When this study was begun, it was hoped to determine the electrochemical equivalent of palladium as compared with silver. Numerous experiments were tried, using the Richards type of coulometer, but the results were never concordant. About this time, L. Wöhler and F. Martin¹ stated that palladium used as the anode in nitric acid solution was oxidized to Pd_2O_3 and PdO_2 . This explained the variable results and seems to prove the method useless for atomic weight purposes.

THE SEPARATION OF THE ALKALI METALS IN THE ELECTROLYTIC WAY.

BY JACOB S. GOLDBAUM AND EDGAR F. SMITH.

Received August 21, 1908.

By reference to earlier work,² done in this laboratory, it will be noticed how readily and completely halide salts of a number of metals, particu-

¹ *Chem.-Ztg.*, 1908.

² *THIS JOURNAL*, 29, 447; *Ibid.*, 29, 1445; *Ibid.*, 29, 1455.

larly the alkali and alkaline earth metals, were analyzed quantitatively with the help of a mercury cathode and rotating silver anode.

The purpose of the present communication is to submit additional results obtained with halide salts of other metals and also to outline separations of the alkali metals which have, at last, been realized. An inspection of the conditions and actual results will convince any one that what, at first suggestion, might seem perplexing, is really not difficult and that these separations are, indeed, made with as much ease as those of the other and more metallic metals, *e. g.*, copper from cadmium. Before, however, entering upon these in more detail it is desired to offer the experiences had in the electrolysis of several ammonium salts. To this end, pure, resublimed ammonium chloride was electrolyzed with the conditions used in the electrolysis of sodium chloride (Smith's *Electro-analysis*, 4th ed., pp. 308, *et seq.*). The results for both the anion and cation were low and not concordant. It was found, upon search, that there were very considerable amounts of ammonia in both the inner and outer compartments of the decomposition cell, so that evidently the amalgam, if formed in the electrolysis, had sustained decomposition in the inner cup with the consequence that the resulting ammonium hydroxide attacked the anode and dissolved a portion of the silver chloride, forming $(\text{NH}_3)_3(\text{AgCl})_2$. At least, when a few drops of dilute nitric acid were added to the clear liquid of the inner cup, silver chloride was precipitated.

It soon became clear that, to avoid decomposition of the amalgam in the inner cup, it would have to be removed as rapidly as it was formed. This was accomplished by bringing the electrodes nearer together (1 cm. apart) and increasing the speed of rotation of the anode to 750 revolutions per minute. It also proved advantageous to employ an initial pressure of 3 volts, slowly increasing it to 8 volts and as the end of the electrolysis was approached, gradually returning the pressure to 3 volts. The cathode surface equaled 20 sq. cm.

To prevent loss of ammonia from the outer cup, because of its volatility, a slight excess of standard acid was introduced and the level of the liquid was raised to insure its complete absorption and retention. The alkaline hydroxide produced in this way was estimated, as in the analysis of sodium chloride, by titration with standard acid, the increase in weight of the silver anode represented the amount of the anion found.

All the determinations given in the following tables were made in aqueous solutions of the various salts. The volume of liquid did not exceed fifty cubic centimeters.

The behavior of these ammonium salts under electrolysis, which is perfectly analogous to that of salts of sodium, potassium, barium, etc., seems to prove the existence of an ammonium amalgam and it should

contribute materially to our ideas regarding the metallic character of the NH_4 group.

As the chlorides of cesium, rubidium and lithium had never been analyzed in the manner in which the corresponding salts of sodium, potassium and ammonium had been, it seemed desirable to devote some attention to them; accordingly, pure cesium chloride was prepared by the method of H. L. Wells,¹ and electrolyzed under the conditions that proved most favorable in the analysis of sodium chloride. The slightest impurity in the cesium salt will cause the amalgam to decompose not only in the outer cell but also in the inner compartment with the consequent formation of brown silver oxide on the anode.

Lithium Chloride.—This salt was freed from sodium and potassium, then subjected to electrolysis under conditions indicated in the attached table. The results are most satisfactory. They demonstrate that the analysis of this particular lithium derivative is, indeed, better effected in the electrolytic way than by any other gravimetric procedure.

Separations.

Having thus determined all the metals of the alkali group, steps were next directed towards their separation, using the rotating silver anode and mercury cathode. Kiliani, in 1883, showed that, by attention to differences in decomposition pressure, metals could be separated in the electrolytic way. In 1891, Le Blanc¹ measured the electromotive force required in order that a continuous constant current may be passed through an electrolyte so as to effect a continuous decomposition. He found that for a given substance under given conditions, this had a definite value which he termed the "decomposition value." Freudenberg,² in his development of this subject, showed that reliable separations of metals may be obtained by arranging the pressure so that it exceeds the polarization value of the one metal and continues below that of the other.

This procedure was followed in the present work. The actual decomposition values furnished by Le Blanc were of no avail because of the peculiar conditions employed in the Hildebrand cell. The use of the rotating silver anode and mercury cathode necessitated the re-determination of the decomposition values. This was done by the method described by Ostwald.³ The electrolyte will not conduct continuously below the decomposition point of a salt in aqueous solution; that is, the pressure can be gradually increased without a corresponding increase in amperage. When, however, the decomposition point is reached, any increase in pressure meets with a proportionate increase in current density. If, then, a curve be plotted with current density as the abscissas and pressure as ordinates the sharp break in the curve, the "knick-punkt," will represent the decomposition value of the salt under investigation.

¹ *Z. phys. Chem.*, **8**, 299 (1891).

² *Ber.*, **25**, 2492 (1892); *Z. phys. Chem.*, **12**, 97 (1893).

³ *Ostwald-Luther Physik-Chem. Messungen* (1902), p. 391.

It must be understood that these decomposition values are not absolute. They are relative only and must be re-determined by each experimenter because they vary with the distance between the electrodes, with the speed of rotation of the anode, with concentration of the electrolyte and with the area of the cathode surface. The determination of the "break-point," however, is merely the work of a few minutes.

Guided by these basic principles, the separation of the alkali metals was undertaken. The Hildebrand cell was used, as in the determination of the alkali metals. The current was derived from storage cells. A Weston milliammeter, a Weston voltmeter (graduated to $1/30$ V.) and a very efficient rheostat, delicate to 0.01 volt, were placed in circuit.

The same apparatus and conditions prevailed in the separation of the metals as in the determination of the decomposition points of their halides. The silver-plated anode made 350 revolutions per minute. The total dilution was 60 cc. The cathode surface had an area of about 20 sq. cm. and the poles were 15 mm. distant from each other.

A mixture of sodium chloride and potassium chloride, for instance, was placed in the inner compartment of the decomposition cell. The anode was rotated and the circuit closed. It had been found that the decomposition point for potassium chloride was $4/30$ volt higher than that of sodium chloride; hence the pressure was raised to $2/30$ volt higher than the "break-point" of the mixture. This pressure was carefully maintained throughout the electrolysis. Sodium chloride alone was decomposed, the chlorine forming silver chloride at the anode while the sodium passed into the mercury and formed sodium hydroxide with the water in the outer cup. The liquid in the latter was tested spectroscopically after the manner suggested by Gooch¹ and found to be entirely free from potassium.

The disappearance of the "break" of sodium chloride and the substitution for it of the higher decomposition value of potassium chloride were evidences of the completion of the electrolysis.

In order to save time it might, theoretically, have been possible to still effect a separation by maintaining a higher voltage at first and then reducing it towards the end to nearly the decomposition value of the sodium chloride. The number of sodium ions at the beginning would be present in sufficient amount to carry the entire charge and it would only be necessary, near the end of the separation, to keep the pressure close to the decomposition value of the sodium chloride. This point, however, was not thoroughly investigated.

This separation may prove to be most helpful in the estimation of small quantities of the alkali metals which occur in silicates.

The decomposition values of potassium and ammonium salts lie so close together that no success was had in the attempts to separate them.

It may be of interest to add in conclusion that Wolcott Gibbs¹ in 1880 predicted that possibly sodium and potassium might be separated in the electrolytic way with the use of a mercury cathode.

UNIVERSITY OF PENNSYLVANIA.

ON THE PREPARATION AND THE COMPOSITION OF THE ACID CARBONATES OF CALCIUM AND BARIUM.

BY EDWARD H. KEISER AND SHERMAN LEAVITT.

Received August 18, 1908.

The acid carbonates of calcium, strontium and barium have never been isolated or separated from solution as far as we have been able to find by searching the chemical literature at our command. We first

¹ *Chem. News*, 42, 291.
