Abstract

Lithium sulfur (Li-S) batteries have the potential to provide higher energy storage density at lower cost than conventional lithium ion batteries. A key challenge for Li-S batteries is the loss of sulfur to the electrolyte during cycling. This loss can be mitigated by sequestering the sulfur in nanostructured carbon-sulfur composites. The nanoscale characterization of the sulfur distribution within these complex nanostructured electrodes is normally performed by electron microscopy, but sulfur sublimates and redistributes in the high vacuum conditions of conventional electron microscopes. The resulting sublimation artifacts render characterization of sulfur in conventional electron microscopes problematic and unreliable. Here, we demonstrate two techniques, cryogenic transmission electron microscopy (cryo-TEM) and scanning electron microscopy in air (airSEM),

that enable the reliable characterization of sulfur across multiple length scales by suppressing sulfur sublimation. We use cryo-TEM and airSEM to examine carbon-sulfur composites synthesized for use as Li-S battery cathodes, noting several cases where the commonly-employed sulfur melt infusion method is highly inefficient at infiltrating sulfur into porous carbon hosts.

Introduction

Lithium sulfur (Li-S) batteries have the potential to provide greater energy storage density at lower cost than current lithium ion batteries. One of the main challenges to improving the performance of elemental sulfur cathodes for Li-S batteries is dissolution and loss of sulfur, in the form of polysulfides, to the electrolyte during battery operation (Bruce et. al., 2011). Recent research has focused on electrodes which attempt to sequester sulfur in nanostructured host materials, most prominently porous carbons, to prevent the loss of sulfur and associated capacity reduction as the battery is cycled (Ji et. al., 2009; Jayaprakash et. al., 2011; Wang et. al. 2011; Xiao et. al., 2012; Seh et. al. 2013; Zheng et. al., 2013; Song et. al., 2014; Zhao et. al., 2014; Werner et. al., 2015; Sahore et. al. 2015). These electrode materials are typically referred to as carbon-sulfur composites. Accurate characterization of the distribution of sulfur in these composites over 100 nm to sub-nm length scales is critical for developing an understanding of how the level of infiltration of sulfur into the host material relates to battery performance, which will aid in the design of more durable, high energy density Li-S batteries (Ma et. al. 2015).

Electron microscopy offers both direct imaging and spectroscopic techniques for characterization of battery electrodes. For reliable characterization of a material using electron microscopy, it is essential that the sample is not altered by conditions in the microscope. However, elemental sulfur readily sublimates under high vacuum conditions similar to those of an electron microscope sample chamber. Sulfur sublimation under high vacuum has been observed in vacuum

45   chamber experiments on bulk sulfur (Nash, 1987), and can be predicted from sulfur's measured

46   vapor pressure (Ferreira & Lobo, 2011), but the sulfur battery community has only recently begun

47   to become aware of the problem of sulfur sublimation in electron microscopy (Raiβ et. al., 2014).

48   As an illustration of this challenge, Figure 1a shows the vapor pressure curve of sulfur, with the

49   conditions of an FEI Tecnai F20 transmission electron microscopy (TEM) sample chamber

50   (8.8×10^{-8} Torr at $\sim 18^{\circ}$C room temperature) indicated. Figures 1b-g show the result of placing a

51   sample of ball-milled sulfur particles into the microscope under these conditions. The sulfur is

52   observed to sublimate at a rate of approximately 1 monolayer of sulfur atoms per second, leaving

53   behind only a small residue of "super-sublimated" polymeric sulfur, which remains relatively

54   stable under vacuum. The measured sublimation rate and residual product are fully consistent with

55   previous macroscopic experiments (Nash, 1987).

56   In nanostructured sulfur composites, sublimation effects in high vacuum may be very

57   severe. In TEM for example, exposed nanoscale features of the sulfur distribution in a sulfur

58   battery cathode composite would disappear within minutes at most. Only super-sublimated

59   polymeric sulfur residue (Figure 1e), and sulfur encapsulated by another material lacking large

60   enough pores for sulfur to escape (Zhou et. al., 2014; Kim et. al., 2015), will remain present under

61   vacuum.

62   In scanning electron microscopy (SEM), the sample is typically held at a higher pressure

63   than in TEM. However, a recent study has observed that even in the vacuum of an SEM sample

64   chamber ($\sim 10^{-6}$ Torr), sulfur sublimation artifacts occur, including the redistribution of sublimated

65   sulfur into the pores of nearby carbon particles. The study concluded that characterization of

66   sulfur/carbon composite materials by vacuum-based methods, including SEM, is very challenging,

67   and results might be misleading (Raiβ et. al., 2014). Sulfur sublimation and the resulting artifacts,

68   including sulfur redistribution, present a serious problem for accurate characterization of the

69   inherent sulfur distribution in battery cathodes in electron microscopy. This may be impeding the

70   scientific community's efforts to gain a systematic understanding of how sulfur distribution in

71   different carbon-sulfur composites relates to their performance in batteries. More reliable

72   alternative techniques for sulfur characterization that suppress sublimation are clearly needed.

73   The sulfur vapor pressure curve (Figure 1a) indicates that sulfur has an equilibrium vapor

74   pressure of ~ 6×10^{-7} Torr at 18°C. This means that at 18°C, a sulfur particle will sublimate until

75   the partial pressure of sulfur surrounding the particle reaches 6×10^{-7} Torr. If a sample chamber is

76   pumped to too low a pressure, sulfur will not be able to reach equilibrium, and will sublimate

77   continually. To avoid sublimation artifacts, either the ambient pressure during imaging must be

78   increased to a level much greater than sulfur's equilibrium vapor pressure, or the ambient

79   temperature must be reduced to much less than 18°C. In this paper, we demonstrate

80   characterization of sulfur and nanostructured carbon-sulfur composite materials in vacuum at low

81   temperature using cryo-TEM, and at atmospheric pressure at room temperature using airSEM.

82   Sulfur sublimation artifacts are not observed using either technique. Our results demonstrate that

83   sulfur infiltration by melt infusion is significantly more efficient in activated porous carbons than

84   in non-activated porous carbons, carbon nanotubes, and hollow carbon spheres, all of which have

85   recently been investigated as Li-S battery electrode materials. Adoption of cryo-TEM, airSEM,

86   and other similar techniques, for more reliable characterization of the sulfur distribution in

87   different carbon-sulfur composites will enable scientists to observe the inherent sulfur distribution

88   in their composite materials, providing important insight and feedback to guide the design of

89   improved Li-S batteries.

90   **Experimental**

91   Cryo-TEM is a well-established method for imaging hydrated biological samples that

92   cannot be exposed to vacuum at room temperature (Dubochet & McDowall, 1981; Adrian et. al.,

93   1984; Kourkoutis et. al. 2012). Cryogenic cooling of sulfur cathode samples inside the microscope

94   was achieved using a Gatan model 626 cryo-holder (Gatan, Inc., Pleasanton, CA, USA), with

95   liquid nitrogen as the cryogen. The cryo-TEM loading method for sulfur cathode samples is

96   simpler than for biological samples, since the sulfur need only be cooled prior to loading into the

97   microscope column, whereas biological samples must be vitrified. Carbon-sulfur composite

98   particles were dispersed from an ethanol solution onto TEM grids, which were then allowed to dry

99   in air. The cryo-holder was cooled so that the tip temperature was ~ -173°C. The sample TEM

100   grids were loaded into the cryo-holder under nitrogen gas near liquid nitrogen temperature. An

101   FEI Tecnai F20 STEM/TEM (FEI Company, Hillsboro, OR, USA) equipped with cryogenically

102   cooled beryllium blades, and operated in scanning TEM (STEM) mode at 200 kV was used to

103   image the samples. An Oxford Instruments XMAX detector (Oxford Instruments PLC, Tubney

104   Woods, Oxfordshire, UK) was used for x-ray energy dispersive spectroscopy (XEDS), and a Gatan

105   865 HR-GIF spectrometer was used for electron energy loss spectroscopy (EELS) acquisition.

106   Experiments in air were performed using a B-nano airSEM (B-nano Ltd. Rehovot, Israel),

107   operated at 30 kV. The airSEM is a relatively new design of electron microscope (a schematic

108   diagram of an airSEM is shown in Supplementary Figure S1), which enables characterization of

109   samples in air, with no sample vacuum chamber (Nguyen et. al., 2013; Solomonov et. al., 2014;

110   Vidavsky et. al. 2014; Nguyen et. al., 2016). Carbon-sulfur composite particles for analysis in

111   airSEM were dispersed onto TEM grids from an ethanol solution and allowed to dry in air, in the

112   same manner as for cryo-TEM. Sample TEM grids were placed directly on top of an airSTEM

113   detector (Nguyen et. al., 2014; Han et. al. 2015; Nguyen et. al., 2016), which was mounted on an

114   optical slide. A white light optical reflectance microscope (Olympus, Centre Valley, PA, USA)

115   was used both for optical imaging, and to set the height of the sample to ~ 50 μm below the electron

116   window, the optimal working distance for airSEM imaging. XEDS maps were acquired using a

117   Bruker XFlash 6160 detector (Bruker Corporation, Billerica, MA, USA).

118   Pure sulfur particles were prepared for analysis by ball-milling sulfur flakes. Carbon-sulfur

119   composites synthesized with ordered mesoporous carbon structures GDMC-15-1600°C and

120   aGDMC-15-10h, were obtained from block copolymer co-assembly and heated to 1600ºC to

121   remove any intrinsic microporosity. The high-temperature treatment yielded low oxygen content

122   and surface functionalization (hydrophobic surface). Carbon aGDMC-15-10h underwent

123   activation by heating in CO_2 at 950ºC for 10 hours. Sulfur infiltration by melt infusion was

124   attempted at a sulfur:carbon ration of 1:1 by weight. The synthesis, and performance of these

125   mesoporous materials in battery testing is described in detail by Werner et. al. (Werner et. al.,

126   2015). Carbon nanotube – sulfur composite samples, CNT-S, were synthesized using multi-walled,

127   > 8% carboxylic acid functionalized carbon nanotubes, average diameter ~ 9.5 nm, length ~ 1.5

128   μm, which were obtained from Sigma Aldrich, and dried before use. Polyethylenimine (PEI)

129   solution (50 wt. % in water) was obtained from Sigma-Aldrich, and PEI was covalently grafted to

130   the carbon nanotubes. Sulfur infiltration by melt infusion was then attempted at a sulfur:carbon

131   ration of 7:3 by weight. Mesoporous hollow carbon sphere – sulfur composites, MHCS-S, were

132   prepared by an organic hard template method. In a typical synthesis, size tunable mono-dispersed

133   melamine-formaldehyde (MF) resin sphere templates (0.5 g) were synthesized by the in-situ

134   polymerization method reported by Xie et al. (Xie et al., 2008). These were then suspended in a

135   50 mL water/ethanol (volume ratio 3/1) solvent containing 0.5 g of Triton X-100 surfactant.

136   Formaldehyde solution (1.0 mL) and resorcinol (0.75 g) were then added to the reaction solution,

137   and stirred for 30 min at 60°C. The solution was subsequently heated for 2 hours at 75°C. The solid

138   product was recovered by filtration and air-dried at 90°C for 8 hours. Mesoporous hollow carbon

139   spheres were formed by carbonization of the as-made resorcinol-formaldehyde encapsulated MF

140   spheres at 950°C for 2 hours under flowing nitrogen gas with a heating rate of 3°C/min. Sulfur

141   infiltration was attempted by melt infusion at a sulfur:carbon ratio of 7:3 by weight.

142   **Results and Discussion**

143   <u>I. Sulfur characterization in cryo-TEM.</u>

144   In order to investigate whether sublimation effects were still apparent at cryogenic

145   temperatures, ball milled sulfur particles, were prepared in an identical manner to those in Figure

146   1, and imaged by cryo-TEM at a temperature of approximately -173°C. A time series of cryo-TEM

147   images from a sulfur particle is shown in Figure 2. No change in the morphology of the particle

148   was observed over a 5-hour period, in stark contrast to the sulfur particle imaged by standard room

149   temperature TEM shown in Figure 1, which sublimated and disappeared in under 40 minutes. The

150   cryogenically cooled sulfur remained stable enough under the electron beam to allow imaging in

151   annular dark field (ADF) cryo-scanning TEM (cryo-STEM, Figure 2d) and XEDS mapping

152   (Figure 2e). The suppression of sulfur sublimation by cryogenic sample cooling demonstrates that

153   cryo-TEM is a viable method for both imaging and spectroscopic characterization of composites

154   containing elemental sulfur such as carbon-sulfur nanocomposites for advanced lithium batteries.

155   Having established that sulfur sublimation is suppressed at cryogenic temperatures, we

156   used cryo-TEM to analyze the sulfur distribution within three different carbon-sulfur

157   nanocomposite materials recently investigated for Li-S battery electrodes. The first two samples,

158   GDMC-15-1600°C and aGDMC-15-10h, are examples of ordered carbon nano-networks (Werner

159   et. al., 2015). These have attracted interest as sulfur battery cathode materials due to the potential

160   of sequestering sulfur in the pores of a torturous carbon network. GDMC-15-1600°C and aGDMC-

161   15-10h were prepared in an identical manner except that, prior to sulfur melt infusion, aGDMC-

162   15-10h underwent an additional activation procedure to substantially increase its microporosity

163   and associated surface area, whereas the non-activated carbon, GDMC-15-1600°C, exhibits very

164   little microporosity (see Experimental). The third sample, CNT-S used a network of carbon

165   nanotubes as the host material for sulfur. Carbon nanotubes have attracted interest as Li-S battery

166   electrodes due to the potential to sequester sulfur inside the body of the nanotubes (Fujimori et.

167   al., 2013; Kim et. al., 2015). In each of our three samples, successful melt infusion would ensure

168   that electrically insulating sulfur is in contact with electrically conducting carbon at the nanoscale.

169   Cryo-STEM imaging and XEDS maps of the activated C-S composite aGDMC-15-10h (Figure

170   3a), showed a high degree of infiltration of sulfur into the carbon following melt infusion.

171   However, in the non-activated C-S composite GDMC-15-1600°C we observed that a majority of

172   the sulfur had not infiltrated the carbon, and remained external to the carbon particles (Figure 3b).

173   External sulfur particles typically had a diameter of several μm or larger. In reported battery

174   performance tests, the activated carbon aGDMC-15-10h outperformed its non-activated

175   counterpart GDMC-15-1600°C in terms of initial capacity, capacity retention over cycling, and

176   rate capability (Werner et. al., 2015). This may be partly explained by our observation that sulfur

177   infiltration was much more successful in the activated carbon aGDMC-15-10h than the non-

178   activated carbon GDMC-15-1600°C, because the external sulfur particles observed in GDMC-15-

179   1600°C would be in poorer electrical contact with the carbon, and more exposed to dissolution and

180   loss to the electrolyte in the form of polysulfides during battery cycling.

181   High magnification STEM imaging and EELS spectra of sample CNT-S indicated that little

182   or no sulfur had infiltrated into the carbon nanotubes, which had remained hollow (Figure 3c).

183   XEDS mapping of sample CNT-S at low magnification showed that much of the sulfur in the

184   composite remained external to the nanotube network after melt infusion, forming particles several

185   microns in diameter (Figure 3d), in a similar way to the sulfur in sample GDMC-15-1600°C. X-

186   ray sum spectra from the datasets used to generate element distribution maps contain information

187   about the relative quantities of carbon and sulfur in the field of view that are not evident from x-

188   ray maps alone. The x-ray spectra used to generate the maps in Figure 3 are shown in

189   Supplementary Figure S2. Each of these spectra show a strong sulfur peak relative to the carbon

190   peak, indicating significant quantities of sulfur in the field of view. Our results show that the degree

191   to which sulfur infiltrates into carbon host particles can vary significantly depending on the

192   porosity and structural characteristics of the carbon host, and how the carbon was prepared. In this

193   case, sulfur infiltrated far more efficiently into the activated, high-surface area carbon aGDMC-

194   15-10h exhibiting both 15 nm mesopores and a large fraction of small micropores (< 4 nm), than

195   into the non-activated carbon GDMC-15-1600°C, exhibiting only 15 nm mesopores, or into a

196   network of carbon nanotubes. In a related cryo-TEM study of sulfur infusion into highly porous

197   carbons synthesized by ice templation, sulfur was observed to have infiltrated far more efficiently

198   into activated carbon 20-2-1.5-80S exhibiting both mesopores and micropores, than into non-

199   activated carbon 20-2-0-80S, exhibiting only mesopores (Sahore et. al., 2016), a very similar trend

200   to the results described above.

201   <u>II. Sulfur characterization in airSEM.</u>

202   An alternative approach to cryogenic cooling to avoid sulfur sublimation is to keep the

203   sample at room temperature, but increase the pressure around the sample, for example by imaging

204   the sulfur at atmospheric pressure. The recently developed airSEM by B-nano enables correlative

205   optical and electron microscopy of samples in air, with no vacuum specimen chamber, by using

206   an electron transparent silicon-nitride window to separate the sample in air from the electron optics

207   in vacuum (Solomonov et. al., 2014; Vidavsky et. al. 2014; Nguyen et. al., 2016). Our cryo-TEM

208   observations of external sulfur particles several μm in diameter in carbon-sulfur composite samples

209   suggested that correlative optical-electron microscopy would be a useful method of high-

210   throughput characterization of these materials. Optical microscopy can screen samples for large

211   external sulfur particles, since external sulfur (yellow) is optically distinct from carbon (black).

212   Electron microscopy and XEDS can then be used to image carbon particles at higher magnification

213   to analyze the degree of sulfur infiltration into the carbon, and investigate nanoscale features of

214   the sulfur distribution.

215   As a demonstration of this technique, we used airSEM to investigate the distribution of

216   sulfur in sample MHCS-S, a composite of sulfur and 3 μm diameter hollow carbon spheres with

217   porous shells. These have attracted interest as candidate materials for Li-S batteries because of the

218   potential for large quantities of sulfur to be sequestered in both the porous shell, and in the hollow

219   interior of the sphere, though some recent studies have questioned whether melt infusion is actually

220   successful at infiltrating sulfur into the hollow interior (Jayaprakash et. al., 2011; He et. al., 2013).

221   In our sample, sulfur infiltration was attempted by melt infusion at a ratio of 7:3 sulfur to carbon

222   by weight prior to imaging, sufficient to ensure that both the pores in the shell wall, and the interior

223   cavity could be filled if melt infusion was successful.

224   Particles of external sulfur were identified by optical microscopy (Figure 4a). Closer

225   inspection of a ~ 30 μm wide external sulfur particle (Figure 4b) with airSEM, using a bright-field

226   STEM detector positioned directly below the sample (Nguyen et. al., 2014; Han et. al. 2015;

227 Nguyen et. al., 2016), shows a morphology that suggests this particle was formed by freezing from

228 a liquid state. XEDS mapping confirmed the identity of the particle as external sulfur (Figure 4c

229 & 4d, spectrum in Supplementary Figure S4a). Clusters of carbon spheres were identified in the

230 optical microscope (Figure 4e) and imaged at high resolution in the airSEM (Figure 4f). The

231 spheres appeared to be unfilled in the airSEM images, suggesting that sulfur had not infiltrated

232 into the sphere interior. This was confirmed by XEDS mapping (Figure 4g & 4h, spectrum in

233 Supplementary Figure S4b). However, XEDS maps did show that sulfur had infiltrated the walls

234 of the spheres, despite not infiltrating the hollow interior as had been intended.

235

236 III. Comparison of airSEM and cryo-TEM

237   The spatial resolution set by electron optics in the airSEM will be more limited than for

238 cryo-TEM. However, an advantage of the airSEM is that samples do not need to be cooled and

239 placed in a vacuum chamber, meaning that airSEM can achieve greater sample throughput.

240 AirSEM will be most suitable for use in conjunction with optical microscopy for high-throughput

241 characterization of samples using a broader field of view where image resolution of < 5 nm is not

242 required, whereas cryo-TEM will be most suitable for characterization of samples that require

243 resolution of finer, nanometer scale features.

244 IV. Limitations due to radiation damage

245   Even after sublimation has been suppressed, radiation damage will ultimately limit the

246 resolution at which sulfur can be characterized in electron microscopy. Electrical insulators, such

247 as sulfur, are vulnerable to ionization damage (Egerton & Malac, 2004). Furthermore, sulfur

248 molecules are weakly bound, making sulfur vulnerable to knock-on displacement damage

249 (Chisney et. al., 1988). When sulfur is imaged at relatively low magnification, as in the results

11

250   presented in this paper, electron dose is spread over a wide area, and beam damage effects to sulfur

251   will be minimal. However, at high magnification, electron dose becomes more concentrated and

252   radiation damage will cause mass loss from sulfur particles. Radiation damage effects have been

253   observed in Supplementary Figure S5, which is accompanied by further discussion of damage.

254   **Conclusions**

255   The high vapor pressure of sulfur creates a serious risk that sublimation artifacts will lead

256   to a mischaracterization of samples containing sulfur in standard high-vacuum electron

257   microscopy. As a solution to this problem, we have demonstrated that sulfur sublimation is

258   suppressed by cooling sulfur samples below the sulfur sublimation point in vacuum using cryo-

259   TEM, or by using airSEM to image sulfur in air. Both techniques are able to detect features of the

260   sulfur distribution across C-S nanocomposite materials that are extremely challenging to observe

261   reliably in standard electron microscopy due to sulfur sublimation in vacuum and resulting artifacts

262   such as sulfur redistribution. Most notably, in three of the four carbon-sulfur composite samples

263   investigated in this paper, we have directly observed that sulfur infiltration by melt infusion is

264   unsuccessful or inefficient, leaving much of the sulfur external to the carbon host material. It may

265   be of interest for future studies to investigate whether inefficient sulfur infiltration by melt infusion

266   occurs in other composite materials, and to what extent this affects battery performance.

267   In conclusion, we strongly recommend adoption of cryo-TEM, airSEM for more reliable

268   characterization of sulfur and sulfur battery cathodes. Other techniques that may also be able to

269   suppress sulfur sublimation artifacts could include environmental SEM, cryo-SEM, and

270   environmental-cell TEM. Applying these techniques to Li-S batteries will allow researchers to

271   reliably characterize the inherent distribution of sulfur in their composite electrodes, helping to

272   guide the design of improved lithium sulfur batteries.

368 **Figures**

370 **Figure 1. a)** Vapor pressure vs temperature for elemental sulfur (Ferreira & Lobo, 2011). Purple

371 marker indicates approximate conditions in specimen chamber of the F20 TEM used for image

372 acquisition. **b) – f)** Sulfur particle sublimating in TEM vacuum chamber at 18°C, at a pressure of

373 8.8×10^{-8} Torr, imaged after (b) 16 min, (c) 21 min, (d) 28 min, (e) 33 min, (f) 40 min under vacuum.

374 Scale bars 1μm. The particle was not exposed to the electron beam between images. After 40 min,

375 particle has sublimated almost completely, leaving a small residue, which was stable in vacuum.

376 STEM-XEDS map **(g)** indicates that the residue is sulfur. Residue morphology suggests the

377 formation of super-sublimated polymeric sulfur, as expected from the macroscopic experiments of
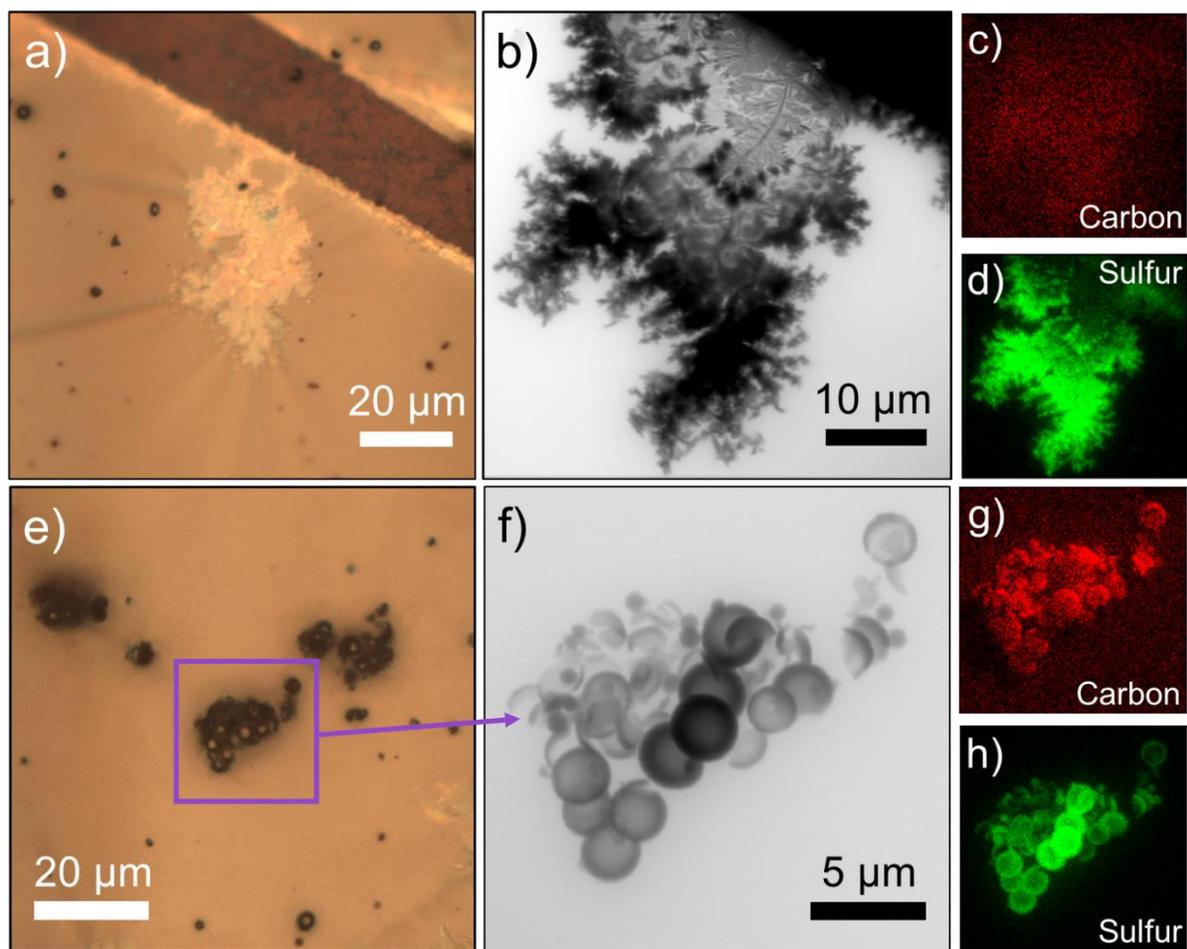

378 (Nash, 1987).

XEDS Map - Sulfur

379

Figure 2. a) – c) Time series of images of a cryogenically cooled sulfur particle at approximately -173°C after **a)** 86 minutes, **b)** 170 minutes, and **c)** 311 minutes under 8.8×10^{-8} Torr vacuum. Scale bars 1 μm. The particle was not exposed to the electron beam between images. No sublimation effects were observed over a 5 hour period. After 4 hours under vacuum, a HAADF STEM image **(d)** (scale bar 500 nm) and STEM-XEDS map **(e)** were taken from the tip of the particle, demonstrating the stability of sulfur for STEM imaging and spectroscopic analysis under cryogenic conditions. Stronger signal on left hand side of particle due to detector geometry.

387

Figure 3. Cryo-STEM ADF images and XEDS maps of: **a)** Composite of sulfur and activated gyroidal mesoporous and microporous carbon aG^{D}MC-15-10h, showing a high degree and homogeneity of sulfur infiltration (overlap in carbon and sulfur signals). **b)** Composite of sulfur

and the same gyroidal mesoporous carbon G^{D}MC-15-1600°C without prior activation and very low microporosity, showing pure sulfur external to the carbon host, indicating poor infiltration efficiency. **c)** Cryo-STEM image of carbon nanotubes after attempted sulfur melt infusion. Tubes remain hollow. EELS spectrum from body of tube (red) on carbon support film shows little or no sulfur L-edge signal. EELS spectrum from an elemental sulfur particle shown for comparison in blue. **d)** Carbon nanotube-sulfur composite CNT-S, also showing most sulfur external to nanotubes.

Figure 4. a) Optical microscope image of pure sulfur that has not infiltrated into carbon spheres. **b)** airSEM BF-STEM image of sulfur particle corresponding to that in the optical image. **c) & d)**

401   carbon and sulfur XEDS maps, confirming that the material is bulk sulfur. **e)** Extended depth of

402   field optical microscope image of clusters of carbon-sulfur spheres recorded on the airSEM's

403   optical microscope. **f)** airSEM BF-STEM image of single cluster of carbon spheres from the same

404   region as (b). **g) & h)** XEDS maps showing carbon and sulfur signals that confirm sulfur

405   infiltration into the sphere walls, but suggests no infiltration into the sphere interior.
