched rendition, embellished with ornamental flourishes and a brisk tempo, the *Araray* mode exudes vitality and jubilation. It serves as a vehicle for conveying animated expressions, elation, and manifestations of compassion, happiness and fulfillment.

⁵ *-ne* is pronounced as in 'Nelson'

⁶ The Ethiopian and Eritrean faithful worldwide served by the chants is additional to the data reported in [14].

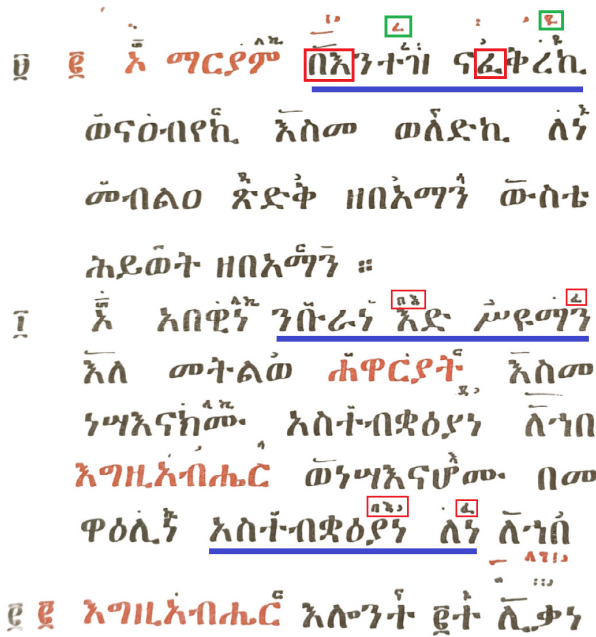

Figure 1. Interlinear letter-based notations with interspersed neumes. From the first underlined two words, the letters enclosed in red rectangles are used as short-form representations of the melody to be used over the other underlined words, sung with the same melody.

The EOTC chants rely on a sophisticated system of interlinear notations, encompassing neumatic signs interspersed between letter-based representations [1, 3]. This notation system serves as the cornerstone of melodic expression in chanting. Although some notations are common across different chanting modes, they produce distinct melodies depending on the mode, making it challenging to identify a specific mode solely based on notation. Figure 1 provides an example of the notation system used in the EOTC chants.

3. DATASET

The dataset was manually collected from the *Eat the Book* website,⁷ a hub of numerous audio books for most of the teachings in the EOTC school departments, with full and partial coverage. From the available audio books, we selected the *Se'atat Zema* (Horologium chant), which is part of *Qidase-bet* department. All the audios selected for our dataset were recorded by a single scholar at a sampling rate of 44,100 Hz and in stereo channel.

Our first step in the audio arrangement process involved narrowing the gap between the longest and shortest duration among the audios. Long audios, such as those over 13 minutes, were segmented into shorter audios of less than three minutes (180 seconds) in a way that preserves meaningful segments. This segmentation process also applied to audios that contained multiple chanting modes. For example, if an audio had 160 seconds of *Araray* mode followed

Figure 2. Distribution of audio recording length (in secs).

Modes	Shelemay and Jeffery [4]		This work	
	#	Length	#	Length
Araray	8	11m36s	118	192m36s
Ezil	6	9m56s	176	291m29s
Ge'ez	10	21m12s	75	118m6s
Total	24	42m44s	369	602m11s

Table 1. Data distribution among the chanting modes.

by 22 seconds of *Ezil* mode content, it would be segmented into two separate audios of 160 seconds and 22 seconds. Recordings that were less than three minutes but still had multiple modes were also segmented based on the respective duration of the included chanting modes.

On the other hand, short audios, like a 19-second audio, were merged with neighboring context audios when applicable to our assumptions. If no neighboring audio with the same mode was found, it would be counted as a separate audio. As we arranged all audios to be in a single mode, we have a corresponding mode label for each audio. Another audio cleaning process was removing non-chant segments as the recordings included short explanatory statements about the corresponding chants. We manually removed them to ensure that the full audio content will be for chanting. In this process we also have shortened the duration of significant silent regions, resulted in only two silent regions above two seconds, particularly 2.25 and 2.14 seconds. After such cleaning procedures, the overall duration distribution of our dataset, ranging from 20.142 seconds to 177.476 seconds, is shown in Figure 2. As our immediate future work, we are working on expanding our dataset by including annotation of word-level lyrics to audio alignment as well as other features, which are not uncovered in this paper to keep the focus. We will do more research regarding other possible additional features.

Table 1 presents the comparison between the previously used dataset (i.e., the recordings collected by Shelemay *et al.* in [4]) and our dataset. While the previous dataset, with a total of 24 instances, is less than one hour, our dataset accounts for more than 10 hours, with a total of 369 instances. The chanting mode annotations of the dataset are available on <https://github.com/mequanent/ChantingModeClassification.git>.

⁷ <https://eathebook.org/>, We acknowledge the website's administrators for their invaluable contribution.

4. YAREDAWI YEZEMA SILT CLASSIFICATION

As a preliminary study, we only consider using time-averaged audio features (i.e., the features ignoring the information lying in the temporal dimension) for *Yaredawi YeZema Silt* classification. Focusing on such features also supports our subsequent discussion on the pitch distributions of different chanting modes (see Section 5).

4.1 Feature Representations and Classifiers

Following previous works on the analysis of various kinds of music [5–11], we consider pitch distribution, the distribution of the frame-level pitch values, for the classification task. Our pipeline of feature extraction mostly resembles [10, 16], by having the stages of pitch contour extraction, stable region extraction, and pitch drift calibration. First, the pitch detection algorithm pYIN [17] is utilized for pitch contour extraction. It sets the time resolution to 128 samples (5.8 ms) while the frequency resolution to 10 cents. After having the pitch contour, the pitch distribution is obtained by having a histogram over the frame-level pitch values with a frequency resolution of also 10 cents. To analyze the time-averaged aspects of the chanting modes, extracting the stable regions of the pitch contour while discarding the sliding, ornamental or other unstable components might be helpful. We therefore reimplement two stable region extraction methods, namely the *morphic* method and the *masking* method, both proposed in [5]. There is also observable pitch drift during the performance. With an investigation of the data, we found that the pitch drifting along the whole recording is relatively small (around 1 semitone upward for the whole recording), so the pitch calibration process can be done straightforwardly with a linear regression. More specifically, the regression is performed on the pitch values 1 semitones around the global maximum of the pitch histogram. With the regression line with slope s , the pitch contour $f[t]$ indexed by time t is calibrated to $f_{\text{calibrated}}[t]$ by having $f_{\text{calibrated}}[t] := f[t] - st$.

The pitch distribution features are therefore based on the six types of pitch contours: three stabilization modes (no stabilization, stabilization with morphetic method, and stabilization with masking method) times two calibration modes (with and without calibration). Besides, several audio features are also compared: time-average mel-spectrogram, mel frequency cepstral coefficient (MFCC), and chromagram. The melspectrogram and MFCC are extracted using the `torchaudio` package [18], while the chromagram is extracted with the `librosa` package [19]. The time-average features of them are obtained simply by taking average over the time axis.

For the classifiers, we utilize the M5 (0.5M) model architecture proposed in [20]. The model is a fully convolutional network containing only 1-D convolution layers, max pooling layers and a global average pooling layer. Such a design has small number of training parameters and can capture the invariance in data [21]. While this network was taken for raw waveform, we adapt it to operate in the frequency domain regarding it as an operator invariant to

pitch shifting. To customize the model to our extracted features, we changed the receptive fields in the first convolutional layer from 80 to 3 when running on the non-raw-audio features in our experiments. For all the experiments, we adopt the categorical cross entropy loss function, Adam optimizer, learning rate of 0.001, batch size of 32, and 50 epochs, due to model convergence.

4.2 Experiment Settings

To observe how the characteristics of *YeZema Silt* vary across different recordings, we consider both the within-dataset and cross-dataset experiments. For the within-dataset experiment, we perform 5-fold cross validation (CV) on the proposed dataset and report the average classification accuracy. For the cross-dataset case, the model is trained on the proposed dataset and then tested on the recordings performed by a chanter from a different chanting department, specifically Zema-bet, in different time and location [4]. The recordings we used from [4], described in Table 1, have a sampling rate of 44100 Hz with stereo channel with 0.33 and 4.05 seconds of shortest and longest audio recordings, respectively. Lastly, to examine the reasonable identifiable audio duration among the chanting modes and how the duration affects the performance, we consider four input durations, namely 5 seconds, 10 seconds, 20 seconds and full length.

4.3 Results

Table 2 lists the classification accuracy of all the experiment settings. First, the results of full length audio show that all the pitch distribution greatly outperform other audio features by a gap of over 25 percentage points. Also, the pitch distribution is more robust than the other audio features in the cross-dataset scenario, with a performance drop by 7 to 23 percentage points. However, comparing the six pitch distributions, it is not clear which calibration or stabilization mode is better. The best accuracy over all in the CV scenario is the calibrated but non-stabilized pitch distribution, but the trend does not apply to the cross-dataset case. Besides, we observe that 1) pitch contour stabilization does help on the accuracy for most of the cases, 2) using stabilization tends to reduce the performance gap between within-dataset and cross-dataset scenarios, and 3) the masking method can reduce this gap better than the morphetic method does, though the morphetic method typically has better classification accuracy. Lastly, there is a clear trend that a longer input audio leads to a better performance. This implies that *YeZema Silt* is a long-term, song-level music concept, while it can also be signified to some extent upon a 10- to 20-sec duration, which is around the duration of a set of music notation.

Table 3 shows two example confusion matrices for both the within-dataset and cross-dataset cases. For the within-dataset case, the accuracy of each class basically follows the amount of data ($Ezil > Araray > Ge'ez$, see Table 1). The trend is different for the cross-dataset case: all classification errors occur between *Ezil* and *Araray*, a result being in line with the experience of analysis [3].

Feature representation			Within-dataset (5-fold CV)				Cross-dataset				
Pitch contour	Calibration	Stabilization	full	20 sec	10 sec	5 sec	full	20 sec	10 sec	5 sec	
	No	No		96.20	91.51	87.93	81.60	87.50	82.98	72.96	74.76
		Morphetic		95.13	87.23	83.47	73.35	83.33	84.40	76.67	70.97
		Masking		94.85	83.85	76.85	64.32	87.50	74.47	68.52	55.41

5. ANALYSIS OF YAREDAWI YEZEMA SILT

The goal of our analysis of *YeZema Silt* is using computational tools to individually identify the pitches utilized in the three chanting modes. Any attempt to this relies on some music theoretical assumptions. The classification results presented in Section 4.3 supports two assumptions that facilitate the analysis: first, *YeZema Silt* is a song-level property that can be satisfactorily described with time-average pitch distributions; second, *YeZema Silt* can be identified by a classifier invariant to pitch-shifting (i.e. convolution). On the other hand, the classification results also expose a few technical limitations. While the raw pitch distribution (i.e., without pitch contour stabilization) yields the best classification accuracy, it is highly noisy and therefore less applicable for our analysis purpose. In fact, we found in our study that the raw and the morphetic pitch distribution are relatively deficient in the below-mentioned analysis process. Therefore, instead of advocating a specific setting in terms of classification accuracy, we decided to use the calibrated pitch contour with masking stabilization method on the full length audio for subsequent analysis, although its performance is not the most favorable. It is worth noting that in this case, the performance gap between within-dataset CV and cross-dataset is relatively small among all settings.

Our approach, which partly resembles [10], contains three steps: 1) shift the pitch distributions of each recording such that each of them are best correlated (i.e., best aligned); 2) compute the average of the aligned pitch distribution for all the recording of the same chanting mode; 3) employ the Gaussian Mixture Model (GMM) to estimate the representative pitch set from the distribution.

Specifically, the pitch distributions of two recordings p_i

and p_j are aligned through pitch-shifting p_j by ξ_{ij} such that their cross-correlation $R_{ij} := R_{ij}[\xi]$ is maximized:

$$\xi_{ij} = -\xi_{ji} := \arg \max_{\xi} R_{ij}[\xi]. \quad (1)$$

The recording which has the highest average correlation with all the other recordings is considered as an anchor: the pitch distributions of all the other recordings are pitch-shifted to this anchor according to their optimal ξ and are then averaged for GMM fitting. The mean (μ), variance (σ^2) and weight (w) of each GMM component then represents the pitch center, pitch variance and pitch weight. The GMM fitting process is initialized by user-specified mean values to enhance convergence [10]. To facilitate the discussion, only the components having variance smaller than 100 cents are considered as representative pitches.

The top row of Fig. 3 illustrates the aligned pitch distributions for the three chanting modes and the two datasets. We observe that the recordings in the same chanting modes typically have similar pitch distributions over the two datasets. Such a consistent trend is also observed from the average pitch distributions (middle row of Fig. 3), which shows that only one pitch (the third peak from the left) from the two dataset in *Araray* is somehow different.

The bottom row of Fig. 3 shows the GMM-estimated pitch distributions for all the recordings from both datasets. By selecting the pitches summing up to maximal weights within one octave, we obtain three representative pitches for *Ge'ez* (denoted as g_1 , g_2 and g_3 , from low to high), five for *Ezil* (denoted as e_1 , e_2 , e_3 , e_4 and e_5) and also five for *Araray* (denoted as a_1 , a_2 , a_3 , a_4 and a_5).⁸ Other representative pitches outside this octave are also notated: the pitch being one octave below g_3 is denoted as G_3 , while the pitch one octave above g_1 is denoted as \hat{g}_1 . The same naming rules also apply for *Ezil* and *Araray*.

Table 4 shows the GMM-estimated parameters for the three modes. First, the pitches used in the *Ge'ez* mode are more flexible than other two modes, as can be observed by their variances than the pitches in other two modes. Among them, only g_2 has the variance less than 10 cents.

⁸ Here, the subscript number does not imply the hierarchical order of the musical scale (e.g., g_1 does not mean “the tonic of the *Ge'ez* mode”). The hierarchy of these pitches is another research question and will be considered as future work.

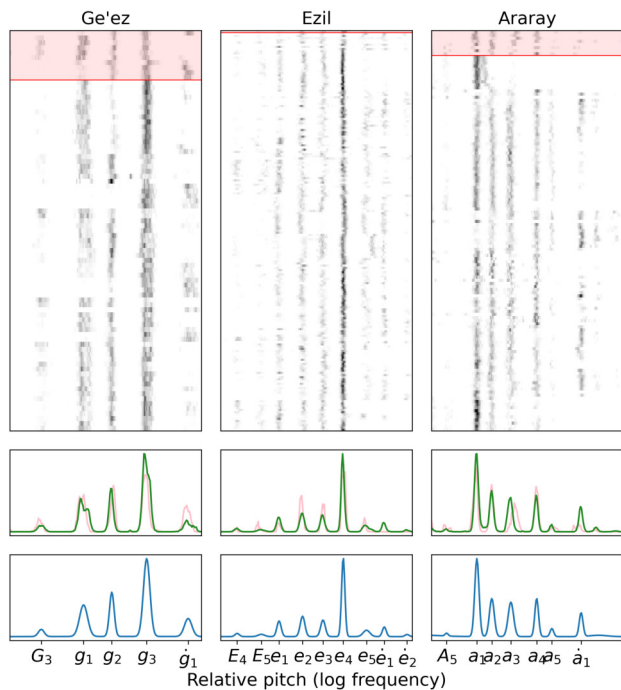

Figure 3. Illustration of pitch distributions for the three *YeZema Siltoch*. Top: the aligned pitch distributions of all the recordings. A row in the 2-D illustration represents the pitch distribution of one recording. Darker color represents larger values. Red background represents pitch distributions of the recordings in [4]. Middle: the average pitch distribution of the proposed dataset (green) and [4] (red). Bottom: GMM-estimated pitch distributions for all the recordings from both datasets. The pitch value of each note name under the bottom row is listed in Table 4.

g_3 and g_2 form a major third ($\Delta\mu = 400$ cents) while g_1 and g_2 form approximately a minor third g_2 ($\Delta\mu = 324$ cents). The pitches of g_1 and g_3 can vary by more or less semitones. Besides, we also observe that the octaves of g_1 and g_3 (i.e., G_3 and \dot{g}_1) also have large variances. This implies that such variance (flexibility of pitch) depend on the pitch name rather than the register. These findings are basically in line with the statements (a scale $\sharp g-a-bb-c'-\sharp d'-e'-f'$ while $g-c'-e'$ are the stem pitches) made in [4].

Both the *Ezil* and *Araray* modes have five representative pitches within one octave. However, the five representative pitches of them are different. For *Ezil*, all the intervals lie between 200 cents (major second) and 300 cents (minor third), while for *Araray*, the intervals distribute from 172 cents (less than a major second) to 347 cents (in between a minor third and a major third). In other words, there is a consistent trend that the intervals in *Ezil* are more equally distributed than *Araray*. There are also some flexible usage of pitch, for example, e_5 (E_5) in *Ezil*. These suggest that the pitch sets found in [4] needs revision: from our observation, each of the pitch sets used in the three EOTC chanting modes is distinctive. Besides, a mode is characterized by not only its pitch centers, but also its pitch variances.

Mode	Note name	μ	σ^2	w	$\Delta\mu$
Ge'ez	G_3	361	11	0.034	486
	g_1	847	21	0.211	324
	g_2	1171	7	0.171	400
	g_3	1571	14	0.419	476
	\dot{g}_1	2047	18	0.112	
Ezil	E_4	189	6	0.022	258
	E_5	447	14	0.023	223
	e_1	670	6	0.106	270
	e_2	940	7	0.151	234
	e_3	1174	7	0.123	232
	e_4	1406	3	0.416	268
	e_5	1674	15	0.068	204
	\dot{e}_1	1878	5	0.059	261
	\dot{e}_2	2139	5	0.013	
Araray	A_5	173	3	0.008	347
	a_1	520	6	0.318	172
	a_2	692	8	0.173	218
	a_3	910	10	0.176	297
	a_4	1207	5	0.134	174
	a_5	1381	4	0.027	335
	\dot{a}_1	1716	5	0.084	

Table 4. GMM-estimated mean (μ , in cents), variance (σ^2 , in cents), weight (w) of the representative note pitches in the Ge'ez, Ezil, and Araray modes. Reference pitch (0 cent) is 82.4 Hz. The intervals (difference between two neighboring pitches, $\Delta\mu$) are listed in the last column.

6. CONCLUSION

In this paper, we presented a research on a relatively under-explored music genre, the Ethiopian Orthodox Tewahedo Church (EOTC) chant, from three computational perspectives. First, through a rigorous data cleaning and annotation process, we presented a new and high-quality EOTC chant dataset, which can be extended for various music information retrieval (MIR) and music generation tasks. Second, we conducted a chanting mode (*YeZema Silt*) recognition task using our dataset and achieved promising results. Additionally, this paper is, to our knowledge, the first to computationally analyze the pitch sets of the EOTC chanting modes, specifically *YeZema Siltoch*, with new musicological insights. In the future, we plan to keep enriching the annotations of the datasets, by incorporating more details like lyrics, chanting options, reading tones and other potential features. Analyzing *YeZema Siltoch* using the features in the temporal dimension and the new data annotations are also our ongoing projects.

The EOTC chants encompass a wide range of styles and forms. In this paper, we specifically concentrated on the *Se'atat Zema* (Horologium chant), which falls under the *Qidase-bet* department. Our objective is to encourage responsible research on EOTC chants, as computational research in this area can lead to technological advancements that enhance the learning process and increase accessibility. Diversifying the data and MIR of EOTC chants for the protection and promotion of this spiritual-cultural heritage is also our future work in the long term.

7. ETHICS STATEMENT

The chants we are working on belongs to the Ethiopian Orthodox Tewahedo Church (EOTC). The oral traditions and beliefs that mainly preserve these chants for more than 1500 years should be credited properly. This work aims to contribute on promoting the chants and finding solutions for their easy understanding. There is no intention to modify the chants in any form.

No explicit permission request is done to the Eathbook.org administrators as recordings are open to the public education and we are using for educational purpose. We value their great effort in making the chants publicly available.

LYRICS TRANSCRIPTION FOR HUMANS: A READABILITY-AWARE BENCHMARK

Ondřej Cífka Hendrik Schreiber Luke Miner Fabian-Robert Stöter

AudioShake

ondrej@audioshake.ai, fabian@audioshake.ai

ABSTRACT

Writing down lyrics for human consumption involves not only accurately capturing word sequences, but also incorporating punctuation and formatting for clarity and to convey contextual information. This includes song structure, emotional emphasis, and contrast between lead and background vocals. While automatic lyrics transcription (ALT) systems have advanced beyond producing unstructured strings of words and are able to draw on wider context, ALT benchmarks have not kept pace and continue to focus exclusively on words. To address this gap, we introduce Jam-ALT, a comprehensive lyrics transcription benchmark. The benchmark features a complete revision of the JamendoLyrics dataset, in adherence to industry standards for lyrics transcription and formatting, along with evaluation metrics designed to capture and assess the lyric-specific nuances, laying the foundation for improving the readability of lyrics. We apply the benchmark to recent transcription systems and present additional error analysis, as well as an experimental comparison with a classical music dataset.

1. INTRODUCTION

Recent general-purpose automatic speech recognition (ASR) models trained on large datasets [1, 2] have shown a remarkable level of generalization, even improving the performance of automatic lyrics transcription (ALT) [3–5]. Remarkably, these state-of-the-art ASR models are able to take in larger temporal contexts and produce natural text with long-term coherence which, in the case of Whisper [2], includes punctuation and capitalization [6]. One may therefore ask how well these capabilities transfer from speech to lyrics. Moreover, producing a high-quality lyrics transcript suitable for user-facing music industry applications (e.g. to be displayed on streaming platforms or lyrics websites) presents some unique challenges, namely the need for specific formatting (e.g. line break placement, parentheses around background vocals) [7–9]. This calls

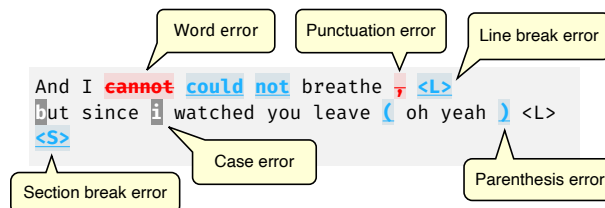

Figure 1: Error types captured by our metrics. Each token is classified as a word, punctuation mark, or parenthesis (enclosing background vocals). Special tokens are added in place of line and section breaks. Each token type is covered by a separate metric; differences in letter case are handled separately.

for a new approach to ALT evaluation and development that accounts for these distinctive nuances.

In ASR, the primary goal is a clear representation of what was said. To that end, formatting is helpful for improving the readability of transcripts [10]. Likewise, fillers like *um*, *uh*, *like*, and *you know* can be omitted to improve readability. Recent work [11] attempts to formalize this concern for clarity, proposing a novel metric geared towards assessing human readability. It employs human labelers, instructed to disregard filler words while, on the other hand, taking account of punctuation and capitalization errors that impact readability or alter the meaning of the text.

In music, on the other hand, lyrics are not simply a means of communicating meaning; they are a form of artistic expression, closely tied to the rhythm, melody, and emotionality of the song. For this reason, lyrics transcription requires a different set of considerations. Line breaks, often missing or arbitrarily placed in speech transcripts, are essential in lyrics for capturing rhyme, meter, and musical phrasing. Fillers like *oh yeah*, non-word sounds like *la-la-la* and contractions such as *I'ma* (vs. *I'm gonna*, *I am going to*) have prosodic significance, and their omission would disrupt the song's rhythm and rhyme scheme. Far from being an impediment to readability, they are key to any faithful rendition of a song for artist and fan alike.

We believe that readability-aware models for lyrics transcription have the potential to facilitate novel applications extending beyond the realms of metadata extraction and relatively crude karaoke subtitles. However, in order to advance in this research direction, the ability to accurately evaluate ALT systems in the aforementioned aspects is vi-

Stöter, "Lyrics Transcription for Humans: A Readability-Aware Benchmark", in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

tal. To the best of our knowledge, existing ALT literature not only overlooks readability, but evaluates on datasets (e.g. [12–15]) that have not been designed specifically for ALT and lack some or all of the desirable features discussed above.

One of the datasets widely adopted by recent works [3, 4, 16–18] as an ALT test set is JamendoLyrics [14], originally a lyrics alignment benchmark. Its most recent (“MultiLang”) version [19] contains four languages and a diverse set of genres, making it attractive as a testbed for lyrics-related tasks. However, we found that, in addition to lacking in the aspects discussed above, the lyrics are sometimes inaccurate or incomplete. While such lyrics may be perfectly acceptable as input for lyrics alignment (and indeed representative of a real-world scenario for that task), they are less suitable as a target for ALT.

To address these issues and help to guide future ALT research, we present the **Jam-ALT** benchmark, consisting of: (1) a revised version of JamendoLyrics MultiLang following a newly created annotation guide that unifies the music industry’s conventions for lyrics transcription and formatting (in particular, regarding punctuation, line breaks, letter case, and non-word vocal sounds); (2) a comprehensive set of automated evaluation metrics designed to capture and distinguish different types of errors relevant to (1). The dataset and the implementation of the metrics are available via the project website.¹ Additionally, to explore the applicability of the proposed metrics to other datasets, we present results on the *Schubert Winterreise Dataset* (SWD) [20].

2. DATASET

Our first contribution is a revision of the JamendoLyrics MultiLang dataset [19] to make it more suitable as a lyrics transcription test set. Different sets of guidelines for lyrics transcription and formatting exist within the music industry; we consider guidelines by Apple [7], LyricFind [8], and Musixmatch [9], from which we extracted the following general rules:

1. Only transcribe words and vocal sounds audible in the recording; exclude credits, section labels, style markings, non-vocal sounds, etc.
2. Break lyrics up into lines and sections; separate sections by a single blank line.
3. Include each word, line and section as many times as heard. Do not use shorthands to indicate repetitions.
4. Start each line with a capital letter; respect standard capitalization rules for each language.
5. Respect standard punctuation rules, but never end a line with a comma or a period.
6. Use standard spelling, including standardized spelling for slang where appropriate.
7. Mark elisions (incomplete words) and contractions with an apostrophe.
8. Transcribe background vocals and non-word vocal sounds if they contribute to the content of the song.

9. Place background vocals in parentheses.

The original JamendoLyrics dataset adheres to rules 1, 3, and 8, partially 2 and 6 (up to some missing diacritics, misspellings, and misplaced line breaks), but lacks punctuation and is lowercase, thus ignoring rules 4, 5, 7, and 9. Moreover, as mentioned above, we found that the lyrics do not always accurately correspond to the audio.

To address these issues, we revised the lyrics in order for them to obey all of the above rules and to match the recordings as closely as possible. As the above rules are fairly unspecific, we created a detailed annotation guide where we have attempted to resolve minor discrepancies among the source guidelines [7–9] and fill in missing details (including language-specific nuances). This annotation guide is released together with the dataset.

Each lyric file was revised by a single annotator proficient in the language, then reviewed by two other annotators. In coordination with the authors of [19], one of the 20 French songs was removed following the detection of potentially harmful content.

Examples of lyrics before and after revision can be found on the project website.

3. METRICS

In this section, we first discuss our adaptation of the conventional *word error rate* (WER) metric and then our proposed precision and recall measures for punctuation and formatting. Our goal here is to design a comprehensive set of metrics that covers all possible transcription errors while allowing us to distinguish between different types of errors (see Fig. 1 for a visual overview of the error types). Note, however, that our goal is *not* to create metrics that completely align with the rules put forth in Section 2 or correlate with a specific notion of readability; the metrics should be general enough to apply to any plain-text lyrics dataset and adapt to its formatting style.

3.1 Word Error Rates

The standard speech recognition metric, WER, is defined as the edit distance (a.k.a. Levenshtein distance) between the *hypothesis* (predicted transcription) and the *reference* (ground-truth transcript), normalized by the length of the reference. If D , I , and S are the number of word *deletions*, *insertions*, and *substitutions* respectively, for the minimal sequence of edits needed to turn the reference into the hypothesis, and H is the number of unchanged words (*hits*), then:

$$\text{WER} = \frac{S + D + I}{S + D + H} = \frac{S + D + I}{N}, \quad (1)$$

where N is the total number of reference words.

Typically, the hypothesis and the reference are pre-processed to make the metric insensitive to variations in punctuation, letter case, and whitespace, but no single standard pre-processing procedure exists. In this work, we apply Moses-style [21] punctuation normalization and tokenization, then remove all non-word tokens. Before computing the WER, we lowercase each token to make the met-

¹ <https://audioshake.github.io/jam-alt/>

ric case-insensitive, but also keep track of the token’s original form. To then measure the error in letter case, for every *hit* in the minimal edit sequence, we compare the original forms of the hypothesis and the reference token and count an error if they differ. We then compute a *case-sensitive word error rate* WER' as:

$$WER' = \frac{S + D + I + E_{\text{case}}}{S + D + H} = WER + \frac{E_{\text{case}}}{N}, \quad (2)$$

where E_{case} is the number of casing errors. We include both variants (1) and (2) in our benchmark.

3.2 Punctuation and Line Breaks

Since the output of ASR systems traditionally lacks punctuation, a common ASR post-processing step – *punctuation restoration* [22] – consists of recovering it. This task is usually evaluated using precision and recall:

$$\begin{aligned} P &= \frac{\# \text{ correctly predicted symbols}}{\# \text{ predicted symbols}}, \\ R &= \frac{\# \text{ correctly predicted symbols}}{\# \text{ expected symbols}}. \end{aligned} \quad (3)$$

In this original setting where the system only inserts punctuation and the words remain intact, computing the metrics is trivial. In contrast, in our end-to-end setting, the hypothesis and the reference may use different words, and hence computing the numerator in Eq. (3) requires an alignment between the two. We leverage the same alignment as used in Section 3.1, but computed on text that includes punctuation. Moreover, we extend this approach to account for line breaks, which, though traditionally ignored in speech data, are particularly important for lyrics.

We use the pre-processing from Section 3.1, but preserve punctuation tokens and, as in [23, 24], add special tokens in place of line and section breaks; this leaves us with five token types: word \bar{W} , punctuation \bar{P} , parenthesis \bar{B} (separate due to its distinctive function), line break \bar{L} , and section break \bar{S} .² After computing the alignment between the hypothesis tokens and the reference tokens, we iterate through it in order to count, for each token type $T \in \{\bar{W}, \bar{P}, \bar{B}, \bar{L}, \bar{S}\}$, its number of deletions D_T , insertions I_T , substitutions S_T , and hits H_T . In general, each edit operation is simply attributed to the type of the token affected (e.g. the insertion of a punctuation mark counts towards I_P). However, a substitution of a token of type T by a token of type $T' \neq T$ is counted as two operations: a deletion of type T (counting towards D_T) and an insertion of type T' (counting towards $I_{T'}$).

We can now use these counts to define a precision, recall, and F-1 metric for each token type:

$$\begin{aligned} P_T &= \frac{H_T}{H_T + S_T + I_T}, & R_T &= \frac{H_T}{H_T + S_T + D_T}, \\ F_T &= \frac{2}{P_T^{-1} + R_T^{-1}}. \end{aligned} \quad (4)$$

² We define a section break as one or more blank lines. Hence, every section break is explicitly preceded by a line break in our representation.

Figure 2: Song-level word error rates by language. Note that strong outliers occur; for clarity, they are not displayed here, but affect the means, which are indicated by triangles.

4. RESULTS

4.1 Benchmark Results

Table 1 shows the performance of various transcription systems on our benchmark. Fig. 2 shows the distributions of song-level word error rates by language.

We include two recent, freely available models capable of transcribing long, unsegmented audio: Whisper [2] (*large-v2* and *large-v3*) and OWSM 3.1 [25] (*owsm_v3.1_ebf*). For both models, we use Whisper-style long-form transcription with a beam size of 5. Both models have language identification capabilities, but may perform better if the correct language is specified; for Whisper, we evaluate both options, while for OWSM, for simplicity, we only evaluate with the language provided. For Whisper, which exhibits great variation between runs due to its stochastic decoding strategy, we report averages over 5 runs. We optionally use HTDemucs [26] to isolate the vocals from the input audio.

Whisper and OWSM are general-purpose speech recognition models and are not designed for lyrics transcription. To make a fairer comparison, we apply simple post-processing to their outputs to improve the formatting: (1) The models do not produce line breaks, but split their output into timestamped segments; we insert line breaks between these segments. (2) We remove unwanted end-of-line punctuation (all non-word characters except for `! ? ' " »`) and uppercase the first letter of every line.³

We also evaluate LyricWhiz [4], a lyrics transcription system combining Whisper with the commercially available instruction-following language model ChatGPT [27]. We report averages over two outputs per song (English only), kindly provided by the LyricWhiz authors. Finally,

³ Although we observed that this transformation tends to improve the outputs for Whisper and OWSM, in general, it may make evaluation results worse if the line break predictions are incorrect. For this reason, we do not include this step as a fixed part of our benchmark.

Table 1: Benchmark results (all metrics shown as percentages). WER is word error rate, WER' is case-sensitive WER, the rest are F-measures. +demucs indicates vocal separation using HTDemucs; +lang indicates that the language of each song was provided to the model instead of relying on auto-detection. Whisper results are averages over 5 runs with different random seeds, LyricWhiz over 2 runs; OWSM and AudioShake are deterministic, hence the results are from a single run. The best results achieved by open-source systems are shown in **bold**. LyricWhiz and AudioShake are listed separately, because they rely on proprietary technology. The last row shows metrics computed between the original JamendoLyrics dataset as the hypotheses and our revision as the reference. For full results by language, see the project website.

as an example of an ALT system built with formatting and readability in mind, we include our in-house lyrics transcription system, which integrates vocal separation.

As a first general observation, consistent with previous studies [4, 5], the performance of Whisper models is relatively good, considering that they were not specifically designed for lyrics transcription. Among the formatting metrics, we highlight a high accuracy in line break prediction. This shows that, although the segments output by Whisper do not always impose a meaningful structure, in music, they do in many cases coincide with lyric lines.

Somewhat counter-intuitively, for Whisper, inputting isolated vocals (+demucs) tends to substantially degrade the results (with the single exception of large-v2 for English). Whisper’s language identification mechanism also turns out to have a significant effect, in that disabling

it and instead inputting the known language of the song (+lang) tends to result in a sizeable drop in WER, especially on languages different from English. This suggests that the language detected by Whisper is often incorrect.

We also observe that Whisper v3 does not necessarily perform better on lyrics than v2. In fact, the WER increases from 27.9 to 32.6 when comparing Whisper v2 +lang to v3 +lang.

The improvement of LyricWhiz over plain Whisper in terms of WER is clear and even sharper than reported in [4]. We also see some improvement in terms of line breaks and punctuation.

Regarding OWSM, its performance is far behind Whisper, with differences far larger than reported in [25] for speech, strongly suggesting that OWSM is poorly suited for ALT, at least without finetuning. With isolated vocals as input, the error is slightly reduced, but still large.

As for our own system, it outperforms all of the above on all metrics shown in Table 1, by a large margin, e.g. with a 57% reduction in overall WER compared to Whisper v2. It is also the only one achieving acceptable accuracy for parentheses (B) and section breaks (S).

4.2 Effect of Revisions

The revisions described in Section 2 have enabled us to compute metrics related to letter case and punctuation, features that are missing from the original dataset. However, the revisions also involved correcting words and line breaks; to measure the effect of these corrections, we present in Table 2 the relevant metrics computed on the original JamendoLyrics data. Comparing Tables 1 and 2, we note that the revisions have mostly improved the results, notably reducing the overall WER (by 1.7, or 5.3%, on average) for all systems, with Spanish seeing the sharpest drop (4.7, or 17.4%, on average, likely due to fre-

quently missing accents in the original data). The general trends – in particular, the ranking based on WER and F_L – remain mostly unchanged.

To quantify the extent of our revisions more directly, we also evaluate both versions of the lyrics against each other and include the results as the last row in Tables 1 and 2. Remarkably, in terms of word tokens, Jam-ALT differs from JamendoLyrics by about 11 % (around 15 % for English and Spanish), which is substantially more than the difference between system performance on the two dataset versions. One potential explanation is that a significant number of the corrections correspond to low-intelligibility singing, which is prone to transcription errors, or to background vocals, which are susceptible to being omitted by transcription systems.

4.3 Error Analysis

In this section, we further analyze the errors made by selected systems on our benchmark.

First, we visualize in Fig. 3 how each type of edit operation contributes to the WER. Besides the basic edit operations (hits, substitutions, insertions, deletions), we include *case errors* from Section 3.1; that is, a hit with a difference in letter case is shown as a case error instead. Moreover, to account for small spelling differences, we consider a substitution as a *near hit* when the replacement differs from the reference in at most two letters.⁴

With Whisper, we observe that inputting separated vocals causes more insertions (and longer output) in v2, but more deletions (and shorter output) in v3. Upon inspecting the outputs, we find that Whisper has a general tendency to omit parts of the lyrics (often the entire song) and instead produce generic or irrelevant text, and that this is more frequent with separated vocals, especially with v3. On the other hand, OWSM shows a slight improvement with separated vocals, but its predictions contain significantly more substitutions, suggesting that they are more often incorrect on a word-by-word basis.

Next, we focus on errors in punctuation and formatting and investigate how often different token types are substituted for each other. To this end, we count the edit operations as in Section 3.2, but preserve the information about substitutions across the four non-word token types (P, B, L, S). We then present this information in a form akin to a *confusion matrix*, adding a special “null” token type \emptyset to account for insertions and deletions.

The result is shown in Fig. 4 for three selected systems. Most errors are insertions and deletions, but another frequent type of error is the replacement of a line break by a punctuation mark, especially in Whisper models. This is explained by the fact that our guidelines forbid most end-of-line punctuation, and hence, when transcription omits a line break, inserting a punctuation mark in its place is often needed to maintain grammatical correctness.

⁴ More precisely, we count a *near hit* if, after removing apostrophes from the two words, their character-level Levenshtein distance is at most 2, and strictly less than half the length of the longer of the two words. Examples include *an/and*, *gon'/gonna*, *therel/their/they/them*, but not *alan* or *this/that*.

Figure 3: Word edit operation frequencies on our benchmark (one run per system). *Near* are substitutions that differ in few characters, *sub* are the remaining substitutions. *case* are hits with case errors, *hit* are the remaining (case-sensitive) hits. The rest are *insertions* and *deletions*. The frequencies are normalized by the reference length, so that:

- $hit + case + near + sub + del = 1$,
- $WER = near + sub + ins + del$,
- $WER' - WER = case$,
- $hit + case + near + sub + ins$ corresponds to the length of the prediction.

By manual inspection of the transcriptions, we find that Whisper tends to produce much longer lines than in the reference and frequently outputs periods (forbidden by our annotation guide as a sentence separator) and, occasionally, spuriously repeated punctuation.

4.4 Schubert Winterreise Dataset

To explore the application of the proposed metrics to other datasets, we additionally perform an evaluation on the *Schubert Winterreise Dataset* (SWD) [20]. SWD comprises nine audio versions of Franz Schubert’s 24-song cycle *Winterreise*, along with symbolic representations, lyrics, and other annotations. An example of Romantic music based on early 19th century German poetry, it contrasts with JamendoLyrics and presents an interesting challenge for ALT. For our evaluation, we pick a single version, SC06 (a 2006 live recording of singer Randall Scarlata), one of the two with audio publicly available.

The lyrics in SWD are formatted as poems – containing line and section breaks –, but their spelling and punctuation, mirroring an 1827 edition of the score [28], does not exactly match our annotation guide. To make them adhere to our punctuation and capitalization rules, we apply a simple transformation to the lyrics: replace all unwanted punctuation (. ; : -) with commas, then remove all end-of-line commas and uppercase the first letter of each line. Note, however, that even after this transformation, the lyrics’ obsolete spelling – predating the 1996 German orthography reform – violates our annotation guide to some extent (mainly in the usage of the letter β and the treatment of elisions), which is expected to distort the WER.

We evaluate all models with the language provided (i.e.

Figure 4: Edit operation counts on non-word (punctuation and formatting) tokens by token type (P = punctuation, B = parenthesis, L = line break, S = section break). ∅ denotes the absence of a token, i.e. it stands for insertion (on the *reference* axis) or deletion (on the *prediction* axis). Substitution of *of/by* a *word* token is counted as an insertion/deletion, respectively. Only a single run per system is considered.

	WER	WER'	F _P	F _L	F _S
Whisper v2	34.5	40.4	42.6	66.2	—
+demucs	41.4	47.2	38.0	61.4	—
Whisper v3	59.0	63.8	40.0	63.6	—
+demucs	52.3	58.6	34.7	63.3	0.0
OWSM v3.1	75.6	82.5	12.9	39.6	4.9
+demucs	82.9	91.8	17.0	39.2	—
AudioShake v3	24.3	29.1	50.9	80.0	72.0

Table 3: Results on performance SC06 from SWD. Only punctuation (P), line breaks (L) and section breaks (S) are included, as the ground truth lyrics do not contain any parentheses. Whisper results are averages over 5 runs with different random seeds. The best result in each column, excluding AudioShake, is shown in **bold**. For full results, see the project website.

disabling language identification). The results are shown in Table 3 and further error analysis in Fig. 5. We notice substantially worse performance on SWD than the German section of our benchmark (Table 1): for example, WER for Whisper v2 + lang increased from 19.9 to 34.5. This likely reflects the more challenging nature of the dataset, but also possibly the mismatched spelling, as suggested by a higher frequency of near hits (see Fig. 5) than seen in Section 4.3 (Fig. 3).

5. DISCUSSION

Given our focus on formatting and punctuation, the question arises to what extent they are in fact dependent on the audio. In particular, could line and section boundaries be accurately predicted just from the textual context, e.g. based on metrical patterns, rhyme, syntax, and semantics? To answer this, we suggest an experiment where a human annotator is tasked with formatting given lyrics first without and then with access to the audio. Such a task would, however, be highly time-consuming and require expert annotators unfamiliar with the songs. As a proxy, one might instead train a *formatting restoration* model on lyrics or use a general-purpose instruction-following language model. Our attempts in this regard have only had limited success

Figure 5: Word edit operation frequencies on SWD. See the caption of Fig. 3.

and we therefore leave such experiments for future work.

Another issue is that there may not always be a single correct division into lines and sections. For example, in a song with relatively short lines, it may be acceptable to join pairs of adjacent lines, especially in the absence of rhyme. Likewise, 4-line sections may be joined to create 8-line sections and so forth. However, it is not obvious how to relax the metrics to allow for this kind of variation. Doing so rigorously would likely require additional annotations, which is contrary to our goal of creating a set of generally applicable metrics. A possible solution compatible with this idea is to create multiple references and pick the best-scoring one during evaluation.

6. CONCLUSION

We have proposed Jam-ALT, a new benchmark for ALT, based on the music industry’s lyrics guidelines. Our results show how existing systems differ in their performance on different aspects of the task, and we hope that the benchmark will be beneficial in guiding future ALT research.

7. ACKNOWLEDGMENT

We would like to thank Laura Ibáñez, Pamela Ode, Mathieu Fontaine, Claudia Faller, Constantinos Dimitriou,

and Kateřina Apolínová for their help with data annotation. We are also thankful to Meinard Müller and Hans-Ulrich Berendes for their helpful comments on the manuscript.

ABSTRACT

This paper surveys 560 publications about music genre recognition (MGR) published between 2013–2022, complementing the comprehensive survey of [474], which covered the time frame 1995–2012 (467 publications). For each publication we determine its main functions: a review of research, a contribution to evaluation methodology, or an experimental work. For each experimental work we note the data, experimental approach, and figure of merit it applies. We also note the extents to which any publication engages with work critical of MGR as a research problem, as well as genre theory. Our bibliographic analysis shows for MGR research: 1) it typically does not meaningfully engage with any critique of itself; and 2) it typically does not meaningfully engage with work in genre theory.

1. INTRODUCTION

Despite much more work [1–560] music genre recognition (MGR) still remains a compelling problem to solve by a machine. This work comes on top of the 467 publications surveyed over a decade ago by Sturm [474]. Of principal concern in that survey is the question: “How does one measure the capacity of a system to recognize and discriminate between abstract characteristics of the human phenomenon of music?” The survey catalogues each of the 467 publications along several dimensions. ¹ Sturm determined whether each publication is mainly a review of MGR research, a contribution to evaluation methodology, or a description of experimental work in which an MGR system is built and tested. For each experimental work (438 of 467 publications) Sturm recorded its experimental designs (of which there are 10), datasets (16), and figures of merit (9).

Now that at least 560 more publications have entered the domain, where does the problem of MGR stand? This paper aims to complement and extend the survey of [474] by

¹The data of that survey can be found here: <https://github.com/boblsturm/Music-Genre-Recognition-Survey--1995-2012>

Wald-Fuhrmann, “A Critical Survey of Research in Music Genre Recognition”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

exhaustively surveying research published between 2013–2022 related to MGR—as well as any earlier publications discovered to have been missed in Sturm’s original work—such that the two surveys give a comprehensive account up to 2022. It also aims to answer several critical questions. Is the experimental design *Classify* and figure of merit accuracy still the most frequent, despite their noted serious flaws threatening the validity of conclusions drawn from them [470, 471, 561, 562]. Is GTZAN [563] still the most used public dataset, despite its noted faults [400, 467, 471, 564]? How have these faults been considered or even reconsidered in the past decade? How has all this new research in MGR engaged with work that is critical of MGR as a research problem, i.e., [231, 232, 329, 401, 467, 469–471, 473, 475–478, 561, 562, 564–574]? How has all this work engaged with genre theory such as [575–598]?

The next section describes the methodology we use to collect and catalogue publications. Section 3 presents our analyses of this collection along several dimensions. Section 4 gives broad observations and recommendations to guide future work in MGR. The resulting catalogue, bibliography and analysis code are available online. ²

2. METHODOLOGY

We assembled a corpus of 560 publications in the following way. We performed a broad search across *Google Scholar* for publications appearing from 2013 onwards using search terms like ‘music genre’, ‘recognition OR classification “music genre”’. This gave over 67 pages of results that we manually browsed. We supplemented these results with searches of the ISMIR proceedings, TISMIR and arXiv. We added each relevant publication we found to a dedicated Zotero collection, ³ which is a convenient means to gather, share and organize bibliographic data.

For each publication in our collection, we read it and manually enter data into a spreadsheet. As done by Sturm [474], we catalogue each publication according to its type, then note the experimental designs, datasets and figures of merit it uses. Additionally, we note whether each publication cites or engages with two kinds of published work: genre-related work from the social sciences and humanities; and work that is critical of MGR. We note what moti-

Figure 1. Annual numbers of publications related to music genre recognition between 1995 and 2022. Dashed vertical line demarcates the end date of publications surveyed in Sturm [474]. The present survey adds ten references before 2013 [115, 149, 155, 181, 194, 202, 209, 354, 423, 426], but 550 other publications surveyed herein are published after 2012. The white plot line shows the number of publications appearing at ISMIR or in the Transactions of ISMIR.

vations the paper describes for researching MGR.

To conduct our analyses of the collection, we query entries in our spreadsheet and Zotero library, but also use python and relevant libraries. We export our collection as a BibTex-formatted file, and the spreadsheet as a text file of comma-separated values. In the following subsections we describe in more detail each dimension of our catalogue. (Further details are given in the Supp. Mat.)

Publication Type We assign each publication to at least one of three categories. A *review* publication is concerned with surveying the domain of MGR, e.g., [474, 599]. An *evaluation* publication is concerned with evaluation methodology in MGR, such as proposing a dataset, e.g., [113, 600], experimental design, e.g., [571, 601], or taking a critical look at work in the domain, e.g., [471, 566]. Finally, an *experimental* publication is concerned with engineering and testing MGR systems, e.g., [563, 602].

Dataset For experimental publications, we note what data sets are used, whether private data was used, and the modality of data used: musical audio (waveform or extracted features), symbolic data, or other types (e.g., lyrics, WWW, playlists). We also note if a publication works with non-Western musics.

Experimental Design Following the categorisations described by Sturm [474, p. 32], we note the design(s) used in the experiments described by a publication. These ten designs are: *Classify, Features, Generalize, Robust, Scale, Cluster, Retrieve, Rules, Compose, Eyeball*. (Supp. Mat. S1.5 describes and gives examples of each of these.)

Figure of Merit (FoM) We note the figure(s) of merit used in the evaluation of experiments [474]. The main FoM we look for include *Accuracy, Recall, Precision, F-measure, Receiver Operating Characteristic (ROC)* and the *Confusion Table*. Where a confusion table has been used we note whether or not there is an accompanying interpretative discussion, and whether specific instances of confusion are discussed. (Supp. Mat. S1.6 defines these.)

Referencing In a direction different from Sturm [474], we record if a publication cites at least one of a collection of 26 publications we deem are *critical* of MGR, i.e.,

[231, 232, 329, 401, 467, 469–471, 473, 475–478, 561, 562, 564–574]. We also determine whether the citation is accompanied by any discussion or concrete effects on the experimental design in the publication. We also record if a publication refers to work on musical genre from the social sciences and humanities, i.e., [575–591, 593–598], and record if that citation is accompanied by substantive discussion. Supp. Mat. S1.7 discusses both sets of references.

Motivation for MGR Where authors explicitly state a motivating rationale for MGR work, we record which of four non-exclusive categories they appeal to: *industrial need, public good, coping with information overload*, or are appealing to *precedent*. There is a degree of unavoidable subjectivity in this designation, and so we opt for parsimony and look only for explicit statements of this kind to avoid unwarranted inference. Supp. Mat. S1.8 provides examples of each of these.

3. ANALYSIS AND RESULTS

We now analyze the 560 publications in this survey in relation to the 467 in Sturm [474]. Figure 1 shows the annual number of publications related to MGR since the earliest reference cited in Sturm [474]—Matityaho and Furst [603]. This shows that MGR publications grew to a high point in 2010 after being established in the MIR community a decade earlier as a “flagship problem” of music information retrieval [604]. Thereafter the mean number of publications related to MGR each year is 56.7 (std dev. 13.1). We see that the annual number of publications related to MGR appearing at ISMIR or in its Transactions since 2010 is less than ten in all but two years (2011, 2016). Our survey does not include 28 publications [605–632] because we cannot get access (e.g., behind a paywall), or the language of the paper is not English.

3.1 Publication Types

Of the 560 publications we survey in this paper, we find only nine review articles or book chapters discussing MGR

[98, 193, 247, 323, 325, 339, 467, 474, 493]. Among these, Corrêa and Rodrigues [98] reviews MGR using symbolic data. Kostek [247] is a review of MIR and has a section about MGR; and Tzanetakis [493] is a book chapter reviewing music informatics generally, where music genre appears in one section. Sturm [467] reviews all publications using the GTZAN dataset up to 2012; and Sturm [474] is the survey we extend in this paper.

We find 19 of our 560 publications that primarily discuss evaluation in MGR research [113, 199, 231, 232, 329, 341, 367, 400, 401, 424, 467, 469–471, 473, 474, 476–478]. In addition to those already described in Sec. 2, Palmason et al. [341] investigates the agreement of music genre ground truth between different stakeholders. Porter et al. [367] discusses enriching the AcousticBrainz audio feature dataset [633] using metadata collected from a variety of online sources, include genre information. Schreiber [424] extends the Million Song Dataset; and Defferrard et al. [113] introduces the FMA dataset. Finally, Hossain and Al Marouf [199] discusses the creation of a dataset of song lyrics exemplifying different genres of Bengali music.

Of the 560 publications we survey in this paper, we find 545 that make experimental contributions. Of these, the next three subsections discuss the datasets, experimental designs, and figures of merit used in this subset of publications, comparing and contrasting with the previous survey [474]. We then go further than Sturm [474]. Subsection 3.7 looks at how all 560 publications we survey engage with work critical of MGR. Subsection 3.8 investigates the extent to which they engage with music genre theory. The penultimate subsection 3.5 looks at how MGR is being motivated as a research problem. Subsection 3.6 looks at the kinds of venues at which MGR research is being published.

3.2 Datasets

Sturm [474] finds the GTZAN dataset [563] from 2002 is the most used public dataset, appearing in 100 out of 435 publications with an experimental component. We find that GTZAN remains the most frequently used dataset, appearing in 254 of 545 publications that have an experimental component. Some publications use GTZAN for learning bases, which are then used for building MGR systems tested in other datasets, e.g., Jao et al. [213] and Markov and Matsui [295]. Some publications we survey use only a portion of GTZAN. For instance, Agarwal et al. [5] uses only five of ten classes; and Rajesh and Bhalke [390] uses only two. Others add classes to GTZAN, e.g., Iloga et al. [205, 206] adds Cameroonian music, Conceicao et al. [95] adds music from Brazil, Wibowo and Wihayati [519] adds Malaysian Dangdut music, and Shashirekha [440] adds songs sung in an Indian language (Kannada). Moving briefly to the entire collection we survey, we find considerations of music from non-Western traditions to appear in only 61 of the 560 publications; Sturm [474] finds 47 in its survey of 467 publications.

Some publications analyze GTZAN as a dataset. Flexer [150] analyzes hubs in GTZAN, and tests methods of outlier detection using it. Lu et al. [286, 287] attempt to auto-

matically find the faults in the dataset identified in Sturm [467]. Rodriguez-Algarra et al. [400] investigates why a particular MGR system performs so well on GTZAN, and finds infrasonic information confounded with labels—more formally explored in Rodriguez-Algarra et al. [401]. Kang and Lin [224] looks at inferring taxonomies of classes in datasets, including GTZAN. Lu et al. [286, 287] use GTZAN as a testbed for anomaly detection.

The next four most popular datasets we find are ISMIR2004 [634] from 2004 (appearing in 50 publications), FMA [635] from 2016 (36), the Million Song Dataset [600] from 2011 (32), and the Latin Music Dataset [636] from 2008 (23). We find that data that is not publicly available (e.g., in-house data, or undisclosed data) appears in 176 of 545 publications. Of those, we find 146 of them exclusively use non-publicly available data.

The predominant data modality in our catalogue is acoustic (or features extracted from acoustic data), which appears in 482 of 545 publications with an experimental component. Sturm [474] finds 344 of 435 publications use such a modality. We find symbolic modalities are used in 40 publications, while Sturm [474] finds them used in 81 publications. We find 11 publications use both modalities [2, 23, 187, 189, 209, 270, 359, 360, 362, 507, 556]. Other modalities (e.g., lyrics, WWW, playlists) appear used in 66 of our publications, while Sturm [474] finds these used in 27 publications.

3.3 Experimental design

The three most used experimental designs we find in the 545 publications we survey with an experimental component match those found by Sturm [474]. The most used design in both is *Classify*: we find 514 publications use this, and of those 264 exclusively use this design; Sturm [474] finds this appears in 397 of 435 publications with an experimental component. The second most used design is *Feature*, which appears in 145 of 545 publications we survey; Sturm [474] finds this appears in 142 of 435 publications. The third most used design is *Generalize*, which appears in 127 of 545 publications we survey; Sturm [474] finds it appears in 69 of 435 publications.

The two least-used designs we find are the same as in Sturm [474]: *Rules* and *Compose*. Among our 545 papers with an experimental component, we find *Rules* appears in six publications [63, 70, 97, 209, 246, 402]. For instance, Campobello et al. [63] derive an analytic formulae for GTZAN genres whereby specific feature values extracted from an audio signal are used to compute the relevance of a class. We find the *Compose* design appears in five [175, 209, 476, 485, 489]. For instance, Sturm [476] inspects the correspondence between randomly generated rhythmic patterns classified with high confidence by a state-of-the-art system trained in the BALLROOM dataset [637], and the classes in that dataset.

3.4 Figure of merit

We find accuracy is the figure of merit that appears the most: 449 out of 545 publications with an experimental

component. Sturm [474] finds this appears in 385 of 435 publications. The confusion table is the next most common figure of merit, appearing in 193 publications surveyed here. In those publications with a confusion table, we find no discussion about it in 78 publications—that is, it is merely presented as a table without interpretation. When a confusion table is discussed, musical motivations for confusions are often given. For example, Chathuranga et al. [73] writes, “[In our confusion table] Rock music is mostly misclassified as country and blue. This is due to the facts that rock music and country music have similar roots and rock music came from a combination of country music and rhythm and blues.” Chen and Ramadge [77] writes, “Rock music is easily confused with other genres—perhaps because of its broad nature.”

Specific instances of confusions are only discussed in nine papers [63, 201, 231, 232, 341, 467, 470, 472, 475]. For instance, Sturm [467] and Campobello et al. [63] show tables of confusions made by classifier for specific excerpts in GTZAN, e.g., Sturm [467] shows GTZAN country excerpt 69 “My Heroes Have Always Been Cowboys” by Willie Nelson is mislabeled “Classical”, and Campobello et al. [63] shows GTZAN filename “country.00069” is mislabeled “Blues”, “Classical” and “Rock”. Sturm et al. [472] do the same but for the Latin Music Dataset. Hsu et al. [201] look at four specific music recordings from a test set they create and inspect how classifications of them differ between systems they test. Finally, Kereliuk et al. [231, 232] and Sturm [470, 475] make use of a set of ten different songs and show how each can be confidently classified in any GTZAN class.

3.5 Justifications of MGR

How is MGR as a research problem being justified? We noted two major shades of justification where one was offered. 155 papers were found that explicitly invoke imagined applications for the music industry (106) or end users (49). In 150 of these papers, applications of MGR were presented as useful or necessary in due contemporary information overload. Conversely, 103 papers were noted to make no direct utilitarian appeal for MGR work, but instead to call upon precedent: MGR problems are important because there has been work on MGR.

In the 150 papers that invoke information overload as a problem that MGR can help solve, a common presumption is that there are problematic quantities of unlabelled musical data that would be more tedious or error-prone to organize by hand than with MGR, e.g [174, 439]. Sometimes, the urgency of dealing with such a problem is emphasised. For example: “a lot of music data has become available recently ... in order for users to benefit from them, an efficient music information retrieval technology is necessary.” [294]; “Given the vast number of current collections, automated genre classification is critical for music organization ...” [376]

Publications seldom motivate through learning something about *music* rather than classifier performance. [301] sets out to understand the temporalities of musical change

over a 50 year period. [329] argues that MGR classifiers can be repurposed towards greater understanding of genre as musico-social. [189, 505] argue that more interpretable models more useful for musicologists and listeners. [348] investigates the potential of MGR for studying underrepresented traditions. [140] examines the ‘tenuous’ relationship between rhythmic similarity and genre.

3.6 Venues for MGR publications

Of the 560 publications we review, 350 are conference papers and 156 appear in journals. The most common venue for MGR publications is the ISMIR conference (43 papers). The next most common conferences are *Int. Conf. Acoustics Speech and Signal Processing* (ICASSP) (12), *Int. Joint Conf. Neural Networks* (IJCNN) (9), and *Inter-speech* (5). Six publications appear at the music computing conferences ICMC, SMC and DaFx. The most common journals were *IEEE Access* (7), *Int. Research Journal of Engineering and Technology* (6), then *IEEE Signal Processing Letters*, *Int. Journal of Computer Applications*, *Journal of Intelligent Information Systems*, *IEEE Trans. on Multimedia*, *Journal of New Music Research*, *Trans. of the Int. Society for Music Information Retrieval*, *Expert Systems with Applications*, and *Applied Soft Computing* (4 publications each).

After stripping edition indicators from conference names, we estimate that papers appeared at 235 unique conferences, of which 195 hosted a single paper in our corpus. Similarly, the 156 journal articles we reviewed appeared across 101 journals, 74 of which hosted a single article from our corpus. 82 publications appear in conferences or journals under the umbrellas of the ACM and IEEE, including ICASSP and WASPAA. In addition to 9 more PhD theses containing work related to MGR [2, 23, 160, 183, 336, 501, 518, 545] we reviewed 14 master’s theses [11, 35, 64, 112, 220, 262, 289, 308, 333, 374, 453, 465].

Elsevier publishes the greatest proportion of the journals encountered (11), followed by Springer (9), IEEE (8), MDPI (5), Hindawi (4), IET (3) and ACM (3). 20 publications were on ArXiv or similar pre-print hosting providers with no corresponding official publication. Many publications appear in venues not specifically concerned with music, audio or informatics, but with computing topics more generally or—more general still—with topics like ‘engineering’ or ‘technology’. Some publications appear in venues apparently unrelated to music informatics. For example, [176] appears in the *International Journal of Early Childhood Special Education*. Others appear in venues whose existence we could not confirm, e.g. [193] was apparently presented at a 2018 ACM Symposium on Neural Gaze Detection of which we can find no online trace.

3.7 Engagement with work critical of MGR

We now turn to another aspect not explored in Sturm [474]: How does research in MGR engage with work that is critical of MGR? How many of the 560 publications we survey cite 26 critical publications [231, 232, 329, 401, 467, 469–

471, 473, 475–478, 561, 562, 564–574]? Do any implement proposed recommendations or alternatives? We find that only 163 of the 560 publications cite at least one of these critical references; and of these, only 77 engage in some way with the critique. Such engagement can be simply applying artist filtering. It can also be motivating the use of a specific experimental design.

Let us look specifically at criticism around GTZAN [563], the most-used dataset in MGR research. Ten years after its creation, this dataset was carefully analyzed by Sturm [467, 471, 564], resulting in a catalogue of its faults and an index of its contents. Kereliuk et al. [231, 232] created and used the first partitioning of GTZAN that considers its contents.⁴ (See Supp. Mat. S2 for an overview of the on-line availability of these materials.)

Considering the faults of GTZAN have been known since 2012, let us focus on the 250 papers published after 2012 that use GTZAN with a *Classify* experimental design reporting accuracy as a figure of merit. Of these, we find only 62 acknowledge the existence of faults in GTZAN, and 46 of those essentially ignore or dismiss them. For instance, Sigtia and Dixon [447], Nanni et al. [320], Jeong and Lee [218], Senac et al. [428] and Palmason et al. [340] are five papers that dismiss consideration of the faults by appealing to the popularity of GTZAN as a benchmark dataset: “Although the GTZAN dataset has some shortcomings [564], it has been used as a benchmark for genre classification tasks” [447]. Others claim that their experimental results are not harmed by such problems, e.g., “Despite [its faults], we still used [GTZAN] because these small problems can not seriously damage our results” [205]. We find 15 publications use the fault-filtered partitions of Kereliuk et al. [231, 232]: [66, 81, 144, 145, 218, 236, 267, 271, 302, 305, 329, 349, 364, 540, 554]. Foleiss and Tavares [152] create their own partitioning following Sturm [467], which was then used by Ng et al. [327] and Cai and Zhang [62]. Three other publications [15, 63, 374] acknowledge the faults in GTZAN and perform their own fault-filtering and partitioning.

The fact that 188 of these 250 publications using GTZAN do not mention its faults could be partly explained by the fact that websites linking to the dataset make no mention of them. At least up to March 20 2022, the original source of GTZAN⁵ makes no mention of any faults or of the cataloguing work of Sturm [467, 471, 564]. There currently exist several online copies of GTZAN (or features computed from the dataset), but none of these mention faults; and at this time we find only two online repositories of GTZAN that mention faults (See Supp. Mat. S2).

Another criticized aspect of MGR research is its use of *Classify* as an experimental design. Sturm [470, 471, 473, 478, 561, 562] argue that this design is essentially a “horse show”: systems are tasked with tapping their hooves the correct number of times, but no reliable measurement of musical intelligence can be made without controlling for numerous independent variables. While the survey in

Sturm [474] finds *Classify* appears in 91.3% of its surveyed publications, the present survey finds it appears in 94.3%. Furthermore, we find 264 publications *only* use *Classify*. While we see at least some work in MGR has cited and engaged with the faults in GTZAN, very few publications in the present survey (outside of those by Sturm and collaborators) meaningfully engage with the criticism of *Classify*. To the best of our knowledge, there are no publications that dispute the argument of Sturm [470, 471, 473, 478, 561, 562]; and we find only 17 publications citing those six publications and engaging with them in any meaningful way when it comes to experimental design [47, 48, 63, 67, 98, 140, 175, 244, 286, 327, 329, 374, 375, 393, 421, 507, 518], e.g., cautiously interpreting results of classification, or motivating additional experimental designs.

3.8 Engagement with genre theory

We now turn to the question: how have the 560 publications in our survey engaged with genre theory from the social sciences and humanities? We find 36 references to such work citing 23 sources [575–598]. Of these 36 publications, 10 go further than just citation [139, 146, 219, 329, 341, 375, 421, 453, 469, 471]. Useful indicators of the ways in which musical genre is a more complex concept than just distributions of acoustic or other features are scattered across these contributions. The following key points emerge from engagements with genre theory in our corpus:

Relational The interrelationships between genres are crucial to understanding them, yet more complex than can be captured through simple taxonomies [329, 341, 375, 469, 471].

More-than-sonic The character of genres is determined not only through sonic traits but that other modalities can be of crucial importance, often as proxies for the social roots of genres [146, 329, 375, 421].

Social The relationships between genres and social formations / identities is complex and bidirectional: genres can articulate identities, but genres can also be used as part of demarcating social groupings. The agency in defining and consolidating genre terms is distributed across different social planes, including the institutions of industry, as well as musicians, critics and fans [219, 329, 341, 421].

Perspectival Genres and their relationships can be understood quite differently by different groups of people [375, 469, 471].

Dynamic No aspect of musical genre stands still. Their salient sonic and other features, interrelationships, connections to social formations are all in constant, unpredictable motion. Crucially this means that the association of particular musical texts and tastes with genres is also subject to change [329, 471].

⁴ Both the catalogue of GTZAN and the fault-filtered partition are available here: <https://github.com/boblsturm/GTZAN>.

⁵ <http://marsyas.info/downloads/datasets.html>.

4. DISCUSSION

Based on a survey of 560 MGR publications from 2013–2022, we find some continuity with the previous survey by Sturm [474]. GTZAN, *Classify* and *Accuracy* remain respectively the most widely used dataset, experiment and figure of merit. Despite an increase in the number of public datasets available to MGR researchers, we also see that the proportion of publications dealing with non-Western musical formations has not changed appreciably. Although the use of alternative modalities of data (e.g., lyrics, WWW, playlists) has roughly doubled, such work remains a minority and treating MGR as an audio-similarity problem still prevails. However, our survey goes further to find that MGR work has by and large not engaged with any critique of its accepted methodologies, critique of the research task itself, or of work in the social sciences and humanities related to genre.

We note that the engagement that there is has introduced to MGR key facets of the challenges of studying musical genre, which warrant greater consideration—we commend the introductory chapter of [577] as a comprehensive overview. Crucially, each of the factors outlined in Sec. 3.8 not only provide key pointers towards threats to validity for MGR [638] but also indicate that for MIR to contend with genre as a *musical* topic, a greater diversity of approaches is called for [639]. However, given the quantity of the surveyed publications that appear outside ISMIR or core MIR venues, it is not certain whether MGR remains a “flagship problem” of music information retrieval [604].

Has it, rather, become autonomous of MIR, as a convenient downstream task for computer scientists that has the appearances of addressing a domain-specific useful problem? Our reading of the given motivations for MGR research found in this corpus supports the plausibility of this interpretation, given the frequency of appeals to vaguely described industrial and user applications. One way to investigate this further would be through a bibliometric analysis of this corpus, geared towards identifying possible clusters of work through co-citation or collaboration.⁶ A possibility is that MIR specialists have shifted their attention to auto-tagging and away from MGR, which as a ‘superset’ problem of MGR, we do not cover here. However, an interesting area for follow-up research could be to perform a similar survey of auto-tagging research along with a bibliometric comparison, which may shed some light on the movement of research within MIR.

Nevertheless, we put forward the normative position that *music* informatics researchers should be oriented to *musical* questions open to investigating their complexities in collaboration with music scholars. Doing so likely involves shifts in how this research is pursued. Currently, what dominates is exploratory analysis where progress is assessed through benchmarks. [641] provides a framework for assessing the suitability of such ‘outcome reasoning’ along dimensions of measurement, adaptability, re-

silience and compatibility with stakeholder beliefs. These are telling questions, as it’s not clear that for much MGR research who the stakeholders are. If one group of potential stakeholders is other music researchers, rather than the imagined needs of music platforms or their users, then this points to more *explanatory* work in MGR. However, benchmark-driven predictive modelling need not be abandoned. In [642] the authors point to ways in which benchmark-driven work can be incorporated and redirected towards richer ends and [643] shows how predictive models can be integrated into contemporary approaches to causal inference, suited to theory-driven, explanatory registers of research.

5. CONCLUSION

We close with some recommendations. Broadly, MGR suffers from threats to validity [638] that warrant more attention. Some progress could be made through a greater role for theory in MGR, both through authors being more explicit about the theoretical perspective on genre at work in a given study, as well as deeper engagement with theories of musical genre.

In particular, a close and critical reading of the introductory discussion of [577] in terms of its implications for MIR genre research could be generative for the field. Specifically, it is the sociality, temporality and heterogeneity of genres that are least addressed in the work we have surveyed, and these bring interesting challenges. One fruitful direction to engaging with the social can be found in [644]: by acknowledging that culture is present in every part of the MIR ‘value-chain’ [645], the authors propose a technical intervention on recommender system design in pursuit of a normative social outcome (‘commonality’) often considered to be outside the scope of engineering concerns. Some of the surveyed work already moves towards dealing with genre as temporal [301], and social-temporal [329]. This suggests a possible intersection with work in music and cultural evolution [646], which could serve as a constructive ‘interface’ between MIR and music studies.

Finally, to contend with the heterogeneity of genres means dealing not only with their sonic variability, but also variability across the many other dimensions that may define a particular genre for a particular aesthetic coalition. On the first point, we would recommend more genre-specific computational-musicological work like [647–649] to cast light on the relationships between computed features and aesthetic saliences for groups of listeners. More fine-grained, genre-specific datasets as in [276] might help here. On the second point, engaging with ‘live’ genres in motion implies the need for work in nonexperimental settings [650] that can cope with diverse, noisy and incomplete data.

6. ACKNOWLEDGMENTS

This work was supported by the European Research Council under the European Union’s Horizon 2020 research and innovation programme (Grant agreements No. 864189 and No. 101019164).

⁶ Open scholarly databases such as OpenAlex [640] could automate at least some of this, although we note that its coverage of references for the papers in this corpus doesn’t extend to around half of its ISMIR papers.

ABSTRACT

Recent years have witnessed a rapid growth of large-scale language models in the domain of music audio. Such models enable end-to-end generation of higher-quality music, and some allow conditioned generation using text descriptions. However, the control power of text controls on music is intrinsically limited, as they can only describe music *indirectly* through meta-data (such as singers and instruments) or high-level representations (such as genre and emotion). *We aim to further equip the models with direct and content-based controls on innate music languages* such as pitch, chords and drum track. To this end, we contribute *Coco-Mulla*, a **content-based control** method for **music large language modeling**. It uses a parameter-efficient fine-tuning (PEFT) method tailored for Transformer-based audio models. Experiments show that our approach achieves high-quality music generation with **low-resource** semi-supervised learning. We fine-tune the model with less than 4% of the original parameters on a small dataset with fewer than 300 songs. Moreover, our approach enables effective content-based controls. We illustrate its controllability via chord and rhythm conditions, two of the most salient features of pop music. Furthermore, we show that by combining content-based controls and text descriptions, our system achieves flexible music variation generation and arrangement. Our source codes and demos are available online ^{1 2}.

1. INTRODUCTION

Controllable music generation encompasses the creation of music under various controls, such as musical or textual descriptions [1–4]. It enables amateur users to create customized music and helps professional musicians explore new ideas for composition and arrangement. Re-

markable advancements have been made in this field in recent years, particularly in text-to-music generation [3–6]. These cross-modality models are trained on extensive sets of parallel text-audio data pairs, utilizing pre-trained large language models [7] or multi-modal embeddings [8, 9] to establish a mapping between natural language and music. They enable high-level controls such as mood and tempo by incorporating them into a text prompt.

However, not all music information can be expressed via text. Existing models cannot yet apply effective controls on intricate musical languages (e.g., chord progressions) or directly refer to musical contents from other audio recordings. The ability to accommodate such *content-based* controls is crucial for tasks such as music editing, music variation generation, and arrangement. For example, in AI-assistant composition systems, the generative models are required to compose based on a rough idea like motifs or counter-melodies; in music re-instrumentation, we tend to keep the underlying harmony unchanged and reinterpret the song with new instruments.

Historically speaking, the shift from text-based (and metadata-based) models to content-based models has once happened in the realm of music information retrieval (MIR), which dramatically improved the model performances and also expanded the boundary of music understanding. In a similar fashion, we aim to push the boundary of music audio generation domain by further equipping off-shelf generative models with content-based controls.

A simple approach to incorporating content-based control is to train a separate generative model conditioned on the provided control content [4, 10]. For example, both the MusicGen and MusicLM systems offer two versions of model: a vanilla text-to-music version, and a melody-conditioned version for accompaniment generation. The main issue with this simple conditioning approach lies in the high training cost, which is at the same scale as the base model in terms of both computational resources and training data. Moreover, each conditioned model can only deal with *one type* of content-based control input. This rigid setting is not practical in real music production and arrangement scenarios where multiple control contents are often required for satisfactory results.

To solve the aforementioned problems, we contribute a unified approach to incorporating different content-based controls with music-audio generative models. Particularly,

¹ <https://github.com/Kikyo-16/coco-mulla-repo>.

² <https://kikyo-16.github.io/coco-mulla/>.

we see the immense potential of large-scale pre-trained models in their semantic-level understanding of music and therefore propose a novel parameter-efficient fine-tuning condition adaptor based on llama adaptor [11].

The current design of the adaptor integrates the joint embeddings of symbolic music chords and piano roll and acoustic drum tracks with the pre-trained MusicGen model. In theory, the adaptor can perform on joint embeddings of any combination of content-based controls and can be integrated with any Transformer-based generative model. In short, the main contribution of this work is as follows:

- **A unified approach on content-based controls:** Our model enables chord and drum pattern controls via acoustic hints, achieving an arbitrary combination of textual, harmonic, and rhythmic description for the controlled generation process.
- **Low-resource fine-tuning on pseudo-labeled datasets:** We provide a method to fine-tune a large auto-regressive audio generative model with a small-size, pseudo-labeled dataset in which all the pseudo labels are extracted using existing MIR tools. We fine-tune MusicGen [4], an excellent text-to-music model, on 4% trainable parameters of the original model with a training set of fewer than 300 songs without text or other annotations.
- **Flexible variation generation and arrangement:** Our model achieves flexible variation generation and arrangement of the given polyphonic piano roll by combining text prompts and content-based controls. This enables numerous downstream music-editing applications.

2. RELATED WORK

We review two realms of related works: 1) large-language models (LLMs) for music audio and 2) existing methods of parameter-efficient fine-tuning.

2.1 Music Audio Generation

Music audio generation necessitates extensive contextual modeling to account for the intricate structure of musical language. Recent large-scale music audio generative models, encompassing auto-regressive and diffusion-based approaches, have made remarkable strides in capturing such a long-term structure while introducing cross-modality conditions. For example, Jukebox [1] leverages VQ-VAE [12] and transformer decoders to achieve lyrics- and genre-based generation; Diffusion-based Moûsai [3] adopts the pre-trained frozen T5 encoder [7] to summarize text conditions; auto-regressive MusicGen [4] realizes monophonic melody and text controls by assembling EnCodec [13], T5 encoder, and an acoustic transformer decoder. Specifically, MusicGen is the first text- and melody-conditioned model, limited to a monophonic melody condition, and it does not accommodate drum tracks. Additionally, a contemporaneous work, Music ControNet [14], shares a similar goal

with ours but is based on a diffusion model rather than on pretrained large language models (LLMs).

2.2 Parameter-Efficient Fine-Tuning

Parameter-efficient fine-tuning (PEFT) methods adapt pre-trained language models (PLMs) without fine-tuning all model parameters [15, 16], significantly reducing computational and storage expenses. [17] and [18] tailor PLMs for specific tasks by appending task-specific prefixes to input sequences. [19] employs low-rank adaption (LoRA) to fine-tune pre-trained linear transformations in PLMs. [11] and [20] propose LLaMA-Adapter, adjusting attention outputs using prompt adaptors and zero gate scalars. LLaMA-Adapter also introduces a multi-modal conditional variant by incorporating *global* image representations into prompt adaptors. In this study, we present a novel PEFT method, inspired by LLaMA-Adapter, designed to fine-tune large-scale models while accommodating external *sequential* multi-modal conditions.

3. BASE MODEL

In this work, we choose MusicGen [4], an excellent Transformer-based music audio language model, as our base model. MusicGen offers two variants: a text-only model and a melody-based model. The melody-based model conditions its generation on the dominant time-frequency bin of the audio chromagram and text prompts, limiting it to monophonic conditioning and preventing it from incorporating rhythmic drum patterns. In this study, we adopt the text-only MusicGen as our base model, augmenting it with content-based controls via the proposed PEFT method.

The largest text-only MusicGen consists of 3 components: a pre-trained EnCodec, a pre-trained T5 encoder, and an acoustic transformer decoder. The transformer decoder comprises $N = 48$ layers, each including a causal self-attention block and a cross-attention block to handle condition text prompts.

MusicGen tokenizes audio signals using EnCodec [13], a Residual Vector Quantization (RVQ) [21] auto-encoder, compressing signals of sample rate $S_r = 32000$ into discrete codes of a low frame rate $f_s = 50$. The acoustic transformer decoder takes these tokens as its input.

4. METHODOLOGY

Our approach consists of 2 components: 1) a joint embedding encoder to integrate content-based controls, and 2) a condition adaptor to fine-tune MusicGen by incorporating the learned joint embeddings. To maintain the ability of the vanilla MusicGen to associate text with music, we train the adaptor for only the self-attention blocks of the acoustic transformer decoder. During training, all the parameters of MusicGen are frozen.

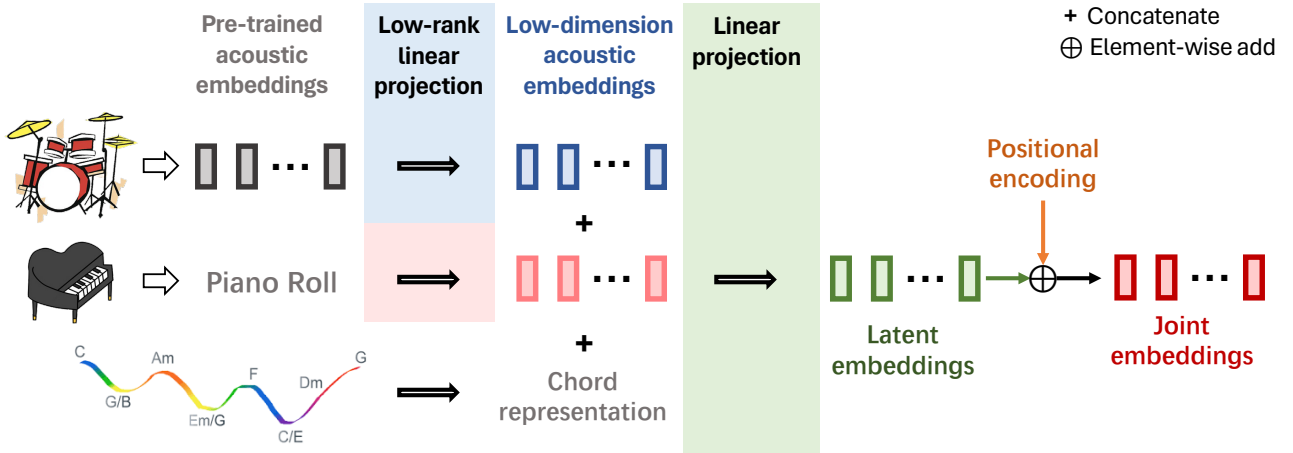

Figure 1. The joint embedding module. We randomly mask acoustic or piano roll embedding with probability r during training.

Chord Name	Pitch	Root	Bass	Pitch Indices
C:maj	C, E, G	C (0)	C (0)	0, 4, 7
C:maj/E	C, E, G	C (0)	E (4)	0, 4, 7
D:min	D, F, A	D (2)	D (2)	0, 3, 7

Table 1. Symbolic chord data structure.

4.1 Joint Symbolic and Acoustic Embedding

To incorporate the desired chord progression and to borrow musical content from another audio recording simultaneously, we design a joint symbolic and acoustic embedding. For precise alignment of generated music with acoustic hints, we use a frame-wise representation for both symbolic and acoustic data.

4.1.1 Symbolic Chord and MIDI Representation

We describe a chord as a combination of a root pitch class, the bass pitch class, and the chroma representation of the chord quality. As shown in Table 1, we represent a chord as $\{\text{root}, \text{bass}, \mathbf{m}\}$ (root, bass $\in \{0, 1, \dots, 11\}$), with $\mathbf{m} \in \mathbb{R}^{12}$ being a multi-hot positional vector indicating the active pitches in the octave starting from the root note. Define $\mathbf{c}_i \in \mathbb{R}^{12+12+12+1}$ to represent the i^{th} -frame chord:

$$\mathbf{c}_i = \begin{cases} [e(\text{root}); e(\text{bass}); \mathbf{m}; 0], & \text{if } i^{\text{th}} \text{ frame has a chord} \\ [0; 0; 0; 1], & \text{otherwise} \end{cases}, \quad (1)$$

where e is a function from an index $j \in \{0, 1, \dots, 11\}$ to its one-hot vector $e(j) \in \mathbb{R}^{12}$.

We represent MIDI using the piano roll format. Assume $\mathbf{p}_i \in \{0, 1\}^{128}$ is the i^{th} frame in the piano roll indicating the presence of each pitch. We further compress the sparse piano roll into a low-dimension MIDI representation \mathbf{p}'_i using a trainable matrix $\mathbf{W}_p \in \mathbb{R}^{d_1 \times 128}$:

$$\mathbf{p}'_i = \mathbf{W}_p^T \mathbf{p}_i \in \mathbb{R}^{d_1}. \quad (2)$$

Throughout the training process, we use pseudo chord annotations obtained through a chord recognition model from [22] and MIDI annotations via an automatic music transcription model from [23].

4.1.2 Acoustic Representation

We convert the separated drum stem to discrete codes using EnCodec [13]. Instead of directly modeling these discrete codes, we pass the i^{th} -frame codes through the frozen input embedding layer of MusicGen transformer decoder to obtain a pre-trained acoustic embedding $\mathbf{h}_i \in \mathbb{R}^{2048}$. Such a continuous pre-trained representation is more robust since it can address the issue of utilizing discrete codes not present in the training data during the inference stage.

To mitigate overfitting and reduce training complexity, we employ a trainable low-rank matrix $\mathbf{W}_a \in \mathbb{R}^{2048 \times d_2}$ to map \mathbf{h}_i into a lower-dimensional space:

$$\mathbf{h}'_i = \mathbf{W}_a^T \mathbf{h}_i \in \mathbb{R}^{d_2}. \quad (3)$$

We set $d_2 = d_1 = 12$ in our experiments.

4.1.3 Masking Scheme and Positional Encoding

During training, we randomly mask MIDI and acoustic representation with a probability r independently:

$$\mathbf{z}_i^p = \begin{cases} \mathbf{p}'_i, & \text{if not masked} \\ \mathbf{s}_i^p, & \text{otherwise} \end{cases}, \quad (4)$$

$$\mathbf{z}_i^a = \begin{cases} \mathbf{h}'_i, & \text{if not masked} \\ \mathbf{s}_i^a, & \text{otherwise} \end{cases}. \quad (5)$$

Here, \mathbf{s}_i^p and \mathbf{s}_i^a are learnable masked embeddings. The masking strategy trains the model to follow an arbitrary combination of conditional tracks during inference. We set $r = 0.4$ in our experiments.

We introduce a learnable matrix $\mathbf{W}_e \in \mathbb{R}^{(d_1+d_2+37) \times d}$ to incorporate the above embeddings and a learnable positional embedding $\mathbf{z}_i^{\text{pos}} \in \mathbb{R}^{d_1+d_2+37}$ to facilitate sequen-

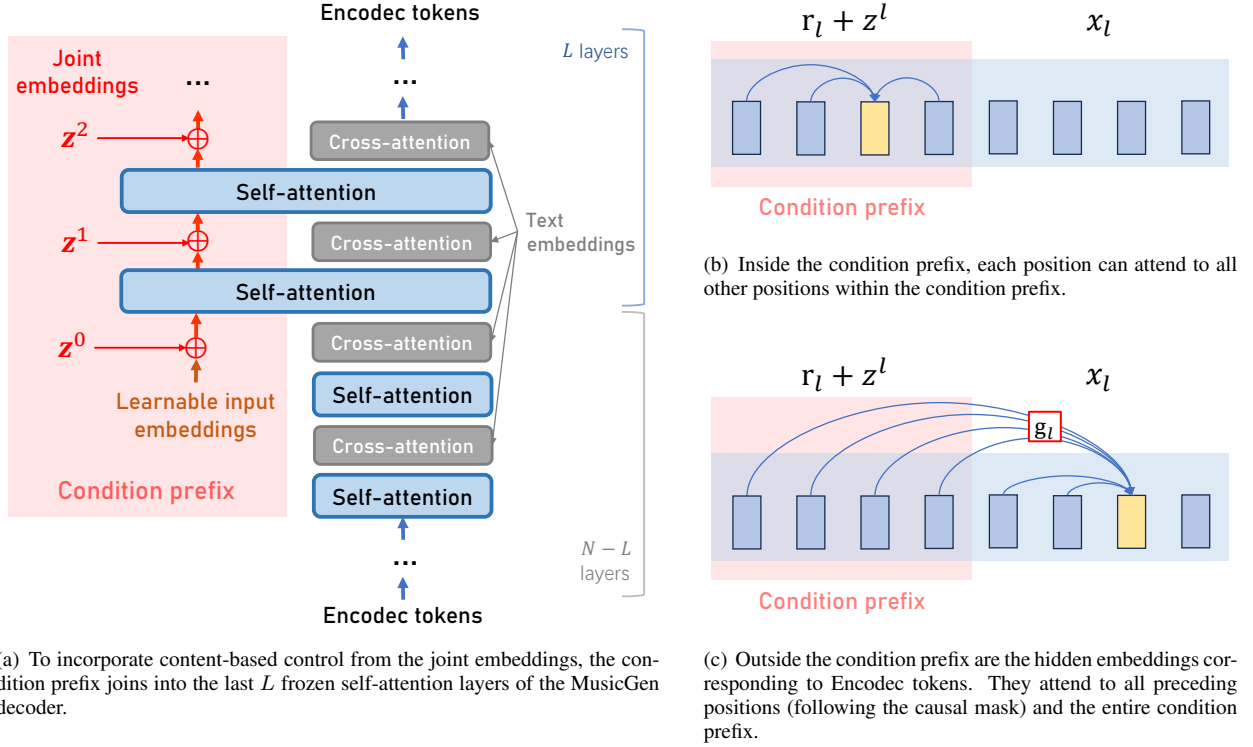

Figure 2. Condition adaptor. The condition prefix is injected to the self-attention mechanism of the MusicGen transformer decoder. All transformation matrices in MusicGen are frozen. Only the input embeddings, joint embedding encoders, and the gate factors are trainable.

tial modeling. The final joint symbolic and acoustic embedding is as follows:

$$z_i = \mathbf{W}_e^T([c_i; z_i^p; z_i^a] + z_i^{\text{pos}}) \in \mathbb{R}^d. \quad (6)$$

Finally, let T be the total number of frames. The complete sequential joint embedding is then:

$$z = \{z_1, z_2, \dots, z_T\} \in \mathbb{R}^{T \times d}. \quad (7)$$

4.2 Condition Adaptor

To plug the joint embeddings into MusicGen, we present a novel condition adaptor that can take time-varying sequential conditions. In the vanilla Transformer, each self-attention layer operates on a sequence of T hidden embeddings corresponding to T frames of Encodec tokens. In the proposed condition adaptor, as shown in Fig 2, for the last L layers of the MusicGen decoder, we expand the sequence of hidden embeddings to $2T$, where T new positions take on the task of incorporating and processing condition-related information. We call the newly introduced positions the *condition prefix*.

Specifically, we insert a sequence of learnable input embeddings into the $(N - L + 1)^{\text{th}}$ MusicGen transformer decoder layer, initiating the condition prefix. Inside the condition prefix, we pass the hidden states only through self-attention layers, skipping cross-attention layers.

Let $\mathbf{H}_l^p \in \mathbb{R}^{T \times d}$ ($N - L + 1 \leq l \leq N$) represent the output of the l^{th} -layer attention layer for the condition

prefix. \mathbf{H}_0^p is a sequence of learnable input embeddings. We compute the condition prefix as follows:

$$\mathbf{Q}_l^p, \mathbf{K}_l^p, \mathbf{V}_l^p = \text{QKV-projector}(\mathbf{H}_l^p + \mathbf{Z}_l), \quad (8)$$

$$\mathbf{H}_{l+1}^p = \text{Self-Attention}(\mathbf{Q}_l^p, \mathbf{K}_l^p, \mathbf{V}_l^p), \quad (9)$$

where the sequential joint embeddings \mathbf{Z}_l is defined in Eq (7). Note that we learn distinct joint embeddings for each decoder layer. Since the adaptor aims at capturing the long-term contextual information of the sequential joint embeddings, it *does not* employ a causal attention mask for the condition prefix. Additionally, the condition prefix does not attend to the Encodec token frames, as shown in Fig 2(b).

For the non-prefix part, hidden states are passed through both self-attention and cross-attention layers. Let $\mathbf{H}_l \in \mathbb{R}^{T \times d}$ ($1 \leq l \leq N$) represent the output of the l^{th} attention layer for the encoded tokens. we compute vanilla attention output \mathbf{S}_l as follows:

$$\mathbf{Q}_l, \mathbf{K}_l, \mathbf{V}_l = \text{QKV-projector}(\mathbf{H}_l), \quad (10)$$

$$\mathbf{S}_l = \text{Self-Attention}(\mathbf{Q}_l, \mathbf{K}_l, \mathbf{V}_l). \quad (11)$$

To incorporate condition information, in the last L layers, we compute cross attention \mathbf{S}'_l between \mathbf{Q}_l and $\{\mathbf{K}_l^p, \mathbf{V}_l^p\}$. We leverage Self-Attention layers to compute \mathbf{S}'_l rather than Cross-Attention layers since the controls are closer to the audio modality than the textual modality. To

Table 3. The performance of models with different L values under the chord-only condition.

make {query, key, value} more compatible, we use the fusion of Q_l and Q_l^p as the query instead of a single Q_l :

$$S'_l = \text{Self-Attention}(Q_l + Q_l^p, K_l^p, V_l^p). \quad (12)$$

Following this, we combine S_l and S'_l using a zero-initialized learnable gating factor g_l . Additionally, to maintain the text controllability of the model, we then compute the cross attention between textual embedding and them:

$$H_{l+1} = \text{Cross-Attention}(S_l + g_l \cdot S'_l, \text{text}). \quad (13)$$

All the layers in MusicGen are frozen, including the QKV-projector, Self-Attention, and Cross-Attention layers. Hence, the total trainable parameters only comprise H_0^p , W_p , W_a , W_e , z^{pos} , and g_l . Moreover, the proposed adaptor can learn in a semi-supervised manner using pseudo-separated tracks, pseudo MIDI, and pseudo chord labels. Additionally, during training, each music piece is assigned to a vague text description randomly sampled from a small set of predefined phrases, eliminating the requirement for text-audio data pairs.

5. EXPERIMENT

5.1 Datasets

The training dataset consists of 299 *unannotated instrumental* songs. We collect 150 of them from an open-source dataset MUSDB18 [25] and download the remain 149 songs from the internet. The latter subset predominantly consists of Pop songs, with a limited data of other genres such as Jazz and Rock. We omit the silent start and end segments of each training song, yielding 17.12 hours of audio. We employ Demucs to extract drum tracks, a chord recognition model [22], an automatic transcription

model [26], and a beat tracking model [24] to generate pseudo chord, MIDI, and beat labels.

The test set comprises 50 songs with chord, beat, and MIDI annotations from RWC-POP-100 [27]. Vocals are excluded by a music source separation model Demucs [28].

5.2 Training Configuration

We train the proposed model using 4 RTX8000s with an initial learning rate of $2e-3$ and a batch of 24 20-second samples for 10 epochs. We set the warm-up epoch to 2 and update the model using a cross-entropy reconstruction loss. During training, for each audio sample, we simply sample a text prompt from a text description set for each music segment: {*melodic music, catchy song, a song, music tracks*}.

5.3 Evaluation

We separate each audio clip in the test set into 4 stems using Demucs and discard the vocal track. As shown in Table 2, “*Chord-only*” signifies no drums and MIDI controls, while “*Full*” indicates both drums and MIDI controls. Within each group, we generate 16 20-second audio samples per given chord progression, employing various text prompts while keeping the same chord unchanged. In total, we have 4 test groups, each with 800 generated audio samples.

We report weighted recall score for chord accuracy, standard F-measure for rhythm control, CLAP [29] score for text control evaluation, and Fréchet Audio Distance (FAD) [30] for audio quality measure. As depicted in Table 2, Chord_{rec} represents chord root accuracy, and Chord_{rec}^{*} assesses full chord accuracy. FAD_{vgg}^{*} quantifies the audio dissimilarity between generated samples

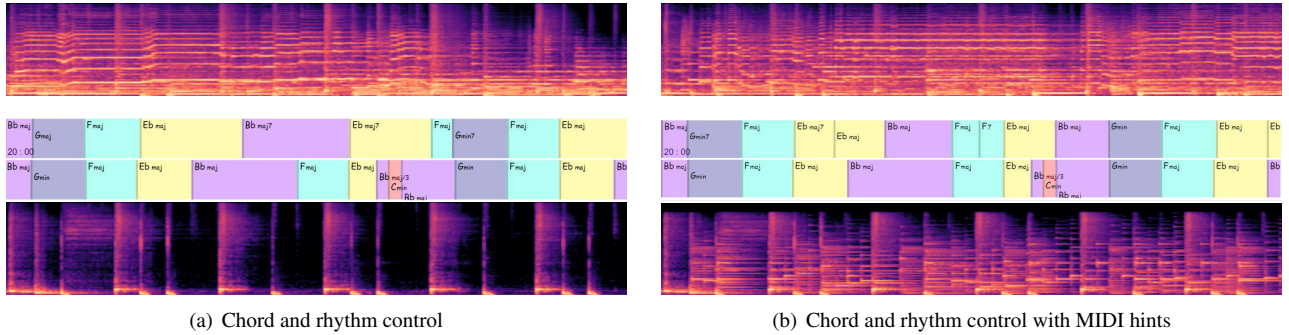

Figure 3. Comparison of generated samples and groundtruth. The top two rows are generated samples, while the bottom rows are reference soundtracks. The text prompt is “*lazy jazz composition features a captivating saxophone solo that effortlessly melds with piano chords, skillfully weaving its way through the melody with languid grace. Instruments: saxophone, piano, drums*”.

Figure 4. The variation of $|g_l|$ during training.

and groundtruth audio from the RWC-POP-100 subset, whereas $FAD_{V_{gg}}$ assesses this dissimilarity using the remaining 50 audios within RWC-POP-100.

5.4 Results

As illustrated in Table 2 and Figure 3, our model excels in chord and rhythm control while maintaining the text-conditioned ability, even though we do not train the model with real text annotations. We do not report chord and beat accuracy for the baseline model, as it cannot use these controls. Code details and more demos are publicly available online.

5.4.1 Low-resource Fine-tuning

During fine-tuning, our observations suggest that our model works better with a smaller training dataset characterized by high-quality audio fidelity than a larger one featuring pseudo-separated instrumental ground truth. As indicated in Table 3, we discern a trade-off between controllability and semantic correlation. As the number of trainable layers increases, the model achieves a simultaneous improvement in chord recall score while witnessing a reduction in $CLAP_{src}$. In addition, as shown in Fig 4, as the layers go deeper, the absolute value of gate factor g_l increases. It demonstrates the proposed adapter primarily affects the topmost layers of the decoder transformer, implying that the lower layers are likely responsible for mod-

eling high-level semantics, while the upper layers shape the finer details of the content.

5.4.2 Chord and Rhythm Control

As shown in Table 2 and Fig 3(a), the chord control capability of our model strengthens as MIDI hints are provided. Additionally, the results highlight the model’s adeptness at rhythm control when a drum track is included. However, in cases of semantic conflict between the content-based condition and the text prompt, we observe that the model tends to prioritize the former, leading to music that aligns with the drum pattern rather than the prompt.

5.4.3 Variation Generation and Arrangement

As depicted in Fig 3(b), our model, with the assistance of MIDI hints, can produce variations by integrating musical elements from conditioned MIDI tracks, such as motifs and walking bass. Furthermore, we have observed instances where the generated audio aligns with the original main or counter melodies. This facilitates idea-driven variation generation and semantic-based arrangement within the provided polyphonic piano roll.

6. CONCLUSION

We present a content-based music generative model, achieved by fine-tuning a pre-trained Transformer-based audio language model using the proposed condition adaptor. Our experimental results substantiate its proficiency in seamlessly integrating chord progressions, rhythm patterns, MIDI, and text prompts into the generated music. Our work bridges the gap of direct control via musical elements and audio conditions in the music audio generation field. Furthermore, the proposed condition adaptor facilitates efficient low-resource fine-tuning, even with a relatively small unannotated training set. Nonetheless, results generated with conflicting audio, MIDI, and text prompts may lack musicality and may not fully meet semantic control expectations. In the future, we aim to explore further enhancements in the areas of harmonic direct control and content-based generation.

ABSTRACT

Generative models are starting to become very good at generating realistic text, images, and even music. Identifying how exactly these models conceptualize data has become crucial. To date, however, interpretability research has mainly focused on the text and image domain, leaving a gap in the music domain. In this paper, we investigate the transferability of straightforward text-oriented interpretability techniques to the music domain. Specifically, we examine the usability of these techniques for analyzing how the generative music model MusicGen constructs representations of human-interpretable musicological concepts. Using the DecoderLens, we gain insight into how the model gradually composes these concepts, and using interchange interventions, we observe the contributions of individual model components in generating the sound of specific instruments and genres. We also encounter several shortcomings of the interpretability techniques for the music domain, which underscore the complexity of music and need for proper audio-oriented adaptation. Our research marks an initial step toward understanding generative music models, *fundamentally*, paving the way for future advancements in controlling music generation.

1. INTRODUCTION

Generative AI systems for music have become mainstream in the past year, and have become a popular application for consumers, an eye-catching product for AI engineers and companies, and a key research topic for researchers. The most successful of these systems are built on top of recent advances in deep learning for text and audio encoding, and add a large *text-to-music* model, using the Transformer-architecture [1], to allow users to generate music from a text and/or audio prompt [2–5].

These systems are typically trained end-to-end, and present us with the infamous *black box problem*: it is ex-

*These authors contributed equally to this work.

tremely difficult to understand what is happening in the billions of mathematical operations between input and generated output. This severely limits the ability of users to influence the generated output (other than by just trying a different prompt), of companies to trace an individual output to examples from the training set (and give credit where credit is due), of engineers to diagnose shortcomings and improve the system (other than by retraining on a better dataset or bigger model) and of music researchers to relate the behavior of these models to the large body of existing theoretical and empirical work on how music works.

‘Opening the black box’ of generative music models is therefore a key new area of research. In this paper, we build on advances with interpretability techniques for generative text models. Although there are many important differences between text and music (including their discrete versus continuous nature, and the temporal resolution needed to build good models), we find that those techniques can be adapted to the music domain and indeed give us insights into the inner mechanisms. We focus on one representative, open-source generative music model, MusicGen [5], and on two representative human-interpretable concepts: *musical instrument* and *genre*. We ask: can we localize and manipulate those concepts in MusicGen? We report success on these tasks, and discuss in the final parts of the paper how these initial steps might be extended to the full toolbox needed to successfully address the negative consequences of the black box problem.

2. RELATED WORK

Interpretability research is relatively sparse in the music domain. Previous work has analyzed neural models trained on symbolic music representations (MIDI) using probing classifiers [6, 7], visual inspection of the embedding space [8], listenable explanations for classification models [9, 10], or post-hoc explanations in the form of highlighted parts of a piano roll [11]. To the best of our knowledge, no previous work has tried to interpret generative music models trained on raw audio data.

In the text domain, the Transformer architecture is dominating the field [1]. Recent advancements in interpretability methods are built on a key characteristic of Transformer models: their use of residual connections across layers. Typically, each layer of the Transformer contains an attention component and a Multilayer Perceptron (MLP), both

Figure 1: Architecture of MusicGen. SA = self-attention, CA = cross-attention, MLP = Multi-Layer Perceptron. The self-attention allows for communication between audio tokens; the cross-attention allows for communication between the audio tokens and the conditioning signal (consisting of an encoded text prompt and optionally an encoded melody prompt).

of which interact with the residual stream. This arrangement ensures that information in the residual stream remains accessible throughout all layers, facilitating the development of stable representations.

One method that exploits this characteristic is the **DecoderLens** [12]. It is an adaptation of the LogitLens [13], which was designed to interpret intermediate representations of decoder-only Transformer models. It applies the unembedding matrix to intermediate layer outputs to obtain a logit distribution over the vocabulary for each intermediate layer. The DecoderLens was designed to interpret the intermediate representations of encoder-decoder models. It applies the decoder to intermediate encoder outputs, providing insight in what information that can be decoded from earlier layers. In the original DecoderLens study, the authors use the DecoderLens to analyze how encoder-decoder models build meaningful representations for tasks like machine translation and question answering.

Additionally, **interchange interventions** have been used to identify model components that are causally involved in specific behavior, such as *greater-than* reasoning [14], pronoun resolution [15], and gender bias [16, 17]. By systematically altering model inputs or components and observing resultant changes in behavior, researchers have gained valuable insights into the underlying mechanisms driving model performance and decision making.

3. EXPERIMENTAL SETUP

We conduct two interpretability experiments, one using the DecoderLens and one using interchange interventions, for interpreting the inner workings of a popular generative music model, MusicGen [5].

MusicGen is an open-source, Transformer-based music generation model, built by researchers at Meta [5]. Its architecture is sketched in Figure 1. The model generates discrete audio tokens, optionally conditioned on a text prompt and/or a melody. Text prompts are first processed by a Transformer-based text encoder; music prompts by a 32-kHz EnCodec [18] tokenizer sampled at 50 Hz. MusicGen is autoregressive, and transforms its input over successive layers through multi-head *self-attention* (integrating information across timesteps) and MLP components, while incorporating information from the text and/or melody prompt through *cross-attention* to the respective

encoders. The generated audio tokens are then decoded into a waveform by an EnCodec decoder.

We analyze three model sizes: **MusicGen-small** (300M parameters, 1024 dimensions), **MusicGen-medium** (1.5B parameters, 1536 dimensions), and **MusicGen-large** (3.3B parameters, 2048 dimensions). We set the generation duration to 4 seconds and keep the rest of the MusicGen parameters at their default values.*

In all of our experiments, we only condition MusicGen on text prompts, not on melody prompts. We constructed the following template for our text prompts: *Compose a [MOOD] [GENRE] piece with a [INSTRUMENT] melody. Use a [TEMPO] tempo.* We only modify the components in between brackets and keep the remaining context fixed.

3.1 Experiment 1: DecoderLens

In our first experiment, we use the DecoderLens to globally examine how MusicGen builds up representations of musical concepts across its Transformer layers. This involves extracting intermediate representations from each layer and using the EnCodec decoder to map these to audio. We examine the representation of *musical instrument* and *genre*. We select four instruments and six genres (listed in Table 1) and construct 100 text prompts per category using our predefined template. We feed these prompts to MusicGen and use the DecoderLens to obtain 100 music outputs for each of the 24 Transformer layers.

We evaluate the **recognizability** of our selected musical concepts within the intermediate music outputs by employing an audio classifier that was among the top-ranking classifiers of the 2021 HEAR challenge [19]. This multi-label classifier, trained on AudioSet [20], provides a logit distribution across 527 audio classes, including both musical concepts and other sounds such as speech and environmental noises. We run each intermediate music output through the audio classifier and compute the **normalized discounted cumulative gain (NDCG)** [21], a metric commonly used in information retrieval to measure ranking quality. We consider this to be a proxy for the recognizability of a specific concept.

For each concept, we establish an ‘ideal ranking’ of the audio classes by assigning relevant labels (listed in Table

*For our code and listening examples, see our GitHub page: <https://github.com/Marcel-Velez/musicgen-mech-interp>

Category	Selection	Relevant Labels
Instrument	Guitar	Guitar, Acoustic Guitar, Electric Guitar, Bass Guitar, Plucked String Instrument
	Piano	Piano, Electric Piano, Keyboard (musical)
	Trumpet	Trumpet, Brass Instrument
	Violin	Violin/Fiddle, String Section, Bowed String Instrument
Genre	Classical	Classical Music
	Jazz	Jazz, Rhythm and Blues
	Pop	Pop Music
	Rock	Rock Music, Rock and Roll, Progressive Rock, Punk Rock
	EDM	Electronic Dance Music, Electronic Music, Techno, Drum and Bass, Dubstep, House Music
	Hip Hop	Hip Hop Music

Table 1: Relevant labels of the external audio classifier [19] for each category.

1) a relevance score of 1, while assigning all other labels a score of 0. This methodology facilitates a comparison between the predicted ranking generated by the audio classifier and our predefined ideal ranking. NDCG returns a high score when the relevant labels from our ideal ranking are ranked high by the audio classifier, with a score of 1.0 indicating a perfect predicted ranking.

3.2 Experiment 2: Interchange Interventions

In our second experiment, we use interchange interventions to identify the crucial model components responsible for generating specific musical instrument and genre sounds. The workflow for performing these interventions, which we apply for every permutation of two categories in Table 1, is as follows.

1. Construct two sets of text prompts: one for a concept such as *guitar* (henceforth the **original concept**), and one for a contrasting concept such as *piano* (henceforth the **desired concept**).
2. Run both sets of prompts through MusicGen and save the output of each individual component within the MusicGen Transformer (these model components are further explained in section 3.2.1). This leaves us with two activation caches: one for the original concept, and one for the desired concept.
3. While running MusicGen on the original concept prompts again, replace the output of a specific model component with the average output of that model component across all desired concept prompts. After the intervention, the forward pass continues as normal, but yields an **intervened music fragment**. Repeat this step for all model components.
4. To evaluate the effect of each individual intervention, run a classifier on the original and intervened music fragment, and assess how the odds for the original and desired concept labels changed (we use the same audio classifier that we used for our DecoderLens experiments). If the intervention was

effective, the odds for the original concept should have decreased, and the odds for the desired concept should have increased.

3.2.1 Intervention techniques

We explore two intervention techniques: **replace** and **adjust**. With the “replace” technique, we entirely substitute an activation from an individual *original concept* prompt with the average activation of 100 *desired concept* prompts. With the “adjust” technique, we first subtract the average activation of 100 *original concept* prompts from an individual *original concept* activation. Then, we add the average activation of 100 *desired concept* prompts to that result. The latter technique is inspired by the idea that, in language models, semantic properties of words can be adjusted by adding or subtracting specific word vectors, e.g., $king - man + woman = queen$ [22], or in our case, $music\ with\ guitar - guitar + piano = music\ with\ piano$.

We perform the interchange interventions across all 24 Transformer layers of MusicGen. Each layer consists of a self-attention block, a cross-attention block, and a Multi-Layer Perceptron (MLP). Thus, each intervention consists of swapping the output of one of these three components per layer individually. For a single text prompt, this adds up to 24 layers \times 3 layer components = 72 interventions.

3.2.2 Within-category vs. cross-category interventions

We investigate intervention effects on both **instrument** prompts and **genre** prompts. For each instrument and genre category listed in Table 1, we construct 100 text prompts based on the template outlined in Section 3. We then perform **within-** and **cross-category** interventions.

In within-category interventions, we interchange model activations between two sets of instrument prompts, or between two sets of genre prompts. For instance, we introduce *piano* activations during a forward pass intended for *guitar*, or we introduce *jazz* activations during a forward pass intended for *classical*.

In cross-category interventions, we interchange model activations between a set of instrument and a set of genre prompts. For example, we introduce *piano* activations during a *classical* forward pass, or we introduce *jazz* activations during a *guitar* forward pass.

3.2.3 Evaluating Intervention Effects

An ideal intervention removes the original concept and introduces the desired concept, but does not change anything about the rest of the music. We therefore evaluate the interventions along two axes: **intervention effectiveness** and **intervention precision**.

We evaluate intervention effectiveness using a metric that quantifies the impact on both the original and desired concept, inspired by the metric used in [23]. Specifically, we calculate:

$$\log \frac{\text{odds}(\text{original}_{\text{before}})}{\text{odds}(\text{original}_{\text{after}})} - \log \frac{\text{odds}(\text{desired}_{\text{before}})}{\text{odds}(\text{desired}_{\text{after}})} \quad (1)$$

A high score indicates that the odds of the original concept decreased as a result of the intervention, or that the odds

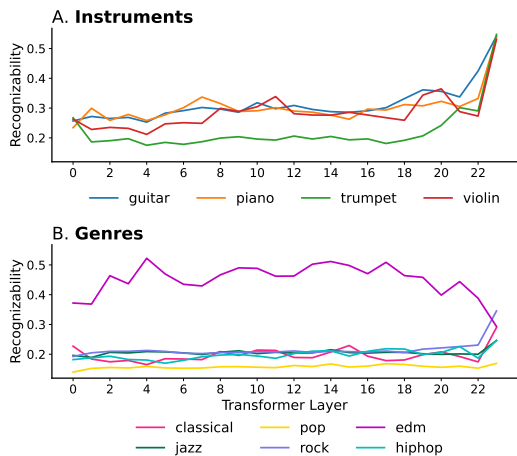

Figure 2: Results for Experiment 1 (**DecoderLens**): Average recognizability of instruments (A) and genres (B) across Transformer layers in MusicGen-small (as measured by the NDCG).

of the desired concept increased. We calculate odds by applying a softmax function over the logit distribution of our external audio classifier.*

We evaluate intervention precision using the **Kullback-Leibler (KL) divergence**, which quantifies the overall shift in softmax distribution across all audio labels. This metric gauges how much the intervened music fragment differs from the original. Ideally, our intervention only has an effect on the odds for the original and desired concept labels, leaving the odds for the others unchanged. This means that low KL scores are desirable, but for ease of interpretation, we reverse them to make higher scores better.

4. RESULTS

4.1 Results Experiment 1: DecoderLens

Figure 2 shows the average recognizability of our selected instruments and genres across the Transformer layers of MusicGen-small. For instruments, we observe relatively stable recognizability in layers 0-19, followed by a gradual increase in layers 20-23. This indicates that MusicGen gradually builds up the representation of individual musical instruments across layers, with the final layers playing a crucial role. The pattern for genres is different. Except for EDM, all genres exhibit the same recognizability across layers, with a slight increase in the final layer. In contrast, EDM exhibits high scores across layers, with a gradual decline in the final layers. This pattern could be attributed to the genre distribution in MusicGen’s training data: EDM is disproportionately represented [5], possibly leading to the model overfitting to EDM characteristics. It could be that most Transformer layers are tuned to generate music reminiscent of EDM, and only the final layer has learned to integrate genre information from the input text prompt.

An alternative explanation is that the DecoderLens is

*For simplicity, we only use one label for each concept in this analysis, i.e., the first label listed for each category in Table 1.

Figure 3: Self-similarity matrices (Euclidean distance) of intermediate layer outputs of the Transformer block within MusicGen-small, when conditioning the model on text prompts containing the instrument *guitar* (left) or containing the genre *EDM* (right). Both matrices are averaged over 100 prompts. A dark color indicates high similarity, a light color indicates low similarity.

currently not optimized for music. Upon listening to DecoderLens outputs, we noted instances of distortion and disorganization. While these outputs predominantly resemble the EDM genre when compared to other genres like *classical* or *jazz*, they may simply reflect artifacts of the EnCodec decoder, trained specifically for decoding representations from the final Transformer layer. The representations of earlier layers may be harder to decode, as they may follow a different representational distribution.

To explore this alternative hypothesis, we examined the similarity of intermediate layer outputs within the Transformer block of MusicGen-small. We re-ran the model with the same 100 text prompts for each concept and extracted the output of each intermediate Transformer layer. We averaged these layer outputs across time and then computed the Euclidean distance between all combinations of layers. Figure 3 displays the results for *guitar* and *EDM*, but similar patterns were observed for the other instruments and genres listed in Table 1. We indeed observe that the final layer (24) is highly dissimilar to the other layers.

Further exploration, possibly involving a “translation model” that maps intermediate layer outputs to final layer outputs [24, 25], could help to refine the DecoderLens for the music domain.

4.2 Results Experiment 2: Interchange Interventions

4.2.1 Intervention effects across model components

Figure 4A shows the average effect of intervening on different components (MLP, self-attention, cross-attention) across the Transformer layers of MusicGen-small, for both the “replace” technique (solid lines) and the “adjust” technique (dashed lines) (results for the medium and large model can be found in the Appendix). Starting with the “replace” technique, we observe a clear contrast between the MLP and the attention components: the MLP consistently shows positive intervention effects, whereas both self-attention and cross-attention predominantly show negative effects. With the “adjust” technique, intervening on the attention components results in positive scores, but they

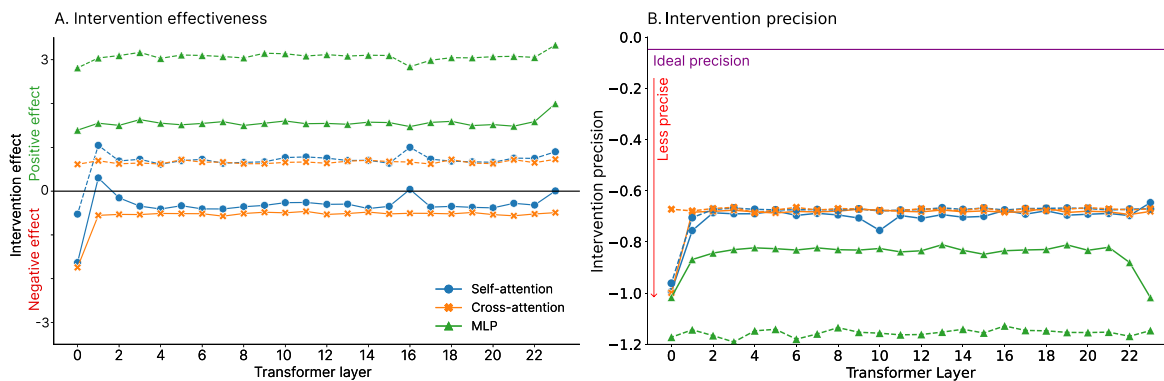

Figure 4: Results for Experiment 2 (**interchange interventions**) across model components and layers, for MusicGen-small only. Solid lines show the result for the “replace” technique, dashed lines show the results for the “adjust” technique. Figure A shows intervention effectiveness (as measured by our log odds ratio); Figure B shows intervention precision (as measured by the inversed KL-divergence). Higher scores are better for both metrics.

Figure 5: Intervention effect vs. intervention precision of the MLP across model sizes (small, medium, large) and intervention techniques (replace vs. adjust). The datapoints are labelled according to the layer where the intervention was performed (b = *beginning*, i = *intermediate*, e = *end*).

are still much lower than intervening on the MLP. This suggests that manipulating the sound of instruments and genres is achievable by intervening on the MLP output, but not to the same extent by intervening on the attention outputs.

Shifting focus to Figure 4B, we observe that interventions on all model components produce negative intervention precision scores. This means that all interventions induce some type of alteration to the audio output. To interpret the magnitude of these changes, we compare them to the “ideal” intervention precision score, where only the original concept and desired concept probabilities flip while everything else remains unchanged. We find that the actual stability scores are much lower than this ideal scenario, suggesting that the interventions are rather invasive and change the audio in a way that goes beyond merely flipping the original concept to the desired concept. A potential future approach could be to perform the interventions on specific frames rather than on the entire audio [26].

4.2.2 Dissecting intervention effects of the MLP

Figure 4A suggests that interventions on the MLP yield the desired alteration (reducing the original concept and

increasing the desired concept). We now analyze these effects in more detail. Figure 5 shows the relationship between intervention effectiveness and intervention precision for different model sizes (small, medium, large) and intervention techniques (replace vs. adjust) for the MLP only. For each combination of model size and intervention technique, we plot three scores: 1) the score for intervening on the **first layer**, 2) the average score for intervening on the **intermediate layers**, and 3) the score for intervening on the **final layer** (we average the intermediate layers since they showed very stable effects in Figure 4).

The effectiveness of intervention techniques seems to depend on model size. We see that the “adjust” technique performs best with the small model, while the “replace” technique shows better results with the medium and large models. We also notice that using the “replace” technique for the large model yields the highest intervention precision overall. This suggests that the large model might represent musical concepts in a more modular manner compared to the smaller ones; thus, we can more easily modify only a single concept without affecting other concepts. One possible explanation could be that in the smaller models, due to limited space, individual neurons represent multiple features simultaneously, a phenomenon known as *superposition* [27].

Finally, for all model sizes, we observe that intervening at the final layer produces the best results, followed by intervening at intermediate layers. Intervening at the first layer tends to be least effective. This pattern may be attributed to the model’s ability to “compensate” for interventions: when we intervene at early layers, the model still has plenty of opportunity to change the original or desired concept as it progresses through its forward pass.

4.2.3 Effect on original vs. desired concept

Figure 6 displays the intervention effect on the original and desired concept **separately**, as well as the **combined** score ($score_{original} + score_{desired}$) for all three model sizes. We also separately show the effects for different intervention types: **inter-category** (instrument-

Figure 6: Combined and separated intervention effect of the **replace** technique on the original and desired concept for the MLP only, in the **small** (A), **medium** (B), and **large** (C) version of MusicGen. Bar colors indicate the intervention type (inter-category/cross-category).

instrument, genre-genre) and **cross-category** (instrument-genre, genre-instrument). Since intervention effects were similar across layers, each bar represents the average intervention effect across layers. We showcase the results for the “replace” technique here; the results for the “adjust” technique can be found in the Appendix.

When examining the scores for the original and desired concepts separately, a clear pattern emerges across all model sizes: the impact on the original concept is much bigger than on the desired concept. This suggests that interventions effectively reduce the original concept, but do not introduce the desired concept as effectively.

For the inter-category intervention effects (blue and orange bars), we observe that instrument–instrument interventions are much more effective than genre–genre interventions. This indicates that it is easier to manipulate the sound of individual instruments in the output than the sound of genres. This in turn suggests that instruments are represented in a more modular fashion than genres, which makes sense given the complex combination of features that are typically involved in a genre.

The pattern for cross-category interventions (green and red bars) is similar: instrument–genre interventions are more effective than genre–instrument interventions. Specifically, interventions inserting genre activations during a forward pass with an instrument prompt notably impact the instrument sound—but interventions inserting instrument activations during a forward pass with a genre prompt have a less pronounced effect on the genre. This supports the notion that genres are represented with multiple features, making them more resistant to manipulation compared to instruments’ more modular representation.

5. DISCUSSION

In this work, we explored the usability of text-oriented interpretability techniques for analyzing the representation of human-interpretable musicological concepts in MusicGen. We applied the DecoderLens for globally analyzing how the model conceptualizes musical instruments and genres across layers, and applied interchange interventions to dissect the role of individual layer components in generating specific instrument and genre sounds across several model sizes.

In our investigation, applying the DecoderLens to Mu-

sicGen revealed significant challenges in generating coherent audio from intermediate layers, a limitation underscored by the self-similarity matrix which showed that the last layer is vastly different from the rest of the model. Similarly, our attempts at interchange interventions, aimed at dissecting the influence of specific model components per layer on musical output, was fairly effective in removing existing musical concepts but was unsuccessful when it came to injecting new ones into the network, across all examined model sizes. These outcomes not only show the complexities inherent in interpreting generative music models but also underscore the need for music/audio specific intervention techniques.

In future work, we aim to adapt these interpretability techniques to be more suitable for audio. As for the DecoderLens, a single linear layer could be trained to map intermediate representations to final layer representations, possibly allowing for better decodability. Furthermore, we aim to explore different intervention techniques (e.g., intervening on specific frames instead of the entire sequence), which could contribute to less drastic alterations of the audio while still changing the desired concepts. These improvements may allow us to additionally explore other facets of music generation, such as tempo and rhythm.

5.1 Limitations

We used quantitative metrics based on a machine learning model to evaluate intervention effects, acknowledging that this approach introduces extra noise. However, it allowed us to investigate a larger parameter space compared to a user-listening study. For instance, we evaluated 100 prompts across multiple model components (100 * 3 components * 48 layers for the large model) for each permutation of concepts. Although human ratings from a listening study could provide many complementary insights, setting up such experiments is costly. Additionally, the authors themselves listened to several intervention results and noticed a lot of variation across samples, complicating the selection of a representative subset for a listening study. Therefore, we believe establishing robust quantitative results first is more practical. These results can inform the design of more focused and efficient listening studies, ensuring effective resource use and meaningful insights.

ABSTRACT

This study aims to measure the similarity of melodies objectively using natural language processing (NLP) techniques. We utilize Mel2word which is a melody tokenization method based on byte-pair encoding to facilitate the semantic analysis of melodies. In addition, we apply two word weighting methods: the modified Tversky measure for word salience and the TF-IDF method for word importance and uniqueness, to better understand the characteristics of each melodic element. We validate our approach by comparing song vectors calculated from an average of Mel2Word vectors to the ground truth in 108 cases of music copyright infringement, sourced from an extensive review of legal documents from law archives. The results demonstrate that the proposed approach is more in accordance with court rulings and perceptual similarity.

1. INTRODUCTION

Since the landmark case of *Millett v. Snowden*¹ in 1844, music plagiarism has been a contentious issue for over a century. The term “plagiarism” refers to the subcategory of copyright infringement that involves the false designation of authorship and other unattributed uses of copyrighted material [1]. In determining plagiarism, courts have traditionally considered three major aspects of music infringement lawsuits: 1) copyright ownership, 2) accessibility, and 3) substantial similarity [2]. “substantial similarity”, which is the most crucial yet debatable factor, lacks a complete definition with no general agreement [3, 4, 5] due to the varying requisite level from case to case [5]. Court analyses are inconsistent within the same circuit, making it more a matter of quality than quantity [6, 7].

¹ *Millett v. Snowden*, available at: <https://blogs.law.gwu.edu/mcir/case/millett-v-snowden/>

Melodic similarity is usually the determining element in assessing whether or not two musical works are substantially similar [8, 6]. Melody is the most memorable and characteristic feature of music [9, 10], and many cases involve the plagiarism of the melody of an original work [11, 9, 12]. Although numerous studies have developed various quantitative measures of melodic similarity [13, 12, 14, 15], it still remains unclear what constitutes substantial similarity. While a high degree of melodic similarity may suggest plagiarism, it does not necessarily indicate plagiarism. Instead, substantial parts of an existing work that are considered essential and worthy of protection can be crucial in determining plagiarism. For example, in the case of *Hawkes & Sons v. Paramount Film Services* (1934, as cited by [16] and [17]), twenty seconds (of 4 minutes) of a musical work without permission was deemed infringement. Therefore, the use of any “recognizable” parts may establish infringement, even if the overall similarity of the pieces is questionable [17].

This study aims to develop a novel approach for quantitatively evaluating the substantial similarities of melodies by employing natural language processing (NLP) techniques. Due to the shared characteristics between music and language [18, 19, 20], various NLP approaches have been applied to music analysis in different ways [21, 22, 23, 24]. The primary focus of the proposed approach is to define the individual elements of melody using NLP-based methods. To achieve this, we employ Mel2word [25], a novel method for melody segmentation using NLP tokenization techniques to represent melodies as word-like units and capture semantic information through word embeddings. In addition, two word weighting methods are proposed to understand the characteristics of individual melodic elements: a modified Tversky measure for *word salience* and the TF-IDF method for *word importance* and *word uniqueness*. The method is evaluated on 108 plagiarism cases with court decisions and perceptual similarity as ground truth, compiling data from diverse sources to represent one of the most extensive symbolic melodic datasets available. This study provides detailed case analyses, showcasing the numerical and graphical representation of the proposed method and its practical applications. By doing so, we aim to provide empirical and quantitative

evidence for the qualitative aspects of substantial similarities in music.

2. LITERATURE REVIEW

There have been numerous studies on plagiarism detection based on melodic similarities, which can be broadly categorized into two types of approaches: (1) audio-based and (2) text-based.

Audio-based approaches employ music signal processing to develop plagiarism detection tools that can identify similar parts of music [26, 27, 28, 29]. While they use advanced audio-based analysis techniques to determine the level of similarity between songs, they mainly focus on identifying similarities rather than explaining how the degree of plagiarism is related to the level of similarity. The audio-based approaches are particularly useful in plagiarism cases involving unauthorized sampling or use of musical works. However, for research purposes related to artistic analysis, notated music provides more useful information than audio-based analysis [15].

Text-based approaches analyze symbolic musical representations, such as notated music. The study by [12] is a remarkable attempt to quantitatively model court decisions in plagiarism cases. This study compared several similarity calculation algorithms and investigated how melodic similarity calculated by text-based algorithms relates to court decisions based on a sample of US copyright cases from 1970. The study unveiled that an algorithm rooted in statistical methods, notably Tversky’s similarity measures [30], outperformed in predicting court decisions. This finding was further corroborated by research conducted by [31]. Percent Melodic Identity (PMI) also stands out as another major measure in this context. Drawing from automatic sequence alignment algorithms in the field of molecular genetics, [32] introduced the PMI method to quantify melodic similarity, which was further utilized by [33, 34] to successfully predict plagiarism. Recent advancements in music research have demonstrated significant progress, particularly in utilizing vectorized representations. These include fuzzy vector-based approaches [8], CNN-based methods [35], and hybrid approaches [36].

While previous studies have explored the quantitative similarities between melodies, the specific elements contributing to plagiarism and the underlying reasons remain unclear. This gap highlights the need for further investigation into what exactly constitutes melodic plagiarism and “why” these particular elements are implicated. To address this, we propose an NLP-based approach to define individual melodic elements by defining words as the basic unit of text to reconstruct a melody as a sentence of meaningful word units. We also introduce a function that combines psychological and NLP models, particularly Tversky and TF-IDF approaches, aiming to provide a comprehensive framework for understanding melodic similarity.

3. METHODS

The proposed method involves three steps: 1) segmenting melodies using Mel2Word [25], 2) vectorizing melodies

Figure 1: Example of (a) the Mel2Word representation with (b) Byte Pair Encoding (BPE) process.

using the Word2Vec [37] algorithm, and 3) applying word-by-word weighted measures to determine word salience, importance, and uniqueness.

3.1 Textual Representation

Mel2word is a novel text-based representation method to segment melodies into word-like units [25]. In this textual representation, each note is translated into a pitch feature indicating the interval’s direction and size, alongside a rhythm feature denoted by the inter-onset interval (IOI) between consecutive notes. Specifically, pitch features are represented by the first character indicating the melody’s direction (“U” for upward, “D” for downward, and “E” for no change), followed by a two-digit number specifying the interval size. Rhythm features are depicted with three-digit numbers, obtained by multiplying the IOI by 100, assuming a quarter note equals one beat with a 16th note quantization. This unit, as depicted in Figure 1-(a), composed of two notes, form “morphemes” utilized for constructing a melody word dictionary using Byte Pair Encoding, a commonly used tokenization technique in the field of NLP.

3.2 Byte-Pair Encoding

Mel2Word represents melodies as word-like units using Byte Pair Encoding (BPE), a data-driven NLP method. BPE is a bottom-up method that builds a vocabulary for computational text analysis by replacing frequently occurring byte pairs with a single and less frequently used byte [38]. Originally developed for data compression, BPE has found widespread adoption due to its successful application in word segmentation for NLP tasks [39]. The utilization of BPE in music, as implemented in Mel2word has been effectively adopted for melody analysis, classifying folk song families and jazz artists [25, 40]. Similar to its application in language, this method involves creating subwords or *tokens* based on the frequency of consecutive pairs. In other words, it identifies the most frequent consecutive pairs in the melody and merges them into a single unit. As a result, the most frequent pairs are combined using an underscore (‘_’) symbol. Figure 1-(b) illustrates the

basic BPE process and the resulting token outcomes.²

3.3 Word Embedding

Word embedding is a vector representation that captures the meaning and relationships of words by representing them as dense, distributed, and fixed-length vectors based on their context in text. Built on the distributional hypothesis [41], it maps words onto a high-dimensional space, placing similar words close together. In music information retrieval, word embeddings have been used to analyze and model relationships between melodic elements. Specifically, the Word2Vec model [37] has been successfully employed in previous studies to represent notes [42, 43], chords [44, 45] or motifs [46, 47] in a distributed vector space. To capture the semantic analysis of melodic elements, we utilize the Word2Vec model in this study.

3.4 Toward the Substantiality of Melody

In determining the substantiality of music, the court has considered the “distinctive characteristics” of the subject matter as a crucial factor [48]. To evaluate the distinctive features of a melody, we propose two methods drawn from the fields of psychology and NLP: 1) assessing the *salience* of a word or how noticeable it is, and 2) evaluating the *importance* and *uniqueness* of a word or how important and rare it is.

3.4.1 Word Salience

The Tversky ratio is a formula for similarity proposed by Amos Tversky, a cognitive psychologist who suggested that human perceptions and judgments of similarity are based on the number of features two objects have in common and the salience of these features [30]. Tversky’s formula is given by:

$$s(A, B) = \frac{|A \cap B|}{(|A \cap B| + \alpha|A \setminus B| + \beta|B \setminus A|)} \quad (1)$$

where A and B are sets, $|A \cap B|$ is the number of common elements in A and B , $|A \setminus B|$ is the number of elements in A that are not in B , $|B \setminus A|$ is the number of elements in B that are not in A . The parameters α and β adjust the impact of the unique elements of A and B respectively, with higher $s(A, B)$ indicating stronger similarity. In the context of melody, features and elements could refer to components such as note pitch or inter-onset interval.

Since the original Tversky model does not account for the individual salience of specific components, we introduce a modified measure specifically designed to evaluate the significance of individual melodic elements. This adaptation evaluates the significance of each melodic element by considering its prevalence in two melodies and its distribution within each, providing a refined perspective on

their commonality and relative frequency. To evaluate the significance of elements shared between two melodic sequences A , B and an element x of A , we propose a salience measure $TV_{A,B}(x)$. When a_x and b_x represent the counts of element x in sequences A and B respectively, along with the lengths l_A and l_B of the sequences, the formula for $TV_{A,B}(x)$ is given by:

$$TV_{A,B}(x) = \frac{\frac{a_x}{l_A}}{\frac{a_x}{l_A} + \alpha \left(1 - \frac{a_x}{l_A}\right) + \beta \left(1 - \frac{b_x}{l_B}\right)} \quad (2)$$

Here, α and β are coefficients designed to adjust for the lengths of A and B , calculated as $\alpha = \frac{l_A}{l_A + l_B}$ and $\beta = \frac{l_B}{l_A + l_B}$.³ The $TV_{A,B}(x)$ measure evaluates the salience of element x from the perspective of sequence A , taking into account both shared and unique elements. This method allows for a balanced evaluation across sequences, aligning with Tversky’s concept of asymmetrical similarity. By incorporating α and β , the measure provides a nuanced assessment of each element’s salience, considering its frequency within the sequences and the overall sizes of the melodies. This approach ensures a standardized measure, assigning a salience score ranging from 0 (indicating no shared elements) to 1 (indicating fully shared), facilitating equitable comparisons regardless of sequence length.

3.4.2 Word Importance and Uniqueness

TF-IDF is a widely used algorithm in NLP that measures the importance and uniqueness of a term in a document compared to a collection of documents. It takes into account the frequency and rarity of each term in the document and the corpus, respectively. The TF component considers the relevance of a term proportional to its frequency in the document, while the IDF component measures its rarity in the corpus. If a term is frequently used in the corpus, it is considered less representative of a specific document, and if it is rare, it is considered more relevant to a specific document. The TF-IDF value is obtained by multiplying the TF and IDF scores of a term in a document. The formula is as follows:

$$\text{TF-IDF}(t, d) = \text{TF}(t, d) \times \text{IDF}(t) \quad (3)$$

where t represents a term or word in a document, d , $\text{TF}(t, d)$ represents the term frequency of t in d , and $\text{IDF}(t)$ represents the inverse document frequency of t in a collection of documents. In this study, each token in a melody is treated as a single unit of text and the entire melody as a single document. To determine the importance and uniqueness of each melodic element, the TF and IDF scores are utilized as weightings for the word embedding vectors, respectively.

4. EXPERIMENTS

This section describes our empirical investigation of analyzing copyright infringement cases.

³ The constant 1 is derived from $\frac{l_A}{l_A}$ for sequence A and $\frac{l_B}{l_B}$ for sequence B .

² Figures 1-(a) and (b) are sourced from [25]. More details on the Mel2word representation and the BPE process, including the subsequent steps of Dictionary Generation (Section 4.2) and Tokenization (Section 4.3) are found at [25].

4.1 The Dataset

We collected copyright infringement cases from various sources, including previous research and law school databases. We prioritized the data provided by [34], who used a similar sampling approach to [12] and included updated metadata with perceptual data.⁴ Additionally, we extensively reviewed cases from the Music Copyright Infringement Resource (MCIR)⁵ and Lost in Music by Westminster Law School⁶ to compile a comprehensive analysis, aiming to consider as many legal cases as possible. After the landmark case of *Arnstein v. Porter*, which established the concept of substantial similarity, our analysis delved into an extensive repository of legal documents and accompanying materials, up to 314 cases from 1946 to 2023. Following an in-depth review, we excluded cases lacking audio or sheet transcription, those not involving similar musical elements (e.g., licensing, sampling, arrangements, rap lyrics, etc.), and those without relevant expert commentary and opinions for the rulings. As a result, we collected and transcribed into MIDI data on 116 cases (Infringed $N=32$, Denied $N=66$, Settled $N=18$), encompassing 232 songs. We included settlement cases collected in our database; however, for evaluation analysis, we included only settlements with official payments or public records of royalties or credit. In total, we analyzed 108 cases in this study.

4.2 Dictionary Generation

We utilized the Meertens Tune Collection - Folk Song dataset (MTC-FS) to train our BPE model, consisting of over 18,000 monophonic melodies from Dutch sources spanning five centuries [49]. The MTC-FS is one of the largest monophonic datasets, offering a rich repository of melodies that have influenced both classical and modern music. We selected this dataset for its diverse range rooted in oral transmission across generations, providing a strong foundation for analyzing copyright infringement cases across various eras and styles. With BPE applied to the MTC-FS dataset, we initially constructed a base dictionary, which serves as the primary resource for tokenization in subsequent analyses. We constructed the base dictionary using the Mel2word code by [25]⁷, applying BPE to extract words with a minimum frequency of 10 occurrences and limiting the maximum unit size to 11 to prevent redundancy.

4.3 Melody Tokenization

For tokenization, we utilized subsets of the base dictionary to enable tokenization with dictionaries of varying sizes for different levels of segmentation. The subsets were selected based on the most frequent tokens in the base dictionary. For instance, choosing 100 tokens would produce

Figure 2: An example of melody tokenization (Dictionary $N=1000$, pitch feature)

a dictionary with the 100 most frequent entries for tokenization. We relied on statistics from the base dictionary for the maximum length (Mode) and minimum count parameters (Q1, 1st quartile). Consequently, we tokenized melodies from copyright-infringed cases for subsequent analyses using dictionaries of sizes $N=100$, 500, 1000, and *Full-token*⁸, which indicates the maximum number of words available with the parameter settings. Figure 2 illustrates an example of the resulting melody tokenization in our dataset.

4.4 Melody Embedding

To build semantic word embeddings for melodic tokens, we utilized Word2Vec embedding in our experiment. Using the MTC-FS dataset, we tokenized all songs for different dictionary sizes ($N=100$, 500, 1000, and Full) and trained the corresponding Word2Vec models for each size. We used the Gensim module [50], a Python implementation of the Word2Vec⁹, with a dimension size of 512, a window size of 10, a minimum count of 2, and the skip-gram model option, which is known to better represent sparse words [51].

4.5 Similarity Calculation

Cosine similarity is a widely used measure of similarity between two vectors that quantifies the cosine of the angle between the two vectors in a high-dimensional space. In this study, we used the cosine similarity to quantify the similarity between two songs in infringement cases. In order to determine the essential effectiveness of different methods, we opted to calculate melody vectors by averaging as a baseline approach. Although vector summarization through averaging involves a loss of information, it also brings several advantages, such as simplicity in computation, low storage memory requirement, and faster processing speed [52]. Consequently, to generate the melody vectors for each song, we calculated the average of all word vectors for each word unit using the trained Word2Vec model.

4.6 Weight Functions

To assess individual melodic elements, we employed multiple weight functions. These weights are utilized for each token when calculating the average vector of words to derive the final melody vector. For each weight function,

⁴ Except for case 14 (*Vargas v. Pfizer*), as the supplied MIDI data did not contain a melody.

Figure 3: Summary of results with various dictionaries and weight presence.

Weight Function(w)	Foundational Method
TV	Tversky Model
TF	TF-IDF
IDF	TF-IDF
$TF * IDF$	TF-IDF
$TV * TF$	Tversky + TF-IDF
$TV * IDF$	Tversky + TF-IDF
$TV * TF * IDF$	Tversky + TF-IDF

Table 1: Summary of Weight Functions

we defined specific parameters, as summarized in Table 1. We calculated term frequency (TF) and inverse document frequency (IDF) values using the *TfidfVectorizer* module from the sklearn library¹⁰ with the default settings. We also computed the Tversky value (TV) using the formula described in Section 3.4.1 (Equation 2). To avoid zero-multiplication for hybrid variables (e.g., $TV * TF * IDF$), we added one to each variable and multiplied it by the subsequent value. Finally, all weights were experimented with various normalization methods.

4.7 Evaluation

We conducted three types of evaluations, following the previous work [32, 33, 34]. First, we assessed how well the similarities evaluated by the algorithm corresponded to the court’s decision. To measure this, we computed the Area Under the ROC Curve (AUC), a commonly used method to evaluate binary classification performance. Second, we utilized AUC to determine TPR and FPR at different thresholds, identifying the threshold with the highest accuracy (ACC). Finally, we measured how well the similarities correlated with human perceptual data provided by [34]¹¹, for which we computed the Pearson coefficient only for the subset of songs with perceptual data available.

5. RESULTS

5.1 Overall Result

Figure 3 presents an overview of the results considering different dictionaries and the presence of weights, with combined feature (Pitch + Rhythm) and $TV * TF * IDF$

weights achieving the highest scores. While the tokenization method has a minor impact on AUC and ACC metrics, it notably influences the correlation with perceptual data, showing better performance across all dictionary sizes. Additionally, the adoption of weights generally enhances performance across most cases (except for morpheme-level and Full-level).

Regarding measures related to legal decisions (AUC and ACC), as previously discussed about performance limits [34], once again, we found that the proposed method was more effective in correlating with perception than with court decisions. This is likely due to courts considering various factors such as lyrics, arrangement, and other musical elements, as well as the worthiness of a melody to be protected (e.g., *Intersong-USA v. CBS*). Additionally, they consider the possibility of subconscious copying (e.g., *Francis Day & Hunter v. Bron*), and proof of access to the original work (e.g., *Ellis v. Diffie*), even when similarities between melodies exist. Since our study targeted all possible cases involving melody, there may be various confounding variables.

Interestingly, we noticed that the weight function underperformed when analyzing melodies at the morpheme-level ($N = 0$), possibly due to the high number of randomly shared features at this level. Performance also decreased at the Full-level, likely because longer words led to a decrease in shared features. Additionally, we found that applying all weights multiplied by the Tversky model improved performance, while the default TF and IDF weights tended to reduce performance. This result supports the basic assumption of Tversky’s model that we perceive similarity based on how many features are shared, which is consistent with previous research [53, 12, 31] showing a strong association of the Tversky model with infringement decisions and perceptual similarity.

5.2 Comparison Results with Previous Studies

Table 2 compares evaluations conducted on subsamples of 17 ($N=17$)¹² and 39 ($N=39$)¹³ cases each, facilitating comparison with existing literature. As observed, our method performed remarkably well, achieving the highest scores for both sets.¹⁴ These subsets consist of cases with

¹⁰ <https://scikit-learn.org/>

¹¹ This data consists of a similarity scale ranging from 0 to 5 points, where 0 represents dissimilarity and 5 represents similarity, available at: <https://github.com/comp-music-lab/music-copyright-expanded>

¹² Based on [33], which includes 14 songs from [32].

¹³ While [34] included 40 cases; we analyzed 39, excluding *Vargas v. Pfizer* due to the absence of melody.

¹⁴ Pitch feature, $N=100$, with quantile Gaussian normalization for 17 cases; pitch + rhythm, $N=100$ (AUC) and Full (ACC) with quantile Gaus-

Cases		Savage [32]	Yuan1 [33]	Yuan2 [34]	Proposed
N=17	AUC	0.69	0.61	0.61	0.94
	ACC	0.80	0.71	0.71	0.94
N=39	AUC	N/A	N/A	0.73	0.79
	ACC	N/A	N/A	0.75	0.79

Table 2: Comparison Results with Previous Studies

a significant indication of melodic similarity from the outset, making them subjects of a number of previous studies [12, 31, 32, 33, 34]. Therefore, they exhibited effective discrimination based solely on the melody itself, compared to our overall findings. Given that our study examined the entire melodies obtained from the archive, we anticipate that further investigation focusing on specific parts or cases emphasizing the melody will yield even more intriguing results.

5.3 Exploratory Result Analysis

Beyond the performance, the strength of our method lies in its ability to numerically represent the characteristics of each melodic element within a song. For example, Figure 4 illustrates a copyright infringement case, *Three Boys Music v. Michael Bolton*, where distinctive and shared melodic features are quantified using TV , TF , IDF , and $TV*TF*IDF$. In this manner, by examining these melodies, we can observe the numerical values of their importance, uniqueness, and the degree to which they are shared for each melodic element. Moreover, this can play a crucial role when melodies are tokenized into more meaningful units, potentially enhancing their interpretability. For example, Figure 5 presents a cross-scape plot visualization, which provides a hierarchical analysis of the similarities between two songs, indicating where and how they are similar [54]. The left side represents the infringed case (*Three Boys Music v. Michael Bolton*), while the right side represents the denied case (*Baxter v. MCA, Inc.*). On the left, (a) depicts the morpheme-level, while on the right, (b) showcases the token-level melody with weighting applied.¹⁵ As observed, at the morpheme level, segmentation of each note leads to overall similarity across all parts due to the frequently shared elements at the note level. However, in the weighted tokenized songs, certain crucial phrases in the infringed case stand out notably darker (i.e., more similar). This visually demonstrates how our approach highlights specific parts that contribute to a stronger similarity between two pieces of music. In this way, by providing a quantitative method to identify the individual characteristics of melody elements, our research can be of significant help in practical applications such as legal analysis, as well as various fields of music research.

sian normalization for 39 cases.

¹⁵ The original plot was modified to compare song similarities using word vectors. Details and base code for the cross-scape plot are at [54] and https://github.com/saebuyulpark/cross_scapeplot.

Figure 5: Cross-scape plots: (a) Word2Vec at morpheme-level, (b) Word2Vec at token-level with $TV * TF * IDF$.

6. CONCLUSION

In this study, we employed natural language processing (NLP) techniques to objectively grasp the substantial similarity of melodies, thereby making notable contributions in several key areas: First, after an extensive review of legal documents, we compiled one of the most extensive public datasets, the Music Copyright Infringement Collection (MCIC).¹⁶ Although it is not big data, this dataset is significant given the limited number of legal cases, as it includes MIDI transcriptions, sheet music, and metadata on legal issues and decisions, forming the crucial groundwork for future studies on music similarity and copyright issues. Second, we encoded melodies into word-like units using Mel2word to analyze melodic similarity for the music plagiarism study. This approach extends semantic analysis beyond the note- or n-gram level, surpassing conventional analysis methods. Third, we introduced the modified-Tversky measure to evaluate the salience of each melodic element. Derived from a prominent psychological theory, this refined measure offers potential applications beyond music, exhibiting its general versatility. Moreover, by incorporating traditional NLP-based weighting algorithms, we conducted an in-depth analysis of individual features to comprehensively grasp substantial similarity. Thus, by integrating computational methods, psychological models, data-driven techniques, and rule-based approaches, we performed a detailed exploration of melodic similarity.

ABSTRACT

Previous research contributions on blind lossy compression identification report near perfect performance metrics on their test set, across a variety of codecs and bit rates. However, we show that such results can be deceptive and may not accurately represent true ability of the system to tackle the task at hand. In this article, we present an investigation into the robustness and generalisation capability of a lossy audio identification model. Our contributions are as follows. (1) We show the lack of robustness to codec parameter variations of a model equivalent to prior art. In particular, when naively training a lossy compression detection model on a dataset of music recordings processed with a range of codecs and their lossless counterparts, we obtain near perfect performance metrics on the held-out test set, but severely degraded performance on lossy tracks produced with codec parameters not seen in training. (2) We propose and show the effectiveness of an improved training strategy to significantly increase the robustness and generalisation capability of the model beyond codec configurations seen during training. Namely we apply a random mask to the input spectrogram to encourage the model not to rely solely on the training set's codec cut-off frequency.

1. INTRODUCTION

Audio codecs can be roughly categorized into two categories: *lossless* and *lossy*. *Lossless* means that an exact preservation of the signal is guaranteed by the codec. In other words, the signal resulting from encoding and decoding is exactly identical to the original. In contrast, *lossy* encoding means that some of the signal is lost in the encoding and decoding process. In other words, the signal resulting from encoding and decoding is not exactly identical to the original signal.

Popular lossy audio codecs like MP3 [1], Ogg Vorbis [2] or AAC [3] are known as "perceptual" codecs because they rely on models of human auditory cognition to prioritise the deletion of parts of the audio signal that have the least

perceptual impact on human listeners. Despite the signal degradation that they result in, perceptual lossy codecs can achieve much greater compression ratios than lossless codecs, and are therefore well suited for applications where data bandwidth is limited. For example, they have been instrumental in enabling music streaming over networks with limited bandwidth.

Digital audio codecs are readily available and are integrated into many widespread professional and consumer tools such as Digital Audio Workstations, software libraries, digital music players etc., which make converting an audio file from one format to another nowadays extremely easy and accessible to anyone. As a result it is easy to mistakenly encode a source audio signal with a lossy codec, which degrades the signal, and then decode it back into a lossless file container. This process may create the illusion that a lossless file container (e.g. WAV) contains unimpaired audio when it does in fact contain lossy-compressed audio.

Guaranteeing audio integrity is essential in many applied scenarios such as large scale music distribution or archiving. Because the aforementioned case of lossy audio disguised as a lossless file would violate this guarantee, there is a need to automatically detect such occurrences. Identification of audio that has been compressed with a lossy codec is a valuable component of quality assurance processes, which form an important part of many modern musical audio content pipelines.

Contributions. In this paper, we present an investigation into the robustness and generalisation capability of a lossy audio identification model. We show that when we naively train a lossy compression detection model on a dataset of music recordings processed with a range of codecs and their lossless counterparts, we obtain near perfect performance metrics on the held-out test set. However, we obtain severely degraded performance on lossy tracks produced with codec parameters not seen in training. We also propose a new training schema in which we randomly mask the input spectrogram to improve the model's robustness. We show that our approach significantly increases the robustness and generalisation capability of the model beyond codec configurations seen during training.

2. BACKGROUND

In the following sections, we will first provide a high level overview of lossy audio codecs (Section 2.1). Next, in Sec-

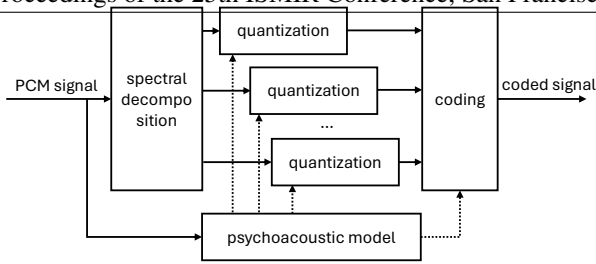

Figure 1. Basic block diagram of a perceptual audio coder. After spectral decomposition, a psychoacoustic model informs the quantization of individual spectral components.

tion 2.2, related work on lossy audio identification is discussed. Finally, in Section 2.3, we briefly present related work in MIR on robustness evaluation.

2.1 Lossy Codecs

Figure 1 shows a basic block diagram with the common modules of a perceptual audio coder. The process of encoding an audio signal with a lossy codec is commonly as follows. First, the original uncompressed (often pulse code modulated - PCM) signal is transformed into a time-frequency representation. This is typically done using a modified discrete cosine transform (MDCT), but many other transforms have been proposed [4]. Commonly used signal block for the spectral decomposition are between 2ms and 50ms. The components of the spectral decomposition are then individually quantized. The quantization of the spectral components is controlled by a psychoacoustic model that describes the time and frequency masking properties of the human auditory system. Auditory masking is a process where one sound (maskee) becomes inaudible in the presence of another sound (mask) [5].

Auditory masking can occur in the time domain (temporal masking) or in the frequency domain (frequency masking). The quantization controlled by the psychoacoustic model effectively controls which spectral coefficients will be removed, resulting in spectral band rupture and holes in spectrograms, as observed in Figure 2. After quantization, Huffman coding (or some other form of entropy coding) is applied to remove or reduce the redundancy in the signal [6]. The bit rate of a codec effectively controls both the size and the perceptual quality of the audio. A low bit rate (like 128 kbps) will produce a small storage footprint, but generally worse perceptual quality compared to a higher bit rate (like 320 kbps). For more detail on audio codecs and standards, we refer to [4].

2.2 Lossy Compression Identification

In previous research, multiple blind lossy compression identification models have been proposed. These can broadly be categorized into two approaches. One approach is to estimate codec parameters from the audio signal, to determine factors such as the decoder framing grid, filter bank parameters and/or quantization information. This

Figure 2. Spectrograms of examples of a lossless (left) and lossy version of the same audio excerpt (right). The latter is compressed with the LIBFDK_AAC codec at 128 kbps bit rate. The version on the right shows the hallmarks of lossy compression: removal of FFT coefficients, holes in the spectrum, and general loss of higher frequency content.

type of approach has been successfully applied for individual codecs like AAC [7], MP3 [8–10]. Although this type of approach can be very effective, it is computationally very expensive, especially when multiple codecs are considered.

The second method utilizes audio quality measures to determine whether the audio is lossy. One effect of lossy audio compression is the introduction of “holes” in the spectrogram, especially right after louder transients. This is the result of the fact that spectral coefficients can be removed when they are perceptually masked by other coefficients. Therefore, most approaches present some form of “hole-detection“, such as estimating the number of inactive spectral coefficients (e.g. [9, 11]) or computing spectral fluctuations [12–15].

In [16], Hennequin et al. presented a method for detecting lossy compression based on a convolutional neural network CNN applied to audio spectrograms. Similarly, Seichter et al. in [17] also proposed a CNN approach for AAC encoding detection and bit rate estimation. All research contributions on lossy compression identification almost uniformly report near-perfect performance metrics on their test set, across a variety of codecs and bit rates.

However, most codecs can be configured with parameters other than the bitrate too, such as a cutoff frequency that controls the amount of higher frequencies that will be preserved. AAC for example has a default cutoff frequency of around 17kHz [18] for constant bit rates of 96 kbps per channel and above, which means that the bandwidth of the encoder is set to 0 - 17kHz. None of the previous research explores what happens when this parameter is changed.

In this paper we show that a model naively trained on default parameters may not efficiently learn to discriminate lossy audio encoded with different parameters and we analyse what happens when varying the cutoff frequency as an example. Therefore, the good results previously reported must be taken with a pinch of salt.

2.3 Robustness Evaluation in Music Information Retrieval

Several studies in music information retrieval have shown that models can seemingly achieve very high evaluation performance, while further research reveals that what those models have learned is some confound with the ground truth dataset [19]. For example, in a research into the robustness of genre classification models, Sturm showed that although these systems might have high mean classification accuracies, they don't actually reflect the underlying properties of the genre [20]. Furthermore, it is shown that by filtering the audio signal in a minimal way, the models produce radically different genre predictions. For a larger overview of music adversaries in music information retrieval research, we refer to [19]. Bob Sturm in [21] introduced the term "horse"¹ to refer to system appearing capable of achieving high evaluation performance, but actually working by using irrelevant characteristics (confounds), and therefore not actually addressing the problem it appears to be solving.

3. METHOD

In the following sections, we will first describe our model setup (in Section 3.1), then our dataset (in Section 3.2) and finally our proposed evaluation methods (in Section 3.3).

3.1 Network Architecture

For the detection of lossy audio we propose a model (visualized in Figure 3) that can be divided into four parts: a spectrogram + random mask module, 4 convolutional blocks, an lstm block and a classification head made of a single dense layer. The architecture is partly inspired by prior work by Hennequin et al. in [16] and Seichter et al. in [17]. In the following sections, we will describe each part in detail.

The model takes as input 2 seconds of raw monophonic audio signal sampled at 44.1 kHz, which is passed to a *torchaudio* spectrogram layer that produces a magnitude spectrogram with 1024 FFT coefficients [22].

Random mask. A random mask is optionally applied to the input spectrogram. This is achieved by uniformly randomly sampling a cutoff frequency between 14 kHz and the Nyquist frequency of the sample, and nulling all *fft* coefficients above that frequency by setting them to the minimum of the input spectrogram. A similar approach called Specaugment was proposed by Park et al. in [23].

In our first experiment (as described in Section 4.1) this layer is not used, and the spectrogram is directly fed to the convolutional blocks. However, in the second experiment (as described in Section 4.2), we use this random mask layer with a different random cutoff frequency for every training example.

CNN. Each of the CNN blocks consist of four layers: a 2D convolutional layer with a kernel size of (3,3), a ReLU layer, a batch normalization layer and a 2D max-pooling

Figure 3. Proposed model for the detection of lossy audio Our model takes as input 2 seconds of audio, which is passed to a torchaudio spectrogram layer (in green). Depending on the experiment, the spectrogram is then passed to a masking layer (in blue), which simulates low-pass filtering. The spectrogram is then passed to four convolutional modules (in pink). We use a bi-directional LSTM (in yellow) for dimensionality reduction. We classify the audio into lossy or lossless in the final model head.

layer. The max pooling size for each block is (2,2), with the exception of the last block, which is (2,4).

LSTM. We connect the CNN to a *long short-term memory* (LSTM) block for two reasons. Firstly, we want to exploit possible sequential properties of the CNN output, and secondly, for dimensionality reduction for the last (dense) part of the network. We use a bidirectional LSTM with two layers of size 128.

Classification head. Our model's lossy/lossless classification head is connected to the LSTM output with a dense layer of size 256 (2x 128 because our LSTM is bi-directional). The classification head has a softmax activation and 2 outputs that model the probability of the example being lossless or lossy.

Training. We back-propagate our model on the binary cross entropy of the classification head and the ground truth. For each audio track, we take a 2-second random crop at training time.

3.2 Datasets

For our experiments, we sample 10k tracks of lossless 16 bit, 44.1kHz WAV files from a large private library of commercial music. From these tracks, we create two datasets.

3.2.1 DS1.

For the first dataset we encode each track with a codec randomly chosen among LIBMP3LAME (MP3), LIBFDK_AAC (AAC) and LIBVORBIS (OGG), with bit rate also randomly chosen among 128, 256 and 320 kbps. Each encoded file is then decoded back into a 16bit, 44.1 kHz WAV file that is used as input to the model. All the encoding/decoding is done using *ffmpeg* [24]. Between lossless and lossy tracks, the dataset comprises of 20k tracks.

3.2.2 DS2.

For the second dataset, we use the same original tracks as were used to create DS1. We also use the same codec parameters, but vary the cutoff frequency of the codecs,

¹ A nod to the Clever Hans horse, see https://en.wikipedia.org/wiki/Clever_Hans

Codec Bit rate	LIBFDK_AAC			LIBVORBIS			LIBMP3LAME			Lossless	Mean
	128k	256k	320k	128k	256k	320k	128k	256k	320k		
DS1	100.0	98.91	100.0	100.0	100.0	100.0	100.0	100.0	98.37	99.88	99.79
DS2	31.38	28.96	24.74	98.91	93.16	86.7	80.63	68.45	60.87	99.88	81.85

Table 1. Accuracy of evaluating the model without random mask on a dataset without (DS1) and with cutoff frequency variations (DS2). Varying the cutoff parameter in the codec greatly degrades model results.

choosing among 14, 16, 18 and 20 kHz. DS1 and DS2, therefore, differ only on the lossy versions obtained for each track. We use the same random 70/10/20 split for training/validation/testing for both datasets. All our experiments are run using DS1 for training and validation. Evaluation is done on DS1 (cf. Sec. 4.1) or DS2 (Sec. 4.2).

3.3 Evaluation

We evaluate the performance of our lossy/lossless detection model in three ways. Firstly, we provide quantitative evaluation and report the model accuracy. Secondly, we inspect saliency maps of the CNN blocks of our model to gain qualitative insight into what signal properties the model is sensitive to. Finally, we also inspect the errors of our model in detail to help us assess the effectiveness our proposed method to make our model more robust, and identify avenues for future work.

4. EXPERIMENTS & RESULTS

In this section we first describe our experiments and report our results on a naively trained lossy/lossless audio detection model (Section 4.1). After an analysis of our results, we report on a more robust variation of our model in Section 4.2, and an analysis of errors in Section 4.3.

4.1 Experiment 1: Naive Model Training

In our first experiment, we train our model on DS1. For each track in our test set, we extract 2-second windows of raw audio with 50% overlap. For each window, we perform a forward pass through our trained network, and collect the output of the classification head. We take the mean of all windowed local model outputs as the global output per track.

4.1.1 Results

In line with previous research (e.g. [16, 17]), we find near-perfect performance on lossy/lossless audio detection of audio with default codec settings. The top row of Table 1 shows the results broken down by codec and bit rate for DS1. We obtain near-perfect results per bit rate/code combination. On average, we obtain 99.79% accuracy across all codecs and lossless files.

However, if we slightly tweak the codec parameters at test time (i.e. we test our model on DS2) the performance drops significantly. The bottom row of Table 1 shows the results of evaluating the model on the dataset with cutoff frequency variations. The results show much poorer results for the lossy tracks across all codec/bit rate combinations. Specifically, we find a big drop in accuracy of around 70

percentage points for the LIBFDK_AAC codec and around 30 percentage points for the MP3 codec. The LIBVORBIS is less impacted, but is still significantly impacted by around 10 percentage points.

4.1.2 Analysis

To get a better sense of what our model has learned, we turn towards a feature analysis of the CNN part of the network. When inspecting the spectrogram of a potentially lossy file with the naked eye, one of the most striking aspects is the nulling of coefficients, resulting in “holes” in the spectrogram. We expected the convolutional part of the network to pick up on those, and to design features that capture this phenomenon.

However, when we visualize saliency maps from our network, we find a different pattern (see Figure 4, top row). It seems that the model is more concerned with the cutoff frequency of the lossy audio than with the holes in the spectrogram. Although the cutoff frequency is a useful feature, by itself it is neither necessary nor sufficient to determine whether an audio signal has been encoded with a lossy codec.

Table 2 shows the results of the model per cutoff frequency, in the columns marked with ‘No’. Here again we see that most cutoff frequency variations are severely underperforming when compared to the previous test dataset.

The model performs best at a cutoff frequency of 16 kHz. This can be explained by the fact that this is the default cutoff frequency of LIBVORBIS, which is therefore not affected by this transformation. In the next section, we adapt the model to be robust against this cutoff effect.

4.2 Experiment 2: Creating a Robust Model

In order to increase the model’s robustness against the lossy codec’s cutoff frequency, we present a second experiment where we randomly mask the upper end of the spectrum. The mask, defined in 3.1, is applied to all input files.

The application of this random mask is intended to force the model not to solely rely on the codec cutoff frequency to make a prediction, and instead also rely on other signal degradations included by codecs, such as “holes” in the spectrogram. A fixed mask at a specific cutoff frequency would have meant throwing away the information given by the spectral rolloff entirely and this would have been suboptimal in the opposite direction.

We train this model on DS1 and evaluate on DS2.

Cutoff	LIBFDK_AAC		LIBVORBIS		LIBMP3LAME		128k		256k		320k		MEAN	
	No	Mask	No	Mask	No	Mask	No	Mask	No	Mask	No	Mask	No	Mask
14 kHz	24.1	81.0	100.0	100.0	76.9	100.0	90.4	82.6	53.7	100.0	49.3	97.8	65.9	93.3
16 kHz	83.9	98.4	100.0	100.0	98.6	100.0	88.2	100.0	97.0	97.7	98.6	100.0	94.6	99.5
18 kHz	0.7	86.7	66.9	100.0	25.3	100.0	50.0	96.2	28.2	94.1	12.4	94.8	29.5	95.6
20 kHz	11.1	96.5	100.0	100.0	82.9	100.0	46.2	100.0	76.1	97.2	70.2	100.0	65.1	98.9
MEAN	28.3	90.1	92.9	100.0	70.1	100.0	70.1	93.6	64.1	97.9	57.3	98.8	63.7	96.8

Table 2. Accuracy (in percentage points) of evaluating our models without (No) and with (Mask) random mask on DS2, per codec and bit rate, for varying cutoff frequency. Lossless accuracy is 99.9% for No and 99.8% for Mask.

Figure 4. Saliency maps from exposing a model trained without (top) and with (bottom) random mask to lossy audio. The model with random mask shows more activation in the holes of the spectrogram without losing any of the activations at the cutoff frequency.

4.2.1 Results

Table 2 shows the results obtained for the model trained with the random mask on DS1 and evaluated on DS2. We observe good classification results on average, 96.8% on lossy files and 99.8% on lossless files. Overall, we obtain 98.4% lossy/lossless classification accuracy across the entire test dataset. Comparing with the naive model, the accuracy on DS2 improves significantly across the board.

With the mean classification accuracy at 90% or above in all conditions (last column of the table), this model is broadly robust against cutoff frequency variations. It is interesting to note that performance on the AAC codec is comparatively lower than on other codecs. This result suggests that the AAC codec is more challenging to detect, and warrants further investigation, which we leave for future work. We hypothesise it may be due to the AAC codec producing less artefacts in the magnitude spectrogram.

Figure 5. F_1 -score for varying thresholds, evaluated on DS2. Each line analyses the subset made of lossless files as negatives and the specified codec as positives; files encoded with different codecs are discarded. Left: model without random mask; Right: model with random mask.

In Fig. 5, for both the model without random mask (cf. Section 4.1) and the model with (cf. Section 4.2) we plot the F_1 score (i.e., the harmonic mean between precision and recall) as a function of the threshold of the binary classification prediction. The F_1 -score for the model without the random mask peaks at very low values of the threshold and then decays for increasing threshold at a rate that highly depends on the codec analysed.

This suggests three conclusions: (1) There are a number of test set files that yield a prediction $p(x)$ in the central region $0.1 < p(x) < 0.9$, which shows a high degree of uncertainty for the model; (2) since the F_1 -score is monotonously decreasing, the model tends to output false negatives rather than false positives; (3) different codecs are identified with different level of proficiency.

Compare this with the output for the model with the random mask: in the case of LIBMP3LAME and LIBVORBIS codecs, the F_1 -score is almost flat and close to 1 for the entire range of thresholds. The LIBFDK_AAC codec still shows some decrease in performance for increasing thresholds, but the peak value increased from 0.875 to 0.982 and the area under the F_1 curve jumped from 0.450 to 0.891. From the results above we can conclude that the introduction of the random mask brings higher peak performance and also reduces the impact of the choice of the threshold.

4.2.2 Analysis

Similarly to the analysis presented in Section 4.1.2, we visualise saliency maps of the model trained with the random mask in the bottom row of Figure 4. Compared to the saliency of the model with no mask (top row), we

Figure 6. The five assumed lossless tracks misidentified as lossy. However, A, C, and D are in fact lossy. B and E are quiet tracks with a single instrument.

see a much brighter activation in the holes of the spectrogram without losing any of the activations at the cutoff frequency. The model has learned to rely on more markers to make its choice.

4.3 Qualitative Analysis of Errors

In this section, we present a qualitative analysis of the erroneous predictions produced by our model trained with the random mask.

4.3.1 Lossless Errors.

From our entire test subset of DS2, we observe only 5 cases (0.2%) where the model made a "lossy" prediction while the recording is in the lossless part of the dataset. The spectrogram of three out of the five tracks (A, C and D in Figure 6) show the hallmarks of lossy compression. It appears that our model was indeed correct in predicting a lossy encoding, and therefore revealed "in-the-wild" cases of accidental lossy compression that were present in our dataset.

The other two tracks (B and E) are quiet and sparsely orchestrated tracks. It is notable that the spectrogram also appears sparse, with very little energy in the upper frequency range. Given that lossy codecs often feature energy depletion in the top part of the frequency range, we hypothesise that the misclassification may be due to the model relying on the absence of energy in the upper register in this case.

4.3.2 Lossy Errors.

Table 2 shows that the entirety of cases where the model erroneously classified recordings as lossless when it should be lossy comes from tracks encoded with the LIBFDK_AAC codec. In Figure 7, spectrograms of 2 second excerpts from a random selection of error tracks are visualized.

From inspecting the spectrograms of LIBFDK_AAC encoded tracks, we find that common characteristics are (1) the spectral roll-off is relatively stable over time, (2) the preservation of transients above the cutoff frequency, which can often span upwards to the Nyquist frequency, and (3) less nulling of spectral coefficients, resulting in fewer holes in the spectrogram. The LIBFDK_AAC codec is a superior codec in terms of compression efficiency, meaning it can provide better audio quality at lower bitrates than other codecs [25].

Figure 7. A random selection of lossy tracks misidentified as lossless. All tracks are encoded with LIBFDK_AAC. The spectrograms show less holes and band rupture compared to other codecs, especially under 14 kHz.

Table 2 shows that AAC with cutoff 14kHz is only 81% accuracy. We hypothesize that the LIBFDK_AAC codec does not produce as much "holes" in the spectrogram below this threshold. Our model applies the random mask to every example in our training dataset, which can be confusing on LIBFDK_AAC samples. That is, as the random mask is applied at a relatively low cutoff frequency, the resulting spectrogram is almost identical to a lossless example. One avenue for future work could be to apply the random mask with a lower probability, to allow the model to also learn other spectral characteristics of LIBFDK_AAC samples.

5. CONCLUSION

In this paper, we presented a lossy audio compression detection method that can robustly estimate whether a given audio file has been lossy encoded before. We show that naively training a model results in near-perfect lossy audio compression detection on the held-out test set generated using the same encoding parameters.

However, we find that, for several widely used lossy codecs, the performance of this model catastrophically degrades when exposed to variations of the cutoff frequency parameter that were not seen during training. This result suggests that a naively trained model is overly reliant on the cutoff value. In response to this shortcoming, we propose to amend the training strategy by applying a random mask to the upper range of the spectrogram, in order to reduce the model's reliance on the codec cutoff frequency value.

We show that this method results in a model that is significantly more robust against frequency cutoff variations. Our experiments reveal compelling performance on all codec and bit rate combinations we considered, but reveal that there remains room for improvement on the detection of the LIBFDK_AAC codec. We hypothesise that the AAC codec is comparatively more difficult to detect than MP3 and Ogg Vorbis because it generates less artefacts in the magnitude spectrogram. An avenue for future work may consist in exploring further development of the training strategy in order to improve performance on the AAC codec.

RNBERT: FINE-TUNING A MASKED LANGUAGE MODEL FOR ROMAN NUMERAL ANALYSIS

Malcolm Sailor

Yale University

malcolm.sailor@gmail.com

ABSTRACT

Music is plentiful, but labeled data for music theory tasks like roman numeral analysis is scarce. Self-supervised pretraining is therefore a promising avenue for improving performance on these tasks, especially because, in learning a task like predicting masked notes, a model may acquire latent representations of music theory concepts like keys and chords. However, existing models for roman numeral analysis have not used pretraining, instead training from scratch on labeled data, while conversely, pretrained models for music understanding have generally been applied to sequence-level tasks requiring little explicit music theory, such as composer classification. In contrast, this paper applies pretraining methods to a music theory task by fine-tuning a masked language model, MusicBERT, for roman numeral analysis. We apply token classification to get a chord label for each note and then aggregate the predictions of simultaneous notes to achieve a single label at each time step. The resulting model substantially outperforms previous roman numeral analysis models. Our approach can readily be extended to other note- and/or chord-level music theory tasks (e.g., nonharmonic tone analysis, melody harmonization).

1. INTRODUCTION

Roman numeral analysis is the task of identifying the chords in a piece of music and then indicating their role with respect to the current key. Although it was developed in the European classical tradition, it is an essential element of the musical toolkit for musicians working in many different Western-derived styles (for instance, a jazz musician might speak of a “ii-V to vi (“two-five to six’”)” or a pop musician might say “the bridge starts on IV”).

A small but growing literature has employed deep learning models for automatic Roman numeral analysis of symbolic music (Section 2), training the models from scratch on labeled data. But labeled data for Roman numeral analysis is scarce, whereas symbolic music is comparatively plentiful. Self-supervised pretraining therefore seems likely to yield dividends, especially considering

that, in order to perform a self-supervised task, the model can be expected to learn latent representations of music theory concepts like chords and scales: if you need to predict a given musical note, you will do a lot better if you can estimate the expected key and chord. Moreover, as a general matter, it seems likely that it will prove more efficient and more practical for MIR researchers and music theorists to fine-tune large-scale foundation models for specific analytical tasks, rather than training bespoke models from scratch for every task. These considerations inspire the present work, where we fine-tune a masked language model on Roman numeral analysis, obtaining state-of-the-art classification accuracy.¹

2. RELATED WORK

Whereas automatic chord recognition using audio signals has an extensive literature [1], this paper contributes to a smaller body of work on Roman numeral analysis of symbolic music, which is both an easier and a harder problem. Easier, because working with symbolic data means the model does not need to devote capacity to identifying the sounding pitches, but harder, because Roman numeral analysis requires not only identifying chords but also describing their harmonic function within their tonal context (e.g., rather than simply labeling a chord as “E major”, labeling it as “V6/vi in C major”). Details of Roman numeral analysis are beyond the scope of this paper but are covered in any textbook of classical harmony such as [2, 3].

While earlier work employed various approaches for automated Roman numeral analysis, more recently, deep learning has come to predominate, including recurrent models [4–7], transformers [8, 9], and, most recently, graph-based architectures [10]. As far as we know, the best performance in the existing literature has been obtained by *AugmentedNet* [6,7] and *ChordGNN* [10], and we compare our results below with those reported in [6, 10].²

All of these models for Roman numeral analysis are trained from scratch, not making use of self-supervised pretraining. A hitherto separate area of research is pretraining large models for the understanding of symbolic music. Both MusicBERT [11], the model used in this paper, and MidiBERT-Piano [12] pretrain BERT-like [13]

² Unfortunately, the results of [7] are reported in a manner that makes them difficult to compare directly with these other papers and with our own results.

encoder-only transformers on a masked language modeling task. [14] adds a GPT-like causal language modeling task as well. So far, these pretrained models have mainly been fine-tuned on sequence-level tasks such as composer, genre, or emotion classification. As far as we know, none of these pretrained models have been applied to Roman numeral analysis, or any other problem involving the prediction of explicit music-theoretical labels.

3. EXPERIMENTAL SETUP

3.1 Corpus

To our knowledge, the corpus used in this study is the largest yet assembled for Roman numeral analysis. The major components of this corpus include the various corpora released by the Digital and Cognitive Musicology Lab [15–17], the TAVERN set of theme and variations by Beethoven and Mozart [18], the set of Beethoven Piano Sonatas first movements introduced in [4], and the various other items included in the When in Rome meta-corpus [19], including analyses of Bach preludes and chorales, and a large number of 19th century lieder, including works of women composers. The total contents of this corpus are enumerated in the first line of Table 1.

Data subset	Scores	Notes	Chords
All	1,404	1,289,888	161,473
AugmentedNet v1	347	701,703	77,570

Table 1. Overall contents of the datasets used for training and evaluation.

For a fair comparison with [6, 10], we also train and evaluate on the subset of our data used in those papers, employing the same training/validation/testing splits.³ We refer to this subset as “AugmentedNet v1” to distinguish it from the somewhat larger dataset used in [7]. Note that, for scores having two analyses (in particular, the scores of the TAVERN dataset, where each score was analyzed by two separate annotators), AugmentedNet v1 includes both versions (following [6]), whereas in the full corpus, we randomly choose only one of the two versions for inclusion. AugmentedNet v1’s note count is substantially increased by the inclusion of these duplicate TAVERN scores, which comprise 106,981 notes.

Unlike some prior work (e.g., [6, 9]), we do not experiment with training and/or evaluating on smaller, more homogenous subsets of our corpus (for example, the Beethoven piano sonatas only). Our goal is to train the best and most general Roman numeral analysis model we can and we expect that such a model will be best obtained and evaluated by using as much data as possible.

³ 7 scores from AugmentedNet v1 were excluded because of preprocessing errors (for example, because they include time signatures not supported by MusicBERT’s OctupleMIDI encoding scheme). These scores exclusively came from the training split and so, if their omission has any effect on RNBert’s performance relative to that of the other models trained on the AugmentedNet v1 dataset, it should bias it downwards.

3.2 Data representation

Figure 1. A hypothetical musical example and its analysis, before and after salami-slicing.

Onset	0	0	0	2	2	2	3	3	3
Release	2	2	2	3	3	3	4	4	4
Pitch	59	67	79	62	69	79	62	69	78
RN	I6	I6	I6	V	V	V	V	V	V
Key	G	G	G	G	G	G	G	G	G

Table 2. The example from Figure 1 in tabular format after salami-slicing. Time signatures, tempi, and bar lines are omitted.

The scores associated with the analyses in our dataset are encoded in a variety of formats, such as MusicXML (.xml or .mxl), MuseScore (.mcsx), or Humdrum (.krn). We convert these into a tabular format, illustrated in Table 2, labeling each note with the associated key and chord annotation. Note that, because we use a model that was pretrained on MIDI data, which does not specify pitch-spelling, our pitch inputs are not spelled (that is, they use midi numbers like “78” rather than pitch names like “F#5”). For further discussion, see Section 3.3.1.

When reading scores, we apply several preprocessing steps.

First, following MusicBERT, the score is quantized at the 64th note level.

Second, we “salami-slice” the score: at each timestep with one or more onsets or releases, we split any ongoing notes into two, in order to obtain a purely homophonic rhythmic texture in which all onsets and releases are synchronized across all parts. (The term “salami-slicing” is due to [20].) Salami-slicing is necessary to ensure that each note belongs to only one chord. Otherwise, a note may persist through multiple changes of chord, either because it is a common tone among each of the chords (like the alto D in Figure 1), or because it realizes a suspension or similar dissonant idiom (like the soprano G in Figure 1). Fortunately for our purposes, salami-slicing should not affect harmonic analysis, because it does not change the pitch content of the score. Moreover, musical idioms like suspensions and pedal tones that cross changes of chord are analyzed the same whether or not they are tied or sounded anew at the onset of the new chord.

Third, we dedouble the notes of the score, removing any notes that have the same pitch, onset, and release (regardless of whether they are performed by the same instrument). Dedoubling has two advantages. First, it reduces the sequence length. Second, it produces a more homogeneous texture between music for small ensembles,

where pitch doubling is less common, and music for large ensembles like orchestras, where pitch doubling is ubiquitous. Such homogeneity is particularly desirable since nearly all the available labeled scores are small-ensemble works like piano sonatas and string quartets, but we would like our model to generalize to large-ensemble works like symphonies and operas.

MusicBERT has a maximum sequence length of 1000 tokens. Therefore, in both training and evaluation, we crop scores into segments of 1000 tokens, stepping through the score with a hop size of 250.

3.3 Task

Roman numeral analysis involves labeling chords with integers (Roman numerals) indicating their root with respect to the scale of the current key (e.g., “V” in C major indicates that the root is G, the 5th scale degree). Figured-bass numerals are typically appended to indicate the chord’s inversion (e.g., “6” for first inversion). While the quality of the chord is often assumed to conform to the scale, alterations of quality can be indicated according to a variety of conventions (e.g., upper-/lower-case for major/minor, appending “+” or “o” to indicate augmented or diminished chords, or combining figured-bass numerals with accidental signs). The Roman numerals can be prefixed with accidentals to indicate altered scale degrees (for example, bVI in C major would be A-flat). “Tonicizations”—that is, one or more chords borrowed from another key—can be indicated by “secondary” Roman numerals, typically following a slash, as in “V/ii”, which in C major would indicate the V chord of d minor. Finally, since the Roman numeral only indicates a harmony with respect to some key, for a Roman numeral to be meaningful, we need to indicate the key as well.

Since a complete Roman numeral consists of multiple distinct elements, the combinatorial space of these elements is very large. Encoding each distinct combination as a token, would require a large and sparse vocabulary, posing challenges for training and generalization. Therefore, the approach adopted here and elsewhere is to treat Roman numeral analysis as a multitask learning problem, where we predict the key, quality, inversion, and degree separately. (The degree is sometimes further decomposed into “primary” and “secondary” components, but in the current work, we predict these jointly.) It should be noted, however, that this multitask may approach obtain a smaller vocabulary size at the expense of some coherence among the different elements of the Roman numeral. For example, suppose there is a passage that is ambiguous between I and vi6 (two chords which share two of their three pitch-classes as well as the same bass note). If the model distributes the probability roughly equally between the two possibilities it may easily occur that the inversion and degree predictions “decohere” and we end up with a plainly incorrect prediction like I6 (rather than I) or vi (rather than vi6). (One solution to this problem of decoherence was proposed by [21], which we discuss in Section 3.6 below.)

3.3.1 Pitch spelling

One difference between our approach and some prior work (e.g., [5, 7]) is that MusicBERT uses unspelled pitch inputs (midi numbers like “67”) rather than letter names (like “F#5”). Our output key predictions are therefore also unspelled (e.g., pitch-class 6, rather than “F-sharp”) because, with unspelled inputs, the output spelling is undefined.⁴

We consider our model’s inability to predict spelled keys unimportant. Given spelled inputs (e.g., pitches like “Db5” rather than MIDI numbers like “61”) and an unspelled key (e.g., “1 major”), predicting a spelled key (e.g., “Db major”) is trivial and could likely be performed with perfect accuracy by a rule-based algorithm (e.g., taking the enharmonically equivalent key closest to the centroid of the spelled pitches on the “line of fifths” [23]). Moreover, keys with plausible enharmonic equivalents (like F-sharp major or E-flat minor) are rarely used. Their classification is therefore unlikely to significantly affect validation/test performance.

3.4 Data augmentation

We employ two data augmentation techniques on the training data. First, we transpose each score to all 12 keys of the chromatic scale. Second, we create a version of each score with the durations scaled by a factor of 2. If the mean duration in the score is greater than the mean duration of the training set as a whole, we scale its durations down by 2; if it is less, we scale them up by 2.

We experimented with adding synthetic data similar to the procedure introduced in [6, 7] and also adopted in [10]. However, we did not find that it improved the model performance. It is possible that synthetic data was less helpful in our case than with AugmentedNet [7] because, whereas for that model, the inputs consist of pitch-vectors at each time step, for our model, the inputs are simply the notes of the score, and therefore the difference between synthetic and real data is more apparent to the model.

3.5 Model

3.5.1 MusicBERT

The model that we fine-tune, MusicBERT [11], is a bidirectional transformer encoder pretrained on a masked language modeling task. The dataset for pretraining is a corpus of over 1 million midi files, 3 orders of magnitude larger than our Roman numeral dataset. This difference in scale motivates the use of a pretrained model. We chose MusicBERT for our experiments because, of the pretrained symbolic music models of which we are aware, it used the largest pretraining dataset (by comparison, [12] pretrains on fewer than 5,000 scores of exclusively piano music) and also because of the elegance of the OctupleMIDI scheme MusicBERT uses to encode its inputs. A more detailed

⁴ This is because the only difference between enharmonically equivalent keys like F-sharp and G-flat is how they are notated. Certain pieces of music, such as Fugue no. 8 of Bach’s Well-tempered Clavier, Book 1, have even been variously printed in two enharmonically equivalent keys [22].

comparison fine-tuning symbolic music models for Roman numeral analysis will have to await further work.

In the OctupleMIDI encoding, eight features of a musical note are first embedded individually: time signature, tempo, bar number, metric position within the bar, pitch, duration, and velocity.⁵ To obtain a single input at each time step, these eight embeddings are concatenated and then projected to the model’s embedding dimension. OctupleMIDI reduces the sequence length when compared with other encoding schemes like Midi-like [24,25], REMI [26], or Compound Word [27]. This reduction occurs because in OctupleMIDI, tokens and notes are in one-to-one correspondence, whereas the other schemes use tokens for other items such as time-signatures or barlines. For our use case, the fact that all tokens correspond to notes has the added virtue that we do not waste computations classifying non-note tokens.

In our experiments, we use the MusicBERT “base” architecture, whose hyperparameters are modeled on those of the BERT base architecture ([13]), with a hidden dimension of 768, 12 layers, and 12 attention heads. We use the pretrained checkpoint provided by [11]. For further details we refer the reader to the original MusicBERT paper.

MusicBERT is not trained solely or even mainly on Classical music, whereas our annotated data consists entirely of Classical music. This does not seem likely to be a problem, because in the first place, a great deal of the tonal idiom (i.e., keys, chords) is shared between different styles of tonal music, and tonal music surely predominates in MusicBERT’s training set. Moreover, to pretrain on only classical music would mean greatly reducing the amount of training data, as it’s extremely unlikely that 1,000,000 distinct midi files of Classical music exist. ([20] is based on what is to our knowledge the largest corpus of Classical midi files in existence and features under 15,000 files.)

3.5.2 Token classification

To perform Roman numeral analysis, we adopt a token classification approach, predicting the key and Roman numeral for each token in the input. Since each token corresponds to a note, this amounts to predicting the chord during which each note occurs. While training, we calculate the loss on a per-token basis. In evaluation, in order to obtain a single prediction for each salami slice, we average the logits of simultaneous notes.

The token-classification heads are two-layer multilayer perceptrons (MLPs) whose inner dimension is the embedding dimension of the model (768, in our experiments).

To obtain the overall loss, we simply take the mean of the cross-entropy loss for each individual task. We tried learning a weighting of the contribution of each task to the global loss, following the approach introduced by [28] and implemented in an MIR context by [29], but observed a small degradation in model quality when doing so.

⁵ Midi velocity is encoded in the OctupleMIDI format but is absent from the symbolic scores of our dataset. Therefore, we use a default value of 96 for all note velocities in our dataset.

3.5.3 Fine-tuning procedure

In our fine-tuning experiments, we found it important to freeze parts of the model to reduce the number of trainable parameters and avoid overfitting. Freezing the first 9 layers of MusicBERT seemed to give the best results. The parameter counts are given in Table 3.

We used a learning rate of 2.5×10^{-4} with a linear warmup of 2500 steps followed by a linear decay of the learning rate to 0. When training on multi-task Roman numeral classification, we fine-tuned for 50,000 steps. When training on key classification only (see Section 3.6), we fine-tuned for 25,000 steps.

When experimenting with varying these hyperparameters, we did not typically find their precise values to have much effect on the performance of the model. This implies that the fine-tuning is fairly robust to different hyperparameter choices.

Model	Total	Trainable
Base	108,805,598	26,782,729
Key conditioned	111,023,816	28,859,891

Table 3. RNBert parameter counts.

3.6 Key conditioning

In preliminary versions of RNBert, we found that high entropy of the output probabilities for the degree task seemed to mainly occur in two distinct scenarios. The first scenario involved unusual or hard-to-analyze chords, where high entropy is to be expected. The second scenario involved chords that, given a key, were straightforward to analyze, but where the model appeared to be uncertain about the choice of key.⁶ To illustrate this latter scenario, suppose we are analyzing a passage, and we recognize an A minor chord, but we are uncertain whether the key is C major or G major. In that case, though we will not know whether to label it with “vi” or “ii,” this uncertainty isn’t about the chord itself, but only about the key. If the model distributes the probability mass roughly evenly between the two possibilities, it may emit an incoherent composite prediction like “ii of C major” (a D minor chord) or “vi of G major” (an E minor chord). In general, the degree task depends on the key task in this way. Therefore, in some of our experiments, we made the Roman numeral prediction by conditional on the key.

In these key-conditioned experiments, we embed the key tokens with a two-layer MLP with hidden and output dimensions of 256 and GELU activation.⁷ We then

⁶ We do not have space to discuss this further, but there are music theoretic reasons to think that a certain degree of uncertainty about key annotations is inevitable because the key of certain passages, especially transitional ones, can be analyzed in more than one way.

⁷ In principle, we should be able to replace this MLP with a simple embedding layer and obtain the same results. In practice, however, we found that using a simple embedding layer barely improved performance above the unconditioned baseline, even with teacher forcing. We suspect that this occurs because the loss landscape of the MLP has better training dynamics. After training, on the other hand, it should be possible to replace the MLP with an embedding table that simply encodes the output

concatenate this key embedding with the output from MusicBERT to obtain the input to the Roman numeral classification heads.

In training, we employ teacher forcing, that is, we condition on the ground-truth key annotations from the labeled data. In evaluation, we first predict the key with a separately fine-tuned model, then condition the chord predictions on these predicted keys.

Another attempt to encourage coherence between key and Roman numeral predictions is [21], who use a neural autoregressive distribution estimator (NADE). Their approach extends beyond ours insofar as it conditions each sub-task of the Roman numeral classification on the previous tasks. In preliminary experiments applying a similar approach to RNBert, we observed a small decline in performance across all metrics. We defer to future work a qualitative evaluation of these predictions and further similar experiments.

3.7 Post-processing steps

In postprocessing, we collate the predictions from each segment, combining the overlapping logits of adjacent segments by linearly interpolating between them. (By analogy to audio signal processing we could say that we cross-fade between the logits of neighboring segments.) We then average the logits of simultaneous notes to obtain a single set of logits for each salami-slice.

To avoid implausibly brief key changes of one or two salami-slices’ duration (which otherwise sometimes occur at transitions between keys, when the model estimates both keys to be approximately equiprobable), we use a dynamic programming approach to decode the key predictions. Specifically, we employ the Viterbi algorithm, using RNBert’s output probabilities as the emission probabilities and defining a transition probability matrix that is uniform, except for self-transitions, whose probabilities are upweighted. This decoding scheme has a negligible effect on the measured accuracy of the predictions, while effectively eliminating implausibly brief key changes.

4. RESULTS AND DISCUSSION

Table 4 provides our results, expressed following [6] as the proportion of time the predicted labels are accurate, with 32nd-note resolution. We give two sets of results: on lines 1 to 3, training on the dataset and training/validation/testing splits used by [6, 10] for a fair comparison with these prior papers, and on lines 4 to 6, training on our complete dataset.

Concerning the composite “RN” labels, RN_{root} refers to the conjunction of degree, quality, inversion, and key, while $RN_{\text{+root}}$ adds to these the chord root. Predicting the root is redundant: the root of a Roman numeral is a deterministic function of the degree and key (e.g., the root of #iv in C major is F-sharp). There is hence no need to include

of the MLP for each key. However, the MLP contributes such a small proportion of the model’s overall parameter count that we did not bother to do so.

it in the composite Roman numeral, or indeed, to predict it at all. Therefore, when training RNBert on our full dataset, we do not predict the root and report only RN_{root} . When training on the AugmentedNet v1 data subset, in contrast, in order to ensure a fair comparison with the prior models, both of which predicted the root, we train RNBert to predict the root and report the results for both $RN_{\text{+root}}$ and RN_{root} . It can be seen that the inclusion or exclusion of the root makes almost no difference, as one would expect. Finally RN_{alt} refers to an alternate task learned in [6, 10], replacing the quality, degree, and root predictions with a vocabulary of the 75 most common Roman numerals in the AugmentedNet v1 training set. We did not train RNBert on this task, but we report the prior results on it to facilitate comparison with our results.

When training on the AugmentedNet v1 subset (Table 4, line 3), RNBert substantially outperforms the prior models on degree and quality. However, it outperforms the earlier models by a much more substantial margin when predicting the composite Roman numeral $RN_{\text{+root}}$. This implies that there is more coherence among the various dimensions of its predictions. Such coherence may be due to the robustness of the representations MusicBERT learns in its pretraining. It implies that, even where RNBert’s predictions don’t agree with a human annotator’s, they are more likely to be useful, since they are more likely to be internally consistent.

When training on the complete dataset (Table 4, lines 4–6), RNBert exceeds the performance of the earlier models by an even larger margin, especially when predicting the composite Roman numeral. We defer a discussion of the effect of key conditioning to Section 4.1.

One thing to note about these results is that, while the models on lines 4 and 5 greatly exceed the performance of the models on lines 1–3 on degree, quality, inversion, and RN_{root} prediction, when it comes to key prediction, the AugmentedNet v1-trained models actually perform better (with the exception of the ChordGNN model). We believe this occurs because key prediction on the subset is simply an easier problem, since it contains less music from the late 19th century and beyond, a period when music tended to modulate more widely.

4.1 Effect of key conditioning

In Table 4, line 6, it can be seen that conditioning the Roman numeral prediction on the ground-truth key (i.e., teacher forcing) has a large effect on degree accuracy. This constitutes a sanity check that the conditioning works as expected: if the model knows the key of the annotation, its ability to predict the Roman numeral’s degree shoots up. By contrast, key conditioning, with or without teacher forcing, has little effect on the “quality” and “inversion” metrics. This is also expected, since these tasks do not depend on the key: a first-inversion minor chord is a first-inversion minor chord regardless of the key in which it occurs.

It is somewhat harder to interpret a comparison of RNBert, conditioned on the predicted key (line 5), with the

Model	Degree	Quality	Accuracy			
			Inversion	Key	RN _{+root}	RN _{-root}
<i>AugmentedNet v1 data subset</i>						
1 AugmentedNet [6]	.67	.797	.788	.829	.464	.515
2 ChordGNN+(Post) [10]	.714	.784	.803	.813	.518	.529
3 RNBert (key conditioned)	.731	.819	.796	.825	.574	.575
<i>All data</i>						
4 RNBert (unconditioned)	.762	.867	.872	.822		.620
5 RNBert (key conditioned)	.749	.864	.872	.823		.624
6 RNBert (key conditioned, teacher forcing)	.859	.865	.872	N/A		N/A

Table 4. Accuracy of RNBert and two prior models. The meanings of RN_{+root}, RN_{-root}, and RN_{alt} are described in Section 4. In the model comparison of lines 1–3, we indicate the best metric in **bold** type. Because the teacher-forcing model on line 6 does not predict key, and RN prediction involves key prediction, we do not report RN results for this model.

Ground truth: F:V V₅⁶ C:IV V₅⁶/V I₄⁶ V⁷ I

RNBert (unconditional): F:V⁶ V₅⁶ I V₅⁶/ii I₄⁶ V⁷/V V

RNBert (conditioned): F:V⁶ V₅⁶ I V₅⁶/ii I₄⁶/V V⁷/V V

Figure 2. Beethoven, String Quartet in F major, op. 18, no. 1, iv, mm. 7–8. Arguably correct predictions that do not agree with the human annotations are printed in *italic* type and serve to illustrate the discussion in Section 4.2. The prediction printed in ~~strikethrough~~ type is straightforwardly incorrect and illustrates the discussion in Section 4.1.

unconditional RNBert (line 4). The unconditional model does better predicting degree, but the conditioned model does better predicting the composite RN_{-root}. These results make sense if key conditioning makes the key and Roman numeral predictions more coherent with one another. Even when the unconditional model does not predict the labeled key, it should still predict the labeled degree some proportion of the time, causing its degree accuracy to be higher. The conditional model, on the other hand, should be less likely to do this, but its composite RN prediction should be more coherent and thus more accurate.

Figure 2 can serve as an illustration. The two RNBert analyses are almost identical, being in the key of F major throughout, with tonicized dominant chords at the half cadence that concludes the example. The lone difference occurs at the cadential 64 chord on the downbeat of the second measure. Here, while the conditioned model gives the correct annotation I₆₄/V, the unconditioned analysis gives I₆₄, which is incorrect, since this is a C major chord, and the annotated key is F. The unconditioned model’s key and Roman numeral predictions are each plausible on their

own—I₆₄ is the most common annotation for a cadential 64 chord—but they do not cohere with one another. And yet, in spite of being incorrect with respect to its predicted key, this I₆₄ prediction happens to agree with the ground truth, and thus the degree accuracy of this example is (spuriously) higher for the unconditioned model.

4.2 The problem of multiple acceptable analyses

One important problem in evaluating Roman numeral analysis models is that there is often more than one correct analysis of a musical passage, so that a model’s predictions can be labeled “inaccurate” even when they present valid alternate readings. For example, this may occur with brief passages in another key, which can be analyzed as either modulations (indicated by a change of key) or as tonicizations (indicated with secondary Roman numerals).

On a priori grounds, as well as based on qualitative sampling of the model’s predictions, we suggest that a high proportion of RNBert’s “inaccurate” predictions are likely to be acceptable alternate analyses. For example, in Figure 2, it is reasonable to analyze the half cadence that concludes the example as a brief modulation to C, as the human annotator did, or as a tonicization, as done by both versions of RNBert. Either analysis is acceptable, but the divergence means that nearly all labels in RNBert’s analysis do not agree with the ground truth, in spite of being arguably correct. These considerations may place a ceiling on the accuracy of all Roman numeral analysis models.

5. CONCLUSION

At the broadest level, our results imply that, by fine-tuning pretrained models, we can obtain state-of-the-art performance on music theory tasks. In the specific case of Roman numeral analysis, we suggest that Roman numeral analysis models have now matured to the point where they are ready to be used in large-scale musicological studies. Finally, we note that the approach described in this paper could be readily extended to many other music theory tasks that can be conceived of as a labeling of the notes of a score, including the analysis of dissonant idioms (suspensions, passing tones, and the like) or melody harmonization (that is, labeling each pitch of a melody with a chord).

ABSTRACT

Multimodal models that jointly process audio and language hold great promise in audio understanding and are increasingly being adopted in the music domain. By allowing users to query via text and obtain information about a given audio input, these models have the potential to enable a variety of music understanding tasks via language-based interfaces. However, their evaluation poses considerable challenges, and it remains unclear how to effectively assess their ability to correctly interpret music-related inputs with current methods. Motivated by this, we introduce MuChoMusic, a benchmark for evaluating music understanding in multimodal language models focused on audio. MuChoMusic comprises 1,187 multiple-choice questions, all validated by human annotators, on 644 music tracks sourced from two publicly available music datasets, and covering a wide variety of genres. Questions in the benchmark are crafted to assess knowledge and reasoning abilities across several dimensions that cover fundamental musical concepts and their relation to cultural and functional contexts. Through the holistic analysis afforded by the benchmark, we evaluate five open-source models and identify several pitfalls, including an over-reliance on the language modality, pointing to a need for better multimodal integration. Data and code are open-sourced.¹

1. INTRODUCTION

Combining the success of large language models (LLMs) with new advances in machine perception that have led to image, audio and video foundation models [1], multimodal LLMs are becoming influential across many fields [2–6]. Recently, models of this kind have started supporting the audio modality, with a subset also being applied to the music domain [7–13]. We refer to such models exhibiting audio understanding capabilities as *Audio LLMs*. In a nut-

Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

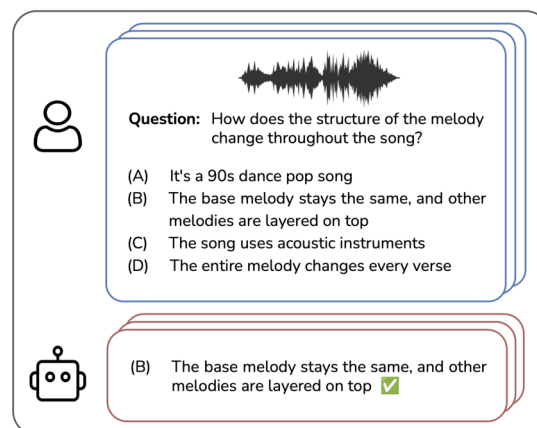

Figure 1. Multiple-choice questions in MuChoMusic have four answer options of different levels of difficulty.

shell, Audio LLMs consist of pre-trained LLMs whose input space has been expanded beyond text to include tokens from an audio encoder, granting them the ability to produce language outputs that require understanding of both modalities. While promising, these models also inherit many of the limitations of LLMs and little attention has so far been given to their evaluation. In most cases, current automatic evaluation relies on match-based metrics which measure the semantic or lexical overlap between model outputs and reference text. However, many works have pointed out deficiencies in this approach [14], which fails to capture the large space of acceptable language outputs admitted by open-ended tasks. For example, the question “*What are some possible uses for this music in a film or TV show?*” may be suitably answered in many different ways. Secondly, automatic music understanding evaluation via language is only supported by a handful of human-annotated datasets [15–17], of which only one [15] has widely been adopted in the context of Audio LLMs. Instead, many prior works have created a variety of ad-hoc datasets built upon synthetically generated captions from tags and other metadata [8, 9, 18] to train and evaluate their models, without explicit data validation mechanisms, which raises questions around their reliability. These three key issues, lack of standardisation, the inadequacy of text generation metrics, and the quality of annotations in current datasets, pose obstacles to the development of the field and has prompted some to resort to human evaluations [7], which can be costly and are hard to scale and reproduce.

In this paper, we present *MuChoMusic*, the first benchmark for evaluating music understanding in Audio LLMs. We design a test that is easy to evaluate by collecting a set of multiple-choice (MC) questions that are scrutinised by human annotators, on which simple classification accuracy can be obtained as a reliable indicator of music understanding over the categories covered by the test. The content of our benchmark is intended to be challenging, grounded in factual music knowledge, and tests core understanding and reasoning skills across several dimensions such as music theory, musical styles and traditions, historical and social contexts, structure and expressive analysis. Using *MuChoMusic*, we carry out a comprehensive evaluation of five existing Audio LLMs with music understanding capabilities. We envision that *MuChoMusic* will complement prior efforts to standardise music understanding evaluation [19–21] by including this new family of models and steering their early development towards robust progress.

2. RELATED WORK

In the music domain, Audio LLMs are commonly evaluated by assessing their text output in the context of a given task defined by an instruction template. Tasks are either designed to test whether the model is able to recognise predefined musical properties such as key (“*What is the key of this song?*”), genre, instrumentation, etc., or they probe for outputs that encompass a variety of musical concepts and that more closely resemble the dialogue format typical of chatbots. Tasks that fall under the former usually mirror canonical MIR tasks and their evaluation leverages standard metrics and benchmarks from the MIR literature. Evaluation of tasks that require broader understanding follows instead less established protocols. Prior works on Audio LLMs most commonly tackle this via two tasks, music captioning (“*Describe the contents of the provided audio in detail*”) [7–9, 11] and music question answering (“*What are some possible uses for this music in a film or TV show?*”) [8, 9]. To perform this kind of evaluation, the authors in [7, 9, 11] make use of the MusicCaps dataset [15], while others [8, 9] employ ad-hoc evaluation datasets created with the help of LLMs. In particular, Liu et al. [8] and Deng et al. [9] propose their own datasets for music question answering, MusicQA and MusicInstruct respectively. These are derived from captions in the MusicCaps dataset or tags from the MagnaTagATune dataset [22] (MusicQA only), by augmenting them into music-question pairs via pre-trained LLMs. Similarly to these works, we also leverage LLMs to generate our set of questions and answers, but we follow a multiple-choice format to ensure meaningful evaluation and validate all generated data through human annotators to guarantee high data quality.

Finally, we note that concurrent work also proposes evaluation benchmarks for music understanding in LLM-based models [23–25], but these all differ from our work in significant ways: MuChin [23] includes only text in Chinese and does not follow a multiple-choice format, while both MusicTheoryBench (MTB) and ZIQI-Eval focus on the symbolic domain and address the evaluation of text-

Benchmark	Size	Source(s)	Audio	HC	MC
MusicQA [8]	4.5k	MagnaTagATune	✓	✗	✗
MusicInstruct [9]	61k	MusicCaps	✓	✗	✗
ZIQI-Eval [25]	14k	Music books	✗	✗	✓
MTB [24]	372	(human-written)	✗	✓	✓
AIR-Bench [26]	400	MusicCaps	✓	✗	✓
MuChin [23]	1k	<i>unknown</i>	✓	✓	✗
MuChoMusic	1.2k	MusicCaps, SDD	✓	✓	✓

Table 1. Comparison of MuChoMusic to existing benchmarks. HC: human-curated, MC: multiple-choice.

based LLMs. AIR-Bench [26] includes a small subset of music-related tasks, but puts its focus on audio understanding more generally. We provide an overview of key differences with other benchmarks in Table 1.

3. MUCHOMUSIC

Through *MuChoMusic*, we aim to alleviate three prominent issues in the evaluation of music understanding in Audio LLMs: a lack of standardisation, the inadequacy of existing text generation metrics, and the quality of current evaluation sets. We address the first two by adopting a multiple-choice format, while our methodical generation and validation procedure attends to the third issue by grounding the data in human-written descriptions and ensuring that the final questions and answers are correct and contextually relevant, as judged by multiple annotators.

3.1 Overview

MuChoMusic consists of 1,187 multiple-choice questions aimed at testing the understanding of 644 unique music tracks sourced from the MusicCaps [15] and the Song Descriptor Dataset [16]. We adopt a multiple-choice format in order to standardise evaluation and follow widespread practice in LLM-centric evaluation scenarios [27–30]. As illustrated in Figure 1, each question has four possible answers. One option is the correct answer, the other three are distractors. Inspired by [31], we structure these as follows: one does not fit the track of interest but is related to the question (*incorrect but related*), one correctly fits the audio, but does not address the question (*correct but unrelated*), and one does not apply to the track and is also irrelevant to the question (*incorrect and unrelated*).

Evaluation dimensions *MuChoMusic* is built from a diverse set of musical works and their detailed descriptions, and serves as a foundation for evaluating Audio LLMs across various dimensions of music comprehension. To delineate the specific evaluation dimensions encompassed by our benchmark, we develop a taxonomy consisting of two primary categories: *knowledge* and *reasoning*. Each category is further divided into several dimensions, informed by insights from national music education programs and existing research on music folksonomies [32]. This structured approach allows us to assess the depth and breadth of music-related competencies systematically, offering a holistic view of models’ capabilities in the music domain.

Figure 2. Distribution of evaluation dimensions covered by MuChoMusic across knowledge and reasoning.

In the *knowledge* category, questions probe a model’s ability to recognise pre-acquired knowledge across various musical aspects: (i) melody, (ii) harmony, (iii) metre and rhythm, (iv) instrumentation, (v) sound texture, (vi) performance, and (vii) structure. Questions that test *reasoning* are instead designed to require the synthesis and analytical processing of multiple musical concepts: (i) mood and expression, (ii) temporal relations between elements, (iii) interpretation of lyrics, (iv) genre and style, (v) historical and cultural context, and (vi) functional context. An example of reasoning might involve using an understanding of tempo, chord quality, and instrumentation in concert to ascertain the mood of a music piece. Each question can cover multiple dimensions and their categorisation is obtained automatically, as described in Section 3.2. Figure 2 shows the coverage of the two categories and their respective dimensions within the benchmark. Over half the questions test at least one aspect of musical knowledge, such as features relating to instrumentation or performance characteristics, while 44% are dedicated to probing reasoning skills. While the distribution of dimensions within each category is not balanced, we note that this reflects the distribution of different musical concepts within music captions [16], resulting in categories such as instrumentation, mood and genre appearing more frequently.

3.2 Dataset construction

To build our dataset, we automatically transform human-written music captions into multiple-choice questions. These are then carefully validated by multiple human annotators, alongside the associated audio, in order to filter out invalid, ambiguous or irrelevant questions resulting from inaccuracies or hallucinations in the model output.

Data sources We source our data from music caption datasets as we aim for elaborate and linguistically diverse information about the music. Currently, only two captioning datasets provide sufficiently detailed music descriptions, namely the Song Describer Dataset (SDD) and MusicCaps. SDD contains 2-minute-long music clips with

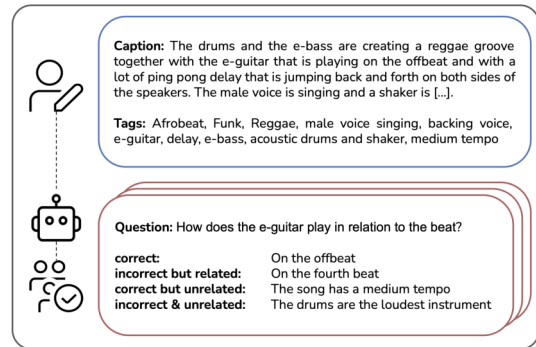

Figure 3. QA generation and validation pipeline. Example shown here is from MusicCaps [15].

single-sentence captions crowd-sourced from music enthusiasts, while the captions in MusicCaps, describing 10-second audio snippets, are written by professional musicians. From SDD, we select all tracks that have at least two captions, to ensure enough information is provided to the model to be able to formulate interesting and challenging questions. While this is not possible for the MusicCaps dataset, where only one caption is available for each track, we note that descriptions are, on average, longer than in SDD and designed to be more comprehensive. From the genre-balanced subset of the MusicCaps test split, we exclude all tracks for which the labels indicate a low recording quality, to prevent differences in audio quality from affecting the results. For both datasets, we employ a state-of-the-art genre tagging model [33] to identify non-musical tracks and to sub-sample songs from the most common genres (e.g. rock and electronic). Through this curation process, we select 227 unique tracks from SDD and 497 from MusicCaps. We supplement the descriptions with short text labels taken from the dataset itself in the case of MusicCaps and from a related dataset for SDD [34].

QA generation We generate the question-answer sets by instructing Gemini 1.0 Pro [3] to formulate question and answer options for a given human-written caption. To leverage the model’s in-context learning capability, we prompt it with a detailed task description and three examples of input (description and tags) and expected output. In addition to the question and answer pairs, we ask the model to start its output with a summary of the provided information about the music recording and to interleave the distractor answer options with explanations of their suitability. This way of prompting is inspired by the chain-of-thought methodology and helps to elicit the best model responses [35, 36]. This way, we obtain three multiple choice questions from each description on average and collect a total of 2,091 question-answer pairs. An example of the generated questions is shown in Figure 3.

Data validation In order to ensure that questions and answers in our benchmark are factually accurate, aptly written and that each question can be correctly answered based on the available audio, we validate all sets of questions via human annotators. For this step, we recruit 222 participants via the Prolific platform (www.prolific.com). During annotation, a question, the corresponding audio clip, and

all four answer options are presented to the participants in random order, for a total of 30 to 50 question items. Participants are then asked to select all options that correctly answer the question or skip the question by indicating that they are unable to provide an answer or that the question is not valid. Following this procedure, for each question, we collect three to five annotations, stopping early if different annotators are in agreement. This task setup is intended to vet questions and detect those that do not adhere to the intended multiple-choice format, either because the expected correct answer is not the only plausible option or because any one of the distractors is more likely. Consequently, we exclude questions from our final dataset for which i) less than 50% of the annotations indicate the intended correct answer or ii) more than 50% of the annotations mark any of the distractors as a plausible answer. The final dataset comprises 858 questions from MusicCaps descriptions and the remaining 329 from SDD captions.

Question categorisation Once questions are validated, we categorise them according to our taxonomy outlined in Section 3.1. To achieve this, we employ Gemini 1.0 Pro, this time prompting it to automatically label each question with one or more of the evaluation dimensions. The prompt includes the full taxonomy including detailed descriptions of all dimensions, a chain-of-thought instruction, and a single question with only the correct answer. The produced output contains an explanation of the categories and dimensions assigned to each question.

4. BENCHMARKING WITH MUCHOMUSIC

We now demonstrate the use of our benchmark, describing our proposed evaluation protocol and metrics, and then detailing our experiments on benchmarking Audio LLMs.

4.1 Evaluation Protocol

In multiple-choice-based evaluation, a model is provided with a question and a set of answer options, and is then tasked with selecting the most suitable answer. In practice, this can be accomplished in different ways [29]. In our experiments, we adopt *output-based* evaluation: given a music clip and an associated question-answer set, the language output produced by the model is mapped to one of the candidate options by string matching. Another common approach in MC evaluation is to determine the selected answer through the conditional log likelihood scores of the tokens forming each of the different options. While this can help estimate uncertainty and confidence in the model predictions, in our experiments, we explore only the output-based setting, for three reasons: (1) this corresponds to real-world use of the models, as interactions usually take the form of a conversation; (2) it has a lower computational cost; (3) prior work has demonstrated that sentence probabilities are not necessarily indicative of the probabilities assigned to the answers [37]. To extract the selected answer from the generated outputs, we match either the option identifier (*A*, *B*, *C* or *D*) or the full answer text, if one and only one is given in the output.

Model	Audio encoder	LLM
MusiLingo [9]	MERT [39]	Vicuna 7B [40]
MuLLaMa [8]	MERT [39]	LLaMA-2 7B [41]
M2UGen [12]	MERT [39]	LLaMA-2 7B [41]

SALMONN [11]	BEATS [42] & Whisper _{large-v2} [43]	Vicuna 7B [40]
Qwen-Audio [13]	Whisper _{large-v2} [43]	Qwen 7B [44]

Table 2. Overview of models we evaluate in our study.

Metrics We look at two main metrics to measure model performance on our benchmark: accuracy and instruction following rate (IFR). Accuracy is given by the percentage of correctly answered questions out of the total set of questions. IFR is given by the percentage of generated answers that correspond to one of the given options. In both cases, finegrained scores can be obtained by considering only the subset of questions covering at least one of the available evaluation dimensions shown in Figure 2.

Adaptation An important design factor in the evaluation of LLM-based models is adaptation [29], the process of adapting the input to a suitable format. While the format of the audio input is typically fixed by the model design, text inputs allow for more flexibility and different prompting techniques have been shown to significantly influence model’s behaviour [35, 36, 38]. Beyond simply passing the question and answer options as the input text, corresponding to *zero-shot prompting*, an effective alternative strategy is to leverage *few-shot in-context learning* (ICL), whereby the model is presented with a set of reference inputs that exemplify the task prior to being shown the question of interest. We experiment with in-context learning in our experiments, providing between 0 and 5 examples in the text input. In the interest of standardisation and to ensure a fair comparison between the models, unless otherwise specified, we keep the prompt selection fixed in our final experiments, following an initial exploration.

4.2 Models

In our evaluation, we consider three music-specific models, MuLLaMA [8], MusiLingo [9], and M2UGen [12], and two general-audio LLMs which can be applied to music, as reported in their respective papers, SALMONN [11] and Qwen-Audio [13]. To the best of our knowledge, these are all the existing Audio LLMs which can be applied to music and for which open-source weights are available. These all share a similar architectural design and are composed of a backbone LLM, an audio encoder and a lightweight learnable adapter module to align embeddings produced by the audio encoder to the input space of the LLM, based on either the LLaMA-adapter [45] (MuLLaMA, MusiLingo, M2UGen) or a Q-Former network [46] (SALMONN). An overview of the backbones used in each model is provided in Table 2. All systems are trained via instruction tuning [38, 47] and all employ a combination of different training datasets, often in multiple training stages including pre-training and fine-tuning. For all models, we follow the official implementation and use default

Model	Accuracy			IFR
	All	Knowledge	Reasoning	All
MusiLingo [9]	21.1	22.0	19.2	71.6
MuLLaMa [8]	32.4	32.3	31.3	79.4
M2UGen [12]	42.9	44.9	41.2	96.4
SALMONN [11]	41.8	41.0	43.3	99.8
Qwen-Audio [13]	51.4	51.1	51.0	89.7
<i>Random guessing</i>	25.0	25.0	25.0	100.0

Table 3. Overall benchmarking results.

inference settings. We repeat all experiments 3 times, randomly shuffling the order in which answer options are presented, and report average performance across all runs.

5. RESULTS AND DISCUSSION

In this section, we first presents findings from our benchmarking experiments, with the goal of elucidating the current state of music understanding in Audio LLMs. We then illustrate how MuChoMusic can be used to derive new insights via a diagnostic analysis, and discuss key takeaways.

5.1 Benchmarking Results

We report results for all models in Table 3, showing the overall accuracy score alongside detailed scores on knowledge and reasoning questions, and the instruction following rate (IFR). Figure 4 presents a breakdown of accuracy scores along all reasoning and knowledge dimensions. Unless otherwise specified, we show one-shot performance for all models, as we find this to be the overall optimal setting, as we discuss in more detail in Section 5.2. From this, we observe that current models generally perform poorly across all settings and along all evaluation dimensions. Among these, Qwen-Audio stands out with a score of 51.4%. Surprisingly, with the exception of M2UGen, music-specialised models generally perform worse than general-audio ones, in some cases performing only marginally above or even below random performance. As evidenced by the IFR, these models struggle to output answers in the correct format, which in turn negatively impacts their accuracy score. As shown later in Section 5.3, we find that, when none of the answer options is selected by the model, this is often due to *auditory hallucinations*, *language hallucinations* or *training biases*.

5.2 Analysis and Discussion

We now investigate factors influencing performance along different axes by using our benchmark as a diagnostic tool.

Are models sensitive to prompts? We first study the effect of varying the number of in-context examples. As shown in Figure 5, providing a single example is occasionally beneficial to accuracy and IFR, but with both the difference magnitude and overall impact differing between models. Additionally, this trend does not hold after the one-shot setting, and we see no consistent improvement when using a larger number of examples. Interestingly,

Figure 4. Finegrained accuracy across evaluation dimensions in knowledge (labelled in blue) and reasoning (red).

we observe that, for M2UGen, Qwen-Audio and MuLLaMa, changes in accuracy from zero- to one-shot prompts are accompanied by a reduction in variance, suggesting that ICL can help minimise variability in the model output. While we do not explore this in our experiments, we also hypothesise that the advantages of ICL may become more prominent through multimodal few-shot prompting [48, 49], which we leave for future work.

How do models respond to different distractors?

Next, we shift our attention to examining how distractors in our benchmark influence the difficulty of the task. To this end, we ablate answer options corresponding to the different kinds of distractors described in Section 3.2, and present the model with only two or three answer options. In Figure 6(a) we show how performance is affected when using only one distractor alongside the correct option, always randomising their order. From this, we observe that the two distractors containing information which is not related to the question (CU and IU) have a similar effect, while including the *incorrect but related* (IR) option consistently makes the task more challenging. This phenomenon persists when adding a second distractor (not shown here), with combinations which include IR invariably leading to worse performance. Intuitively, the two *unrelated* options can be ruled out based on the text input only, while selecting the correct answer between two options that appear relevant requires engaging multimodal understanding to relate information in the audio content to the text in the question. Crucially, this indicates that models particularly struggle to discern between options that are equally plausible based on the text input only, suggesting that less attention is given to the audio content. This forms the basis of our hypothesis that current Audio LLMs are characterised by a strong language bias, leading to poor performance in tasks that are more audio-dependent. We test this hypothesis in the next section.

Do models actually pay attention to the audio? In order to verify whether the audio input is effectively being ignored or is overshadowed by its text counterpart, we de-

Figure 5. Effect of the number of in-context examples on accuracy (left) and instruction-following rate (right).

vis a simple test, which we call *audio attention test*, where we replace the audio clip corresponding to a given question with either white Gaussian noise or a randomly chosen track from the dataset. In order to pass this test, a model should display a statistically significant drop in performance when either form of audio perturbation is used, compared to its baseline performance. We showcase results on this test in Figure 6(b). From this, we clearly see that, with the exception of SALMONN and Qwen-Audio, all models fail the audio attention test, and the severity of this failure is often negatively correlated to their overall performance on the benchmark (see Table 3). This confirms that current Audio LLMs are biased towards textual information, often choosing answers that score well under their language prior. Additionally, it provides an explanation for their low performance on the benchmark, as this is effectively bounded by the maximum score they can attain mostly based on the language input. We argue that this constitutes a major pitfall in the design and training procedure of these models, which results in music understanding abilities that do not match the expected performance, as obtained through prior evaluations.

5.3 Failure Modes

While the core goal of our benchmark is to provide standardised automatic evaluation to objectively measure general music understanding capabilities, we argue that it can also constitute a useful tool for qualitative assessment. We showcase three examples here, focusing on the two lowest-performing models. While this is not an exhaustive analysis, these examples offer a bird’s-eye view of how language pre-training biases percolate through multimodal training, resulting in failures to attend to the inputs in our evaluation. To describe these, we borrow terminology from [50].

Auditory hallucination One of the ways models fail to provide a suitable answer falls under the category of *auditory hallucination*, whereby a response includes references to musical elements that are not present in the audio. For example, when asked about an accompaniment instrument, models with this type of hallucination may ignore any suitable option provided (“*acoustic guitar*” or “*strings*”), instead answering “*The song is accompanied by a piano.*”, when the audio clip clearly contains no piano.

Figure 6. (a) Effect of using different types of distractors: models tend to perform worst when tasked with distinguishing between two related answers. (b) Audio attention test: only some models display a significant drop in performance when provided with incorrect audio inputs. For these experiments, we adopt zero-shot prompting.

Language hallucination Another instance of hallucination concerns mundane statements that deviate from the topic of the question altogether. Among others, an observed case of this failure mode is a statement of the form “*The song has a clear and coherent rhythm structure*” to a question specifically asking about the “*type of drum beat*”.

Training data bias The last failure mode we encounter is related to a bias towards frequent patterns occurring in the training data. While some of the benchmarked models undergo a stage of training that includes instruction-tuning examples with questions and answers, occasionally they still produce trivial outputs. For example, when asked “*What is the intended purpose of this song?*”, a model with this type of bias may answer “*The intended purpose of this song is not mentioned in the caption*”. Reviewing MusicQA, used in training MuLLaMa and MusiLingo, reveals that a high number of the LLM-generated training examples mention similar phrases, thus likely biasing the model towards this type of uninformative but highly likely output.

6. CONCLUSION

We have presented MuChoMusic, a multiple-choice music question answering benchmark designed to test music understanding in Audio LLMs. From an evaluation of five state-of-the-art systems, we find that our benchmark acts as a challenging and informative test, and that current models do not yet leverage both the audio and text modalities fully. All questions in our benchmark are synthesised from human-written music descriptions and manually reviewed to guarantee high data quality. A categorisation of the questions highlights that MuChoMusic offers a broad coverage of areas targeted by current models, and additionally pinpoints gaps that could guide future developments in the field. While we demonstrate that our approach leads to new insights, we note that the multiple-choice format presents some limitations [51]. Therefore evaluation on MuChoMusic should be complemented via further benchmarking efforts to address additional aspects of music understanding through different tasks and formats.

7. ETHICS STATEMENT

7.1 Annotator welfare

Prior to participation, the annotation experiment described in Section 3.2 was approved by the Queen Mary Ethics of Research Committee to ensure alignment with ethical guidelines and protections for human subjects in research. We did not collect any personal data from our annotators, safeguarding their privacy and confidentiality. Annotators were fully informed about the objectives of the research, the nature of their tasks, and the use of their annotations, underpinning their informed consent before contributing to the project. In an effort to provide a fair compensation for their contributions, annotators were paid £9 per hour.

7.2 Biases and fairness

In constructing the MuChoMusic benchmark, our data collection strategy included sourcing music tracks from a variety of backgrounds, acknowledging the inherent challenges in representing the rich diversity of global music cultures within our dataset. We recognise that our initiative does not fully balance the benchmark across all genres, languages, and cultural backgrounds, and annotations were conducted exclusively in English due to logistical constraints, highlighting areas for future expansion and improvement.

HUMAN POSE ESTIMATION FOR EXPRESSIVE MOVEMENT DESCRIPTORS IN VOCAL MUSICAL PERFORMANCES

Sujoy Roychowdhury Preeti Rao Sharat Chandran
{214077004, prao, sharat} @ iitb.ac.in
Indian Institute of Technology Bombay

ABSTRACT

Vocal concerts in Indian music are invariably associated with the performers’ hand gesticulations that are believed to convey emotion, music semantics as well as the individual style of the performers. Video recordings, with one or more cameras, along with markerless human pose estimation algorithms can be employed to capture such movements, and thus potentially solve music information retrieval (MIR) queries. Nevertheless, off-the-shelf algorithms are built for the most part for upright human configurations contrasting with seated positions in Indian vocal concerts and the upper body movements in the context of performing music. Current state-of-the-art algorithms are black box neural network based and this calls for an investigation of the components of such algorithms. Key decisions involve the choice of one or more cameras, the choice of 2D or 3D features, and relevant parameters such as confidence thresholds in common machine learning methods. In this paper, we quantify the increase in the performance with three cameras on two music information retrieval tasks. We offer insights for single and multi-view processing of videos.

1. INTRODUCTION

Performances of vocal music in the Indian classical traditions involve the use of hand gestures that accompany the singing. We therefore wish to perform the automated analysis of performances with audiovisual recordings. One or more video cameras can be used to record musical performances. Our goal in this work is to explore different Human Pose Estimation (HPE) methods for the computational analysis of expressive movements of upper body limbs of the vocalist.

Markerless Human Pose Estimation algorithms constitute a novel technology that is available to investigate hand gestures by looking at important *keypoints* such as wrists and elbows. These algorithms are trained with artificial deep neural networks on whole body movements, and occasionally on music recordings. One important concern in

Figure 1: We analyze seated vocalists with multiple cameras. We identify singers purely based on hand gestures, and predict stable notes.

the use of HPE in musical gesture studies is that the gestures are typically expressive movements and not routine motor movements such as walking, jumping, or performing yoga poses, the latter motor movements being the bulk of the training data used in the development of HPE algorithms. Indian classical music, in both Northern and Southern traditions, is particularly rich in the use of gestures invariably in a seated position.

Paschalidou [1] studied associations between sound and “effort” in gesture in *Dhrupad* performances using an optical motion capture system. Although she finds correspondences, generalizing to multiple singers was challenging. Pearson and Pouw [2] look at vocal-gesture coupling in Karnatak music performance; the Kinect camera and an older, machine learning technique is used for obtaining keypoints. With the current deep-learning HPE technology, Clayton et. al. [3,4] use OpenPose-based wrist keypoints to classify *raga* and identify singers on a dataset of multimodal Hindustani music recordings. Nadkarni et al. [5] also use OpenPose to explore the correspondence between vocal singing and gestures.

However, to the best of our knowledge, there has been no work which uses multiple camera views for studying gesture and vocal correspondence in music. While it is natural to expect that more cameras help HPE, on a careful examination of prior work, we see that the process of estimating keypoints requires multiple design decisions. Several options present themselves in terms of camera position, the number of views, the keypoint detection method and its parameters, and finally, methods for combining information from multiple camera views.

1.1 Scope of this paper

In this paper, we choose 3 recent models for keypoint detection and 3 different HPE methods to obtain information from multiple views for the purposes of analyzing gestures. We restrict our study to wrist and elbow of both hands since they appear to be the ones most relevant when singers are seated. We consider two MIR tasks.

Stable Note Prediction from Gestures This problem was studied by Nadkarni et al. [5]. The authors define a stable note as a region of at least 250 ms duration across which the singer’s pitch lies within a 25 cent interval of the mean intonation of the raga note.

Gesture-based Singer Identification In this task, the goal is to identify the singer purely from gestures, i.e., without accessing the audio stream, or the face. Rahaim [6] emphasises that gestures in music are not taught or rehearsed and therefore tend to be idiosyncratic. The proposed MIR task attempts to validate the hypothesis that it should be possible to identify the singer from the gesture using 12s randomly chosen snips from the video. Similar problems may be interesting in other MIR settings such as a western music conductor’s motions when the face is not visible, or in dance and musical performances where the face is hopelessly masked. A gesture-based singer identification system can also be used to validate a digital avatar system that is attempting to realistically mimic singers.

1.2 Contributions

Although our work is focused on the two tasks mentioned above, we offer insights more generally useful in the HPE analysis of multiview recordings of music performances.

- Every HPE algorithm provides confidence scores. We suggest an approach to the choice of confidence thresholds for fair comparisons across algorithms.
- Multiple cameras lend themselves to 3D reconstruction, and indeed a single camera can also be used in recent state-of-the-art methods to infer 3D. We suggest that decision fusing 2D information from multiple cameras can be almost as competitive as using 3D reconstruction.

In term of concrete results for the two problems we report the following:

1. By considering position coordinates and individual coordinates of velocity and acceleration as features, a systematic choice of confidence thresholds, and the best HPE method, we improve the performance of stable note prediction (from gestures) from $\sim 66\%$ [5] to $\sim 83\%$ (single camera).
2. We report the accuracy of the best performing HPE method for gesture-based singer identification (8-way) to be $\sim 93\%$.

It is to be noted that the two MIR tasks are solved using two different methods. The Stable Note problem uses the

classical machine learning method of SVM. There is no artificial neural network here. On the other hand, the gesture-based singer identification problem uses a deep neural network with an inception block.

The rest of the paper is organized as follows. In Sec. 2 we look at different keypoint detection methods, and the reported performance. Sec. 3 describes the dataset used. Task agnostic comparisons of HPE methods is discussed in Sec. 4. Our two suggested methods of consuming information from multiple cameras is described in Sec. 5. The details of our experiments and the results are reported in Sec. 6. A summary appears in Sec. 7.

2. BACKGROUND

We first briefly describe three popular HPE methods, one [7] of which is *proprietary*. Later we describe the applications of these to areas in sports, and medicine in order to understand current understanding of their usage. We are not aware of the direct use of HPE for gesture understanding except the ones mentioned in the introduction.

2.1 Human Pose Estimation Techniques

The pose of a human in HPE methods results in a stick diagram (similar to Fig. 1) of important joints such as the shoulder, wrist, elbow, hip, knee and so on from images and videos. At the turn of the century, the joints, referred to as *keypoints* were obtained with markers placed on different parts of the body — however this can only be set up in controlled experimental settings and may also affect the natural movement of the subject. Subsequently specialized cameras such as the Kinect was employed using classical machine learning techniques. With the advent of deep learning (DL), nowadays standard RGB cameras may be employed for markerless pose estimation.

One of the first DL-based techniques is OpenPose [8] which can identify 25 keypoints in terms of pixel coordinates reported as (x, y) . OpenPose is based on estimating confidence heatmaps for keypoints and part affinity fields (PAF) which are vector fields encoding the connection across limbs between different joints. Since their method estimates keypoints and parts directly from the image using a multi-stage Convolutional Neural Network (CNN) their method is called a bottom-up approach in the literature [9]. OpenPose is trained on the MP-II human dataset [10] and the COCO [11] datasets. The MP-II dataset, with 25K images in 20 activity categories like cycling, running, violin playing, etc., has both full body and seating position data. The COCO dataset has 200K annotated images of 17 body keypoints in both seated and full body positions.

Alternatively, approaches based on Mask R-CNN [12] perform semantic segmentation of the image to identify masks on people in the image. Detectron2 [13] uses this mask to identify 17 keypoints for the body parts. As this method uses an identified mask for the prediction of the keypoints, this is often referred to as a top-down keypoint estimation method. Detectron2 is trained on the COCO dataset [11].

Multiple calibrated cameras can use well understood geometric computer vision methods of the 90s for depth estimation from 2D keypoints, thus producing 3D coordinates (x,y,z). Aniposelib [14] is a library which implements the 3D reconstruction from multiple synchronized calibrated cameras. However, the 2D keypoints in Detectron2 can be extended to 3D by a different deep learning based model VideoPose3D [15]. Videopose3D uses two DL models – a temporal dilated convolution for estimating depth per person and a separate 3D trajectory model for the center of the body viz. center-hip coordinate. Depth is estimated as a distance with respect to the center-hip of the body. Videopose3D is trained on Human 3.6M [16] and Human Eva [17] datasets.

There is, however, a direct way of obtaining 3D provided the face of the image is visible. BlazePose [18] identifies thirty-three 3D keypoints from single-view images. This model is trained on a custom dataset consisting of 60K images and is used in the Mediapipe library [7].

2.2 HPE-based Applications

A number of studies (for example, [19]) in HPE have involved evaluation of the accuracy of the HPE models by comparing markerless pose estimation with marker based pose estimation and shown that the Mean Absolute Error to be less than 30mm on 80% of trials.

Markerless systems are evaluated in clinical settings by Zhang et al. [20] and Mroz et al. [21] where they compare Hyperpose [22] vs OpenPose and OpenPose vs BlazePose (Mediapipe) respectively. Zhang et al. [20] establishes that OpenPose is better than HyperPose using manual annotations and then compares OpenPose with BlazePose via Root Mean Squared Error (RMSE) and correlation metrics. Their findings are that while BlazePose is faster, OpenPose provides for more accurate results in their setting. A similar comparison study [23] between three models – OpenPose, BlazePose and AlphaPose looks at a multi-camera setting for estimating biomechanical parameters like Ground Reaction Force (GRF). They observe that the detection rate is dependent on the camera view and the model. Also, they observe the BlazePose has lower detection rate than the other models.

Mehdizadeh et al. [24] look at estimating gait variables comparing OpenPose, AlphaPose [25] and Detectron and do not find any differences between their correlation with gait variables. Since all of the HPE models estimate a confidence score, they choose a confidence threshold for each model independently and discard estimates with a lower confidence than threshold and interpolate the values linearly. They choose the confidence thresholds so that less than 10% of frames were interpolated as a result.

Evaluating athlete anterior cruciate ligament (ACL) injury risk in jumps is important for athletes and the studies by Blanchard et. al [26] and Roygaga et al. [27] look at this using a multi-view camera setting and OpenPose model for HPE. They train models to identify if the jump is erroneous on each view independently and also a fusion model combining the individual models. Their choice of a confidence

threshold of 0.3 for OpenPose confidence is validated by an ablation study across different thresholds. Their results indicate that the task performance depends on the view and the type of error. They drop frames below threshold of 0.3 but do not interpolate dropped frames.

2.3 Synopsis

All of these studies bring us to some conclusions which motivate our research in MIR space. First, we are aware of a variety of techniques and approaches for HPE estimation and 3D reconstruction. Second, markerless pose estimation models have acceptable accuracy This is necessary in a musical setting since performers may not be comfortable using markers. Third, we realize the possible benefits of doing multi-view reconstruction in downstream tasks. We understand that performance on any downstream task depends on the view and model of choice. Finally, we are aware of the importance of the choice of thresholds in rejecting or retaining HPE estimates and how these are dependent on the model and view in question.

3. DATASET

We used the dataset from our earlier study [5]. The details of the dataset, data processing and links to download the data are available on github.¹ The dataset consists of 11 professional singers singing 2 *alaps*² each of 9 *ragas*. Recordings are captured by 3 synchronized cameras. However, we discovered that the recordings for 3 of the 11 singers were done with uncalibrated cameras and thus, since we are interested in 3D information, Anipose [14] cannot be used. Therefore we base our MIR tasks described in Sec. 1.1 on only the remaining 8 singers. We are left with 143 recordings with about 7 hours 10 mins of recording. These recordings are at 24 fps with a resolution of 1920 × 1080. The angle between the front and the right camera is approximately 55 degrees and the front and left camera is approximately 47 degrees. We refer to left and right camera based on the singer’s point of view. Fig. 1 shows a sample of the singer in the three views.

4. TASK-AGNOSTIC COMPARISONS

We choose the three HPE models because they provide a mix of bottom-up (OpenPose), top-down (Detectron) single view 2D keypoint estimation as well as single view 3D keypoint estimation (Mediapipe). In addition, our reconstruction techniques involve both frame-wise geometric reconstruction via Anipose [14] as well as DL-based methods (Videopose3D [15]) which uses information from neighbouring frames. Thus our methods of estimation and reconstruction are relatively independent of each other.

4.1 Confidence Threshold

All HPE models provide a confidence score for each of the estimated keypoints and it is conventional to choose

¹ Dataset github

² Alap is the unmettered introduction in raga performances.

a threshold for the confidence score to ignore predictions with a lower confidence score. Various previous studies [5, 27–29] have used a 0.3 threshold for OpenPose. However, we find that this method is not based on the actual data distribution and also cannot be extended to other HPE models like Detectron and Mediapipe. Due to this, we approach the problem similar to [24]. In every frame, if any of the left and right wrist and elbow keypoints have a confidence score to be less than some value x then we remove the position coordinate in question and interpolate it from the available neighbouring frames. For each model-view combination we change the threshold from 0 to 1 in steps of 0.01 and, in line with [24], choose the threshold so that no more than 10% of frames are dropped in that model-view combination. The corresponding obtained confidence thresholds are given in Tab. 2 and used for all our experiments. Abbreviations used in this paper are in Tab. 1.

OpenPose - OP2	Detectron - DE2	Mediapipe - MP2
Aniposelib - AP3	Videopose3D - VP3	Mediapipe3D - MP3

Table 1: Abbreviations for the various HPE techniques.

View	OP2	DE2	MP3
Front	0.49	0.17	0.27
Left	0.20	0.10	0.01
Right	0.38	0.15	0.12

Table 2: Confidence values obtained when the maximum number of interpolated frames is 10%.

4.1.1 Observations

We observe that thresholds for the left view are lower in all the 3 HPE models and this indicates that the keypoints are predicted with lower confidence for this view. The obtained threshold is particularly low for Mediapipe. Also, we observe that thresholds for OpenPose are higher than the other models indicating that OpenPose predicts keypoints with a higher confidence score. If we use the previously reported threshold of 0.3 for OpenPose then we would have 3.67%, 15.49% and 7.23% of interpolated frames in front, left and right views respectively. However, as seen from Tab. 5, there is no particular advantage of using the previous reported confidence value of 0.3 with its performance lower than what we have in Tab. 4.

4.2 Correspondence between models

Given that the models are attempting to predict the same joints, we expect that that the predictions would be close to each other in the pixel coordinate system. To verify this we consider the Euclidean distance of the predicted keypoints between 2 models in a pair in every frame. We ignore frames where any of the four keypoints have a confidence less than the corresponding threshold as defined in Tab. 2. The results are presented in Fig. 2.

4.2.1 Observations

We observe that the three models correspond well to each other in the front view (noting that the dimensions of the

frame to be 1920×1080). However, in other views, while OpenPose and Detectron predictions maintain pair-wise consistency, the same cannot be said for Mediapipe. We repeat these experiments by choosing thresholds corresponding to 5% and 15% interpolated frames and the same trends hold true. These trends also hold when we study the pair-wise correlations (instead of RMSE distances). This analysis, however, can only say that the models concur with each other in the front view but not so in the other views with least concurrence in the left view. We cannot conclude that one model is better than the other based on this analysis. A partial intuition for these results is that the left hand obscures the right hand in the left view, and most singers are right-handed.

5. MULTIPLE CAMERAS

In this section, we provide the details of the use of multiple cameras for the downstream MIR tasks. Fig. 3 shows the algorithms we use to get 2D and 3D coordinates.

5.1 Reconstruction

Reconstruction involves the combination of the data from multiple views to estimate a depth-coordinate either via classical computer vision [14] or DL. The z-coordinate is measured in distance from the camera in geometric reconstruction. On the other hand, with DL the depth is estimated to be a distance with respect to the center hip with larger values indicating further distance from the center. In the recording setting, a higher value of the estimated z-coordinate (e.g., for an outstretched hand) would mean closer to the camera. Mediapipe which predicts the z-coordinate from a single view uses a similar definition of the z-coordinate. Reconstruction using both Aniposelib [14] and Videopose3D can be done using any of the cameras as reference view and information from other cameras used for reconstruction. The results for the downstream tasks can be different.

5.2 Model Fusion

The second method for consuming data from multiple views in a machine learning based MIR setting is to have the downstream task (e.g. classifiers) trained individually on each view and then use the probability predictions of these classifiers as an input to a further classifier. This can be done based on classifiers on three sets (each using 2D data) in which case this will be an alternative to reconstruction. On the other hand, one can use classifiers trained on three reference views using 3D reconstructed data (anipose, videopose3D) or predicted data (e.g. Mediapipe), and then use their probability outputs as an input to a further model. Both of these approaches are examples of multi-view fusion which exploit the complementary information present in different views.

Figure 2: The average Euclidean distance in pixel coordinates different keypoints for pairwise HPE techniques. Non-interpolated frames considered are shown in parenthesis and four joints are considered. See Table 1 for the legend.

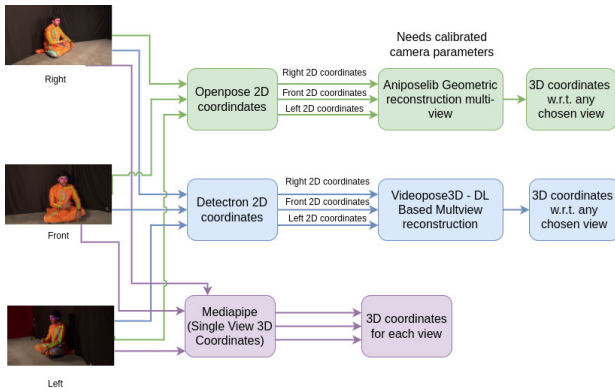

Figure 3: The three HPE methods (see Table 1) in this paper. *Left* and *Right* are views defined with respect to the singer.

6. EXPERIMENT DETAILS

6.1 Kinematic Features

The keypoint detection methods algorithms give us the x and y pixel coordinates for the keypoints and the 3D estimation gives us the z-coordinate to some scale. We linearly interpolate keypoints in frames that having confidence levels lower than the thresholds defined in Tab. 2. We use a low-pass Savitzky-Golay filter [30] to remove any jitter. We next interpolate the gesture data from the video frame rate to 10 ms sampling interval. We use z-score normalization for each keypoint by considering the mean and standard deviation for that keypoint and that coordinate across all frames of the recording. For repeatability, following [5], we estimate velocity and acceleration on each coordinate axis by a 101-point biphasic filter to get a smooth velocity and acceleration profile. We re-use the parameters of the biphasic filter defined in the supplementary link provided in [5].

6.2 Stable Note Detection

Although we replicate from [5] the stable note identification algorithm on audio, we use different features for the gesture classification. Instead of using the velocity and acceleration vector magnitudes, we consider the position, velocity and acceleration along each coordinate axis inde-

pendently. We thus have 9 kinematic features per wrist. As in [5], we only consider stable and non-stable segments which are at least of 500 ms duration. Using this for the 8 singers, we have 15312 segments with 40.65% of them as stable notes. We use the mean and standard deviation per segment of each of the kinematic features for both wrists as input to our classifier. Thus, for models trained on 3D data (aniposelib, Videopose3d, Mediapipe) we have $9 \times 2 \times 2 = 36$ features considering both wrists. For models trained on 2D data (aniposelib, Videopose3d, Mediapipe2D) we have $6 \times 2 \times 2 = 24$ features. With these features, we train a SVM classifier per singer using 10-fold cross-validation and report the mean cross-validation accuracy. (Note that Mediapipe outputs 3D coordinates but we drop the z-coordinate in the experiments for comparison of 2D results.)

6.3 Gesture-based Singer Identification

We use randomly chosen 12s splits from the video in an attempt to identify the singer. We use a time series for the position, velocity and acceleration (PVA) features along each coordinate axis at (each) 10ms time interval for both wrists and elbows. Thus we have 36 features considering wrist and elbow for models using 3D data and 24 features for models using 2D data. We keep aside data for 3 *ragas* as test data (4103 samples), and train on the rest of the data using a random 80–20 train–validation split. We use a deep neural network consisting of convolutional layers followed by a 2D inception block as shown in Fig. 3 of [3]. We find best hyperparameters separately for each HPE technique, retrain the model with best hyperparameters and then report the results on the test set.

6.4 Fusion models

In the fusion models (for both 2D and 3D classifiers) for the stable note classifier we use the predicted probability for the stable note classifier. Thus we have 3 features in the fusion classifier and we train per singer using 10-fold cross-validation a classification model by a hyperparameter choice over logistic regression, random forests and support vector machines. We report the average of the mean per-singer cross-validation F1-score.

For the fusion models (both 2D and 3D) for the gesture-based identification of 8 singers, we take the softmax output of the final layer of the classifier from all views. Thus we have 24 features in the fusion classifier and we train a classifier by 10 fold hyperparameter tuning across logistic regression, random forests and support vector machines. Our training data for the fusion model consists of the softmax predictions on the train and val data of the neural network. We report the accuracy using features generated from the excerpts corresponding to the 3 held-out ragas.

6.5 Results

The results of the stable note detection appears at the first row of Tab. 3. We report the best result across camera views (or reference view for 3D reconstruction) for the HPE method. We note that the performance for the 2D models, MP2 performs better than either OP2 or DE2. Moving to 3D coordinates, we see a significant improvement in AP3 and VP3.

The results of the (pure) gesture-based singer identification classifier is given in the second row of Tab. 3. We report the best result across camera views (or reference view in the case of 3D). The classification accuracies, compared to a chance accuracy of 12.5%, indicate (given gestures are idiosyncratically singer-specific) that the HPE methods are reliable. We observe to our surprise that the method of classical computer vision (AP3) is the best performing model.

	2D			3D		
	OP2	DE2	MP2	AP3	VP3	MP3
StableNote	77.7	78.6	83.0	78.6*	82.5*	83.5
SingerID	83.2	81.9	79.6	83.3	81.4	82.9*

Table 3: F1-score (%) for stable note detection and accuracy (%) for gesture-based singer identification. star(*) indicates significant (p<0.05) difference between 2D and 3D, and bold indicates best result for a task in corresponding methods of 2D/3D.

The first row of Tab. 4 shows the results of decision fusion models based on the corresponding models across views for the stable note task. The results show that 2D fusion gives us comparable performance to reconstruction. The results of the models using fusion of classifiers across views are present in the second row of Tab. 4 for the gesture-based singer identification task. We see that when we use fusion instead of reconstruction, the results are much better with every possible technique for both MIR tasks. Accordingly we recommend this method. All fusion results are statistically significantly better than the corresponding best single view results in Tab. 3.

6.5.1 Ablation Study of Thresholds

Tab. 5 has the OpenPose results using a constant threshold of 0.3 for all views and the Aniposelib result tasks. Tab. 6 has the results ablation study for various levels of interpolated frames.

The results show that our chosen threshold has comparable performance with default 0.3 threshold but our

7. SUMMARY AND CONCLUSION

Given the importance of reliable joint pose estimation in gesture analysis, we investigated a set of distinct available approaches to the keypoint detection of wrists and elbows for an application of expressive hand movements in two MIR tasks. We showed that the different ways of using multiple camera views, in terms of the single-view pose estimation method and the manner of combining multiple views, can influence task performance significantly. While 3D reconstruction affords a complete description of the gesture movements, the fusion of multiple 2D information is competitive. The fusion of multiple 3D representations is seen to bring in further benefits. The superiority of fusion results over single view is established via statistical significance. The two MIR tasks involve the use of distinctly different machine learning methods (classical SVM, and recent deep-learning) and involve scenes where the action is only in the upper body, providing evidence for the use modern HPE methods. We expect the outcomes of this study therefore to be useful in any application of expressive movement analysis involving upper-body limbs.

Future work would involve the fine-tuning of HPE algorithms with a set of manually labelled keypoints to see whether the optimization with respect to upper body keypoints helps improve the estimates.

ABSTRACT

Predicting a listener’s experience of music based solely on audio features has its limitations due to the individual variability in responses to the same music. This study examines the effectiveness of electroencephalogram (EEG) in predicting the subjective experiences while listening to music, including arousal, valence, familiarity, and preference. We collected EEG data alongside subjective ratings of arousal, valence, familiarity, and preference from both fans (N=20) and non-fans (N=34) of the K-pop idol group, NCT127 to investigate response variability to the same NCT127 music. Our analysis focused on determining whether the inclusion of EEG alongside audio features could enhance the predictive power of linear mixed-effect models for these subjective ratings. Specifically, we employed stimulus-response correlation (SRC), a recent approach in neuroscience correlating stimulus features with EEG responses to the ecologically valid stimuli. The results showed that familiarity and preference was significantly higher in the fan group. Furthermore, the inclusion of SRC significantly enhanced the prediction of familiarity compared to models based solely on audio features. However, the impact of SRC on predictions of arousal and valence exhibited variation depending on the correlated audio features, with certain SRCs improving predictions while others diminished them. For preference, only a few SRCs negatively affected model performance. These results suggest that correlations of EEG responses and audio features can provide information of individual listeners’ subjective responses, particularly in predicting familiarity.

1. INTRODUCTION

The neuroscience of music, employing neuroimaging methods, has revealed how the brain processes music through regions responsible for auditory, motor, and emotional functions, with recent approaches focusing on the brain’s predictive processes [1, 2, 3, 4]. The convergence

of music information retrieval (MIR) and neuroscience has gained significant traction in recent years [5, 6, 7]. For example, Rajagopalan and Kaneshiro have highlighted the potential of electroencephalogram (EEG) in the analysis of musical structure [8]. Furthermore, Ofner and Stober demonstrated the reconstruction of perceived and imagined music from EEG data [9]. These findings highlight the synergistic benefits of integrating MIR and neuroscience. In this paper, we aim to investigate how EEG can enhance the predictive model of subjective listening responses to music, given the individual variability in such experiences.

1.1 Predicting Subjective Music Listening Experience using Audio Features

Subjective music listening experience refers to the individual and unique responses that people have when they listen to music. It encompasses a wide range of aspects, including emotional reactions, preferences, familiarity, and overall enjoyment of the music. Subjective experience acknowledges that each listener’s response to music is personal and may be influenced by various factors such as their musical background and cultural upbringing [10, 11, 12, 13].

Predicting listeners’ subjective experiences of music through audio features has been a significant focus within MIR research. For example, Music Emotion Recognition (MER) aims to predict listeners’ emotional responses using various techniques [14, 15, 16, 17]. Audio features, including tempo, rhythm, melody, and harmony, have been shown to correlate with listeners’ emotional responses and preferences [18, 17]. However, the relationship between audio features and subjective experiences is complex, influenced by individual differences in musical background, culture, and personal taste [19, 20, 21]. Notably, emotional responses can significantly vary depending on individual differences [21, 22, 23, 24]. Thus, relying solely on audio features may not capture the full spectrum of music’s impact on the listener, emphasizing the need for incorporating physiological measures such as EEG in understanding subjective music experiences [18].

1.2 Stimulus-response Correlation

The use of EEG offers a breakthrough in predicting subjective music listening experiences [25]. EEG provides real-time measures of brain activity, allowing direct observa-

Lee, “Enhancing predictive models of music familiarity with EEG: Insights from fans and non-fans of K-pop group NCT127”, in *Proc. of the 25th Int. Society for Music Information Retrieval Conf.*, San Francisco, United States, 2024.

tion of neural responses to musical stimuli. Specifically, stimulus-response correlation (SRC), a recent method correlating stimulus features with EEG responses, enhances the ecological validity of studies by using real-world music stimuli and offers interpretable insights into the direct effects of stimulus features on the listener’s experience [26, 27]. For example, SRC analysis revealed that neural responses are strongly correlated with specific task-relevant visual areas [28]. Additionally, SRC enabled the prediction of speech intelligibility [29]. Despite employing a different method to calculate the correlation between audio features and EEG responses, Weineck et al. found that neural response intensity increased with music familiarity [30]. Therefore, SRC is considered to be useful tool for predicting subjective music listening experiences.

1.3 Research Question

In this study, we aim to investigate the variability of subjective music listening experiences by comparing responses of fans and non-fans to K-pop idol music. Subsequently, we explore the effectiveness of SRC in predicting this individual response variability. To achieve this goal, we formulated the following research questions:

RQ 1: How do subjective music listening experiences, such as arousal, valence, familiarity, and preference, vary individually for the same music among fans and non-fans of K-pop idol music?

RQ 2: How does the inclusion of SRC alongside audio features affect the predictive power of models for arousal, valence, familiarity, and preference in music listening?

RQ 3: Does the effectiveness of SRC in predicting subjective experiences vary depending on the type of audio feature it is correlated with?

To address these questions, we conducted an experiment collecting EEG data and subjective ratings from both fans and non-fans of NCT127 as they listened to music by the group. Utilizing linear mixed-effects models, we analyzed the contribution of audio features and SRC in predicting subjective experiences, providing a comprehensive understanding of how these components interact to shape individual music listening experiences.

2. MATERIALS AND METHODS

2.1 Participants

We recruited 20 fans of NCT127 (mean age 24.8 years, 2 males) and 34 non-fans (mean age 26.1 years, 7 males). To participate in the experiment as part of the fan group, participants were required to meet at least one of the following conditions: they must have attended at least one event featuring NCT127, such as a concert or fan meeting, or they must own at least one piece of NCT127-related merchandise, such as an album, light stick, photocard, LP, or sheet music. This was verified through a photo submission process when applying for the experiment. All participants were Korean non-musicians. All participants had normal hearing and provided written informed consent before starting the experiment.

Figure 1: Schematic view of data collection and analysis.

2.2 Stimuli

The music used in the experiment consisted of the NCT127’s top 10 songs based on the YouTube Music rankings as of December 26, 2023. The music was edited from the beginning to the end of the first chorus. The length of the edited audio varied between 60 to 92 seconds. Each audio was edited to began with a 0.5 second fade-in and ended with a 0.5 second fade-out. Then, volume normalization was applied to each channel before being exported. As a result, ten stereo audio files with a 44100Hz sampling rate and 16-bit depth were created for the stimuli.

2.3 Experiment

The EEG experiment was conducted using the Compu-medics Neuroscan system. For EEG recordings, a Synamp RT 64-channel amplifier and a 64-channel Quik-Cap with sintered Ag/AgCl electrodes were used. The data collection was carried out through the Curry 8 acquisition software. EEG electrodes were placed in accordance with the international 10-20 system, and EEG data were collected at a sampling rate of 1000Hz across 64 channels.

The experiment was conducted using STIM2 software in a soundproof room to eliminate noise interference. Participants listened to each stimulus through insert earphone while focusing on a cross in the center of the monitor. Each stimulus was played once, and after listening to each, participants rated their arousal, valence, familiarity, and preference using a 7-point scale. Participants were able to proceed to the next stimulus after completing their ratings. There was a 5-second silence window before and after each stimulus, and the stimuli were played in a randomized order. An overall view of the data collection and analysis is presented in Figure 1.

2.4 Analysis

2.4.1 EEG Preprocessing

The preprocessing of EEG data was conducted using MATLAB with the EEGLAB toolbox [31]. From the 64 channels, the reference channels M1 and M2 were excluded. The EEG data underwent a 1-55 Hz bandpass FIR filter, followed by epoching for each stimulus. Subsequent steps included baseline removal and downsampling from 1000Hz to 125Hz. The data were re-referenced using

the common average reference method, and all EEG data were merged by each participant. Independent Component Analysis (ICA) decomposition (using *runamica15* function) was performed to remove artifacts [32]. Artifactual components (eye, muscle, heart) were chosen by automated artifact IC classifier 'ICLabel' and additional artifactual components were manually chosen [33]. Finally, the EEG data were epoched by each stimulus.

2.4.2 Stimulus-response Correlation

To calculate SRC, we applied a hybrid encoding-decoding technique, performing canonical correlation analysis to maximize the correlation between temporally filtered stimuli (audio) and spatially filtered neural responses (EEG). A detailed explanation of the method, including the computation of spatial and temporal response functions for each component, can be found in Dmochowski et al.'s paper [26].

For SRC calculations, stimulus features were extracted from each audio stimulus using MATLAB *mirtoolbox* [34]. From audio features that Lange and Frieler explored [18], only audio features permitting extraction in a time-by-feature value manner, thus enabling SRC calculation, were selected for investigation. This process resulted in extracting ten audio features: sound envelope, root mean square (RMS), spectral flux, zero-crossing rate, roughness, spectral entropy, spectral centroid, spectral spread, spectral rolloff, and spectral flatness. Each feature was extracted using *mirtoolbox* functions—*mirenvelope*, *mirrms*, *mirflux*, *mirzerocross*, *mirroughness*, *mirentropy*, *mircentroid*, *mirspread*, *mirrolloff*, *mirflatness*—and adjusted to a sample rate of 125Hz. If the sample number of audio features slightly differed from the EEG data, they were adjusted to match the length of the EEG data: longer samples were cut, and shorter ones were zero-padded. Finally, all audio features were z-scored for normalization.

The SRC calculation was performed using a modified version of a publicly available MATLAB implementation by Dmochowski¹. SRCs were computed on a per-stimulus basis for each participant. The regularization parameters were set to 7 for both stimuli and EEG data. The representative SRC value for each stimulus and participant was determined by summing the three components with the highest values. As a result, a total of 54 x 10 x 10 (participants x songs x audio features) SRC values were computed.

2.4.3 Modeling Subjective Experience

Our analysis used linear mixed-effects models to examine the effects of individual audio features, both in isolation and in conjunction with their corresponding SRC, on subjective music listening experiences: arousal, valence, familiarity, and preference. Separate models were constructed for each dependent variable, with each model incorporating a single audio feature as a fixed effect (AF model). In the case of AFSRC models, compared to AF model, SRC was added as a fixed effect. This approach

allowed for a detailed examination of the influence of specific audio features and their neural correlates on listeners' subjective experiences.

The general form of the linear mixed-effects model used in this study is given by:

$$y = X\beta + Z\gamma + \epsilon \quad (1)$$

where y is the vector of observed dependent variables (e.g., arousal, valence), X is the matrix of fixed effects, β represents the coefficients for the fixed effects, Z is the matrix for random effects, γ represents the coefficients for the random effects, and ϵ is the error term.

We fitted two types of models for each dependent variable:

For the audio feature only models, the general form of the model can be represented as:

$$Y_{ij} = \beta_0 + \beta_1 X_{ij} + u_j + \epsilon_{ij} \quad (2)$$

where Y_{ij} is the dependent variable (arousal, valence, familiarity, or preference) for the i -th song listened to by the j -th participant, β_0 is the intercept, β_1 is the fixed effect coefficient of the audio feature X_{ij} , u_j is the random effect for the j -th participant, and ϵ_{ij} is the error term.

For the models with audio feature and SRC as the fixed effects, the equation expands to include the SRC:

$$Y_{ij} = \beta_0 + \beta_1 X_{ij} + \beta_2 S_{ij} + u_j + \epsilon_{ij} \quad (3)$$

where β_2 is the fixed effect coefficient of the SRC S_{ij} related to the audio feature X_{ij} .

The fitting of models was carried out using the *lme4* and *lmerTest* packages in R software. All AF and AFSRC models were cross-validated using leave-one-subject-out cross-validation. To evaluate the significance of each model, we compared it against a null model predicting the same dependent variable using *anova* function. Specifically, we compared AF models with AFSRC models, again using the *anova* function. When comparing models, it is generally accepted that a difference of 2 or more in AIC values indicates a meaningful difference in model performance [35]. In our experiment results, we also categorized a difference in AIC value of 1.9 as a marginal but meaningful difference. This approach allowed us to quantitatively determine the added value of incorporating EEG-derived SRCs into the predictive models of subjective music listening experience.

3. RESULTS

3.1 Subjective Experience of Fans and non-Fans

Independent samples t-test were conducted to examine the group differences between NCT127 fan group and non-fan group while listening to 10 NCT songs in terms of arousal, valence, familiarity, and preference (Figure 2).

For arousal, there was no significant difference between the fan group ($M = 4.54$, $SD = 1.38$) and the non-fan group ($M = 4.98$, $SD = 0.75$); $t(25.812) = -1.320$, $p = .199$.

¹ <https://github.com/dmochow/SRC>

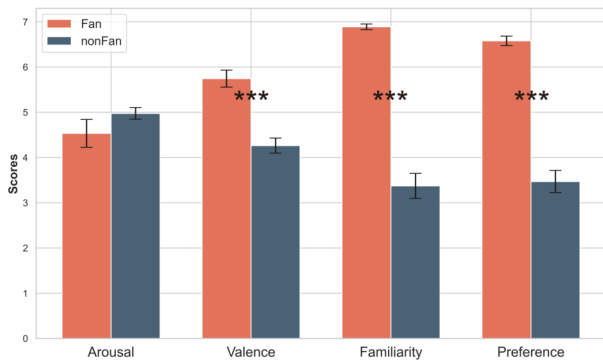

Figure 2: Average subjective ratings by fan and non-fan group. Error bar indicates standard error. *** = $p < .001$

Valence scores were significantly higher for the fan group ($M = 5.75$, $SD = 0.84$) compared to the non-fan group ($M = 4.26$, $SD = 0.97$); $t(52) = 5.665$, $p < .001$, indicating that fans experienced more positive emotions towards NCT127 songs.

A significant difference in familiarity with the songs was observed, with the fan group reporting much higher familiarity ($M = 6.89$, $SD = 0.28$) than the non-fan group ($M = 3.37$, $SD = 1.61$); $t(36.199) = 12.425$, $p < .001$.

Preference ratings were also significantly higher in the fan group ($M = 6.58$, $SD = 0.47$) compared to the non-fan group ($M = 3.47$, $SD = 1.42$); $t(43.705) = 11.734$, $p < .001$. This result suggests a strong preference for NCT127 music among fans.

Overall, the results indicate that while fans and non-fans do not differ significantly in arousal when listening to NCT127 songs, fans report significantly more positive valence, greater familiarity, and a stronger preference for the NCT127 songs compared to non-fans.

3.2 Predicting Subjective Music Listening Experience with Stimulus-response Correlation

Integrating SRC into the audio feature only models yielded variable results depending on the subjective ratings and audio features. Most importantly, for familiarity, SRC significantly enhanced predictive power of the models across various audio features (Figure 3C). Among ten audio features, SRC correlated with eight audio features showed significant improvement in predicting familiarity.

The prediction of arousal was enhanced from SRC calculated with specific audio feature—spectral flux, spectral centroid, spectral rolloff, and spectral flatness—while roughness was found to negatively impact model performance (Figure 3A). For valence, SRC correlated with spectral flux improved the model performance, whereas sound envelope, RMS, and zero-crossing rate increased the AIC values by 1.9 or more, suggesting reduction in model performance (Figure 3B). In models predicting preference, the addition of SRC related to sound envelope, roughness, spectral centroid, and spectral rolloff resulted in an increase of 1.9 or more in the AIC values, indicating a de-

cline in performance (Figure 3D).

In our analysis of the significance of AF models by comparison to null models, we observed distinct patterns across subjective music listening experiences (Table 1). Specifically, roughness and spectral flatness were key predictors for arousal, while sound envelope, RMS, spectral flux, and zero-crossing rate significantly predicted valence. Familiarity was well predicted by RMS, spectral rolloff, and spectral flatness, and preference was effectively predicted by sound envelope, RMS, spectral flux, zero-crossing rate, spectral entropy, and spectral flatness. Notably, the inclusion of SRC based on RMS, spectral flux, zero-crossing rate, spectral entropy, and spectral flatness did not significantly enhance the performance of models predicting preference (Figure 3D), yet these models demonstrated a good fit using only audio features. For detailed comparisons and summaries of all model fits and cross-validation results, refer to the supplementary materials².

4. DISCUSSION

We compared subjective music listening experiences, specifically focusing on arousal, valence, familiarity, and preference when fans and non-fans of NCT127 listened to the same NCT127 songs. The results showed that valence, familiarity, and preference were significantly higher in the fan group, while there was no significant difference in arousal. Then, we investigated the combined effects of audio features and SRC derived from EEG data on predicting subjective music listening experiences. Through comparing linear mixed-effects models based solely on audio features with those incorporating both audio features and SRC, we revealed that integrating SRC with audio features significantly enhances the predictive power for familiarity. However, the influence of SRC on predictions of arousal and valence showed variation depending on the correlated audio features. The inclusion of few SRC decreased the predictive power of preference.

The notably higher familiarity and preference ratings observed in the NCT127 fan group were anticipated outcomes, aligning with the criteria we set for participant recruitment: participants in the fan group were required to regularly listen to NCT127’s music, confirm their attendance at an NCT127 event, and own NCT127-related merchandise.

The absence of significant difference in arousal between groups suggests that arousal ratings were predominantly influenced by the acoustic characteristics of the music, such as tempo and timbre, rather than personal traits [36]. This finding aligns with previous research indicating minimal variability among individuals in arousal ratings for the same musical piece. [37, 38].

Incorporating SRC alongside audio features enhances the predictive accuracy for familiarity. SRC, derived from a hybrid encoding-decoding technique, captures distributed representations in neural response [26]. Since

SRCs in this study were computed by correlating particular audio features with EEG responses, it is possible that audio features of highly familiar music were more effectively represented in neural responses. Familiar music is known to enhance brain activity related to recurring musical patterns and structures [39]. Familiarity may foster better recall of the song, leading to enhanced representation in the brain [40]. Thus, exposure to or familiarity with stimuli may facilitate the processing of specific stimulus features.

In a previous study examining the relationship between audio features and neural responses, Weineck et al. used temporal response function and reliable component analysis to calculate neural synchronization, employing methods distinct from our study [30]. They investigated how synchronization varied with music familiarity, enjoyment, and beat easiness. Their findings indicated that the in-

tensity of neural responses increased with familiar music. While a direct comparison with our study is challenging due to the methodological differences, both studies demonstrate that music familiarity is reflected in the relationship between stimulus (audio features) and response (EEG).

The impact of SRC on the predictions of arousal and valence varied depending on the correlated audio features. In the case of preference, the inclusion of few SRC decreased the model performance, suggesting that emotions or preferences evoked by music may be relatively less dependent on how the audio features are represented in the brain compared to familiarity. Contrary to our findings regarding preference, Pandey et al. demonstrated that stronger SRCs predict increased levels of enjoyment of music [41]. This difference may be due to the selection of features for SRC calculation. Our study used various audio features separately, whereas they used the principal component of 18

audio features for SRC calculation.

The fitting of AF models demonstrated that specific audio features alone can predict subjective music listening experiences. This aligns with the effectiveness of using audio features for training deep learning models in prior MER research.

There are few limitations of this work. First, the demographic composition of our participants, particularly regarding gender distribution, may limit the generalizability of our findings. The process of recruiting fans of a specific artist resulted in a gender imbalance among our participants. Future research should aim to recruit a more balanced participants to enhance the reliability of the results. Second, our analysis only used linear mixed-effects models, making it challenging to generalize the significance of specific audio features in relation to subjective music listening experiences. Since the impact of audio features and SRC on subjective experience may have an inherent nonlinear characteristics, future studies should validate the efficacy of SRC as a learning feature or predictor using a broader range of models, including deep learning-based models capable of capturing nonlinearity. Finally, we only considered ten low-level signal components as audio features in our study. However, the correlations of higher-level audio features, such as chromagrams and various rhythmic features, and EEG might contain unique information about the subjective music listening experience. Therefore, future research should investigate the use of a broader range of audio features, including higher-level audio features.

5. CONCLUSION

This paper explores individual differences in music listening experiences among both fan and non-fan groups of the K-pop idol group NCT127. We aim to demonstrate how responses to the same NCT127 music vary in arousal, valence, familiarity, and preference across different individuals. Furthermore, we investigate the predictive capability of EEG responses, particularly through SRC, regarding subjective music listening experiences. By comparing linear mixed-effects models that solely rely on audio features with those incorporating SRC, our findings underscore the significant role of EEG data in improving the prediction accuracy of music familiarity. This result suggests that using SRC could enable the prediction of individual music listening experiences, which would be challenging using audio features alone.

ABSTRACT

We present a novel system for automatic music mixing combining diverse music information retrieval (MIR) techniques and sources for song selection and transitioning. Specifically, we explore how music source separation and stem analysis can contribute to the task of music similarity calculation by modifying incompatible stems using a rule-based approach and investigate how audio-based similarity measures can be supplemented by lyrics as contextual information to capture more aspects of music. Additionally, we propose a novel approach for tempo detection, outperforming state-of-the-art techniques in low error-tolerance windows. We evaluate our approaches using a listening experiment and compare them to a state-of-the-art model as a baseline. The results show that our approach to automatic song selection and automated music mixing significantly outperforms the baseline and that our rule-based stem removal approach significantly enhances the perceived quality of a mix. No improvement can be observed for the inclusion of contextual information, i.e., mood information derived from lyrics, into the music similarity measure.

1. INTRODUCTION

DJs have become an essential aspect of many large social events today. The quality of their performance heavily depends on the DJ's experience, knowledge of music, and understanding of what resonates with the audience [1]. Although many attempts [2–8] have been made to automate this role, a DJ is still considered indispensable for providing enjoyable and seamless listening experiences and mixing, i.e., transitioning of tracks.

In this paper, we propose *Mosaikbox*, an automatic music mixing system primarily focused on EDM, incorporating state-of-the-art MIR methods to mimic aspects considered by DJs when selecting and mixing tracks. For selection, these aspects include timbre, which has been shown to improve methods for judging music similarity if combined

with other auditory descriptors [9]. For mixing, a typical transition technique is the fade in/fade out. During its transition period, the two songs are audible for some time. Even if the tempo and key match perfectly and the timbral compatibility is high, a dissimilar drum pattern, e.g., with off-beats at different times than the original track or clashing vocals, can result in a combination that does not sound right. Removing incompatible stems during transitions would solve many traditional mixing challenges.

A rather open question is the use of contextual information for track selection by DJs. Contextual information, such as song lyrics, contains information that audio-based approaches cannot capture and vice versa. Since approaches such as [10] have shown that lyrics can be used to predict the mood of a song, combining audio-based and contextual information might further improve the quality of track selection.

The objectives of this paper are therefore: (1) to introduce a novel automatic music-mixing pipeline, (2) to investigate how a rule-based stem modification procedure can support a music similarity measure in automatic music mixing, and (3) to explore whether we can improve the used musical similarity measure by complementing it with contextual information.

2. RELATED WORK

Besides commercial, closed-source tools, such as VirtualDJ, djay, and NI Traktor, various academic approaches have been proposed for automatic music mixing. Jehan [2] introduced an automated DJ system focused on beat matching on downbeats and transitioning on rhythmically similar segments without incorporating harmonic or timbral information or automatic track selection. Building on this, Lin et al. [3] incorporated pitch information and introduced a method for automatic track selection and ordering. Ishizaki et al. [4] further proposed a method for reducing discomfort when mixing songs with heavily differing tempi in his automatic DJ system. Davies et al. developed AutoMashUpper (AMU) [5], an automatic mashup system that mixes songs using a mashability estimate over phrase-level segments. AMU incorporates a weighted combination of rhythmic and harmonic similarity and spectral balance into its mashability measure. Hiari et al. [6, 7] introduced another automated DJ system based on latent topic modeling of the chroma features and beat similarity for

song selection and cue point estimation. Vande Veire and De Bie [11] built an automatic mixing system similar to AMU with multiple transition methods and a focus on musical style similarity, but less powerful similarity measures compared to AMU to optimize for runtime performance. Huang et al. [8] proposed a pure mashup system that uses isolated stems of different songs to create a mashup. Unlike the previously described automated mixing systems, this approach focuses on mixing a combination of stems, ensuring that each stem type is used only once.

Our work differs from existing methods by proposing a more comprehensive mixability measure to capture additional audio and contextual aspects to better match DJ music selection techniques. Furthermore, we focus on working with completely mastered tracks, integrate state-of-the-art MIR techniques, and perform stem separation to support our mixability measure.

3. METHOD

Our method for automatic mixing comprises the following components to build the *Mosaikbox* system: beat grid estimation and tempo detection, structural segmentation, multi-faceted estimation of music similarity, and mixing of tracks.

3.1 Beat Grid Estimation and Tempo Detection

We build our beat and tempo detection pipeline upon a fixed beat grid approach using a 4/4 time signature, similar to popular DJ software. To build a beat grid, we need two types of information: the song’s tempo and the location of the first downbeat. We derive the beat positions, including the beat types (1st, 2nd, 3rd, and 4th beat) using the state-of-the-art beat tracking system *BeatNet* [12].

Calculating the tempo by averaging inter-beat intervals or using their median can lead to octave errors ($\frac{1}{2}$, $\frac{1}{3}$, 2, 3 multiples of the tempo), where the problematic tempi are the $\frac{1}{3}$ and 3 multiples of the true tempo for non-duple meter music. To address this, we model the beat grid estimation as a 2-dimensional constrained minimization problem, given the detected beat timings t_i , where $i = 1, 2, \dots, n$. Note that some beats might be missing due to detection errors. We want to find the optimal first downbeat position g_1 and the tempo bpm such that the beat positions of the constructed beat grid g_j are evenly spaced and have minimal deviation from the detected beat positions t_i .

To restrict the search space, we estimate the tempo bpm_{est} by using the inter-beat median Δt_{Mdn} . We then perform a global search twice using the dual annealing algorithm, a variant of the simulated annealing algorithm, paired with a local search algorithm for accepted solutions [13]. The objective is to minimize the mean of the absolute differences between each estimated beat grid position g_i and detected beat positions t_j . The initial global search spans a wide range, from 60 bpm to +15% of bpm_{est} and the first downbeat from 0 to +40% of Δt_{Mdn} . To avoid local minima, we conduct a subsequent narrower search within $\pm 5\%$ of bpm_{est} and 0 to +5% of Δt_{Mdn} . Finally, we

fine-tune the beat grid by performing local minimization over only the offset of the first downbeat position from 0 to +40% of Δt_{Mdn} .

3.1.1 Benchmark

We evaluated the performance of our beat grid and tempo estimation algorithm on the GiantSteps dataset [14, 15], as it has not been used for training BeatNet [12] nor current state-of-the-art tempo estimation approaches such as the one by Böck and Davis [16].

Slight deviations in the estimated tempo lead to significant errors in the beat grid estimation. Thus, we deem the metrics *Accuracy 1* and *Accuracy 2* as defined by Gouyon et al. [17] using a 4% tolerance window as too loose, and additionally evaluate the performance of our tempo estimation algorithm for smaller tolerance windows of 1% and 0%. Table 1 compares our tempo estimation algorithm and its inter-beat interval (IBI) pre-estimation with the state-of-the-art tempo estimation algorithm by Böck and Davis [16] on the GiantSteps dataset. While our approach does not outperform the state-of-the-art algorithm for the 4% tolerance window, it demonstrates better performance for the 1% and 0% tolerance windows. The results also show that while IBI is important, it is not the primary contributor to our method’s performance.

	Böck & Davis [16]	IBI	Ours
Accuracy 1 (4%)	87.29	74.13	82.30
Accuracy 1 (1%)	67.02	58.40	69.59
Accuracy 1 (0%)	0.15	3.03	19.97
Accuracy 2 (4%)	96.97	78.08	90.77
Accuracy 2 (1%)	74.38	61.35	76.70
Accuracy 2 (0%)	0.45	3.11	24.51

Table 1. Comparison of our tempo estimation algorithm and its inter-beat interval estimation with a state-of-the-art approach on unseen data from the GiantSteps dataset.

3.2 Structural Segmentation

Music transitions sound most pleasing when performed at musically fitting positions of a song. We therefore combined the boundary detection algorithm by Serrà et al. [18] with the labeling approach by Nieto and Bello [19].

In electronic music, segments typically align with downbeats. Therefore, we quantize the detected segment boundaries to the nearest beat position and shift them by one beat to the nearest downbeat. Boundaries starting or ending on the third beat are not shifted, due to potential causes, such as errors in the downbeat detection, time signature estimation, or different song structures.

Although mixing intros with outros is a straightforward way of transitioning whole songs, we abstain from this practice as we aim for a more energetic mix. Thus, we penalize intro and outro segments by the factor 0.5, which is then multiplied by the similarity measure. The progression of the energy level is a task addressed in the similarity measure. We assume that low-energy and high-energy

segments will not be mixed and thus do not differentiate between other segment types.

3.3 Music Similarity

3.3.1 Rhythmic Similarity

We believe that drums are the primary rhythmic component in EDM music. Instead of relying on onset detection functions, which have poor performance in polyphonic audio, we employ the drum transcription system by Southall et al. [20, 21] to extract drum patterns from the audio. To be able to detect different kinds of rhythm patterns besides the classical "straight" pattern, such as "swing", "shuffle" or "offbeats" which are a primary component in EDM sub-genres such as drum and bass, we follow the AMU approach of Davies et al. [5] and sub-divide the beat grid into 12 equally spaced intervals. We then detect the *kick*, *snare*, and *hi-hat* drum positions, quantize them over the sub-beat grid, and stack them on top of each other to obtain a 3-dimensional binary vector R_n for all songs n of length $K * 12$, where K is the number of beat positions of a song. The rhythmic similarity is then calculated between phrase sections p of the seed song s and a candidate song c for all k beat shifts of c . While AMU uses cosine similarity as a rhythmic similarity measure, we decided to employ a stricter similarity measure to capture dissimilarities in the drum patterns. Thus, we defined the similarity measure as the average of the sub-beat positions where the drum patterns of the seed song section and the candidate song section match.

For each drum vector $R_{s,p,d}$ within phrase section p of the seed song s , where $d \in 1, 2, 3$ denotes the drum vector dimensions corresponding to the *kick*, *snare*, and *hi-hat*, we compute the average number of matching sub-beat positions l over all beat shifts k against all candidate songs c . The overall rhythmic similarity $M_{R,s}(k)$ is then derived by averaging the similarities obtained across the three drum dimensions d as

$$M_{R,c}(k) = \frac{1}{3} \sum_{d=1}^3 \left(\frac{1}{m} \sum_{l=1}^m [R_{s,p,d,l} = R_{c,k,d,l}] \right), \quad (1)$$

where m is the length of the drum vector $R_{s,p}$ of the phrase section in the seed song, and $[R_{s,p,d,l} = R_{c,k,d,l}]$ denotes the Iverson bracket.

3.3.2 Timbral Similarity

To model the timbral component, we will follow the approach of Rocha et al. [22] and Panteli et al. [23], using MFCCs and the auditory descriptors spectral flatness and dirtiness. By stacking the MFCCs, spectral flatness, and dirtiness descriptors on top of each other, we obtain a 28-dimensional vector $T_{n,p}$ for a song n and phrase section p . Due to high computational demands, we calculate the timbral component once per phrase section instead of every beat shift k of the candidate song c , assuming the timbral component remains relatively constant across phrase sections. The timbral similarity is then calculated by computing the cosine similarity between the timbral component

$T_{s,p}$ of phrase section p of seed song s and the timbral component $T_{c,q}$ of all phrase sections q of candidate song c as

$$M_{T,c}(q) = \frac{T_{s,p} \cdot T_{c,q}}{\|T_{s,p}\| \|T_{c,q}\|}. \quad (2)$$

3.3.3 Key Similarity

Harmonic compatibility is essential when mixing songs, as it avoids dissonance and supports continuity between songs by enabling smooth transitions. We decided to use the key detection algorithm *KeyFinder* [24] due to its open-source availability and still good performance compared to recent state-of-the-art key detection algorithms. Additionally, we incorporate pitch shifting in the song selection process to be more flexible and less constrained by the harmonic aspect of the songs. As pitch-shifting algorithms can hurt the audio quality [25], we nonetheless want to keep pitch-shifts as small as possible. To this end, we identify key distances.

We define a harmonic key distance measure $D_{K_1}(K_2)$ as the minimum semitone distance between the tonic notes of two keys K_1 and K_2 . The key similarity measure $M_{K,c}$ is then defined as

$$M_{K,c} = \begin{cases} 1, & \text{if } D_{K_s}(K_c) = 0 \\ D_{K_s}(K_c)^{-1}, & \text{otherwise} \end{cases}, \quad (3)$$

where $D_{K_s}(K_c)$ is the key distance between the key K_s of the seed song s and the key K_c of the candidate song c .

3.3.4 Harmonic Similarity and Spectral Balance

Harmonic content and the energy across the low-, mid-, and high-frequency bands change throughout a song and thus must be reflected in the similarity measure. We compute the harmonic similarity and spectral balance measure, $M_{H,c}(k)$ and $M_{L,c}(k)$, respectively, based on the approach by Davies et al. [5].

3.3.5 Contextual Similarity

Mixing songs at positions with similar lyrics is a transition technique that could make the transition more related and seamless, independently of audio-based similarity. This method is commonly executed by playing a repeated phrase of the first song and then mixing in the second song with a similar vocal phrase.

Although lyrics are content information, they are often analyzed using contextual methods and are thus treated accordingly [26]. Due to the significant variation in lyrics across song sections, we find classical textual similarity measures such as *TF-IDF* unsuitable for our task. Instead, we capture the lyrics' similarity by extracting the whole lyrics' semantic meaning. We use Reimers and Gurevych [27] approach to compute sentence embeddings C_n over the lyrics of all songs n . The similarity measure $M_{C,c}$ is then calculated by computing the cosine-similarity between the sentence embedding C_s of the seed song s and the sentence embedding C_c of the candidate song c as

$$M_{C,c} = \frac{C_s \cdot C_c}{\|C_s\| \|C_c\|}. \quad (4)$$

3.3.6 Mixability

We compute the beat-wise mixability for a candidate song c against the phrase section p of the seed song s by combining the weighted similarity measures of rhythm, timbre, key, harmony, and spectral balance, as follows:

$$M_c(k) = \omega_R M_{R,c}(k) + \omega_T M_{T,c}(q) + \omega_K M_{K,c} + \omega_H M_{H,c}(k) + \omega_L M_{L,c}(k), \quad (5)$$

where q is the phrase section of c corresponding to the beat shift k . The mixability measure considers the 64 beats after the phrase section p of the seed song s instead of the entire phrase section p . This forward-moving approach enables us to maintain a song's dynamics by focusing on the upcoming segments instead of past segments. Through extensive, informal testing, we found the following weights to give the most convincing results: $\omega_R = 0.3$, $\omega_T = 0.75$, $\omega_K = 0.2$, $\omega_H = 0.2$, and $\omega_L = 0.1$.

To incorporate the contextual similarity measure, we extend the audio-based mixability measure $M_c(k)$ by the contextual similarity measure $M_{C,c}$ with the weight $\omega_C = 0.25$, as follows:

$$M'_c(k) = M_c(k) + \omega_C M_{C,c}. \quad (6)$$

Our initial experiments showed that choosing the transition point by selecting the beat shift k with the highest mixability score did not yield satisfactory results. Songs were transitioned at non-downbeat positions or unnatural downbeat intervals (e.g., 7, 9, 15, 17 downbeats), leading to a misaligned mix. To counteract this, we consider only beat shifts k that correspond to the segment boundary q of the candidate songs c and calculate the transition (cue) point as follows:

$$k_{\text{cue}}(c) = \arg \max_{k \in q} M_c(k). \quad (7)$$

We also record the timbral and rhythmic similarity at the transition point, $t_{\text{cue}}(c)$, $r_{\text{cue}}(c)$, and will use this information to improve the equalization in the mixing process.

We compute the song schedule by selecting the candidate song c with the highest mixability and extract the phrase section p for c up to the next segment boundary q , but at least for a minimum of λ_{minPlay} . We found that a λ_{minPlay} value of 55 seconds leads to a good balance between how long a song is played and how often songs are changed. We then select the phrase section p of c as the seed phrase section and repeat the process until the desired length of the mix is reached.

3.4 Mixing

Before transitioning, we first bring the loudness of each song to a consistent level of -14 LUFS. We then pitch-shift the audio to a harmonically compatible key and beat-match the song by time-stretching the audio to the same tempo as the previous song, using a maximal tempo change of $\pm 8\%$ as a limit. We use a transition length of 16 downbeats, where the transition starts with eight downbeats before the song excerpt's end and ends with eight downbeats after the transition point of the current song.

To prevent clashing frequency bands in the mix, we mainly base our equalization process on the "bass-swap" technique [28, Chapter 16] and extend it to the high-frequency band as well. A visualization of our standard equalization process is depicted in Figure 1.

Figure 1. Standard equalization applied to both excerpts.

Overequalization can lead to a dull mix, which is why we will use information from our mixability calculation to identify and adjust problematic frequency ranges. We consider mid frequencies of songs with a dissimilar timbre ($t_{\text{cue}}(c) < 0.95$) as clashing and reduce the mid frequencies of the song that is currently playing, shifting the focus on the mid frequencies to the new song. In case of a high rhythmic similarity ($r_{\text{cue}}(c) \geq 0.95$), we apply less attenuation to the bass frequencies. Finally, we also assume that songs with an attenuated drum stem need even less equalization in the high frequencies, as drums, especially hi-hats, are a primary contributor to the high frequencies. We therefore introduce the high frequencies of the song that are to be mixed in earlier and with less attenuation.

3.4.1 Rule-based Stem Modification

We employ the pre-trained music source separation (MSS) model *HT Demucs* [29, 30] to separate the audio into the four stems: vocals, drums, bass, and other.

As previously noted, our tempo estimation algorithm predicts the tempo for only around 25% of songs with perfect accuracy. Even though the rhythmic similarity measure implicitly captures errors in tempo detection, rhythmic compatibility is only one of the components of the mixability measure, thus opening up the possibility of mixing in a rhythmic incompatible song. To counteract this, without entirely excluding rhythmic incompatible songs, we introduce a drum stem modification procedure for songs with rhythmic compatibility below $r_{\text{cue}}(c) < 0.95$.

Further, we generally want to prevent mixing song excerpts containing vocals, as vocal clashing can similarly lead to a reduced mix quality. We detect vocal segments by splitting the vocal stem, obtained by our MSS stage, into boundaries on "silent" sections that persist for one second or longer with a loudness below -40 dBFS and filter our vocal segments with a length below 400ms. We consider two song excerpts as clashing if the vocals during the transition intersect for more than two seconds and attenuate the vocals of the currently playing song. Figure 2 depicts the drum stem and vocal modification procedure.

Figure 2. Equalization over the vocal and drum stems.

4. LISTENING EXPERIMENT

Due to the subjective nature of mixes [8] and the lack of ground truth corpora for similarity ratings between songs [22], we will evaluate the performance of our proposed solutions with qualitative methods, specifically using a listening experiment. For this, we developed a web-based survey that facilitates the evaluation of the models by human participants.

4.1 Models

We select AMU by Davies et al. [5] as our baseline model because it aligns with our methodology in prioritizing optimal mixing over runtime compromises and continues to be recognized as a relevant benchmark in recent research, such as [8]. To ensure a fair comparison of our models and counteract the negative influence of mismatched beats, we replace outdated components of AMU with state-of-the-art approaches. In particular, we replace their beat tracking and percussion detection method with our approaches and utilize our mixing procedure to create the mix.

To compare the performance of our models, we evaluate three models: MB_{base} , our approach without the stem modification and contextual information; MB_{stem} , our approach with the stem modification but without contextual information; and MB_{full} , our approach with the stem modification and contextual information (using M'_c). The code of our implementations is available open-source¹.

Note that, in order to maintain full control over the approaches and integration into a common interface, no commercial tools are included in the evaluation.

4.2 Setup

To understand the impact of musical knowledge on evaluation, we first ask the participants about their musical background and DJing experience. We split the following survey for each model into two parts. In the first part, we gather Song-Pair Compatibility (SPC) ratings by asking the participants to rate the song-scheduling aspect of the models. This allows us to compare the song selection of the models to the collected SPC ratings later on. For all pairs of songs, the participants assess the compatibility based on four categories by answering the following questions: *Timbre*: Are the songs similar regarding timbre?

¹ <https://github.com/robaerd/mosaikbox>

Rhythm: Do the songs have a similar rhythmic pattern?
Harmony: Do the songs have a similar harmonic structure?
Overall Mixable: Are the songs overall mixable?

In the second part, the participants are presented with the generated mix of a model and are asked to rate the overall quality of each transition of the mix on a scale of 1 (awful) to 5 (excellent), where 3 represents a neutral rating. The models are presented in random order to prevent presentation bias, with no details about the model type disclosed to the participants.

4.3 Dataset

Due to the tempo "lock-in", only songs with a tempo tolerance of maximum $\pm 8\%$ are considered. This commonly results in a genre "lock-in" as well, as songs of the same genre usually have a similar tempo. A preliminary poll among potential participants revealed that most are familiar with the drum and bass genre (DnB). We therefore decided to base our dataset on this genre to make the evaluation more relevant and valid.

We collected a dataset of 250 songs from the most popular DnB playlists of streaming services and randomly sampled 16 songs from this collection to use as input for the mix generation of the models. Out of these 16 songs, we sampled one song as the starting song for all models. To highlight the song selection aspect of the models, we used a top-k approach with $k=8$ for song selection instead of forcefully mixing all 16 songs.

5. RESULTS AND DISCUSSION

We recruited 30 participants (22 male/8 female), primarily academics aged 23-30 with backgrounds in STEM and economics, 8 of whom had prior experience in DJing. Among the participants, 10 classified their musical background as novice, 13 as intermediate, 7 as advanced, and none stated being a professional musician.

Model	Transition	SPC _{Timb}	SPC _{Rhy}	SPC _{Har}	SPC _{Mix}
AMU	2.490	0.457	0.505	0.429	0.624
MB_{base}	3.076	0.486	0.648	0.505	0.648
MB_{stem}	3.457	0.486	0.648	0.505	0.648
MB_{full}	3.033	0.500	0.619	0.529	0.705

Table 2. Average transition and SPC ratings for all models from all transitions. MB_{base} and MB_{stem} share identical SPC ratings due to the same song selection.

Table 2 shows that all our models significantly outperformed the AMU baseline in average transition and SPC ratings. The MB_{full} model received the highest SPC ratings for timbre, harmony, and mixability, while the $MB_{base, stem}$ models scored higher in rhythm and the MB_{stem} model achieved the best average transition rating.

In Figure 3, we can observe that AMU mostly received negative ratings, while those of MB_{full} had a more consistent distribution, declining towards the end of the mix. Except for the first two transitions, MB_{stem} consistently

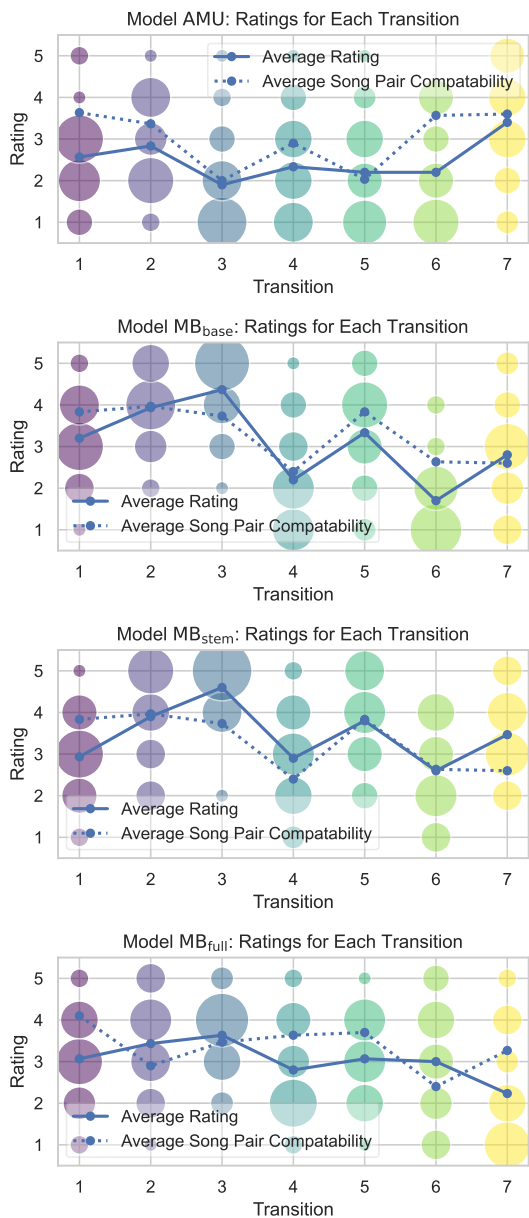

Figure 3. Transition ratings across all models, with bubble size indicating the number of ratings per transition and lines representing each transition’s average rating and SPC.

outperformed MB_{base}, suggesting that stem separation positively impacts mix quality.

After confirming non-normality with the Shapiro-Wilk test, we test for significant differences using the Friedman test, resulting in a p-value < 0.00001. To determine the best-performing model, we then conduct Wilcoxon signed-rank tests for pairwise comparisons. To account for the family-wise error rate, we correct the p-values using the Holm-Bonferroni method and reject the null hypothesis if the corrected p-value \hat{p} is less than the significance level $\alpha = 0.05$. The results in Table 3 show that all our models significantly outperform AMU, while MB_{stem} significantly outperforms its base counterpart MB_{base}. No significant difference is found between the MB_{full} and MB_{stem} models,

which suggests that contextual information does not have a significant impact on the mix quality.

Model 1 (F)	Model 2 (G)	\hat{p} -value _{F(u)<G(u)}
MB _{base}	AMU	< 0.0001
MB _{stem}	AMU	< 0.0001
MB _{full}	AMU	< 0.0001
MB _{stem}	MB _{base}	< 0.0001
MB _{full}	MB _{base}	×
MB _{full}	MB _{stem}	×

Table 3. Pairwise tests for significance between models showing corrected p-value levels of the Wilcoxon signed-rank test (‘×’ means no significance at 0.05 level).

Further significance tests using Mann-Whitney U tests revealed a significant difference in ratings between DJ experience and all musical knowledge levels only for the baseline model AMU, with p-values of 0.001 and 0.0001, respectively. Participants with DJing experience rated the AMU model significantly worse. Analogous, based on the mean ranks of the transition ratings, the higher the musical knowledge level, the worse the rating.

Finally, we tested for significance of the Pearson correlation between transition ratings and the averaged SPC values, indicating a significant strong correlation for MB_{base} with ($r = 0.83, p = 0.02$), suggesting mixes align closely with participant expectations. In contrast, there was a moderate non-significant correlation ($r = 0.6, p = 0.1$) for AMU and MB_{stem} and no significant correlation for MB_{full} ($r = -0.03, p = 0.95$).

The performance gains of our models over AMU in SPC ratings may stem from our rhythmic similarity calculation and the integration of timbral and key similarities into the mixability estimate. Improved transition ratings could be linked to our updated structural segmentation approach. Higher timbre, harmony, and mixability SPC ratings, alongside lower rhythm ratings, might be influenced by mood-related contextual similarities. Lower transition ratings could stem from the lesser relevance of lyrics’ semantic meaning in DnB. The listening experiment results are available online.²

6. CONCLUSION

In this paper, we proposed the automatic mixing system *Mosaikbox* and demonstrated that it outperforms comparable state-of-the-art systems. We showed that our rule-based stem modification significantly improves the overall mix quality. However, we could not show that including contextual information has any significant positive impact on the mix quality.

Future work will include the impact of new features, such as the energy level of songs and the use of similarity measures obtained by collaborative filtering approaches. In addition, a dynamic transition length will be explored to enhance creativity and adaptability across various genres.

8. ETHICS STATEMENT

One of the main factors in the similarity measure of *Mosaikbox* is timbre, which could lead to a bias towards songs of the same artist or label, neglecting songs of other artists, due to production effects captured by MFCCs (a phenomenon often referred to as album or artist effect [31, 32]). This constitutes a technical algorithmic bias, cf. [33,34]. In the interest of transparency and ethical rigor, we also acknowledge a potential bias in the participant demographics. The participants were mainly academics aged 23-30, with a majority having backgrounds in STEM and economics and a significant portion having familiarity with the drum and bass genre.

Additionally, the rule-based approach of our system offers the advantage of not requiring training on a large dataset of copyrighted music, including DJ interpretations. However, this does not remove the issues related to automating a craft traditionally performed by humans. This raises several concerns, including potential impacts on artistic expression and reception, the role of human creativity, and the future of DJing as a skilled profession.

Furthermore, as with every form of automation, a general adoption of automatic music mixing systems could significantly reduce the demand for DJs, especially in smaller venues. However, automatic music mixing systems, such as ours, can also be used as a tool by DJs to explore new ideas, get suggestions for transitions they might not have thought of, break out of their comfort zone, and increase diversity and creativity in mixes, if designed accordingly.

ABSTRACT

Generative models guided by text prompts are increasingly becoming more popular. However, no text-to-MIDI models currently exist due to the lack of a captioned MIDI dataset. This work aims to enable research that combines LLMs with symbolic music by presenting **MidiCaps**, the first openly available large-scale MIDI dataset with text captions. MIDI (Musical Instrument Digital Interface) files are widely used for encoding musical information and can capture the nuances of musical composition. They are widely used by music producers, composers, musicologists, and performers alike. Inspired by recent advancements in captioning techniques, we present a curated dataset of over 168k MIDI files with textual descriptions. Each MIDI caption describes the musical content, including tempo, chord progression, time signature, instruments, genre, and mood, thus facilitating multi-modal exploration and analysis. The dataset encompasses various genres, styles, and complexities, offering a rich data source for training and evaluating models for tasks such as music information retrieval, music understanding, and cross-modal translation. We provide detailed statistics about the dataset and have assessed the quality of the captions in an extensive listening study. We anticipate that this resource will stimulate further research at the intersection of music and natural language processing, fostering advancements in both fields.

1. INTRODUCTION

The recent development of large-language models (LLMs) has revolutionised how we interact with text, images, and even audio. By incorporating elements of multimodal learning, researchers have combined LLMs with other modalities. The resulting models can analyze and generate accurate descriptions and captions, which in turn facilitates downstream tasks such as question answering [1], image generation [2], and music generation [3]. However, we have yet to see such an evolution for MIDI files.

*These authors contributed equally to this work.

Figure 1: Overview of our approach. We extract meaningful and relevant features from MIDI files. These features are then added as tags to the human instructions that are sent to an LLM (Claude-3) to generate meaningful text captions of MIDI files.

In the field of Music Information Retrieval (MIR), MIDI plays a crucial role as a symbolic and musically meaningful representation of music. The format is often used by music producers and composers working in Digital Audio Workstations (DAWs). It is also a useful format for the computational analysis of music and related tasks such as music transcription, genre classification, similarity measurement, and music recommendation [4]. Furthermore, due to the symbolic nature of music, it has long been used by music generation algorithms [5]. In recent years, we have seen a surge of interest in music generation from free-flow text instructions [3, 6–9]. These studies leverage the expressive capabilities of LLMs to translate textual representation of musical attributes into actual music audio. This necessitates a meticulous alignment between the textual and musical feature spaces to ensure that the generated music closely follows text instructions. To validate and establish benchmarks for this text-to-music mapping, large-scale datasets with text captions have been developed [3, 10].

No such efforts, however, have yet been made for the MIDI format, despite its widespread use by musicians and its obvious, historically supported usage in music generation. This lack of text-MIDI datasets, in turn, has inhibited

researchers from exploring interesting and novel tasks such as MIDI generation from free-flow text prompts. In this work, we identify this shortcoming and develop a robust solution in the form of a large-scale curated MIDI dataset accompanied by text captions. Our goal is to obtain captions that are i) large in volume, ii) contain accurate information about the musical contents, and iii) feature a rich and refined vocabulary. We posit that such a dataset-level approach opens up further opportunities for researchers in MIDI-LLMs-related tasks.

To address the first goal, we identify an open source large-scale MIDI dataset in the form of Lakh MIDI dataset [11], that contains over 170K MIDI examples. Second, to attain the musical contents in each MIDI file, we extract meaningful features encompassing tempo, chord progression, time signature, instruments present, genre and mood. Each of the features are extracted using state-of-the-art MIR tools that ensure the quality and accuracy of the features extracted. After feature extraction, we are still left with the task of caption generation. Relying on traditional human annotation is tedious, time-consuming, and costly. Instead, motivated by the recent success of LLMs, we utilize in-context learning – a model’s ability to temporarily learn from human-provided instructions [12]. Our decision is motivated by Melechovsky et al. [3], who have demonstrated the efficacy of in-context learning in generating captions that are accurate, rich in description as well as grammatically coherent. In our approach, we furnish the LLM with instructions to generate captions based on the extracted music features, supplemented by a small set of feature-caption pairs created by expert annotators. Given the current absence of freely available MIDI-caption datasets, we anticipate that the provision of a substantial volume of detailed and informative captions will inspire the research community to delve further into tasks related to MIDI and Large Language Models (LLMs). The main contributions of this work can be summarized as follows:

- We introduce the first curated large-scale open dataset of MIDI-caption pairs, termed **MidiCaps**¹.
- Furthermore, we present a comprehensive set of music-specific features extracted from MIDI files. These features succinctly characterize the musical content, encompassing tempo, chord progression, time signature, instrument presence, genre, and mood.
- Finally, we provide a text caption annotation framework tailored specifically for MIDI data (see Figure 1). Leveraging the in-context learning capability of large language models (LLMs), we enable the generation of captions using only a small number of feature-caption training pairs. This framework, a first of its kind, is made freely accessible to users², facilitating the generation of MIDI-caption pairs for their individual MIDI files.

2. RELATED WORK

To the best of our knowledge, there are no publicly available MIDI caption datasets. In this section, we briefly mention various publicly available MIDI datasets and discuss the closely related topic of caption generation from audio and music.

Despite the scarcity of MIDI caption datasets, existing repositories offer potential resources that could be adapted for this purpose. Among these, the Lakh MIDI Dataset [11] stands out, comprising a vast collection of MIDI files. While primarily tailored for MIR tasks such as melody extraction and chord estimation, its volume and diversity present an opportunity for repurposing towards captioning tasks, albeit requiring appropriate preprocessing. The MAESTRO Dataset [13] offers aligned pairs of MIDI and audio files, primarily for piano music generation. The MuseGAN Dataset [14] focuses on multi-track songs, and the MAPS Dataset [15], contains recordings of classical piano pieces alongside aligned MIDI files and thus also present potential avenues for MIDI captioning research. Additionally, the Wikifonia Dataset [16] features a substantial collection of lead sheets accompanied by MIDI files. Closest to our proposed MIDI-caption dataset is the WikiMusicText (WikiMT) dataset [17], which includes lead sheets in ABC notation with metadata including text descriptions. These descriptions, however, pertain to general information about the music piece rather than detailed descriptions of musical contents provided in MIDI files within our captions.

In the last three years, several models were released for automatic caption generation from music `audio` files. One of the earlier models, MusCaps [18], uses an architecture based on recurrent and convolutional layers as well as a multimodal encoder. Recent research includes the use of large language models (LLMs) for captioning [3, 7, 10]. In [7], a pseudo labeling approach is used to label a large training dataset. First, existing captions from other datasets are curated, then the MuLaN [19] model, a joint music-text embedding model, evaluates the distance between captions and unlabeled audio files. The top caption candidates are selected based on their frequency to ensure balance among all samples. In [20], the focus is on capturing the full sentiment of classical music recordings through text descriptions, introducing a Group-Topology Preservation Loss to be used with their cross-modality translation model. A recent study by Doh et al. [10] targets pseudo labeling of audio data with the help of an LLM, utilizing the MusicCaps [6] dataset as ground truth and instructing GPT-3.5 Turbo [21] to generate full captions from these tags.

In [3], Melechovsky et al. curate a new dataset based on the MusicCaps dataset [6], called MusicBench. In MusicBench, the original captions are enhanced by including additional music descriptors such as chord sequence, musical key, time signature, and tempo. After performing audio and text augmentations to expand the dataset size, they use ChatGPT [22] for rephrasing captions to create more diverse captions. Furthermore, they employ in-context learning to guide ChatGPT using a small set

¹huggingface.co/datasets/amaai-lab/MidiCaps

²github.com/AMAAI-Lab/MidiCaps

of human-annotated examples, instructing it to generate diverse captions to create an evaluation dataset from extracted tags, named FMACaps. Inspired by their methodology, we adopt a similar approach and utilize in-context learning alongside a large-language model to generate captions from MIDI features. In the subsequent section, we offer an in-depth description of our proposed framework for MIDI captioning.

3. METHOD

In this section, we discuss details regarding the music-specific features we extract from MIDI files.

3.1 Feature extraction

In a first step, as per Figure 2, we extract various musical features from the MIDI files. This is achieved in two ways: a number of features are extracted directly from the MIDI files, and others are extracted from the synthesized MIDI files. The details of our approach are described below.

3.1.1 Preprocessing

We preprocess all files to remove faulty files. For instance, we found multiple files that had never-ending notes. Using Mido [23], we further exclude files of duration shorter than 3 seconds and longer than 15 minutes.

3.1.2 MIDI feature extraction

We use Music21 [24] and Mido [23] libraries to extract the following features from MIDI: Musical Key (Music21), Time Signature (Music21), Tempo (Mido), Duration of the MIDI file (Mido), and a list of Instruments (Mido).

The **Key** and **Time Signature** features are obtained through `music21.midi.analyze('keys')` and `music21.midi.getTimeSignatures()` functions, respectively. To calculate the **Tempo**, we first look for the `set_tempo` MIDI message to get the MIDI tempo. Then, the `mido.tempo2bpm()` function is used to convert this MIDI tempo to beats per minute (bpm). For MIDI file **Duration**, we retrieve the `length` attribute of a `mido.MidiFile` object.

To extract a list of **instruments**, we filter the MIDI messages based on channel number and their associated instrument program obtained from the program change message. To treat ambiguity given by some faulty files, we always take the last assigned program number as the definite instrument number for each MIDI channel. For channel 10, which is reserved for drums, we always consider the assigned instrument to be drums, unless there is another percussion instrument specified.

We further process the extracted instruments in three steps to identify the most prominent instruments. First, we extract total note duration for each of the instruments by scraping through note-on and note-off messages, and rank them by this duration. Second, we map the program numbers to their respective instrument names, grouping similar variations (e.g., both nylon and steel string acoustic guitars

as ‘acoustic guitar’). Third, we reduce the list of instruments to only include one instance of the same instrument name (in the previous example, the two acoustic guitars would merge into one), and then take top five instruments sorted by their total note duration.

3.1.3 Synthesized audio feature extraction

We use the Midi2Audio library [25] that utilizes FluidSynth [26, 27] to synthesize audio from MIDI with the Fluid Release 3 General-MIDI sound font. Then, we use these audio files to extract genre, mood, and chord features.

To extract **genre** and **mood**, we use Essentia [28], specifically the MTG-Jamendo genre and mood/theme discogs effnet models³. We keep the top two genre tags with the highest confidence score, and the top five mood/theme tags, also based on their confidence score. The confidence scores for each tag are also stored.

Next, we extract the single most occurring **chord sequence** of length 3 to 5. To obtain this, we first extract all chords from the audio using Chordino [29]. To obtain the most frequent short chord sequence, we first iterate through the chord list to find the most frequent patterns consisting of 3, 4, and 5 consequent chords. We do not allow these patterns to have the same first and last chord, e.g., [A, B, C, A] for a pattern of length 4 is not allowed, as this is likely an [A, B, C] pattern of length 3. Then, we decide on which pattern to keep through a set of rules described in Algorithm 1. In the below algorithm n_i represents the occurrence count of the most frequent pattern (p_i) of length i . We save the final selected pattern along with a number denoting how many times it occurred. Once we have extracted all of the features extracted, we move on to caption generation, described in the next subsection.

Algorithm 1 Selecting the most frequent chord pattern.

```

▷  $p_i$ : most frequent pattern of length  $i$ 
▷  $n_i$ : occurrence count of  $p_i$ 
▷  $p$ : final selected most frequent pattern
 $n = n_3 + n_4 + n_5$ 
if ( $n_5 \geq 0.8 \cdot n_4$ ) & ( $n_5 \geq 0.25 \cdot n$ ) then
     $p \leftarrow p_5$ 
else if ( $n_4 \geq 0.8 \cdot n_3$ ) & ( $n_4 \geq 0.3 \cdot n$ ) then
     $p \leftarrow p_4$ 
else if ( $n_3 == 0$ ) then
    if ( $n_4 == 0$ ) then
        if ( $n_5 == 0$ ) then
             $p \leftarrow \text{None}$ 
        else
             $p \leftarrow p_5$ 
        end if
    else
         $p \leftarrow p_4$ 
    end if
else
     $p \leftarrow p_3$ 
end if
    
```

³essentia.upf.edu/models.html#discogs-effnet

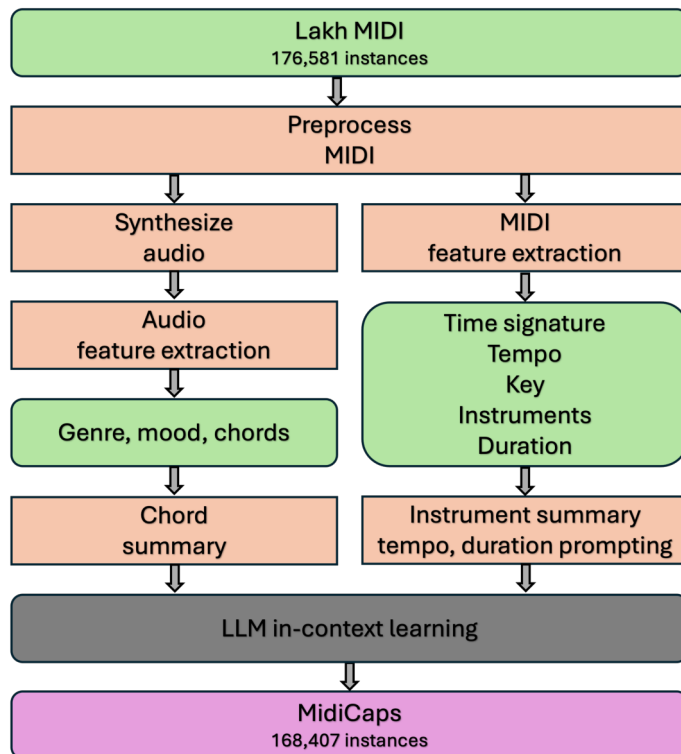

Figure 2: Detailed overview of our proposed captioning framework.

3.2 Caption generation

In this step, we take the extracted features and execute caption generation. To harness the expressive power and few-shot capability of a Large Language Model (LLM), we refer to a recent benchmarking study on LLMs [30], and ultimately selected Claude 3 Opus [31] due to its superior performance compared to other LLMs such as GPT4. Employing in-context learning (a task in which the LLM is given example data of paired input-output to serve as ‘context’, and is expected to continue producing outputs for new unpaired inputs in a similar manner), we begin by selecting 17⁴ diverse examples from the extracted features and request a human annotator to craft appropriate text captions for each of these based solely on the extracted features. This approach aims to prevent any auditory influence on human captioning, as Claude 3 (or any LLM, for that matter) will subsequently only process text inputs, not audio files. Once the 17 examples are prepared, we construct a text prompt instructing Claude 3 to analyze the human-prepared feature-caption pairs and generate suitable captions for new sets of features. To maintain clarity, we specify that the generated captions should be between three to seven sentences. Before generating captions for all 168K MIDI files, we conduct a sanity check on ten examples to evaluate Claude 3’s response to in-context learning, ensuring our prompt does not produce unrelated output or “hallucinate.” Please note, this check differs from the quality evaluation of the generated captions reported in the next section. In our study, a single round of sanity checks sufficed, obviating the need to modify prompts or alter the feature-caption pairs for in-context learning. Finally, us-

⁴Optimized based on limit on input tokens in Claude 3 text prompts.

ing the features extracted from each MIDI file, we generate corresponding captions, creating our proposed **MidiCaps** dataset, which we describe in detail in the next section.

4. EVALUATION AND STATISTICS

In this section, we first introduce the **MidiCaps** dataset and subsequently detail subjective evaluation in form of listening study.

4.1 MidiCaps dataset

To generate our **MidiCaps** dataset, we start with MIDI files provided in the Lakh MIDI dataset [11], comprised of a collection of 176,581 unique MIDI files, designed to facilitate large-scale music information retrieval. Additionally, the dataset is distributed under a CC-BY 4.0 license, enabling us to expand the dataset without encountering copyright constraints. Subsequently, we process the raw MIDI files and extract musical features as described in Section 3.1, which we used in the captioning process Section 3.2 to create our final **MidiCaps** dataset consisting of 168,407 MIDI files with matching text caption. A couple of examples of captions generated are provided below. They encapsulate key information regarding the music contents while infusing a fluid human touch:

1. “A melodic and happy rock and pop song featuring a string ensemble, piano, clean electric guitar, slap bass, and drums. The song is in the key of F major with a 4/4 time signature and a tempo of 120 BPM. The chord progression alternates between Bb and F throughout the song, creating a motivational and energetic corporate vibe.”

(a) Distribution of primary genre.

(b) Distribution of secondary genre.

Figure 3: Genre distributions.

(a) Distribution of instruments present in the summary.

(b) Distribution of key.

Figure 4: Instrument and key distributions (in log scale).

(a) Distribution of time signature.

(b) Distribution of tempo.

Figure 5: Time signature and tempo distributions (in log scale).

2. “A melodic and happy pop song with a Christmas vibe, featuring piano, clean electric guitar, acoustic guitar, and overdriven guitar. The song is in the key of A major with a 4/4 time signature and a moderate tempo. The chord progression revolves around D, E6, D, and E, creating a motivational and loving atmosphere throughout the piece.”

Moreover, we provide a summary of some of the extracted features below to gain further insight into the diversity within the dataset. In Figure 3a, we illustrate the distribution of the primary (highest confidence score) and secondary (second highest confidence score) genres present in the dataset. In both cases, electronic and pop genres are

most prominent in the dataset. The secondary genre exhibits more variation, such as folk, instrumental pop, and easy listening, which have more occurrences as secondary genre but do not appear in the primary genre figure. This means that they can be used by the captioning system to further specify and narrow down the broad primary genres (e.g. classical) into more specific descriptions such as ‘ambient classical’ etc. Please note that only genres with more than 1,000 occurrences are displayed in the figures. Figure 4 summarizes the instruments and keys present in the dataset. Piano, drums, and various types of guitars are predominant in the instrument summary, corroborating the fact that a significant portion of the songs belongs to electronic, pop, and rock genres. Additionally, the keys

Audience: Annotated by:	General audience		Music experts	
	Human	AI	Human	AI
Question	Avg. rating (1-7)			
Overall matching	5.46	5.63	5.40	4.92
Human-like	5.21	5.32	5.09	4.98
Genre matching	5.80	5.63	5.54	4.73
Mood matching	5.50	5.62	5.43	4.82
Key matching	5.87	5.70	5.51	5.69
Chord matching	6.12	5.78	5.74	5.09
Tempo matching	5.71	5.86	5.37	5.77

Table 1: Results of the listening study. Each question is rated on a Likert scale from 1 (very bad) to 7 (very good). The table shows the average ratings per question for each group of participants.

of C, G, F, and D major have the highest occurrences in the dataset. Regarding time signature, 4/4 is significantly more common than any other (Figure 5a), while most songs follow a moderate tempo (Figure 5b).

4.2 Listening study

Since there is no ground truth or baseline model to compare our new dataset to, we conduct a listening study with the help of the PsyToolkit platform [32,33]. Listeners were asked to listen to 20 MIDI files, chosen at random, from which 15 are captioned by our framework and 5 are annotated by an expert human rater with absolute pitch. Then, listeners were asked to rate these captions in seven aspects, which are: 1) Overall matching of caption to audio, 2) How human-like the caption is, 3) Genre matching of caption with audio, 4) Mood matching, 5) Key matching, 6) Chord matching, and 7) Tempo matching. Those listeners who indicated that they do not have the ability to recognize chords/key were tagged as General audience. A total of 16 participants belong to this general audience, of which 25% has more than 1 year of musical training. Another 7 participants indicated that they can recognize chords and key or have absolute pitch. These were tagged as Music experts.

4.3 Results and discussion

Table 1 shows the results of the listening study. The average rating for overall matching of the text caption with the MIDI file for the general audience is even slightly higher (5.63) for the AI generated caption compared to the human-written caption (5.46). When it comes to the ratings by music experts, the overall matching rating is slightly lower, but still well above average (4.92). In term of how human-like the captions are, the general audience again provides high ratings, comparable to those given to the human-written captions (5.21). The music experts are slightly more critical and rate them at 4.98, which is still very close to their rating for human-written captions (5.09). A similar pattern can be seen for ratings of genre matching and mood matching. The ratings for tempo matching outperformed the human-written ones for both general audience and music experts.

In terms of key and chord matching, the general audience provide good ratings. For these questions the ratings from the music experts, however, are more reliable, as these participants have explicitly indicated that they are able to recognize chords and keys. Their rating for key matching (5.69) is on par with the rating for human-written captions (5.51), and confirm the high agreement that the musical key described in the caption matches the audio pieces. For chord matching, the music experts’ average rating of 5.09 falls below the rating for the human-written caption. Please note, however, that this particular question was not easy to answer. Extracting a single ‘main’ pattern (3-5 chords) from the entire list of extracted chords is challenging as there are many different cases, e.g., very short fragments of a few chords, and very long pieces with many chord patterns. Slight changes in chord patterns can also be intentional, e.g., a chord progression of C, G, D, C, G, D6 would likely be detected as a C, G, D, C, G pattern instead of a C, G, D variation. All this makes it hard to objectively judge a single-chord pattern in the text captions. Despite this, the chord matching rating of 5.09 provides support that our caption contains a matching chord summary. Overall, the results from the listening study support that our text captions provide a high-quality, human-like textual description that matches the MIDI files well.

The task of automatically labelling files of various length is difficult by nature as longer music pieces might require more text to be described precisely, while shorter pieces may need only a single sentence. This problem is further magnified when considering chord progressions and their summary as mentioned above. Additionally, extracting features from synthesized audio files is not optimal, as the choice of the sound font has an impact on the obtained results, which is likely to be most apparent in genre and mood features. Future research could focus on improving accuracy related to these features. In sum, we are confident that our **MidiCaps** dataset will facilitate the development of the first Text-to-MIDI generation models.

5. CONCLUSION

We present the first large-scale open MIDI captioned dataset, **MidiCaps**. This dataset also includes a comprehensive set of musical features such as chord patterns, genre, and mood. To facilitate the development of this dataset, we have developed a MIDI captioning framework. This approach includes music feature extraction and summarization from MIDI and the synthesized audio, as well as the use of the Claude-3 LLM to generate the final captions using in-context learning. To evaluate the final dataset, we have conducted two subjective listening studies, which confirm that the captions are natural and indeed contain a text description of the musical features contained in the accompanying MIDI file. The resulting new **MidiCaps** dataset contains 168,407 MIDI files with descriptive text captions and is available online⁵ under a Creative Commons licence.

ABSTRACT

Schenkerian Analysis (SchA) is a uniquely expressive method of music analysis, combining elements of melody, harmony, counterpoint, and form to describe the hierarchical structure supporting a work of music. However, despite its powerful analytical utility and potential to improve music understanding and generation, SchA has rarely been utilized by the computer music community. This is in large part due to the paucity of available high-quality data in a computer-readable format. With a larger corpus of Schenkerian data, it may be possible to infuse machine learning models with a deeper understanding of musical structure, thus leading to more “human” results. To encourage further research in Schenkerian analysis and its potential benefits for music informatics and generation, this paper presents three main contributions: 1) a new and growing dataset of SchAs, the largest in human- and computer-readable formats to date (>140 excerpts), 2) a novel software for visualization and collection of SchA data, and 3) a novel, flexible representation of SchA as a heterogeneous-edge graph data structure.

1. INTRODUCTION

With the continuously growing availability of “big data,” machine learning models and algorithms have made enormous strides in many fields, such as computer vision and language modeling. Recent approaches to music information retrieval (MIR) and music generation tasks are increasingly fueled by massive datasets as well, particularly when working with raw audio. For instance, for generation tasks, Meta’s *MusicGen* is trained on approximately 20,000 hours of licensed music [1], OpenAI’s *Jukebox* on 1.2 million songs [2], and Google’s *Noise2Music* on 340,000 hours of music [3]. Castellon et al. show how these large generation models produce useful representations for downstream MIR tasks [4]. Won et al. perform

multimodal metric learning for tag-based music retrieval using approximately 158,000 tracks [5].

Despite this promising body of work, many areas of music research do not have access to such data and are therefore under-researched and underappreciated, particularly in the realm of symbolic music or Schenkerian Analysis (SchA). By infusing an understanding of Schenkerian musical structure, generative machine learning models may be able to learn more artistic, theoretically-informed structural features beyond simple form and metric features when making inference. Unfortunately, there is currently only one sizeable publicly available dataset for SchA in computer-readable format, and it is relatively small with 41 excerpts [6].

Schenkerian analysis provides a powerful, flexible, and broadly-used analytical framework for understanding musical melodic-harmonic structure in a sensitive, “human” way. Rather than viewing a piece of music as a series of vertical chunks or horizontal melodies, SchA instead analyzes music as an artistic “unfolding” of harmony through time, taking into account elements of melody, harmony, form, and counterpoint. Schenker’s theories have inspired numerous performers and composers [7–9], helping them to understand their own interpretations of musical structure, which in turn may inform their own performance and/or composition. An understanding of Schenkerian structure helps performers determine what notes deserve emphasis and which may be more transient. A composer can learn to imitate and develop structures they have seen in other pieces of music they admire.

Because Schenkerian theory requires a significant amount of background knowledge in music theory and practice and has a difficult learning curve, it is often overlooked or misunderstood. For instance, SchA is often deemed too narrow due to its origins in repertoire of Western common practice tonal music. However, aspects of Schenkerian theory have shown strong analytical power in works of popular, rock, jazz, and even African folk music, Chinese opera, and 20th century western atonal music [10–13]. To be clear, we see SchA as a broad and evolving field with various analytical tools that can be applied to a wide array of musical genres, not as a static theory solely designed for common practice tonality.

It is our belief that research in computational SchA can enable performers and composers to more easily analyze music and guide the process of understanding mu-
