Traceable accounts

The chapter references enclosed in curly brackets (e.g. {2.3.1, 2.3.1.2, 2.3.1.3}) are traceable accounts and refer to sections of the chapters of this IPBES Assessment. A traceable account is a guide to the section in the chapters that contains the evidence supporting a given message and reflecting the evaluation of the type, amount, quality, and consistency of evidence and the degree of agreement for that statement or key finding.

SUGGESTED CITATION

IPBES (2023). Thematic Assessment Report on Invasive Alien Species and their Control of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services. Roy, H. E., Pauchard, A., Stoett, P., and Renard Truong, T. (eds.). IPBES secretariat, Bonn, Germany. https://doi.org/10.5281/zenodo.7430682

MEMBERS OF THE MANAGEMENT COMMITTEE WHO PROVIDED GUIDANCE FOR THE PRODUCTION OF THIS ASSESSMENT

Eric Fokam, Shizuka Hashimoto, Rizwan Irshad, Ruslan Novitsky, Rashad Allahverdiyev, Vinod Bihari Mathur, Youngbae Suh.

This report in the form of a PDF can be viewed and downloaded at www.ipbes.net

The Assessment of Invasive Alien Species and their Control was made possible thanks to many generous contributions received during the production of the Assessment including non-earmarked contributions to the IPBES trust fund from Governments (Australia, Austria, Belgium, Bulgaria, Canada, Chile, China, Denmark, Estonia, European Union, Finland, France, Germany, Japan, Latvia, Luxembourg, Netherlands [Kingdom of the], New Zealand, Norway, Republic of Korea, Slovakia, Spain, Sweden, Switzerland, United Kingdom of Great Britain and Northern Ireland and United States of America); earmarked contributions to the IPBES trust fund toward the Assessment (France – Office Français de la Biodiversité); and in-kind contributions targeted at the Assessment, including from the Institute for Global Environmental Strategies (IGES) which hosted the technical support unit. All donors to the trust funds are listed on the IPBES web site: www.ipbes.net/donors

Table of Contents

IPBES is an independent intergovernmental body comprising over 140 member Governments. Established by Governments in 2012, IPBES provides policymakers with objective scientific assessments about the state of knowledge regarding nature and the contributions it provides to people, as well as options for actions to protect and sustainably use these vital natural assets.

The Assessment of Invasive Alien Species and their Control was initiated by a decision from the IPBES Plenary (decision IPBES-6/1) at its sixth session (IPBES 6, Medellin, Colombia, 2018), based on the scoping report (annex III to decision IPBES-4/1) approved by the Plenary at its fourth session (IPBES 4, Kuala Lumpur, Malaysia, 2016). The Assessment was produced in accordance with the procedures for the preparation of the Platform's deliverables set out in annex I to decision IPBES-3/3.

The Assessment of Invasive Alien Species and their Control was considered by the IPBES Plenary at its tenth session (IPBES 10, Bonn, Germany, 2023), which approved its summary for policymakers, and accepted its chapters. All material can be found here: https://www.ipbes.net/ias

FOREWORD

A key objective of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) is to provide Governments, the private sector and civil society with scientifically credible and independent up-to-date assessments of available knowledge for better evidence-informed policy decisions and action at the local, national, regional and global levels.

The thematic Assessment of Invasive Alien Species and their Control, or "Invasive Alien Species Assessment" in short, is part of a series of reports whose production was initiated during the "first work programme of IPBES, 2014-2018" and concluded during the current "IPBES rolling work programme up to 2030". The Invasive Alien Species Assessment has been carried out by a multidisciplinary team of 86 selected experts from all regions of the world, including early career fellows, assisted by about 200 contributing authors. More than 13,000 scientific publications were analyzed as well as a substantive body of Indigenous and local knowledge. Its chapters were accepted, and its summary for policymakers was approved, by the IPBES Plenary composed of 143 member States at its tenth session held from 28th August to 2nd September 2023 in Bonn, Germany.

The Invasive Alien Species Assessment builds on the landmark IPBES Global Assessment Report on Biodiversity and Ecosystem Services launched in 2019. The Global Assessment identified invasive alien species as a one of the five main direct drivers of biodiversity loss, with 1 million species of plants and animals now at risk of extinction.

The Invasive Alien Species Assessment explores how invasive alien species affect nature and people globally. It analyzes the status and trends of alien and invasive alien species in all regions of Earth, and identifies major pathways for and drivers of the introduction and spread of such species between and within countries. The Assessment also assesses the

effectiveness of management actions across scales and in various contexts. The Invasive Alien Species Assessment finally outlines key responses and policy options for the prevention, early detection, and effective control of invasive alien species and mitigation of their impacts in order to safeguard nature, nature's contributions to people and good quality of life.

The Invasive Alien Species Assessment highlights that invasive alien species are a major and growing threat to nature, nature's contributions to people, with, in some cases, irreversible changes to biodiversity and ecosystems. Invasive alien species also dramatically impact the economy, food security, water security and human health, sometimes adding to marginalization and inequity. The Assessment demonstrates that with sufficient resources, political will, and long-term commitment, preventing and controlling invasive alien species are attainable goals that will yield significant long-term benefits for people and nature.

As the Chair and the Executive Secretary of IPBES, we wish to recognize the leadership and dedication of the co-chairs, Prof. Helen Roy (United Kingdom), Prof. Aníbal Pauchard (Chile), and Prof. Peter Stoett (Canada) and the hard work and commitment of all the coordinating lead authors, lead authors, review editors, fellows, contributing authors and external reviewers, and to warmly thank them for contributing their time and ideas freely to this important report. We would also like to recognize the hard work and dedication of Naoki Amako and Noriko Moriwake, heads of the technical support unit for this Assessment, Tanara Renard Truong, assessment coordinator, and Ryoko Kawakami, administrative officer. Our thanks go also to the current and former members of the Multidisciplinary Expert Panel (MEP) and of the Bureau who provided guidance as part of the management committee for this report, and to members of the IPBES secretariat including those of other technical support units within the IPBES secretariat, who have supported the production of this report, and its successful launch in the media. We would also like to thank all Governments and other institutions that provided financial and in-kind support for the preparation of this Assessment. We are profoundly aware that work was made more challenging over the past couple of years because of the COVID-19 pandemic which prevented the experts from meeting and connecting in-person as planned, and which created very difficult personal circumstances for many. We express again our deepest thanks and recognition to all involved, on behalf of IPBES.

The Invasive Alien Species Assessment provides the best-available evidence, critical analysis and options for governments, civil society, Indigenous Peoples and local communities, the private sector and all those seeking to address the issue of biological invasions. The Assessment is also expected to support sharing of information within and across countries and capacity building globally. It is our sincere hope that this Assessment will support the implementation of the Sustainable Development Goals of the 2030 Agenda for Sustainable Development (especially Goal 15) and form a significant contribution to the implementation of the Kunming-Montreal Global Biodiversity Framework of the Convention on Biological Diversity, and especially of its Target 6.

Ana María Hernández Salgar
Chair of IPBES (2019-2023)

Anne Larigauderie
Executive Secretary of IPBES

STATEMENTS FROM KEY PARTNERS

Humanity has been moving species around the world for centuries. This practice has brought some positives. However, when imported species run rampant and unbalance local ecosystems, indigenous biodiversity suffers. As a result, invasive species have become one of the five horsemen of the biodiversity apocalypse that is riding down harder and faster upon the world.

While the other four horsemen – changing land- and sea-use, over exploitation, climate change and pollution – are relatively well understood, knowledge gaps remain around invasive species. The IPBES Invasive Alien Species Report is a welcome effort to close these gaps. By providing critical information on trends in invasive species and policy tools to address them, this report can provide a springboard to concrete action on invasive species.

I ask all decision-makers to use this report's recommendations as a basis to act on this growing threat to biodiversity and human well-being – and make a real contribution to achieving the Kunming-Montreal Global Biodiversity Framework by 2030.

Inger Andersen
Executive Director
United Nations Environment Programme
(UNEP)

It is urgent to accelerate efforts against invasive alien species, one of the five major drivers of biodiversity loss that also threatens our health, social development, and culture. UNESCO, as an institutional partner of IPBES, takes pride to have supported this new Assessment Report. It provides a valuable analysis of how invasive alien species are distributed globally and the diverse strategies used to manage them. The report draws on a wide range of knowledge and perspectives from around the world, including Indigenous and local knowledge, which is a central focus of UNESCO's programmes. This crucial information will strengthen ongoing initiatives in UNESCO-designated sites and help decision-makers shape their policies worldwide.

Audrey Azoulay
Director-General,
United Nations Educational,
Scientific and Cultural Organization
(UNESCO)

Invasive alien species pose a substantial threat to livelihoods and food security around the world. They can, for example, manifest as destructive crop or forest pests or displace species targeted by fisheries. They are an important driver of biodiversity loss and hence a threat to the various ecosystem services that support agricultural production and sustainable livelihoods.

The information contained in this report will contribute greatly to efforts to combat the spread of invasive alien species and to meeting Target 6 of the Kunming-Montreal Global Biodiversity Framework. It will be especially valuable for all of us who work to integrate the conservation and sustainable use of biodiversity into the world's agrifood systems to enhance their productivity and resilience.

QU Dongyu
Director-General,
Food and Agriculture Organization of
the United Nations
(FAO)

Invasive alien species – plants, animals or microorganisms that are introduced intentionally or unintentionally into areas where they are not native – remain one of the most striking symptoms of the adverse effect of human activities on our natural world. They not only contribute to wildlife species extinctions, but also pose a rapidly growing risk to progress on the Global Goals – affecting entire ecosystems, economies and food security to human health, wellbeing, and livelihoods.

As anthropogenic factors such as climate change provide the perfect petri dish for alien species to multiply and spread, our decisions and actions must be rooted in a comprehensive understanding of this threat and its future implications.

Addressing this need, this timely analysis by IPBES combines the latest science, data, and new thinking to guide countries, communities, and the United Nations family to prevent, mitigate, and manage invasive alien species, a pivotal step towards advancing the Kunming-Montreal Global Biodiversity Framework targets. That includes leveraging invaluable local knowledge and outlining a range of practical solutions.

This new understanding will allow our global community to take new measures to protect both people and planet from the unwanted and severe consequences of invasive alien species.

Achim Steiner
Administrator,
United Nations Development Programme
(UNDP)

Invasive alien species are one of the five main direct drivers of biodiversity loss globally and the threats they pose to species, to ecosystems and to human well-being are rapidly increasing.

The Kunming-Montreal Global Biodiversity Framework, in its Target 6, aims to tackle the impacts of invasive alien species on biodiversity and ecosystem services, and to reduce the rate of introduction and establishment of invasive alien species by at least 50% by 2030. This is an ambitious target, especially when we consider the increasing levels of global trade and travel.

The IPBES Assessment will provide the best available scientific knowledge to help countries and stakeholders understand and address this growing threat. It will identify tools and policy measures for identifying and regulating pathways of introduction and for eliminating or controlling invasive species that have already been established. Critically, the assessment will take into account different value systems and help to focus actions on priority species, pathways and sites.

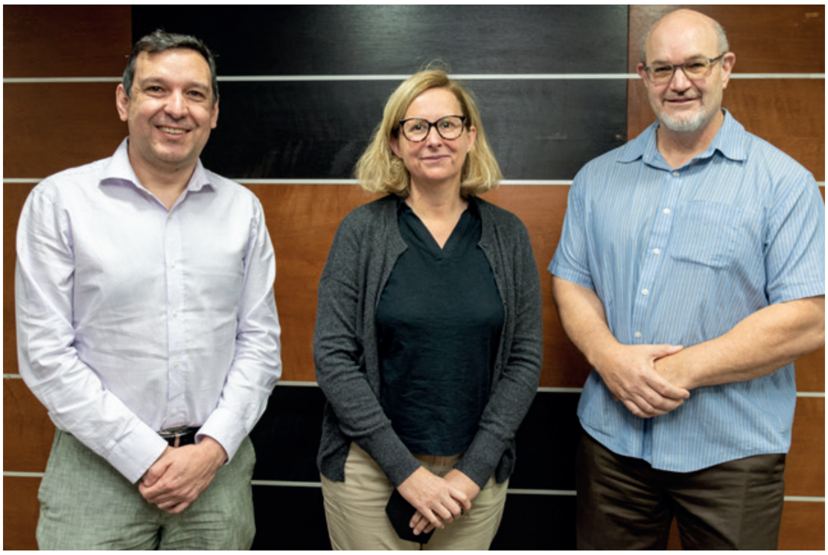
Congratulations to IPBES for this critical work. I look forward to seeing its active use by Parties and stakeholders. I believe it will be a critical resource to facilitate the urgent actions necessary to achieve Target 6 and work towards living in harmony with nature.

David Cooper
Acting Executive Secretary
Convention on Biological Diversity
(CBD)

We are indebted to the hundreds of experts, policymakers, and practitioners, including members of Indigenous Peoples and local communities, who generously contributed their time and knowledge as authors, fellows, review editors (all of them listed below) and contributing authors of the Assessment of Invasive Alien Species and their Control, as well as to the management committee who provided oversight and guidance to its development. The Assessment team has contributed thousands of hours of collaborative and voluntary work to provide the best available knowledge on invasive alien species and their control. We have all encountered various challenges, not least the COVID-19 pandemic, throughout the assessment, but the dedication, determination and commitment of everyone involved has been outstanding.

Throughout our time working on the Assessment we have benefited enormously from the invaluable advice, dedication, and constructive contributions from the IPBES secretariat, particularly from the Executive Secretary, Anne Larigauderie, and from Simone Schiele, Bonnie Myers and Hien Ngo, the IPBES Chair, Ana María Hernández Salgar, representatives of member States, and the Multidisciplinary Expert Panel (MEP) and Bureau, especially members of the management committee, Eric Fokam, Shizuka Hashimoto, Rizwan Irshad, Ruslan Novitsky, Rashad Allahverdiyev, Vinod Bihari Mathur, and Youngbae Suh. We have been honored to work with such talented people. The Invasive Alien Species Assessment would not have been possible without the phenomenal contributions and excellent guidance of our technical support unit, headed by Naoki Amako and Noriko Moriwake and supported by Ryoko Kawakami and Tanara Renard Truong during the four years of its production. These colleagues went far beyond expectations, ensuring sustained quality while being thoughtful of and responsive to the needs of the assessment process and our many authors. Further, Tanara is listed as an author on both Chapter 1 and the summary for policymakers, recognizing her incredible contributions to the knowledge and information gathered. We are extremely appreciative of her insights and leadership. We also thank Tom August, Kate Randall and Maro Haas for their skillful and experienced work on data visualization and graphic design. We hugely appreciated the many contributions from Peter Bates who also facilitated collaboration with Indigenous Peoples and local communities. We thank the IPBES communications team for their outstanding work providing expert guidance, training and support through every stage of the Assessment, to ensure the widest outreach of the main

ACKNOWLEDGEMENTS



findings of this Assessment. Indeed, the Assessment received media coverage in over 100 countries, with over 5,000 press articles, in the weeks following approval – testament to the meticulous and tireless work of the IPBES communications team.

We are also grateful to the Government of Japan, which generously hosted the technical support unit at the Institute for Global Environmental Strategies (IGES) and the first author meeting, and all the governments who nominated and supported experts. We thank Aarhus University (Denmark) and the University of Concepción (Chile) for hosting our author and/or summary for policymakers meetings. We thank the secretariat of the Convention on Biological Diversity who hosted our first dialogue on Indigenous and local knowledge in Montreal, Canada. We would especially like to acknowledge the support of our home institutions and governments: the UK Centre for Ecology & Hydrology (United Kingdom); the Faculty of Forestry Sciences, University of Concepción and Institute of Ecology and Biodiversity (Chile); and Ontario Tech University (Canada). We have appreciated the encouragement given to us from them and the value they have placed on the work we have been collaboratively leading.

Our gratitude goes to Bureau members Douglas Beard and Sebsebe Demissew Woodmatas, for co-chairing the sessions on the Assessment at the IPBES 10 Plenary (28 August – 2 September 2023, Bonn, Germany) which approved its summary for policymakers and accepted its chapters. We also thank MEP co-chairs Luthando Dziba and Shizuka Hashimoto for their roles in facilitating discussions.

We would lastly like to thank all our friends and relatives who supported us throughout this demanding assessment process. This work would not have been possible without their love, endless support and understanding.

The dedication and contributions of all those mentioned above ensured the outcome of the Assessment of Invasive Alien Species and their Control as a unique, robust and rich report. It has been a privilege to have the opportunity to collaborate with so many inspiring people, in all their many and varied roles. We are confident that the Assessment will be impactful, increasing global awareness of the significant threats to biodiversity and human communities posed by invasive alien species and, very importantly, what can be done to prevent and control them.

Aníbal Pauchard, Helen E. Roy, Peter Stoett
Co-Chairs

WE ARE GRATEFUL TO THE FOLLOWING PEOPLE WHO CONTRIBUTED TO THE IPBES ASSESSMENT OF INVASIVE ALIEN SPECIES AND THEIR CONTROL:

The coordinating lead authors, lead authors and fellows:

Authors are listed with, in parentheses, their country or countries of citizenship, separated by a comma when they have more than one; and, following a slash, their country of affiliation, if different from that or those of their citizenship, or their organization if they belong to an international organization. The countries and organizations having nominated the experts are listed on the IPBES website.

DEFINITIONS, CONCEPTS AND THE CONTEXT OF THE ASSESSMENT

The thematic assessment of invasive alien species and their control produced by the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) critically evaluates evidence on biological invasions[2] and the impacts of invasive alien species. In alignment with the United Nations Sustainable Development Goals and the Kunming-Montreal Global Biodiversity Framework adopted by the Conference of the Parties of the Convention on Biological Diversity, the assessment outlines key responses and policy options for prevention, early detection and effective control of invasive alien species and mitigation of their impacts in order to safeguard nature, nature's contributions to people, and good quality of life.

For the purposes of this assessment, the terms "native species", "alien species",[3] "established alien species", "invasive alien species", "impacts", "introduction pathways" and "drivers" are represented and defined in **Figure SPM.1**.

The term "biological invasion" is used to describe the process involving the intentional or unintentional transport or movement of a species outside its natural range by human activities and its introduction to new regions, where it may become established and spread.

Species introduced to new regions through human activities are termed alien species. Invasive alien species represent a subset of alien species, being animals, plants and other organisms known to have established and spread with negative impacts on biodiversity, local ecosystems and species. Many invasive alien species also have impacts on nature's contributions to people (embodying different concepts such as ecosystem goods and services and nature's gifts) and good quality of life.[4] Some of the most problematic invasive alien species arrive through multiple introduction pathways and repeated introduction.

Invasive alien species are recognized as one of the five major direct drivers of change in nature globally, alongside land- and sea-use change, direct exploitation of organisms, climate change, and pollution.[5] This assessment considers how biological invasions are facilitated by all those direct anthropogenic drivers, noting that interactions among invasive alien species can enable further biological invasions. The assessment also considers how biological invasions can be influenced by indirect drivers, as identified in the IPBES *Global Assessment Report on Biodiversity and Ecosystem Services:* these include demographic, economic, sociocultural and technological drivers, as well as those relating to institutions and governance. Finally, the assessment considers how biological invasions, and ultimately the impacts of invasive alien species, can be facilitated by natural drivers of change, in particular natural hazards (such as floods, storms and wildfires) and by biodiversity loss itself.

In the context of this assessment, management of biological invasions includes the development of decision support tools; prevention (supported by regulation) and preparedness planning and actions; eradication, containment and control of invasive alien species; site- and ecosystem-based management; and ecosystem restoration.

Other important concepts associated with biological invasion are defined in the glossary of the assessment report. The conceptual basis underpinning the assessment, including the IPBES conceptual framework,[6] and the methodology for reviewing literature are outlined in chapter 1 of the assessment report.

2. This assessment acknowledges that national and local legislation to address biological invasions differ between countries and may include different definitions appropriate to specific national and local contexts.
3. Multiple alternative terms exist to refer to alien species.
4. Annex III to decision IPBES-4/1.
5. IPBES (2019): *The Global Assessment Report on Biodiversity and Ecosystem Services of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services.* Brondizio, E. S., Settele, J., Díaz, S. and Ngo, H. T. (eds.). IPBES secretariat, Bonn, Germany. https://doi.org/10.5281/zenodo.3831673
6. The conceptual framework for the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services was approved by the Plenary in decision IPBES-2/4 (2013) and updated in decision IPBES-5/1 (2017).

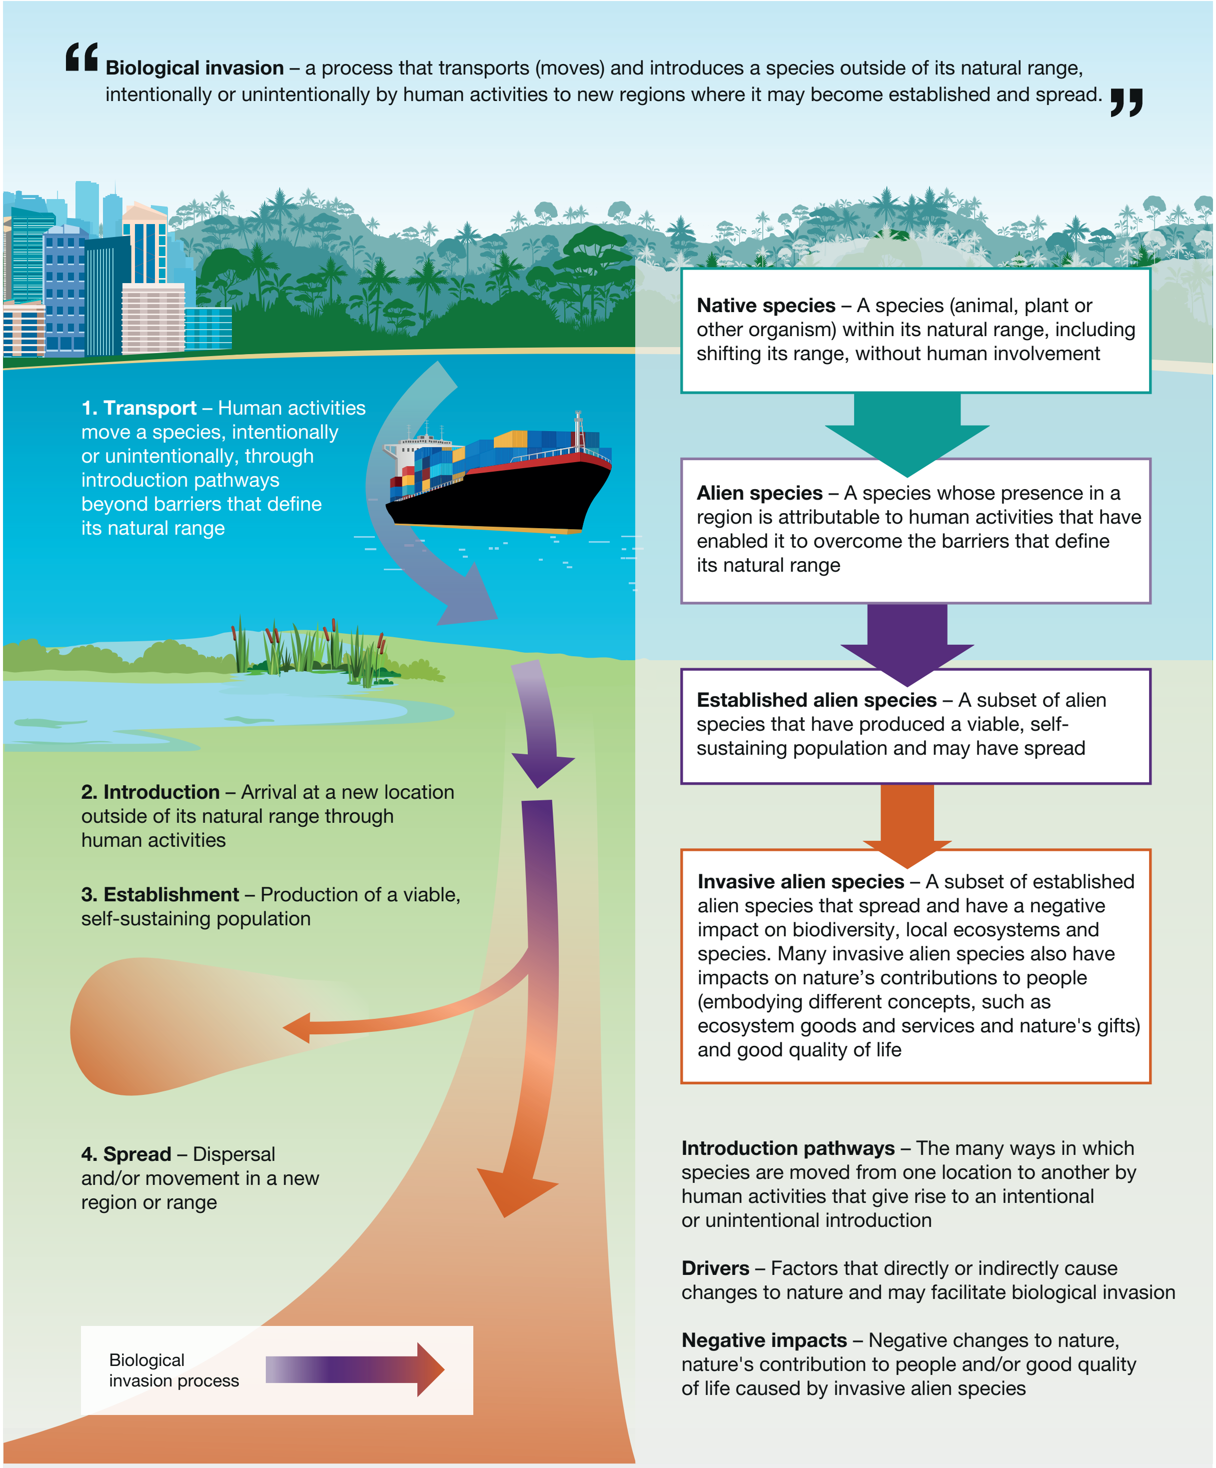

Figure SPM 1 **Key concepts within the biological invasion process.**[7]

Invasive alien species are one of the main direct drivers of change in nature. The biological invasion process comprises the following stages: transport, introduction, establishment and spread (or dispersal). Definitions of native, alien, established alien and invasive alien species are provided. Indirect and other direct drivers of change facilitate biological invasion.

7. This assessment acknowledges that national and local legislation to address biological invasions differ between countries and may include different definitions appropriate to specific national and local contexts.

KEY MESSAGES

KEY MESSAGES

A. Invasive alien species are a major threat to nature, nature's contributions to people, and good quality of life

Alien species are being introduced by human activities to all regions and biomes of the world at unprecedented rates. Some become invasive, causing negative and in some cases irreversible impacts on nature, including loss of uniqueness of biological communities, contributing to the unparalleled degree of deterioration of the biosphere upon which humanity depends.

KM-A1 People and nature are threatened by invasive alien species in all regions of Earth {A1} (Figure SPM.2). More than 37,000 established alien species have been introduced by human activities across all regions and biomes of Earth, with new alien species presently being recorded at an unprecedented rate of approximately 200 annually. Studies with evidence of negative impacts exist for more than 3,500 of these species, which are categorized as invasive alien species. The proportion of established alien species known to be invasive varies among taxonomic groups, ranging from 6 per cent of all alien plants to 22 per cent of all alien invertebrates. Twenty per cent of all impacts are reported from islands. A disproportionate number of documented negative impacts have been reported in terrestrial realms, especially in temperate and boreal forests and woodlands and cultivated areas (including agricultural land). About one quarter of documented negative impacts have been reported from aquatic realms, especially from inland surface waters/waterbodies and shelf ecosystems. In addition to their impacts on nature, about 16 per cent of invasive alien species have negative impacts on nature's contributions to people, and about 7 per cent on good quality of life.

KM-A2 Invasive alien species cause dramatic and, in some cases, irreversible changes to biodiversity and ecosystems, resulting in adverse and complex outcomes across all regions of Earth, including local and global species extinctions {A2, A3} (Figure SPM.3). Invasive alien species have contributed solely or alongside other drivers to 60 per cent of recorded global extinctions, and are the only driver in 16 per cent of the documented global animal and plant extinctions. Biotic homogenization, whereby biological communities around the world become more similar, is a major negative impact of invasive alien species, with consequences for the structure and functioning of ecosystems. Changes in the properties of ecosystems, such as soil and water characteristics, account for more than a quarter of documented impacts. The magnitude and types of impacts vary for different invasive alien species and across ecosystems and regions. The majority of documented global extinctions attributed mainly to invasive alien species have occurred on islands (90 per cent), and local extinctions account for 9 per cent of documented impacts of invasive alien species on islands. Some areas, despite being protected for nature conservation or being remote, are also vulnerable to the negative impacts of invasive alien species.

KM-A3 The economy, food security, water security and human health are profoundly and negatively affected by invasive alien species {A4, A5} (Figure SPM.3). In 2019, global annual costs of biological invasions were estimated to exceed US$423 billion. The vast majority of global costs (92 per cent) accrue from the negative impacts of invasive alien species on nature's contributions to people or on good quality of life, while only 8 per cent of that sum is related to management expenditures of biological invasions. The benefits to people that some invasive alien species provide do not mitigate or undo their negative impacts, which include harm to human health (such as disease transmission), livelihoods, water security and food security, with reduction in food supply being by far the most frequently reported impact (more than 66 per cent).

KM-A4 Invasive alien species can add to marginalization and inequity, including, in some contexts, gender- and age-differentiated impacts {A5, A6}. People with the greatest direct dependence on nature, including those involved in gender- and age-specific activities, such as fishing or weeding, may be disproportionately affected by invasive alien species. More than 2,300 invasive alien species are found on lands managed, used and/or owned by Indigenous Peoples across all regions of Earth, threatening their quality of life and often leading to general feelings of despair, sadness and stress. Indigenous Peoples and local communities, ethnic minorities, migrants, and poor rural and urban communities are disproportionately impacted by invasive alien vector-borne diseases. Biological invasions negatively affect the autonomy, rights and cultural identities of Indigenous Peoples and local communities through the loss of traditional livelihoods and knowledge, reduced mobility and access to land, and increased labour to manage the invasive alien species. Impact reports by some Indigenous Peoples and local communities document 92 per cent

negative impacts and 8 per cent positive impacts on nature caused by invasive alien species.

KM-A5 Overall, policies and their implementation have been insufficient in managing biological invasions and preventing and controlling invasive alien species {A7, A8}. Up to 2020, only partial progress was made towards international goals and targets (e.g., Aichi Biodiversity Target 9 and Sustainable Development Goal Target 15.8). While most countries have targets related to the management of biological invasions within their national biodiversity strategies and action plans, effective policies are often lacking or inadequately implemented. Eighty-three per cent of countries do not have national legislation or regulations directed specifically toward the prevention and control of invasive alien species. Policy relevant to biological invasions is also fragmented within countries and across sectors. To date, capacity to respond to biological invasions has varied widely across regions, with nearly half of all countries (45 per cent) not investing in management of invasive alien species (SDG indicator 15.8.1). Differences in perception, including conflicting interests and values, of the importance and urgency of the threat of invasive alien species, coupled with lack of awareness of the need for a collective and coordinated response, as well as gaps in data and knowledge, can hinder the management of invasive alien species. Economic development policies and those aiming to manage other drivers of change sometimes facilitate biological invasions. Demographic drivers also facilitate the introduction and spread of invasive alien species while acknowledging that drivers differ across regions and level of impact. The lack of border biosecurity (such as inspections undertaken by quarantine officers of commodities, goods and people) in one country weakens the efficacy of such measures in other countries.

B. Globally, invasive alien species and their impacts are increasing rapidly and are predicted to continue rising in the future

The threats from invasive alien species are increasing in all regions of Earth and are predicted to do so in the future. Even without the introduction of new species, existing populations of invasive alien species will continue spreading through all ecosystems. Amplification of and interactions among direct and indirect drivers of change will profoundly shape and exacerbate the future threats from invasive alien species.

KM-B1 Many human activities facilitate the transport, introduction, establishment and spread of invasive alien species {B9, B11, B12, B14}

(Figure SPM.5). Many invasive alien species have been intentionally introduced outside their natural range around the world for their perceived benefits without consideration or knowledge of their negative impacts, but there have also been many unintentional introductions, including as contaminants of traded goods and stowaways in shipments. Indirect drivers of change, particularly those associated with economic activities, of which international trade is the most important, are increasingly facilitating transport and introduction, the early stages of biological invasion. Direct drivers, particularly land- and sea-use change and climate change, are increasingly important later in the biological invasion process, facilitating the establishment and spread of invasive alien species, with fragmented ecosystems being more vulnerable to invasive alien species. Transport and utility infrastructures in terrestrial and aquatic environments can create corridors that facilitate the spread of invasive alien species, including into remote, undisturbed and protected areas. For some invasive alien species, the spread is immediate, but others only begin to spread long after first introduction, meaning that currently observed threats of invasive alien species can lead to underestimation of the magnitude of the future impact. Invasive alien species may increase in numbers after a long period at low density as a result of changes in interactions with other species, for example as a result of the introduction of a missing dispersal agent or the removal of a competitor.

KM-B2 The threats from invasive alien species are increasing markedly in all regions of Earth, with the current unparalleled high rate of introductions predicted to rise even higher in the future {B10} (Figure SPM.4). The number of alien species has been rising continuously for centuries in all regions, and the global economic costs of invasive alien species have quadrupled every decade since 1970. Even without the introduction of new species, already established alien species given the opportunity, may continue to expand their geographic ranges into new countries, regions and ecosystems, including remote environments. Under a “business-as-usual” scenario, which assumes that trends of drivers will continue as observed in the past, by 2050 the total number of alien species globally is expected to be about one-third higher than in 2005. However, the number of alien species worldwide is expected to increase faster than predicted under the business-as-usual scenario.

KM-B3 The ongoing amplification of drivers of change in nature may substantially increase the number of invasive alien species and their impacts in the future {B9, B11, B12, B14}. The causal links between indirect and direct drivers imply that ongoing and future amplification of these drivers will increase the frequency and extent of biological invasions and the impacts of invasive alien species, which, in some cases, may exacerbate the impacts of other drivers. At a global scale, the number of invasive alien species and their negative impacts are likely to increase due to the amplification of multiple drivers including but not limited to demographic, economic and land-use and sea-use change while noting regional variation. Additionally, climate change will further exacerbate the establishment of some invasive alien species and will be a major cause of future establishment and spread. Delays in the response of invasive alien species to drivers of change may result in a long legacy of future biological invasions due to past and present amplification of drivers.

KM-B4 The magnitude of the future threat from invasive alien species is difficult to predict because of complex interactions and feedback among direct and indirect drivers of change in nature {B10, B13, B14}. Climate change interacting with land- and sea-use change is predicted to profoundly shape and amplify the future threat from invasive alien species. Interactions among climate change, land-use change and invasive alien species can alter and intensify natural disturbance regimes, such as wildfires. Variations in human perceptions and values add yet another level of complexity, as sociocultural drivers interact with other indirect drivers and influence direct drivers. Such interactions may lead to unprecedented numbers of invasive alien species, with the consequent amplification of their impacts.

C. Invasive alien species and their negative impacts can be prevented and mitigated through effective management

Curbing the rising number of invasive alien species and reducing their spread and impacts are achievable through management actions in the short as well as long term. There are many decision frameworks and approaches for supporting management of invasive alien species at all stages of the biological invasion process. Prevention is the best option, but early detection, eradication, containment and control are also effective in specific contexts. Management of biological invasions benefits from engagement with stakeholders and Indigenous Peoples and local communities.

KM-C1 The number and impacts of invasive alien species can be reduced through management of biological invasions {C15, C16, C17, C18, C22, C23} (Figure SPM.6, Table SPM.1). There are decision-

making frameworks and tools for inclusively identifying and supporting management goals related to (a) management of pathways of introduction and spread of invasive alien species; (b) management of target invasive alien species at either local or landscape scales; and (c) site-based or ecosystem-based management. There are many sources of accessible literature and information, tools, and novel and emerging technologies, including biotechnology, bioinformatics, eDNA, remote sensing and data analytics, for supporting the management of biological invasions. Consideration of both potential benefits and risks of the management of biological invasions can improve outcomes. A risk assessment and a risk management framework in line with a precautionary approach, as appropriate, can be effective to guide management actions, including the use of novel and emerging and environmentally sound technologies. The success of any management programme depends on the availability of adequate, sustained resources, including for building capacity, which is sometimes lacking, especially in some developing countries. Multi-stakeholder engagement, including risk communication and context-specific application, can improve public acceptability and adoption of new tools and technologies for managing biological invasions.

KM-C2 Prevention and preparedness are the most cost-effective options and thus crucial for managing the threats from invasive alien species {C15, C17, C18}. Prevention can be achieved through pathway management, including strictly enforced import controls, pre-border, border and post-border biosecurity, and measures to address escape from confinement. Prevention is particularly critical in marine and connected water systems, where most attempts at eradicating or containing invasive alien species have mostly failed. Prevention has been particularly effective on islands. Preparedness includes border surveillance, early detection and rapid response planning, and is critical to reduce rates of establishment. Horizon scanning and risk analysis can support prevention and preparedness by prioritizing emerging invasive alien species. Sustained and adequate funding, capacity-building, technical and scientific cooperation, transfer of technology, monitoring, relevant and appropriate biosecurity legislation and enforcement, and quarantine and inspection facilities are necessary for effective prevention measures.

KM-C3 Eradication has been successful, especially for small and slow-spreading populations of invasive alien species in isolated ecosystems {C19}. Over the last 100 years, 88 per cent of eradication attempts on 998 islands have proven successful, especially for invasive alien vertebrates. Large-scale eradications have been achieved but in many cases are likely to be infeasible. There are also examples of eradication of invasive alien plants and invertebrates, particularly for those with limited distribution. Adoption of appropriate tools and technologies and involvement of relevant stakeholders underpin and improve the success of eradication programmes. Sustained investment is required for eradication programmes but they are generally more cost-effective than long term and permanent control or the costs incurred through inaction.

KM-C4 Containment and control can be an effective option for invasive alien species that cannot be eradicated for various reasons from terrestrial and closed water systems, but most attempts in marine and connected water systems have been largely ineffective {C20}. Physical control alongside chemical control options in terrestrial and closed water systems are generally only effective at a local scale and can have non-target effects. Biological control can be applied for widely distributed invasive alien species and has been successful in managing some invasive alien plants, invertebrates and, to a lesser extent, plant pathogenic microbes and vertebrates, but it may also have non-target effects if not well regulated. International standards and risk-based regulatory frameworks for biological control have been used in many countries to manage risks, and continue to be successfully applied. Integrated management, where more than one containment or control option are used, can improve outcomes.

KM-C5 The recovery of ecosystem functions and nature's contributions to people can be achieved through adaptive management, including ecosystem restoration in terrestrial and closed water systems {C21}. Management outcomes can be improved by the integration of site- and/or ecosystem-based management options that enhance ecosystem function and resilience. Frequent long-term monitoring of sites ensures early detection of invasive alien species, including re-invasions, and can inform further management actions. In marine and connected water systems, ecosystem restoration has so far proved to be largely ineffective. Adaptive management, possibly combining multiple options, will improve management of biological invasions under ongoing climate and land-use change. Integrating site and/or ecosystem-based approaches can improve management outcomes of biological invasions and also enhance ecosystem functioning under ongoing climate and land-use change.

KM-C6 Engagement and collaboration with stakeholders and Indigenous Peoples and local communities improve outcomes of management actions for biological invasions {C23, C24}. Engaging stakeholders, including the private sector, and Indigenous Peoples and local communities in the collaborative management of biological invasions is important for social acceptability and improving environmental, social and economic outcomes, particularly where there are conflicting perceptions of the value of invasive alien species and the ethics of management options. Management actions also benefit from sharing and collaboration across knowledge systems. Recognizing Indigenous Peoples' and local communities' knowledge, rights and customary governance systems in accordance with national legislation also helps to improve long-term management.

D. Ambitious progress to manage biological invasions[8] can be achieved with integrated governance

One of the greatest threats to biodiversity, invasive alien species can be overcome through a context-specific integrated governance approach to biological invasions, including well-resourced, coordinated and sustained strategic actions, with closer collaboration across sectors and countries. Managing biological invasions is realistic and achievable, with substantial benefits for nature and people.

KM-D1 Through a complementary set of strategic actions, integrated governance can limit the global problem of invasive alien species throughout the biological invasion process and at local, national and regional scales {D25}. Strategic actions to prevent the introduction and impact of invasive alien species include: enhancing coordination and collaboration across international and regional mechanisms; developing and adopting effective and achievable national strategies; sharing efforts and commitment and understanding the specific role of all actors; improving policy coherence; broad engagement across all stakeholders and Indigenous Peoples and local communities; resourcing innovation, research and technology; and supporting information systems, infrastructures and data sharing.

KM-D2 The threat of invasive alien species could be reduced with closer collaboration and coordination across sectors and countries to support the management of biological invasions {D26, D30} (Figure SPM.7). International, national and local agencies involved in developing policies for the environment, agriculture, aquaculture, fishing, forestry, horticulture, border control, shipping (including biofouling), tourism, trade (including online trade in animals, plants, and other organisms), community and regional development (including infrastructure), transportation and the health sector can all play a role in developing a coherent approach

8. This assessment acknowledges that national and local legislation to address biological invasions differ between countries and may include different definitions appropriate to specific national and local contexts.

to managing biological invasions and preventing and controlling invasive alien species. Enhancing coordination and collaboration across international and regional mechanisms is one of the key strategic actions for rapid and transformative progress. International and regional partnerships can improve management of biological invasions. Collaboration and co-development with Indigenous Peoples and local communities can increase the effectiveness of implemented strategies.

KM-D3 The Kunming-Montreal Global Biodiversity Framework provides an opportunity for national governments to develop or update aspirational, ambitious and realistic approaches to prevent and control invasive alien species {D27, D28} (Figure SPM.7). Implementation-focused national biodiversity strategies and action plans can help to spur strategic actions and establish the properties of the governance systems required for the successful prevention and control of invasive alien species and the management of biological invasions, and work towards delivering Target 6. Coordinated efforts to strengthen national regulatory instruments are also priorities, including those for online trading and the creation of appropriate policies for the development and use of environmentally sound technologies, as well as making available data and information accessible. Market-based instruments such as tax relief and subsidization can be used to incentivize action and spur relevant investment. Sharing efforts and commitment, understanding the specific roles of all actors and encouraging engagement across sectors on prevention, control and environmental liability are integral to the effective management of biological invasions.

KM-D4 Preventing and controlling invasive alien species can strengthen the effectiveness of policies designed to respond to other threats to biodiversity and contribute to achieving several Sustainable Development Goals {D26, D33}. Awareness of the risks of biological invasions will contribute to the effective delivery of several of the Sustainable Development Goals, especially those addressing the conservation of marine biodiversity (Goal 14) and terrestrial biodiversity (Goal 15, including but not restricted to Target 15.8), food security (Goal 2), sustainable economic growth (Goal 8) and sustainable cities (Goal 11), as well as climate change (Goal 13) and health and wellbeing (Goal 3). Existing collaborative and multisectoral approaches (e.g., One Health) could provide frameworks for cross-disciplinary thinking and could contribute to the management of biological invasions.

KM-D5 Open and interoperable information systems will improve the coordination and effectiveness of the management of biological invasions, within and across countries {D31, D32}. By delivering current data to relevant actors, information systems can facilitate the prioritization of actions and allow for early detection and rapid response. Information systems can also support improved governance and help develop indicators of biological invasions, which in turn feed into policy support tools. Collaboration between biological invasion experts and across knowledge systems in all regions, and enhancement of research capacity where needed, can improve data and information availability and the understanding of the context-specific features of biological invasions and their impacts.

KM-D6 Public awareness, commitment and engagement, and capacity-building, are crucial for the prevention and control of invasive alien species {D29, D31, D32} (Table SPM.2). Advances can be achieved through adequately and sustainably resourced public awareness campaigns, education, citizen science, and targeted investment in research innovation and environmentally sound technology. Public engagement with citizen science platforms and community-driven eradication campaigns can raise awareness and contribute to actions that reduce the threat of invasive alien species. This can also be aligned with efforts to share efforts and commitment and understand the specific roles of all actors. Communication strategies based on evidence can help to bring about community action on biological invasions by supporting the co-design of management actions, knowledge exchange and enhanced partnerships among stakeholders.

KM-D7 There is compelling evidence for immediate and sustained action to manage biological invasions and mitigate the negative impacts of invasive alien species {D32, D33} (Table SPM.2). With sufficient resources, political will and long-term commitment, preventing and controlling invasive alien species are attainable goals that will yield significant long-term benefits for people and nature. Increasing the availability and accessibility of information and means of implementation and addressing major knowledge gaps on biological invasions, particularly in developing countries, would result in more robust and effective policy instruments and management actions. Additional efforts and cooperation are particularly needed to improve data collection in Africa, Latin America and the Caribbean and Asia.

BACK-GROUND

BACKGROUND

A. Invasive alien species are a major threat to nature, nature's contributions to people, and good quality of life

A1 More than 37,000 established alien species, including more than 3,500 invasive alien species with documented impacts, have been recorded worldwide *(well established)* {2.1.4, 4.2}. Alien species (plants, animals, fungi and microorganisms, including pathogens) are being introduced globally at an unprecedented rate; currently, approximately 200 new alien species are recorded every year *(well established)* {2.2.1}. Invasive alien species represent a subset of alien species, consisting of those that have established and spread and are known to have a negative impact on nature and, in some cases, people **(Figure SPM.1)**. Although their numbers are likely to be underestimated and expected to increase, to date 1,061 alien plants (6 per cent of all established alien plants), 1,852 alien invertebrates (22 per cent), 461 alien vertebrates (14 per cent) and 141 alien microbes (11 per cent) are known to be invasive globally *(established but incomplete)* {4.2}. Although some invasive alien species can provide benefits for people (e.g., through provision of food and fibre), those benefits do not mitigate or undo their negative impacts on nature, nature's contributions to people, and good quality of life across all regions and taxa globally *(well established)* {1.3.4, 4.1.2, 4.3, 4.4, 4.5}. In addition to their impacts on nature, about 16 per cent of invasive alien species have negative impacts on nature's contributions to people, and about 7 per cent on good quality of life **(Figure SPM.2)** *(established but incomplete)* {4.2}. Based on data and information included in this assessment, most impacts are reported in the Americas (34 per cent), Europe and Central Asia (31 per cent) and Asia-Pacific (25 per cent), with fewer reported in Africa (7 per cent) *(established but incomplete)* {4.2}. Twenty per cent of all impacts are reported from islands *(established but incomplete)* {4.2}. A disproportionate number of documented negative impacts have been reported from the terrestrial realm (75 per cent), especially temperate and boreal forests and woodlands and cultivated areas (including agricultural land) *(established but incomplete)* {Table 4.2}. About one quarter of the documented negative impacts have been reported from aquatic realms (freshwater: 14 per cent; marine: 10 per cent), especially from inland surface waters/waterbodies and shelf ecosystems *(established but incomplete)* {Table 4.2}.

A2 Invasive alien species are a major direct driver of change, causing biodiversity loss, including local and global species extinctions (Figures SPM.2 and 3) *(well established)* {4.3.1}. Invasive alien species have contributed solely or alongside other drivers of change to 60 per cent of recorded global animal and plant extinctions *(established but incomplete)* {Box 4.4, 4.3.1}, while invasive alien species are the only driver attributed to 16 per cent of documented global extinctions *(established but incomplete)* {Box 4.4}. The majority of documented global extinctions (90 per cent) with invasive alien species as one of the major causes are reported from islands *(established but incomplete)* {Box 4.4}. At least 218 invasive alien species have caused 1,215 documented local extinctions of native species across all taxa **(Figure SPM.3)** *(established but incomplete)* {4.3.1}. Invasive alien species harm native species most often by changing ecosystem properties (27 per cent), for example soil and water characteristics, and through competition between species (24 per cent), predation (18 per cent) and herbivory (12 per cent) *(established but incomplete)* {4.3.1.3}. The majority of reports of the impacts of invasive alien species on native species document negative effects (85 per cent), primarily negatively impacting the growth, survival and reproduction of individuals, which lead to local population declines and local and global extinctions *(well established)* {4.3.1}. Some invasive alien species have a profound ecological impact that spans various levels, from individual species and communities to whole ecosystems, resulting in complex, undesirable and in some cases irreversible outcomes when the system has crossed a threshold beyond which ecosystem restoration is not possible *(well established)* {Box 1.5, Box 4.12, 4.3.3}. For example, *Castor canadensis* (North American beaver) and *Magallana gigas* (Pacific oyster) change ecosystem properties by transforming habitats, with cascading effects on a myriad of native species *(well established)* {4.3.2.1, Box 4.11}. On Christmas Island, the arrival of the invasive alien *Anoplolepis gracilipes* (yellow crazy ant) caused the decline of the native Christmas Island *Gecarcoidea natalis* (red crabs), which resulted in the population explosion of the invasive alien *Lissachatina fulica* (giant African land snail) *(well established)* {3.3.5.1}. Increased biotic homogenization (or loss of uniqueness) of biological communities is a major negative impact of invasive alien species *(well established)* {1.3.4}. The magnitude of the negative impacts of invasive alien species on nature depends on the context, and the factors that determine the highest magnitudes of impact are not well understood *(established but incomplete)* {Box 4.9, 4.3.2.1, 4.7.1}. For

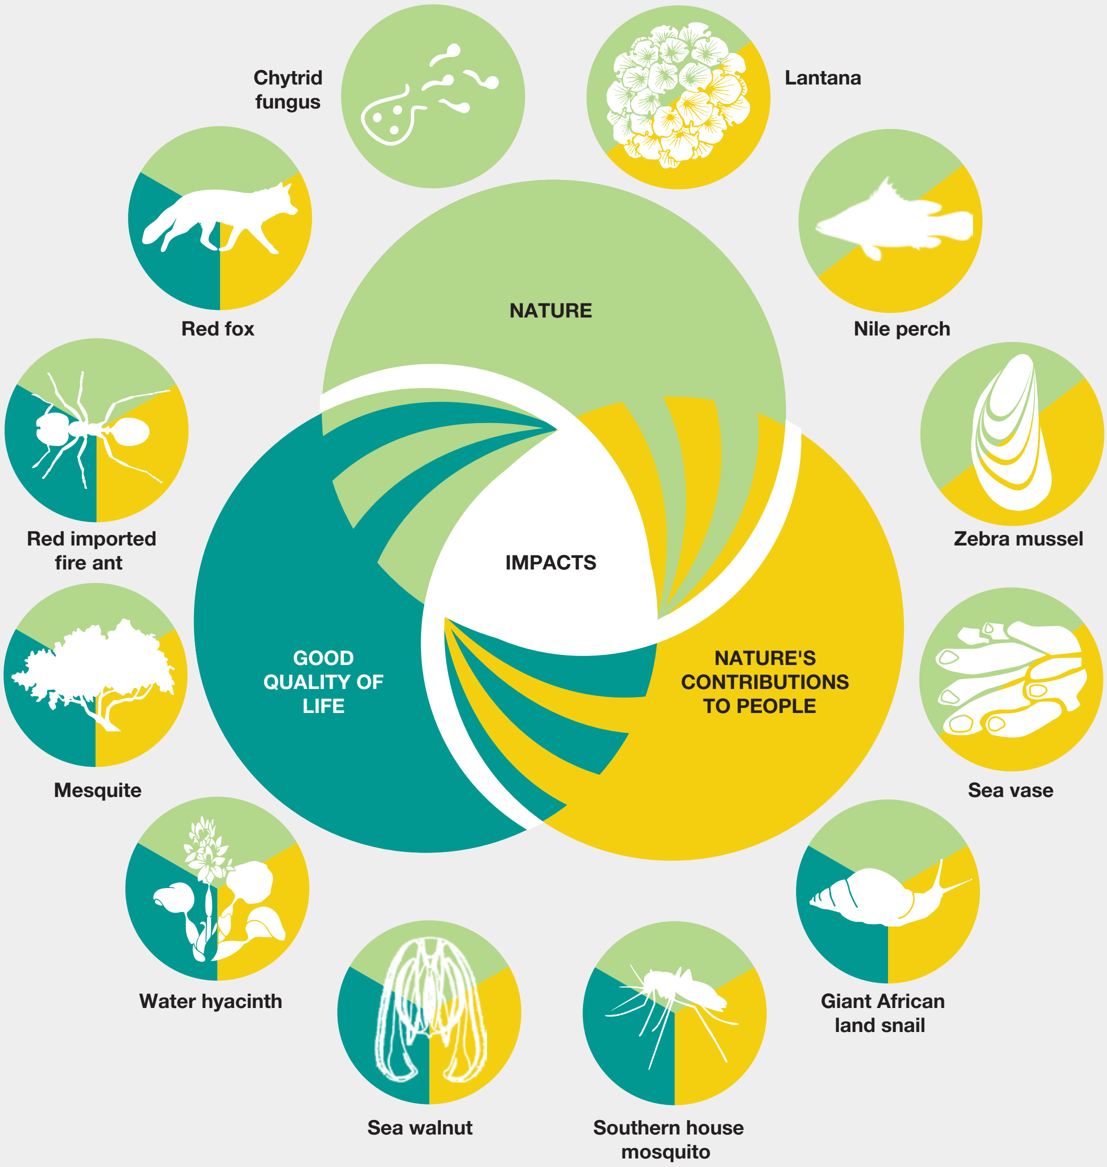

Figure SPM 2 **Examples of invasive alien species with a negative impact on nature (green), and, in some cases, nature's contributions to people (yellow) and/or good quality of life (teal).**

Many invasive alien species have documented negative cross-cutting impacts, indicated by multiple colours in the examples: 16 per cent of invasive alien species have a negative impact on both nature and nature's contributions to people; 7 per cent on both nature and good quality of life; and 5 per cent on nature, nature's contributions to people and good quality of life {4.2}. The scientific names of the example species are *Lantana camara* (lantana); *Lates niloticus* (Nile perch); *Dreissena polymorpha* (zebra mussel); *Ciona intestinalis* (sea vase); *Lissachatina fulica* (giant African land snail); *Culex quinquefasciatus* (southern house mosquito); *Mnemiopsis leidyi* (sea walnut); *Pontederia crassipes* (water hyacinth); *Prosopis juliflora* (mesquite); *Solenopsis invicta* (red imported fire ant); *Vulpes vulpes* (red fox); and *Batrachochytrium dendrobatidis* (chytrid fungus).

example, the ctenophore *Mnemiopsis leidyi* (sea walnut) has depleted zooplankton, the main food source of the anchovy, and consequently contributed to the collapse of anchovy populations in the Black Sea, but this has not occurred in the Mediterranean Sea, the Baltic Sea or the North Sea *(well established)* {4.3.2.3}.

A3 On islands, invasive alien species are a major cause of biodiversity loss *(well established)* {Box 2.5, 4.3.1.1, Box 4.4}. Islands, and particularly remote islands with high endemism, are more susceptible to impacts from invasive alien species than mainlands *(well established)* {1.6.8, 4.3.1.1}. Indeed, in addition to the majority of documented global extinctions attributed mainly to invasive alien species occurring on islands, local extinctions account for 9 per cent of documented impacts of invasive alien species on islands, in contrast to 4 per cent on mainlands *(well established)* {4.3.1.1}. For example, *Boiga irregularis* (brown tree snake) caused the global extinction of *Myiagra freycineti* (Guam flycatcher) and local extinction or serious population reduction for many other resident bird species in Guam *(well established)* {4.3.1}. Islands are also vulnerable to climate change, which can increase the rate of establishment and spread of many invasive alien species *(well established)* {Box 2.5}. Many invasive alien species on islands only occupy a small portion of their predicted range and are likely to expand further *(established but incomplete)* {Box 2.5}. The number of alien plants exceeds the total number of native plants on more than one quarter of islands *(well established)* {Box 2.5}. Invasive alien species have been reported in areas protected for nature conservation, some remote areas (e.g., high mountains), and also in tundra and deserts, which emphasizes that these areas, despite being protected for nature conservation or remote, are also vulnerable to the negative impacts of invasive alien species *(well established)* {Box 2.4, 4.3.1.2, 4.3.2.1}. Fifty-three invasive alien species have caused the local extinctions of 240 native species in protected areas globally *(established but incomplete)* {4.3.1.2}. The invasive alien *Rattus rattus* (black rat) has been documented as the only cause of the global extinction of *Nesoryzomys darwini* and *Nesoryzomys indefessus* (rice rats), which were endemic to the protected areas of the Galapagos Islands *(well established)* {4.3.1}.

A4 Invasive alien species adversely affect the full range of nature's contributions to people, imposing an economic burden *(well established)* {4.4.1}. Some alien species have been intentionally introduced for their benefits to people, often without consideration or knowledge of their negative impacts *(well established)* {3.3.1}. However, nearly 80 per cent of the documented impacts of invasive alien species on nature's contributions to people are negative *(well established)* {4.4.1}. Reduction in food supply is by far the most frequently reported impact across all taxa and regions *(well established)* {4.4.1, 4.6.2}. In terrestrial systems, invasive alien plants are the taxonomic group most frequently reported as having a negative impact, particularly in cultivated areas and temperate and boreal forests *(well established)* {4.4.2.1}. For example, in north-western Europe, *Picea sitchensis* (Sitka spruce) severely alters habitats such as coastal heathlands and mires, which are important habitats for threatened and endangered plants, birds and other species, and for local cultural heritage *(well established)* {4.3.2.1}. In coastal areas, invasive alien invertebrates are the most frequently reported taxonomic group with an impact on nature's contributions to people, particularly provision of food *(well established)* {4.4.2.3}. For example, *Carcinus maenas* (European shore crab) has had an impact on commercial shellfish beds in New England and Canada, *Asterias amurensis* (northern Pacific seastar) and *Ciona intestinalis* (sea vase) have negatively affected mariculture and fisheries along the Korean coast, and *Mytilopsis sallei* (Caribbean false mussel) has displaced native clams and oysters that are locally important fishery resources in India *(well established)* {4.4.2.3}. In 2019, global annual costs of biological invasions were estimated to exceed US$423 billion, with variations across regions, but this is likely to be a gross underestimate **(Figure SPM.3)** *(established but incomplete)* {Box 4.13}. Ninety-two per cent of this cost is attributed to the damage that the invasive alien species have caused to nature's contributions to people and good quality of life; only 8 per cent is related to the management expenditures for biological invasions *(established but incomplete)* {Box 4.13}. Economic benefits are often gained by a few people or sectors while costs, often long-term ones, are borne by many others *(established but incomplete)* {3.2.3.5, 4.2.1, 6.2.2(6)}.

A5 Invasive alien species overwhelmingly undermine good quality of life *(established but incomplete)* {4.5, 4.6.3}. Invasive alien species can threaten livelihoods, water and food security, economies and human health (e.g., causing diseases, allergies and physical injuries) **(Figure SPM.3)** *(well established)* {4.5.1, 4.5.1.3}, with 85 per cent of the documented impacts of invasive alien species on good quality of life being negative **(Figure SPM.3)** *(well established)* {4.5.1}. Invasive alien species can also serve as vectors for infectious zoonotic diseases that can lead to epidemics, such as malaria, dengue fever, chikungunya, Zika, yellow fever and West Nile fever, which are transmitted by invasive mosquito species (e.g., *Aedes albopictus* and *Aedes aegypti*) *(well established)* {Box 1.14, 4.5.1.3}. Invasive alien plants can impact human health directly, particularly through the production of highly allergenic pollen, for example, *Prosopis juliflora* (mesquite) and *Ambrosia artemisiifolia* (common ragweed) *(well established)* {4.5.1.3}. Indigenous Peoples and local communities, ethnic minorities, migrants, poor rural and urban communities are disproportionately impacted by invasive alien vector-borne diseases *(established but incomplete)* {4.5.1}. Although there is limited research on the interplay between gender relations and invasive alien species *(established but incomplete)* {4.5.1, 4.7.2}, there is some evidence of inequities and marginalization in gender- and age-specific activities where invasive alien species impede access to natural resources or require management *(established but incomplete)* {4.5.1, 5.2, 5.2.1, 5.5.5}. For example, in Lake Victoria artisanal fisheries mainly involving men have declined following the introduction, establishment and spread of the invasive alien plant *Pontederia crassipes* (water hyacinth), which has led to the depletion of tilapia *(established but incomplete)*

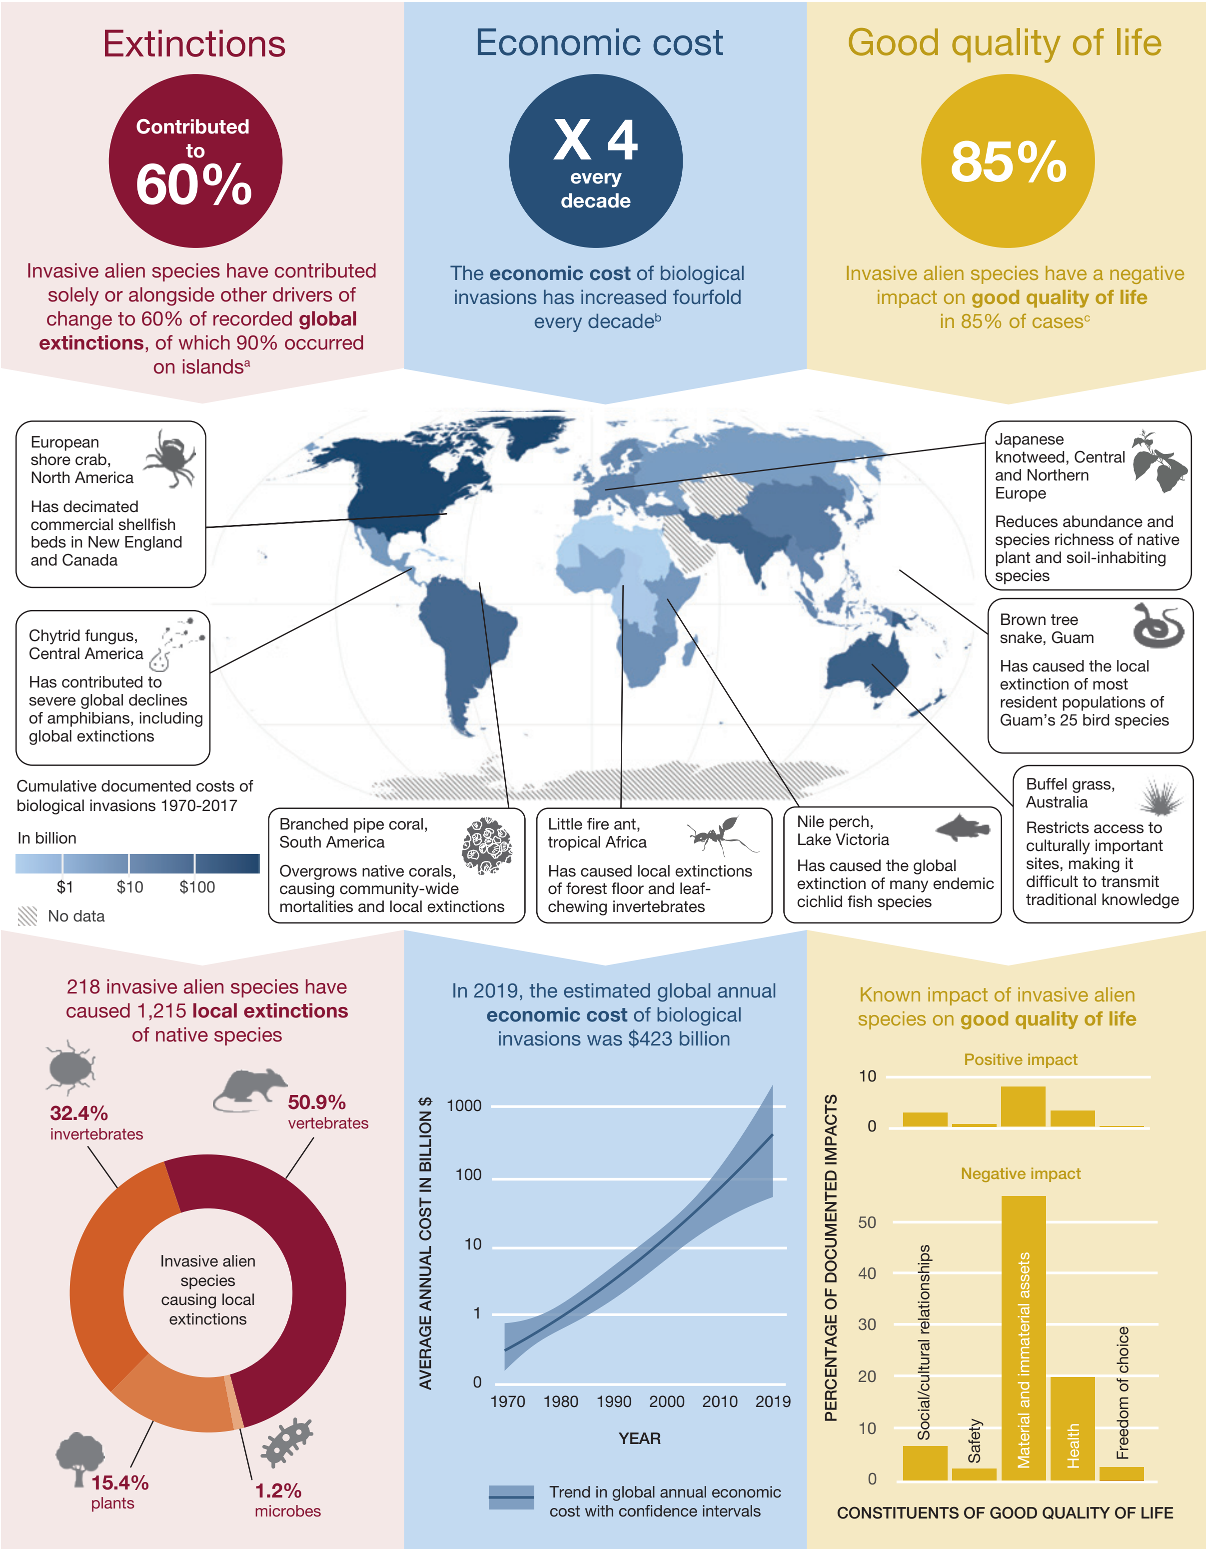

Figure SPM 3 **Extent of the problems caused by invasive alien species.**

Illustrative examples of the impacts of invasive alien species on native species (red; left column), on the economy (blue; centre column) and on good quality of life (yellow; right column). The top row illustrates the documented numbers of global and local extinctions of native species to which invasive alien species have contributed (left); the rate of increase in the economic cost of biological invasions per decade (centre); and the percentage of cases where the impact of invasive alien species on good quality of life is reported as negative (right). The map in the centre row shows the documented cumulative economic cost of invasive alien species per IPBES subregion from 1970 to 2017. The case studies illustrate a variety of impacts of invasive alien species on both nature and good quality of life in different geographic regions, taxonomic groups and realms, but are not meant to be representative. The bottom row shows the taxonomic distribution (i.e., plants, invertebrates, vertebrates and microbes, including fungi) of the percentage of invasive alien species documented as causing local extinctions of native species (left); the estimated global annual average economic cost of biological invasions in billions of United States dollars (centre); and the percentage of the number of documented positive and negative impacts of invasive alien species on the constituents of good quality of life (i.e., freedom of choice, health, material and immaterial assets, safety, social and cultural relationships) (right). a: {4.3.1, Table 4.3}; b: {4.4.1, Box 4.13}; c: {4.5.1, Table 4.20}. The scientific names of the example species are *Carcinus maenas* (European shore crab); *Batrachochytrium dendrobatidis* (chytrid fungus); *Carijoa riisei* (branched pipe coral); *Wasmannia auropunctata* (little fire ant); *Lates niloticus* (Nile perch); *Cenchrus ciliaris* (buffel grass); *Boiga irregularis* (brown tree snake); and *Reynoutria japonica* (Japanese knotweed).

{4.5.1}. In East Africa, management of the invasive alien plant *Opuntia* spp. (prickly pear) requires repeated weeding by hand, which is often undertaken by women and children and has in many cases become their most time-consuming activity *(established but incomplete)* {5.5.5}. Invasive alien species may be introduced for economic development, for example through financing large-scale infrastructures *(well established)* {3.2.5, 3.3.1.3, 3.3.1.4, Box 3.11, 3.3.1.1, 3.3.2.1.1}. In some cases, invasive alien species have been unintentionally transported and introduced through emergency relief and aid (e.g., seeds of the invasive alien plant *Parthenium hysterophorus* (parthenium weed) arrived with grain in aid shipments in several countries) *(well established)* {3.2.2.3}, increasing the risk of possible negative impacts on quality of life *(established but incomplete)* {4.5.1, 4.6.3}.

A6 Many invasive alien species have been documented on lands managed, used and/or owned by Indigenous Peoples and local communities *(established but incomplete)* {Box 2.6; 4.6}. More than 2,300 invasive alien species have been documented on lands managed, used and/or owned by Indigenous Peoples, with some negatively affecting their quality of life and cultural identities. Indigenous lands in Oceania and North America have particularly high numbers of recorded invasive alien species *(established but incomplete)* {Box 2.6}. However, numbers of invasive alien species are, on average, consistently lower on Indigenous lands compared to other lands *(established but incomplete)* {Box 2.6}. Many Indigenous Peoples and local communities emphasize the inter-relatedness of the land, water and humans and other species, which can lead to a range of diverse perceptions of specific invasive alien species *(well established)* {1.6.7.1}. In some cases, Indigenous Peoples and local communities may consider an invasive alien species a valued part of their nature *(established but incomplete)* {1.6.7.1}. There are also examples where Indigenous Peoples and local communities have created new income sources by relying on invasive alien species *(well established)* {4.5.1, 4.6.2}, but that often occurs through necessity rather than choice. However, impact reports by some Indigenous Peoples and local communities document 68 per cent negative impacts and 32 per cent positive impacts on their good quality of life caused by invasive alien species *(established but incomplete)* {4.6.1, 4.6.3.2, Table 4.33}. Indigenous Peoples and local communities often have a good understanding of how the complex interactions among drivers facilitate the introduction and spread of invasive alien species on their lands *(established but incomplete)* {3.2.3.6, Box 3.15}. For example, Indigenous Peoples and local communities recognize that the use of invasive alien species for food, fibre, income generation or medicinal purposes can cause negative impacts on nature's contributions to people and their good quality of life *(well established)* {3.2.3.6, Box 3.6}, especially in situations where the native species they traditionally depended on for those benefits have declined *(established but incomplete)* {3.2.3.6; 3.2.5}. Impact reports by some Indigenous Peoples and local communities document 92 per cent negative impacts and 8 per cent positive impacts on nature caused by invasive alien species *(established but incomplete)* {Table 4.31}. Negative impact reports include water security and human and livestock health, as well as acknowledging that invasive alien species limit access to traditional lands, reduce mobility and require increased labour to manage *(established but incomplete)* {Box 4.9, 4.5.1, 4.5.1.4, 4.6.3.1, 4.6.3.2, 5.5.5}. Invasive alien species can also adversely affect the autonomy, rights and cultural identity of Indigenous Peoples and local communities *(established but incomplete)* {Box 4.15} through the loss of traditional livelihoods, knowledge and cultural practices *(well established)* {4.6.3.2}, often leading to general feelings of despair, sadness and stress *(established but incomplete)* {4.6.3.2}.

A7 Perceptions of the threat of invasive alien species can vary depending on different human perspectives *(well established)* {1.5.2}. Perceptions of specific invasive alien species and their value differ among and within stakeholder groups and Indigenous Peoples and local communities, as different community members can experience different impacts depending on gender, age, livelihood and a multitude of other factors *(established but incomplete)* {1.5.2, 1.6.7.1, 3.2.1, 5.6.1.2}. Value conflicts arise when invasive alien species are considered to be a major threat by some stakeholders and beneficial by others *(well established)* {5.6.1.2}. An invasive alien species may

Box SPM 1 **Voluntary codes of conduct can complement legislation for managing the risks of transport and the introduction of invasive alien species through trade.**

Voluntary codes of conduct have limits, but they provide practical and concise guidance in establishing common standards of good practice and sustainable attitudes and behaviours for managing the risks of transport and the introduction of invasive alien species through trade. For example, awareness of horticulture as a major pathway for the introduction of many (46 per cent) invasive alien plants worldwide {3.2.3.2} has led to industry–government collaboration that has resulted in the implementation of voluntary codes of conduct for the horticultural industry, complementing legislation to ban the sales of invasive alien plants considered to be high risk {Box 6.6}. When designed in a collaborative manner, codes of conduct can help producers and consumers make informed choices. The adoption of voluntary codes of conduct can encourage e-commerce platforms to adopt better practices by screening their lists for invasive alien species, complying with relevant legislation and providing information on the species, including taxonomy, potential invasiveness and appropriate measures that a buyer could use to prevent escape. Codes of conduct have also been developed in Europe for other activities that can facilitate the introduction of invasive alien species, including boating, botanic gardens, horticulture, hunting, international travel, plantation forestry, pets, protected areas, e-commerce, recreational fishing, zoological gardens and aquaria.

Published in 2013 by the Council of Europe, the *European Code of Conduct for Botanic Gardens on Invasive Alien Species* outlines voluntary principles for all botanic garden personnel to support them in protecting ecosystems from the impacts of invasive alien species.

See: Heywood, V. H., & Sharrock, S. (2013). *European Code of Conduct for Botanic Gardens on Invasive Alien Species.* Council of Europe Publishing, F-67075 Strasbourg www.coe.int/Biodiversity

have been intentionally introduced for a particular purpose, including to mitigate other drivers of change *(well established)* {Box 3.9}, but can have negative impacts on other sectors *(well established)* {3.3.1.1, 3.2.5, 5.6.1.2}. For example, introduced pigs are important culturally in Hawaii and are hunted for subsistence, ceremony and recreation, despite causing severe negative impacts by driving and maintaining the spread of invasive alien plants within Hawaiian rainforest *(established but incomplete)* {5.6.1.2}. Divergence of perceptions of invasive alien species can prevent effective decision-making and management *(established but incomplete)* {5.6.1.2, 6.2.2(9)}. The management of invasive alien species can, in some cases, raise multiple ethical debates about animal welfare and rights *(well established)* {1.5.3, 5.6.2.1, Box 6.13} (e.g., the challenges of effectively managing the biological invasion of *Hippopotamus amphibius* (African hippopotamus) in Colombia due to it being considered a charismatic species *(established but incomplete)* {5.4.3.1}).

A8 Current policy instruments for biological invasions have led to only partial progress towards international Targets on invasive alien species, including Aichi Biodiversity Target 9 and Sustainable Development Goal Target 15.8 *(well established)* {6.1.2, 6.1.3}. Most countries (80 per cent, 156 out of 196) have targets for the management of biological invasions within their national biodiversity strategies and action plans, 74 per cent (145) of which are aligned with Aichi Biodiversity Target 9 *(well established)* {6.1.2}. Assessment of the progress towards meeting Aichi Biodiversity Target 9 concluded that there was still a considerable gap between the development and adoption of invasive alien species policy and implementation at national levels *(well established)* {6.1.2}. Although the number of countries with national invasive alien species checklists, including databases, has more than doubled in the last decade (196 countries in 2022) **(Table SPM.A3)** {6.1.3}, 83 per cent do not have national legislation or regulations specifically on invasive alien species *(well established)* {6.1.3}, which also increases the risk of biological invasions for neighbouring countries *(well established)* {6.3.2.1}. Only 17 per cent of countries have national legislation for biological invasions, whereas an estimated 69 per cent have biological invasions-specific legislation as part of legislation in other sectors *(well established)* {6.1.2, 6.1.3}. Although many agribusinesses do not manage the risk of the plants they trade *(established but incomplete)* {5.6.2.1}, in some cases the business sector has developed voluntary codes of conduct in tandem with government regulations **(Box SPM.1)** *(well established)* {5.4.1, 6.3.1.4(4), Box 6.7}. It should be noted, however, that voluntary codes of conduct are intended to complement, not replace, obligations within national legislation that regulate activities that transport, sell or use alien species *(well established)* {6.3.1.4(4)}. The transport of invasive alien species along trade supply chains (e.g., in shipping containers) may be poorly managed and consequently may constitute a biosecurity risk *(well established)* {5.6.2.2}. There are many reasons for the limited adoption, implementation and efficacy of policy instruments, including varying capacity and resources across regions *(well established)* {6.2.2(7), 5.6.2.2} and lack of coordination, with unclear roles and responsibilities among government agencies, stakeholders and Indigenous Peoples and local communities *(well established)* {6.2.2(3), 6.2.2(7), 6.2.3, 6.7.2.5}. Nearly half of all countries (45 per cent) do not invest in management of biological invasions (Sustainable Development Goal indicator 15.8.1) *(established but incomplete)* {6.1.3}. Lack of awareness of the need for collective and coordinated responses can also hinder implementation {6.1.1, 6.2.2(9)}.

B. Globally, invasive alien species and their impacts are increasing rapidly and are predicted to continue rising in the future

B9 Intentionally or not, many human activities facilitate biological invasions globally *(well established)* {3.1.1, 3.2, 3.3, 3.4}. The transport and introduction of an invasive alien species can be intentional or unintentional, or in some cases both *(well established)* {3.2, 3.3}. Historically, many invasive alien species have been intentionally introduced outside their natural range around the world for their perceived benefits to people, without consideration or knowledge of their negative impacts *(well established)* {3.2.1, 3.2.3, 3.3.1, 3.3.2}. For example, invasive alien species are often used in forestry, agriculture, horticulture, aquaculture and as pets *(well established)* {3.2.3.2, 3.3.1.1}.[9] In the Mediterranean basin alone, more than 35 per cent of alien freshwater fish have arisen from aquaculture *(well established)* {3.3.1.1.1}. Invasive alien species have also been intentionally introduced for recreation and amenity *(well established)* {3.2.1, 3.2.3.3} and for soil stabilization *(well established)* {3.3.1.1.2, 3.3.1.6, 3.3.4.6}. Many invasive alien species have also been introduced unintentionally, including as contaminants of soils and traded goods, stowaways in shipments *(well established)* {3.2.3.1, 3.2.3.2, 3.2.3.4}, stowaways in ballast water and sediments, and as biofouling organisms that attach themselves to ships' hulls and other surfaces on vessels *(well established)* {3.2.3.1, 3.2.5, 3.3.2.3, Box 3.7}. Additionally, online trade in animals, plants and other organisms is contributing to the introduction of invasive alien species worldwide *(well established)* {2.1.2, 3.2.4.2}. Progressive degradation of nature, including from pollution and fragmentation of ecosystems, has facilitated the establishment and spread of invasive alien species *(well established)* {3.3.1.2, 3.3.1.3, 3.3.1.5, 3.3.1.6, 3.3.3}. Demographic drivers[10] also facilitate the introduction and spread of invasive alien species, although it is acknowledged that drivers differ across regions *(well established)* {3.2.2}. In the last 50 years, the number of people in the world has more than doubled, consumption has tripled, and global trade has grown nearly tenfold, with shifting patterns across regions *(well established)* {3.1.1}. This acceleration of the world economy is increasing the rate and magnitude of many direct and indirect drivers, particularly those related to trade, travel and land- and sea-use change,[11] leading to further biological invasions *(well established)* {3.1.1, 3.2.2}.

B10 The number of alien species is rising globally at unprecedented and increasing rates (Figure SPM.4) *(well established)* {2.2.1}. Thirty-seven per cent of all known alien species have been reported since 1970

9. IUCN. 2017. *Guidance for interpretation of CBD categories on introduction pathways. Technical note prepared by IUCN for the European Commission.* Available at: https://www.cbd.int/doc/c/9d85/3bc5/d640f059d03acd717602cd76/sbstta-22-inf-09-en.pdf

10. Demographic drivers have been identified by the IPBES Global Assessment Report on Biodiversity and Ecosystem Services of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services as one of the indirect drivers of change in nature, as described in Table 3.1

11. IPBES (2022). *The Thematic Assessment Report on the Sustainable Use of Wild Species of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services.* Fromentin, J.M., Emery, M.R., Donaldson, J., Danner, M.C., Hallosserie, A., Kieling, D., Balachander, G., Barron, E.S., Chaudhary, R.P., Gasalla, M., Halmy, M., Hicks, C., Park, M.S., Parlee, B., Rice, J., Ticktin, T., and Tittensor, D. (eds.). IPBES secretariat, Bonn, Germany. https://doi.org/10.5281/zenodo.6425599

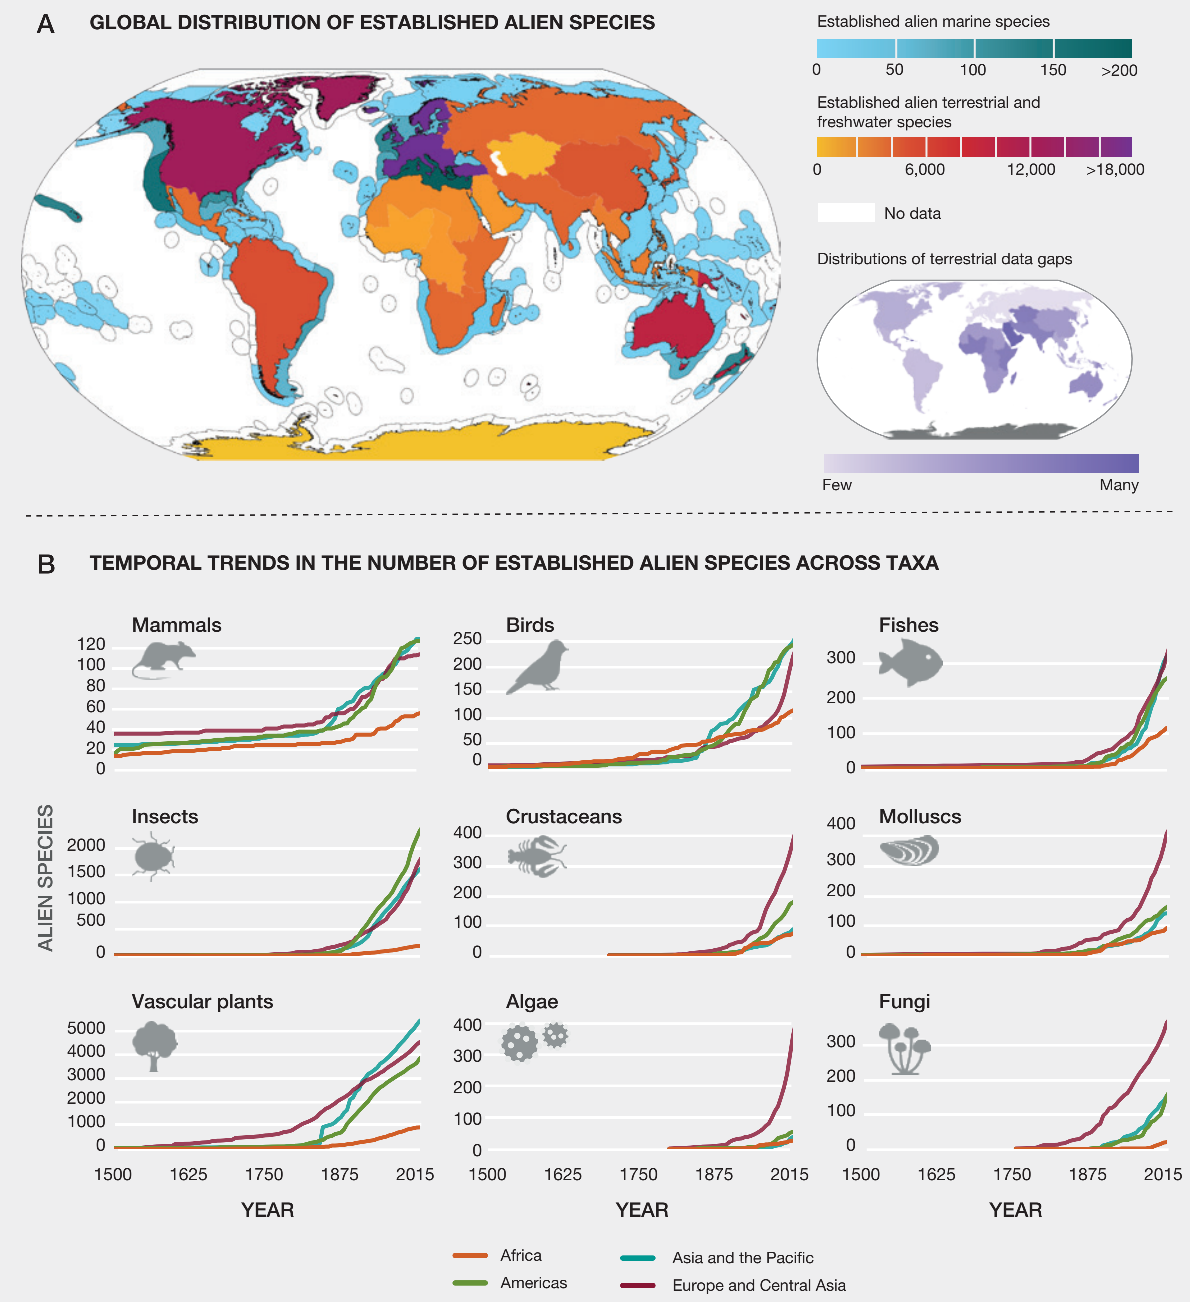

Figure SPM 4 **Global distribution and temporal trends in established alien species.**

(A) Total numbers of established alien species (terrestrial and freshwater) in the 18 IPBES subregions and marine ecoregions (marine) are indicated. White denotes missing information {2.2}. A gap analysis was conducted to identify data gaps for terrestrial regions, which are indicated in the inset {2.1.4, 2.2.3}. The data gap analysis could not be done for marine regions (white) and Antarctica (grey). **(B)** The temporal trends in the number of established alien species from 1500 to 2015 are shown for mammals, birds, fishes, insects, crustaceans, molluscs, vascular plants, algae and fungi, for the four IPBES regions {2.1.4, 2.4.1}.

(Figure SPM.3) *(established but incomplete)* {2.2.1}. The number of alien species has been rising continuously for centuries in all regions *(well established)* {2.2.1} and is expected to continue increasing in the future *(well established)* {2.6.1}. Global exploration and colonialism beginning in 1500, with the associated movement of people and goods, and industrialization from 1850 resulted in the transport and introduction of alien species and were historically important. Increases in global trade since 1950 have resulted in unprecedentedly high and increasing numbers of alien species being introduced **(Figure SPM.4)**. Some of these have become invasive *(well established)* {2.1, 3.2.3}. Even without the introduction of new species, given the opportunity, many already-established alien species in a region may continue to expand their geographic ranges and spread into new countries and regions *(well established)* {2.6.1}, including into remote environments such as mountain, polar (i.e., Antarctica and the Arctic) and desert ecosystems *(well established)* {2.5.2.8, 2.5.2.7, Box 2.7, Box 3.11}. Under a "business-as-usual" scenario, which assumes the continuation of past trends in drivers, the total number of alien species is projected to further increase globally, and by 2050 is expected to be approximately 36 per cent higher than in 2005 *(established but incomplete)* {2.6.1}. As trends in major drivers are predicted to accelerate in the future *(well established)* {3.1.1}, the number of alien species worldwide is expected to increase faster than predicted under the "business-as-usual" scenario *(established but incomplete)* {2.6.1}. There is a lack of quantified projections for invasive alien species under different scenarios **(Table SPM.A1)**, which impedes a comparison of trends for alternative futures *(well established)* {2.6.5}. Projections of long-term trends for invasive alien species numbers are not available but they are expected to be similar to those for established alien species *(established but incomplete)* {2.2.1}. The documented global economic cost of biological invasions has increased fourfold every 10 years since 1970 **(Figure SPM.3)** and is anticipated to continue rising *(established but incomplete)* {Box 4.13}.

B11 The increase in the transport and introduction of invasive alien species worldwide is primarily influenced by economic drivers, especially the expansion of global trade and human travel (Figure SPM.5) *(well established)* {2.1.2, 3.1.1, 3.2.3}. There has been a fivefold increase in the size of the global economy over the last 50 years *(well established)* {3.1.1}. International trade, which has increased nearly tenfold over the same period, represents the most important pathway through which invasive alien species are transported worldwide **(Figure SPM.5)** *(well established)* {3.1.1, 3.2.3.1}. There is a strong link between the volume of commodity imports and the number of invasive alien species in a region, and patterns in the global spread of species mirror shipping and air traffic networks *(well established)* {3.2.3.1}. The construction of shipping canals (e.g., Suez, Panama) has connected previously separated marine and freshwater regions, facilitating the spread of invasive alien species through species migration, ballast water transfers **(Box SPM.2)** and biofouling *(well established)* {3.2.3.1, 3.3.1.3}. For example, 150 years after the opening of the Suez Canal, marine alien species are still being newly recorded in the Mediterranean Sea *(well established)* {Box 3.7}. Biosecurity measures at international borders have not kept pace with the growing volume, diversity and origins of global trade (including e-trade) and travel *(well established)* {3.2.4.2, 3.2.3.4, 5.6.2.2}. Projected growth in international trade and the movement of people, including tourism, will lead to further pressure on border inspection regimes and could soon overwhelm the biosecurity capability of most countries *(well established)* {3.2.3.1, 6.3.1.4}.

B12 Accelerated establishment and spread of invasive alien species within countries are primarily driven by direct drivers, notably changes in land- and sea-use (Figure SPM.5) *(well established)* {2.2.1, 3.3.1, 3.6.2}. Land- and sea-use changes may increase the vulnerability of natural ecosystems to the establishment and spread of invasive alien species through increasing fragmentation and habitat disturbance, for example by changing grazing, fire regimes, soil disturbance, or watershed flow *(well established)* {3.3.1.2, 3.3.1.5}. Transportation and utility infrastructures such as roads, tracks, railways, pipelines, canals and bridges, among others, can create corridors that facilitate the spread of invasive alien species, including into remote, undisturbed and protected areas *(well established)* {3.3.1.3, Box 2.7, Box 3.7}. Marine and aquatic infrastructure may alter seascapes and the functioning of marine ecosystems, facilitating the spread of invasive alien species *(established but incomplete)* {3.2.2.4, 3.3.1.4, 5.6.1.4}. The numbers of invasive alien species were reported to be 1.5 to 2.5 times higher on pontoons and pilings than on natural rocky reefs *(established but incomplete)* {3.3.1.4}. More generally, land-use change can facilitate biological invasions through alteration of processes that cause natural disturbance of landscapes, such as wildfire or grazing regimes *(established but incomplete)* {3.3.1.5}. In several regions of the world, grazing by feral alien ungulates (horses, camels, buffalo, pigs) facilitates the spread of invasive alien plants, sometimes through complex species interactions involving the suppression of native species and the facilitation of other alien species *(well established)* {3.3.1.5.1}. As a specific example, invasive alien ungulates (wild boar, deer) can transport invasive ectomycorrhizal (root associated symbiotic) fungi, which are beneficial for the establishment and spread of alien pine trees, over long distances, rendering habitats susceptible to pine invasion *(well established)* {Box 3.10}. Climate change, along with the continued intensification and expansion of land-use change may lead to future increases in the establishment and spread of invasive alien species in disturbed habitats and in nearby natural habitats *(established but incomplete)* {3.3.4}.

B13 No driver acts in isolation, and interactions among drivers are amplifying biological invasions, leading to outcomes that can be difficult to predict *(well established)* {2.6.1, 3.1.5, 3.5}. The outcomes of interactions among multiple drivers, including feedback, are complex and varied *(well established)* {1.3.3, 3.1.5, 3.5}. Some of the highest current rates and greatest magnitudes

Box SPM 2 **The International Convention for the Control and Management of Ships' Ballast Water and Sediments: an example of international collaboration to prevent biological invasions.**

Many invasive alien species have been introduced to coastal and inland water ecosystems globally through ballast water discharges {3.2.3.1}. For example, following its introduction its introduction *via* ballast water discharge, *Dreissena polymorpha* (zebra mussel) has become widespread in the Great Lakes of North America {Box 2.9}. *Dreissena polymorpha* has been implicated in the transfer of botulinum toxin to higher trophic levels, which has been further facilitated by climate change, specifically by increased water temperatures, leading to mortality of waterfowl in the Great Lakes {Box 4.5}. Furthermore, the shells of *Dreissena polymorpha* can cause skin injuries to recreational swimmers and commercial fishers {Box 4.15}. The International Maritime Organization has developed an international instrument to address the transfer of harmful aquatic organisms and pathogens in ballast water of maritime vessels {5.5.1}. The International Convention for the Control and Management of Ships' Ballast Water and Sediments was adopted by the International Maritime Organization in 2004 and came into force in 2017 {5.5.1}. It is the first international legally binding legislation requiring ships to manage their ballast water so that aquatic organisms and pathogens are eliminated before the ballast water is released in a new location {3.2.3.1, 5.5.1, 6.1.3, 6.31}. While the global efficacy of ballast water management cannot be assessed yet, there is evidence that it has reduced invasive alien species introductions in the Great Lakes of North America {5.5.1}: between 1959 and 2006, one new alien species was discovered every seven months, but there was an abrupt shift (85 per cent decline) in the number of newly established alien species following the implementation of the ballast water regulations by Canada and the United States of America in 2006 and 2008 respectively {Box 2.9}.

Dreissena polymorpha (zebra mussel) was introduced through ballast water discharge in the Great Lakes of North America, causing a negative impact on nature, nature's contributions to people, and good quality of life.

of biological invasion occur where land-use change interacts with one or more additional drivers *(established but incomplete)* {3.5.1, 3.5.2, 3.5.3}. For example, interactions among land-use change, climate change and nutrient pollution have driven the introduction, establishment and spread of *Pontederia crassipes* (water hyacinth) across Africa *(well established)* {Box 3.12}. Extraction of natural resources is closely linked with major economic and demographic drivers and can lead to a range of wider ecosystem impacts, including habitat degradation and loss, which facilitates invasive alien species *(well established)* {3.3.2, 3.4.2}. Climate change is predicted to lead to major changes in land- and sea-use and, in some regions, in human migration patterns *(established but incomplete)* {3.3.4}, but also to more extreme events among natural drivers, such as droughts, floods, wildfires, tropical storms and oceanic storm waves *(established but incomplete)* {3.3.4.3}. Additionally, invasive alien plants, especially trees and grasses, can sometimes be highly flammable and therefore promote more intense and frequent fire regimes, causing increased risks to nature and people and increased carbon release into the atmosphere *(well established)* {Box 1.4}. Climate change is also predicted to enhance the competitive ability of some invasive alien species and to extend areas suitable for them thus offering new opportunities for introductions and establishment *(established but incomplete)* {3.3.4}. Invasive alien species can facilitate the establishment and spread of other invasive alien species, resulting in positive feedback that increases impacts through a process known as "invasional meltdown" *(well established)* {3.3.5.1}. Biodiversity loss can reduce the resilience of ecosystems to invasive alien species, with

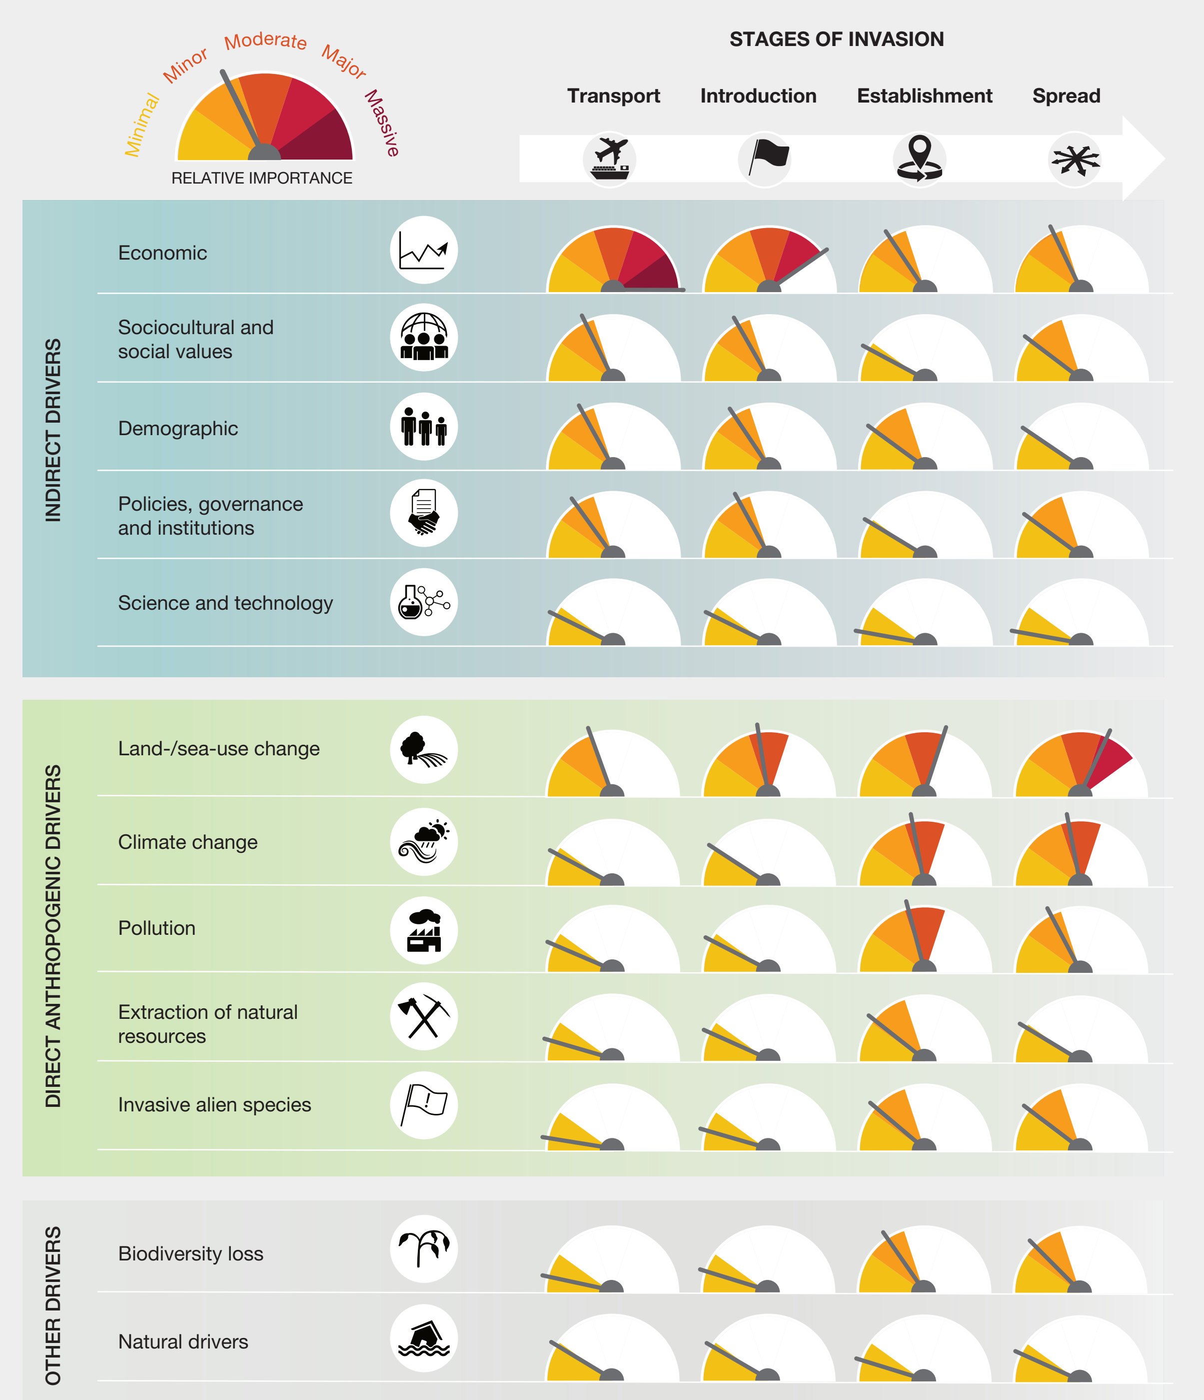

Figure SPM 5 **Relative importance of different drivers of change in nature in facilitating biological invasions across biomes per different stages of the biological invasion process (transport, introduction, establishment and spread), as determined through expert assessment, based on the evidence in chapter 3 {3.6.2}.**

These estimates are summarized across ecosystems and terrestrial biomes at the global scale. Drivers are classified according to the IPBES conceptual framework as direct or indirect drivers {3.1.3, Table 3.1}. Additionally, other drivers are included, namely biodiversity loss and natural drivers, as they can increase native ecosystem vulnerability or in other ways facilitate biological invasions {3.1.3}. Note that the role of invasive alien species as a driver refers to their role in facilitating other invasive alien species {3.3.5} and that this analysis focuses on the unintended consequences of policies, governance, institutions and technologies in facilitating biological invasions {3.2.4, 3.2.5}. The relative importance of drivers for each stage of the biological invasion process accounts for multiple, interacting, and non-additive effects of drivers, with differences in the overall importance of drivers across stages. While all drivers can potentially influence each biological invasion stage, indirect drivers, particularly those associated with economic growth, are more important in facilitating the transport and introduction stages {3.6.2}. In contrast, direct drivers, particularly land- and sea-use and climate change, are proportionally more important in facilitating the later stages of biological invasion {3.6.2}.

subsequent feedback facilitating the establishment and spread of other invasive alien species *(well established)* {3.4.2}. Indirect drivers also interact with one another. For example, sociocultural changes may lead to increased rates of infrastructure development through urbanization, and these interactions may further influence the rate and magnitude of change in land- and sea-use and other direct drivers that may in turn facilitate biological invasions *(well established)* {3.2.1}. Feedback and non-linear relationships among interacting drivers are likely to be exacerbated with ongoing and concurrent amplification of drivers *(established but incomplete)* {3.1.1, 3.5, 3.6.3, Box 4.5}, potentially leading to numbers of invasive alien species never previously encountered *(established but incomplete)* {2.6.1}.

B14 **Negative impacts of invasive alien species can occur long after first introduction, and currently observed threats from invasive alien species can lead to an underestimation of the magnitude of the future impact *(well established)* {1.4.4, 2.2.1}.** There are often time lags in detection and reporting of newly introduced invasive alien species *(well established)* {2.2.1}. Some invasive alien species spread very rapidly, while others take longer to spread and fully occupy their potential ranges *(well established)* {2.2.1, 2.2.3}. For some invasive alien species, the impact is immediate and continues into the long-term (e.g., fast-spreading pathogens such as Zika virus and *Batrachochytrium dendrobatidis* (chytrid fungus), and fast-spreading predators such as lionfish), while for others there may be a considerable time lag, spanning decades in some cases, before the impact is apparent (e.g., many invasive alien trees) *(well established)* {1.5}. Such time lags can lead to people not perceiving the ongoing slow changes in their environment, including the impacts of invasive alien species *(well established)* {1.5.2}. There can also be significant time lags in the response of invasive alien species to various drivers because the underlying processes that facilitate biological invasions operate at varying temporal scales (short- to long-term) *(well established)* {1.5, 3.2.3.1, 3.6.3}. Invasive alien species may increase in numbers after a long period at low density as a result of changes in interactions with other species, for example as a result of the introduction of a missing dispersal agent or the removal of a competitor (3.3.5.1). For example, in the western United States, the invasive alien *Carcinus maenas* (European shore crab) reduced the abundance of a native clam, releasing another alien species, *Gemma gemma* (the amethyst gem clam), from competition, allowing it to become superabundant and to spread, after having been locally distributed and at low abundance for over 50 years *(well established)* {3.3.5.1}. Patterns in the numbers of alien species seen today reflect the drivers of decades ago (i.e., invasion debt) *(established but incomplete)* {3.1.1, 3.1.5}. Consequently, past and ongoing amplification of drivers may lead to a long legacy of future invasive alien species as, for example, the number of new alien species that become invasive increases over time (i.e., invasion debt) *(established but incomplete)* {2.3.1.5, 3.1.5, 3.6.3}.

C. Invasive alien species and their negative impacts can be prevented and mitigated through effective management

C15 **Management of invasive alien species has been successful in many contexts (Figure SPM.6, Table SPM.1) *(well established)* {5.5.1, 5.5.2, 5.5.3, 5.5.4, 5.5.5, 5.5.6}.** There are three options for preventing or reducing the number and negative impacts of invasive alien species:

- Pathway management, based on the analysis of pre-border, border and post-border risks, can prevent the movement and spread of invasive alien species through surveillance and the implementation of biosecurity response measures *(well established)* {5.3.1.1, 5.5.1, 5.5.2}.
- Species-based management at a local or landscape level, which includes surveillance, early detection and rapid response, eradication, containment and widespread control (including biological control), and can be applied throughout the biological invasion process *(well established)* {5.3.1.2, 5.5.2, 5.5.3, 5.5.4, 5.5.5}.
- Site- or ecosystem-based management, which can both protect and restore native species and ecosystems *(well established)* {5.3.1.3, 5.5.6}.

The use of individual species-based and site-based approaches for the management of multiple invasive alien species has been both successful and cost-effective for terrestrial and closed water systems, especially in biogeographically isolated areas such as small islands and lakes *(well established)* {5.3.1, 5.3.2, 5.5.4}. While some management approaches can be applied at multiple scales across terrestrial and closed water systems *(well established)* {5.1.1, 5.3.1.4.}, pathway management (e.g., ballast water and biofouling; **Box SPM.2**) is by far the

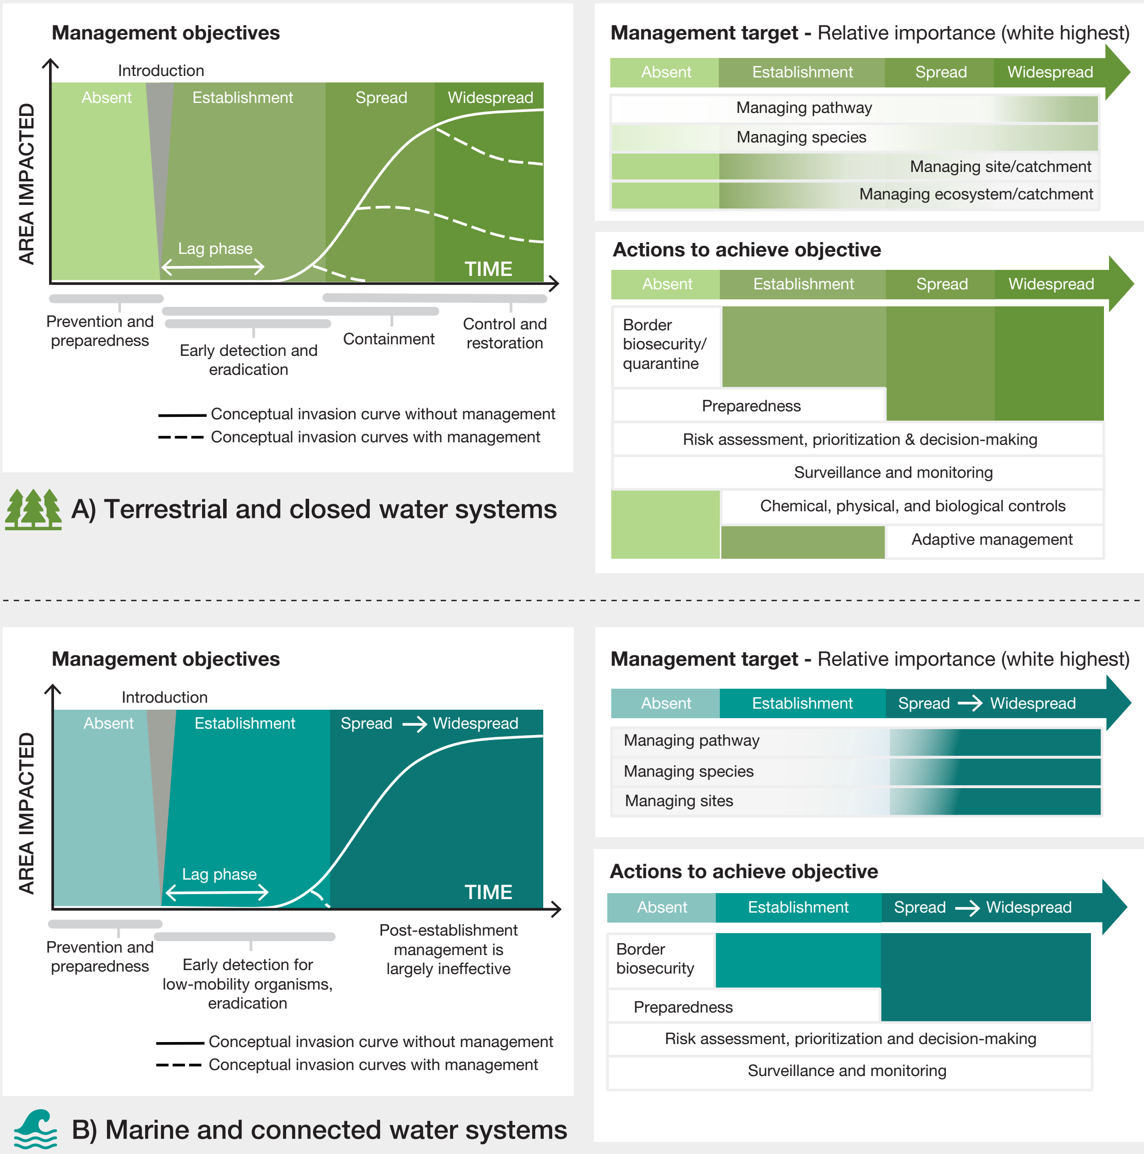

Figure SPM 6 **Conceptual diagram of management–invasion continuum.**

Management objectives panels A and B show the generalized invasion curve without management and the expected changes in the trajectory of the invasion curve with appropriate management actions in (A) terrestrial and closed water systems (including lakes and coastal systems such as salt marshes) and (B) marine and connected water systems (including rivers). Post-establishment management actions (such as containment and control) are not shown in panel B as they are generally not achievable in such systems. In a management context, the first detection (introduction point), lag phase and exponential spread phase are important points at which to implement an early detection and rapid response management plan. This figure is conceptual, and the curves do not represent actual population dynamics of invasive alien species. In the **Management target** panels, the white boxes indicate the optimal management options at each stage of the biological invasion process. The colour gradient of the managing pathway, managing species, managing site and managing ecosystem boxes show how the relative importance of each changes as a biological invasion progresses (managing ecosystems is not applicable in marine and connected water systems). In the **Actions to achieve objective** panels, the white boxes indicate the typical management actions needed to achieve each management objective.

Table SPM 1 **Objectives and actions for managing biological invasions.**

Objectives and actions for managing biological invasions within terrestrial and closed water systems or marine and connected water systems and the level (high, medium, low) of their (a) current availability (availability of target-specific tools for implementing management); (b) ease of use (ease of implementation or specialist or technological expertise to implement); and (c) effectiveness (likely long-term efficacy and outcomes of implementation). Hashed boxes indicate responses with a low level of confidence and crossed boxes indicate there was no data available to perform an assessment. Actions are aligned with **Figure SPM.6** and encompass pathway management, species-, site- and ecosystem-based management targets. All management approaches may have non-target impacts, as indicated by superscript a.

OBJECTIVES	MANAGEMENT ACTIONS	TERRESTRIAL AND CLOSED WATER SYSTEMS			MARINE AND CONNECTED WATER SYSTEMS		
		Current availability	Ease of use	Effectiveness	Current availability	Ease of use	Effectiveness
Prevention and preparedness	Horizon scanning	High	Medium	High	Medium	Medium	Low

Column values

High Medium Low

most effective option for managing biological invasions in marine and connected water systems, and can be achieved by enhanced international and regional cooperation *(well established)* {5.5.1, 6.3.2.2}.

C16 There are effective decision-making frameworks and tools that can support management of biological invasions (Table SPM.1) *(well established)* {5.2.1, 5.2.2}. Frameworks and tools have been developed based on evidence from practice, science and other knowledge systems, including those of Indigenous Peoples and local communities. These can underpin impact assessment, monitoring and prioritization of intentional and unintentional introduction pathways, species and sites for the successful management of biological invasions *(well established)* {5.2.2}. Although many knowledge and data gaps exist **(Table SPM.A1)**, the tools enable management actions to proceed under a risk assessment and risk management framework in line with a precautionary approach, as appropriate, using inclusive decision-making that leads to the review of all the measures *(well established)* {5.2.2.1, 5.2.2.3, 5.2.2.4, 5.3.3, 6.4.1}. Decision-making may be challenged by multiple sources of uncertainty, such as projections in other drivers of change, which can be recognized, quantified and documented to contextualize decisions *(well established)* {5.6.2.5}. Many sources of accessible literature and information (including open-access data), analytical tools and other types of knowledge can be used to support decision-making for all countries, which could lead to coordinated management outcomes globally **(Table SPM.A3)** *(established but incomplete)* {6.6.1.5}.

C17 Preventing the introduction of invasive alien species is the most cost-effective management option (Figure SPM.6) *(well established)* {5.5.1}. Prevention measures through pathway management, including strictly enforced pre-border quarantine, import controls and border biosecurity, have increased interception rates and slowed the rate of invasive alien species arriving and establishing globally *(well established)* {5.4.3.1, 5.5.1}. For example, in Australasia, the number of interceptions of *Halyomorpha halys* (brown marmorated stink bug), recognized as a major threat in the agricultural sector, have declined following implementation of a systems-based pathway management approach *(well established)* {5.5.1}. Measures to address escape from confinement are also necessary *(established but incomplete)* {5.3.1.1}. It is, however, difficult to prevent further natural dispersal of invasive alien species from a previously invaded range *(well established)* {5.5.1, Box 1.6}. Prevention is important on islands and in ecosystems where eradication poses significant technical challenges *(well established)* {5.3.2}. Effective prevention measures depend on adequate and sustained funding, capacity-building, technical and scientific cooperation, transfer of technology, monitoring, and relevant and appropriate biosecurity legislation and enforcement, which is supported by strong infrastructure, quarantine and inspection facilities, including diagnostic support services *(well established)* {5.4.2, 5.6.2, 5.6.2.2, 5.7}. Risk assessment could be used by businesses to engage different sectors in the prevention and management of biological invasions *(established but incomplete)* {5.6.2.1}. Adoption of regulated species lists with explicit prohibition of or permission for the importing of specific alien species, underpinned by risk analysis, has been an effective prevention strategy *(well established)* {5.6.2.1, 6.3.1.4}. It is estimated that nearly 70 per cent of marine invasive alien species established worldwide were introduced *via* biofouling *(established but incomplete)* {5.5.1}.

C18 When prevention fails or is not possible, preparedness, early detection and rapid response are effective at reducing rates of invasive alien species establishment in terrestrial and closed water systems, and critical for marine and connected water systems *(well established)* {5.4.2, 5.5.1, 5.5.3, 5.5.2, 5.6.3.3}. Horizon scanning and risk analysis are examples of the many decision-support tools used to identify and prioritize emerging invasive alien species to support preparedness *(well established)* {5.2}. Such tools can inform the development of rapid response plans in advance of an incursion to guide action effectively following the detection of priority invasive alien species *(well established)* {5.2.2.1.a, 5.2.2.1.b, 5.5.1}. Early detection of invasive alien species can enable rapid intervention to contain and eradicate invasive alien species before they spread *(well established)* {5.1.1, 5.3.1.1, 5.5.2}. General surveillance strategies (e.g., through citizen science, sentinel sites, and remote sensing) for detecting new invasive alien species can also underpin effective preparedness *(established but incomplete)* {5.3.1.1, 5.4.2.1.a, 5.4.2.2.a, 5.5.2, Box 6.20}. For example, in Africa, Asia and Latin America, the PlantwisePlus programme assists smallholder farmers with the identification of pests and damaged crops, contributing to early detection of invasive alien species outbreaks *(well established)* {5.5.2}.

C19 Eradication has been successful and cost-effective for some invasive alien species, especially when their populations are small and slow-spreading in isolated ecosystems such as islands *(established but incomplete)* {5.5.3}. Over the last 100 years, there have been 1,550 documented examples of eradication on 998 islands, with success cited in 88 per cent of cases *(well established)* {5.5.3}. One of the many examples is French Polynesia, where *Rattus rattus* (black rat), *Felis catus* (cat), *Oryctolagus cuniculus* (rabbit) and *Capra hircus* (goat) have been successfully eradicated *(well established)* {Box 5.8}. Eradication of invasive alien plants is particularly difficult because of the longevity of dormant seeds that can persist in soil (i.e., soil seed bank), although there are examples of successful eradication of invasive alien plant species with limited distributions *(well established)* {5.5.3}. Also, rapid response to incursions, detected early, of some invertebrates have been successful, for example, eradication of *Solenopsis invicta* (red imported fire ant) in New Zealand *(well established)* {Box 5.14}. There are examples of larger-scale eradications, such as *Ondatra zibethicus* (muskrat) and *Myocastor coypus* (coypu) from the United Kingdom *(well established)* {5.5.3}. However, large-scale eradications are difficult and unlikely to be feasible in many cases *(well established)* {5.5.3}. In addition to the extent of the area invaded, the success of eradication programmes depends on the support and engagement of relevant stakeholders and Indigenous Peoples and local communities *(well established)* {5.4.2.2.a, 5.5.3, 5.6.2.1, 5.6.2.2}. Eradication programmes are aided by a rapid flow of information on the extent and location of invasive alien species, which can be provided by people who live nearby *(well established)* {5.4.2.2.a, 5.5.3}. Evidence suggests that there have been no fully successful eradication programmes for established invasive alien species in marine ecosystems *(well established)* {5.5.3}. While eradication programmes can only be achieved with access to upfront cost, they are generally cheaper than long-term and permanent control cost and impacts *(well established)* {5.5.3}.

C20 When eradication is not possible for different reasons, invasive alien species can be contained and controlled, particularly in terrestrial and closed water systems *(well established)* {5.4.3, 5.4.4, 5.5.4, 5.5.5}. There are many examples of successful containment and control of invasive alien species in terrestrial and closed water systems and aquaculture (e.g., containment of *Styela clava* (Asian tunicate) invading the aqua-cultured blue mussel in Canada) *(well established)* {5.5.4}, but most attempts in marine and open water ecosystems have been largely ineffective *(established but incomplete)* {5.5.4, 5.5.5}. Containment of invasive alien species can be achieved with physical, chemical and biological control actions or in combination **(Table SPM.1)** *(well established)* {5.4.3.2, 5.5.4}. Physical and chemical control options are mostly effective at a local scale but can also be effective at larger scales; these control options are limited by labour costs and generally provide short-term suppression but not sustained control *(well established)* {5.4.3.2.a}. Furthermore, chemical control may have non-target impacts, needs to be implemented under regulatory compliance requirements and has decreasing societal acceptability *(well established)* {5.4.3.2.b}. Biological control has been very effective in controlling some invasive alien plants, invertebrates and, to a lesser extent, plant microbes and a few invasive alien vertebrates, but it may have non-target impacts if not well regulated *(well established)* {5.5.5.3}. To reduce the risks of unintended consequences, including non-target impacts, from biological control, international standards and risk-based regulatory frameworks (developed under the International Plant Protection Convention) have been applied and continue to be effective across many countries *(well established)* {5.5.2}. The use of biological control for invasive alien plants and invertebrates has been successful in more than 60 per cent of documented cases **(Box SPM.3)**, with one third of the alien plant species requiring no further form of control, while also leading to benefits to biodiversity and ecosystem resilience *(well established)* {5.5.5.3}. Classical biological control to suppress invasive alien species populations at landscape scales has been effectively practised for more than 100 years *(well established)* {5.5.5.3}.

C21 Adaptive management, including ecosystem restoration, can improve the management of invasive alien species and support the recovery of nature's contributions to people in terrestrial and closed water systems *(well established)* {5.3.3, 5.4.4.3a, 5.5.6, 5.7}. The integration of site- and/or ecosystem-based management, including ecosystem restoration, can improve management outcomes, enhancing ecosystem function and resilience to environmental change, including future invasive alien species, especially under climate and land-use change **(Box SPM.4)** *(well established)* {5.3.1, 5.3.2, 5.4.3, 5.5.6, 5.6.1.3}. The success of any applied adaptive site- or ecosystem-based

Box SPM 3

Classical biological control of *Mikania micrantha* (bitter vine): an example of effective suppression of a widespread invasive alien species.

Classical biological control uses host-specific natural enemies (biological control agents) of invasive alien species (target) to suppress and control such species. *Mikania micrantha* (bitter vine), a native species of Central and South America, is one of the highest-impact fast-growing {2.5.2.1} invasive alien plants within the agricultural systems and natural and planted forests of the Asia-Pacific region {Box 5.21}, affecting the livelihoods of farmers and rural communities, including women {4.5.1, 4.6.1}.

In the native range of *Mikania micrantha*, a rust fungus (*Puccinia spegazzinii*) specific to this invasive alien plant causes necrosis of leaves and cankers on the stem and petioles {Box 5.21}. Starting in 2006, *Puccinia spegazzinii* was introduced as a classical biological control agent and established in five countries in the Asia-Pacific region, where it has provided effective control of *Mikania micrantha* {Box 5.21}. However, in India the rust fungus failed to survive in the field following introduction {Box 5.21}.

Box SPM 4 **Working for Water programme: an example of management of invasive alien species leading to recovery of nature's contributions to people.**

Control of widespread invasive alien species requires sustained, large-scale efforts but can lead to improvement in the provision of a range of nature's contributions to people {Box 5.19}. Certain invasive alien plants, such as shrubs and trees, can reduce water availability, especially in scenarios of increasing drought caused by climate change {Box 5.4}. In South Africa, the Working for Water programme, an Expanded Public Works Programme, was introduced in 1995 and targeted historically disadvantaged communities, primarily women, youth and disabled people, creating jobs to reduce poverty nationally through the removal of widespread woody invasive alien species threatening water conservation {Box 5.19}. The programme generated 20,000 jobs per year over the first 15 years and has helped to improve nature's contributions to people by improving water security {Box 5.19}. It has contributed to rural development by providing training in entrepreneurial and management skills while encouraging a sense of community and dignity among workers, especially women. The Working for Water programme shows how partnerships with rural communities to manage invasive alien species can bring both ecological and social benefits {Box 5.19}.

management approach, including ecosystem restoration, depends on long-term monitoring to assess management efficacy using ecological and social indicators *(established but incomplete)* {5.5.2, 6.6.3}. Long-term monitoring of sites ensures early detection of new introductions, reintroductions and re-emergence of invasive alien species (e.g., from a seed bank that includes invasive alien plants) and can inform further management actions *(well established)* {5.4.3.3.b, 5.5.6}. However, most studies failed to quantify the effectiveness of ecosystem restoration since they failed to measure the initial status of native vegetation. This has led to inconsistent conclusions regarding the best invasive alien plant control option which may lead to the most effective ecosystem restoration {5.4.3.3b; 5.5.6}. Regarding freshwater ecosystems, monitoring biodiversity using macroinvertebrate-based indices is a widely used method globally. However, knowledge is lacking on how invasive alien species may affect the metric scores and therefore classification of a river's status *(established but incomplete)* {5.6.2.3}. In marine and connected water systems, ecosystem restoration has so far proved to be largely ineffective because the systems are open, leading to difficulties in implementing and evaluating management actions *(established but incomplete)* {5.5.6, 5.6.1.1}.

C22 **Tools and technologies increase efficiencies when managing biological invasions and controlling invasive alien species, with many new options emerging *(established but incomplete)* {5.4}.** The development of tools and technologies ranging from biotechnology to bioinformatics and data analytics is ongoing for managing pathways, surveillance and detection, rapid response and eradication, local containment and control of widespread invasive alien species *(well established)* {5.4.1, 5.4.2, 5.4.3}. eDNA-based approaches have been used for detection and identification of invasive alien, mostly aquatic, species such as *Orconectes rusticus* (rusty crayfish) *(well established)* {5.4.2.1}. New approaches can be integrated with existing management actions to support site- and ecosystem-based management and restoration *(established but incomplete)* {5.4}. Multi-stakeholder engagement, including risk communication and context-specific application of approaches through local communities, can improve public acceptability and adoption of new tools and technologies for managing biological invasions and the control of invasive alien species *(well established)* {5.2.1, 5.4.3, 5.6.2.1, 6.4.1}. Potential benefits and risks of novel technologies can be assessed using a risk assessment and risk management framework in line with a precautionary approach, as appropriate *(well established)* {5.4.3.2.f}. Using this framework in consultation with regulators, stakeholders and Indigenous Peoples and local communities can limit the potential for unintended consequences *(well established)* {5.4.3.2}. However, most countries do not have the regulatory frameworks and/or technical capabilities needed to guide and support development and implementation of new tools and technologies *(established but incomplete)* {5.4.3.2, 6.3.3.4}. Access to modern tools and technologies and the ability to utilize them can be limited, particularly in developing countries, meaning greater capacity-building is required and improved technical and scientific cooperation *(well established)* {5.6.2.4, 6.7.2.7}.

C23 **Stakeholder engagement, capacity-building and sustained resourcing are critical to the success of adaptive management *(well established)* {5.2.1, 5.6.2.1, 5.6.2.2, 5.6.2.4, 6.4.1, 6.5.3, 6.5.6, 6.5.7}.** Access to adequate and sustained financial and other resources, including international funding to support developing countries, underpins and improves the effectiveness of actions for long-term management of biological invasions, including eradication, control and ongoing monitoring, by, for example, providing access to modern tools and enhancing capacity to deploy them *(well established)* {5.3.1, 5.5.7, 5.6.2.1, 5.6.2.2, 5.6.2.4, 6.5, 6.5.7}. Engagement by all stakeholders, governments and the private sector helps to optimize management of biological invasions in terms of economic, environmental and social outcomes, particularly when resources are limited *(well established)* {5.2.1, 6.5.1}. Societal support is important for eradication and control of some invasive alien species, particularly vertebrates, for which there are ethical considerations {5.3.1.4, 5.4.3.2, 5.6.2.1}. A lack of stakeholder participation in adaptive management can lead to negative consequences for good quality of life, especially for Indigenous Peoples and local communities who have adapted by using invasive alien species, that include loss of livelihoods, marginalization and/or gender inequity *(well established)* {Box 4.18, 5.2.1, 5.4.3.3.a, 5.5.3, 5.6.1.2, 6.4.1}. The involvement of all stakeholders can be achieved by using an adaptive co-management approach to the process, from decision-making to the implementation of management actions *(well established)* {5.4.3.3.a, 5.6.2.5}. Adaptive co-management includes capacity-building; co-creation, co-design, co-development and co-implementation; social learning; and broad partnerships *(established but incomplete)* {5.7, 6.4.2, 6.4.3.2, 6.4.4}. Collaboratively addressing the management of biological invasions around which there are conflicting values among different sectors, stakeholders and Indigenous Peoples and local communities is a significant global policy challenge *(well established)* {5.6.1.2}.

C24 **The knowledge, practices, values and customary governance systems of Indigenous Peoples and local communities can improve management outcomes *(established but incomplete)* {5.2.1, 5.5.2, 5.5.4, 5.5.5, 5.6.1.2, 6.4.3}.** Many communities successfully manage invasive alien species on their lands *(established but incomplete)* {Box 5.6, 5.5.2, 5.5.4, 5.5.5}, leading to increases in nature's contributions to people **(Box SPM.4)** *(established but incomplete)* {5.5.4, 5.5.5}. Consultation with Indigenous Peoples and local communities, through their free, prior and informed consent, by applying co-design principles for decision-making and actions helps to ensure efficacy of management outcomes at the local level *(established but incomplete)* {5.2.1, 6.4.3}. Co-delivered biocultural management plans based on shared scientific, technical and Indigenous and local knowledge systems have assisted surveillance and detection, eradication, containment and control of invasive alien species *(established but incomplete)* {5.5.3, 5.6.1.2, 6.4.3.2}. Such co-governance structures improve quality of life for Indigenous Peoples and local communities *(established but incomplete)* {6.4.3}.

D. Ambitious progress to manage biological invasions can be achieved with integrated governance

D25 **Management of biological invasions and prevention and control of invasive alien species can be achieved through a context-specific integrated governance approach with a set of complementary strategic actions (Figure SPM.7) *(established but incomplete)* {6.2.3, 6.7.1, 6.7.2, 6.7.3}.** Integrated governance for biological invasions consists of establishing the relationships between the roles of actors, institutions and instruments. This involves all those elements of the interactions between people and nature that act on biological invasion and their management, in order to identify the strategic interventions needed to improve outcomes of prevention and control of invasive alien species {Box 6.5}. A context-specific integrated governance approach provides flexibility for countries to identify which strategic actions should be prioritized and can help in managing trade-offs and policy conflicts and in avoiding unintended policy consequences and inefficient expenditure *(established but incomplete)* {6.2.3, 6.7.1}. Strategic actions to prevent the introduction and impact of invasive alien species include:

1. Enhance coordination and collaboration across international and regional mechanisms *(established but incomplete)* {6.2.3.4, 6.7.2.1};
2. Develop and adopt effective and achievable national implementation strategies *(well established)* {6.2.3.2, 6.3.3.1, 6.7.2.3};
3. Share efforts and commitments and understanding of the specific roles of all actors *(established but incomplete)* {6.7.2.5};
4. Improve policy coherence *(well established)* {6.3.1.1, 6.3.2, 6.3.3.1, 6.7.2.2};
5. Engage broadly across governmental sectors, industry, the scientific community, Indigenous Peoples and local communities and the wider public *(established but incomplete)* {6.4.2, 6.4.3, 6.7.2.4};
6. Support, fund and mobilize resources for innovation, research and environmentally sound technology *(established but incomplete)* {6.3.3.4, 6.7.2.7};
7. Support information systems, infrastructures and data sharing *(established but incomplete)* {6.6.2.3, 6.7.2.6}.

Effective implementation, robustness of relevant institutions, responsiveness and equitability are key properties of

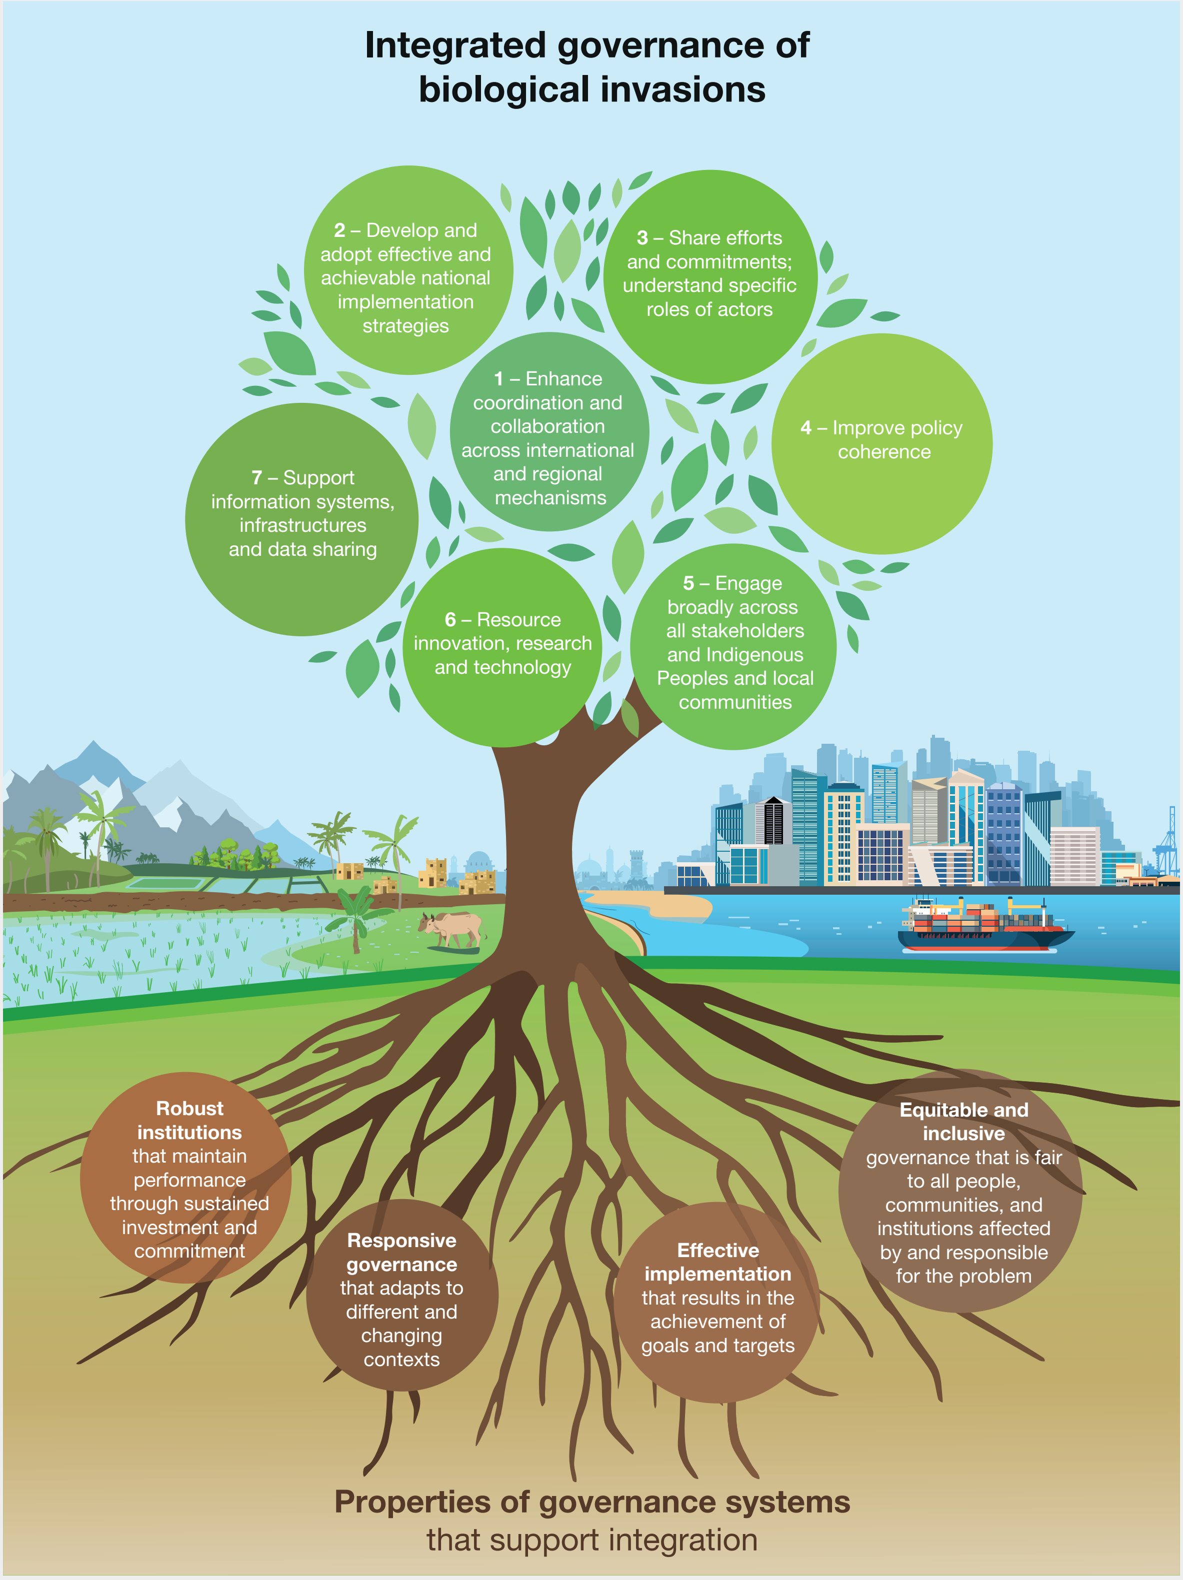

Figure SPM 7 **Integrated governance of biological invasions.**

A context-specific integrated governance approach to biological invasions is enabled by a governance system with properties that support integration, and a set of strategic actions that together are designed to bring about the progress needed to meet national and international goals and targets for biological invasions. Integrated governance is rooted in four essential properties of governance systems (tree roots) that support the strategic actions (branches) to be achieved. Together, the properties and actions will bring about the step change needed for effective and sustainable management of biological invasions. Integrated governance for biological invasions reinforces the enabling conditions identified as necessary to fulfil the 2030 mission of the Kunming-Montreal Global Biodiversity Framework. An integrated governance approach activates specific strategic actions that promote transformative change to meet the goals of preventing and controlling biological invasions.

The strategic actions are:

1. Enhance coordination and collaboration across international and regional mechanisms.
2. Develop and adopt effective and achievable national implementation strategies.
3. Share efforts, commitments and understanding of the specific roles of all actors.
4. Improve policy coherence.
5. Engage broadly across governmental sectors, industry, the scientific community, Indigenous Peoples and local communities and the wider public.
6. Support, fund and mobilize resources for innovation, research and environmentally sound technology.
7. Support information systems, infrastructures and data sharing.

The proposed strategic actions are enabled when the system-wide properties of governance (roots) are robust, equitable and inclusive, responsive and focused on effective implementation. The numbers on the branches do not imply a ranking.

governance systems that enable integrated governance **(Figure SPM.7)**, while the importance of context-appropriate solutions is acknowledged *(established but incomplete)* {6.2.3, 6.7.3}.

D26 One of the most effective ways to manage biological invasions is to develop coherent policy instruments that reinforce strategic actions across sectors and scales *(established but incomplete)* {6.3.1, 6.3.2, 6.5.4}. Many policy instruments aimed at preventing the introduction of invasive alien species have been adopted, including multilateral agreements, national laws, multi-level regulations and voluntary codes of conduct *(well established)* {6.1.2, 6.3.1}. They have jointly contributed to reducing the impacts of invasive alien species on nature, nature's contributions to people, and good quality of life *(established but incomplete)* {5.5.1, 6.1.3}. The work under various relevant international organizations, partnerships and multilateral environmental agreements (e.g., the Convention on Biological Diversity, the World Trade Organization, the International Maritime Organization, the International Plant Protection Convention, the World Organisation for Animal Health, the Convention on the Conservation of Migratory Species of Wild Animals and the Convention on International Trade in Endangered Species of Wild Fauna and Flora) is not adequately aligned to address the problem posed by invasive alien species *(well established)* {6.3.1.3, 6.3.1.4}. Enhanced coordination and collaboration across international and regional mechanisms are key strategic actions for rapid and transformative progress *(established but incomplete)* {6.7.2.1} and could help international, national and local agencies that implement policies for the environment, agriculture, aquaculture, fishing, forestry, horticulture, border control, tourism and trade (e.g., in wildlife, but also including online trade in other animals, plants and other organisms), community and regional development (including infrastructure), transportation and health deliver a coherent approach to biological invasions *(well established)* {6.3.1.1}. Such coordination and collaboration efforts would consider the trade-offs across sectors {6.3.1.1(2), 6.3.1.3}, stakeholders and Indigenous Peoples and local communities {1.5.1}, and the interdependence between invasive alien species and other drivers *(established but incomplete)* {3.1.1, 3.1.5, 6.2.3.2, 6.7.2.2}. Collaborative, multisectoral and transdisciplinary approaches (such as One Health) provide frameworks to prevent and control invasive alien species by strengthening the interconnections between the human, animal, plant and environmental health sectors, including biosecurity (e.g., as outlined in the One Biosecurity framework among others) *(established but incomplete)* {1.6.7.2, 6.3.1, 6.7.2.2}.

D27 National-scale strategies and action plans are instrumental to successfully managing biological invasions as part of a context-specific integrated governance approach *(well established)* {6.2.3.2, 6.3.2.1, 6.7.2.3}. The national strategies and action plans could be developed or updated to align with and implement the Kunming-Montreal Global Biodiversity Framework, particularly Target 6, as well as other relevant international guidelines for sustainable development, through aspirational, ambitious and realistic approaches *(well established)* {6.1.2, 6.2.3.2, 6.3.2.1, 6.6.3, 6.7.2.3}. Coordinated efforts to strengthen national regulatory instruments, including for the regulation of online trade {6.3.1.4(3)}, are key to reducing the transport and introduction of invasive alien species *(established but incomplete)* {6.3.1.1, 6.7.2.1}. Voluntary codes of conduct **(Box SPM.1)** have limitations but they can be a valuable part of integrated systems to reduce the risk of biological invasions, when in line with relevant international obligations and national legislations *(established but incomplete)* {6.3.1.4(4)}. Adequately designed and implemented national biodiversity strategies and action plans are instruments to help manage biological invasions and mitigate the impacts of invasive alien species *(established but incomplete)* {6.1.2, 6.3.3.1}. Implementation of strategies could be accelerated by measuring and monitoring resourcing of actions, implementation processes, outputs and outcomes of policy management *(established but incomplete)* {Table 6.5, Box 6.3, 6.6.3}, which could also create a conducive policy environment for the utilization of environmentally sound technologies *(established but incomplete)* {6.3.3.4}.

D28 Long-term commitment and resourcing from governments and institutions will support the implementation of strategic actions to underpin the integrated governance of biological invasions *(established but incomplete)* {6.2.3.2, 6.5.1, 6.5.3, 6.5.7}. With adequate levels of sustained investment and resources **(Table SPM.2)**, including support to developing countries {6.5.7}, specific options that address the gaps and inconsistencies in current policy instruments and coordination can be implemented over appropriate timeframes *(established but incomplete)* {6.7.2.2, 6.7.2.3}. Regulatory and market-based instruments such as tax relief and subsidization can be used to incentivize action on and investment in prevention and control of invasive alien species *(established but incomplete)* {6.3.1, 6.5.1, 6.5.2}, especially when responsibility for the burden of biological invasions, including environmental liability, is shared **(Figure SPM.7)**. These instruments may be non-market mechanisms or voluntary codes of conduct **(Box SPM.1)** {6.3.1.4}, transparent and conducive regulatory settings for new technologies {6.3.3.4, 6.7.2.7}, information-sharing {6.6.2, 6.7.3}, product labelling {6.3.1.4} or direct regulatory intervention {6.3.3.1, 6.3.3.3}. Regulations could be enforced with economic penalties and tariffs *(established but incomplete)* {6.5.1, 6.5.2}. However, taxation incentives, international standards and cost-sharing mechanisms are generally the preferable policy instruments for encouraging entities to participate in prevention and control activities *(established but incomplete)* {5.6.2.1, 6.5.1, 6.5.2, 6.5.4, 6.5.5, 6.5.6}. Efforts to overcome the asymmetries and differences in resource capacity among stakeholders and the potential unequal burden and responsibilities of addressing the causes and impacts of invasive alien species can be embedded in policies *(established but incomplete)* {6.2.3.3, 6.4.4.3}. Cost-benefit and "willingness to pay" analyses and stakeholder consultation can support the development of national policies to assist in justifying the use of public resources and developing the most appropriate incentives *(established but incomplete)* {5.2.2.1.i, 6.2.3.1(2), 6.2.3.4}.

D29 Public awareness and engagement contribute to the effective management of biological invasions *(well established)* {5.6.2.1, 6.2.2(9), 6.3.1.4, 6.4.1, 6.6.2.1, 6.7}. Public understanding of the risks associated with invasive alien species is particularly important for preventing new introductions *(well established)* {6.2.2(9), 6.4.1}. Increased understanding of possible biological invasions and the negative impacts of invasive alien species can be achieved through public awareness campaigns {Box 6.11, 6.7.2.5}, education across all age groups {6.7.2.4} and citizen science *(established but incomplete)* {5.4.2.2.a, 6.6.2.1}. Engagement of the general public *via* citizen science platforms, awareness campaigns and community-driven eradication campaigns also contributes to establishing shared responsibilities for managing biological invasions *(established but incomplete)* {6.7.2.5}. Surveillance for detecting invasive alien species through citizen science and social media provides broader security by empowering and engaging the public *(established but incomplete)* {5.4.2.1.a, 5.4.2.2.a, 6.6.2.1}. Communication is an effective tool for inspiring collective action to monitor and control invasive alien species {6.2.3.1(4), 6.2.3.4, 6.4.4.4} by supporting the co-design of management actions, knowledge exchange and enhanced partnerships among stakeholders and researchers *(established but incomplete)* {6.2.3.3, 6.4.4.3}. It can also enable alignment of resource managers' responses with national plans and policy priorities *(well established)* {6.3.1.3, 6.3.2.1}. An effective communications strategy considers the most appropriate timing, media and channels/interfaces for the target audience *(established but incomplete)* {Box 6.13, 6.6.2.6}.

D30 Indigenous Peoples and local communities have invaluable knowledge systems that could contribute to addressing biological invasions *(established but incomplete)* {Box 4.18, 5.5.3, 5.5.4, 6.4.3.2}, yet their lack of land tenure and access rights can limit the extent to which they are able to take action *(well established)* {3.2.5, 6.4.3.1}. Indigenous Peoples and local communities can be partners in co-developing policies and strategies to address biological invasions while giving consideration to the challenge of conflicting perceptions and values in order to achieve consensus on management actions *(established but incomplete)* {5.6.1.2, 6.2.3.3, 6.4.3.1}. Participation of Indigenous Peoples and local communities can be enhanced with sufficient legal, political and financial support *(well established)* {6.4.3, Box 6.16}. Successful strategies respect the knowledge, priorities and rights of Indigenous Peoples and local communities, including customary governance systems, in accordance with national legislation *(established but incomplete)* {5.1.3, 5.2.1, 5.6.2, 6.4.3}. In cases where the impact of invasive alien species on the quality of life of Indigenous Peoples and local communities is unavoidable, those communities need ongoing support and

Table SPM 2 **Options for strengthening the governance of biological invasions at national, regional and global scales.**

Indication of the duration of investment needed to implement different options. The contribution of each of these options, together forming integrated governance, are given in **Figure SPM.7**. This table presents concrete options for action.

Governance purpose	Options	Duration of investment needed
Coordination and resourcing	Enhance multilateral coordination and collaboration to support the integrated governance of biological invasions	Ongoing
	Engage broadly across affected and responsible parties	Ongoing
	Build capacity to enable strategic actions	Ongoing
Policy	Share efforts, commitments and understanding of the specific roles of all	Short
	Strengthen compatibility of relevant regulatory instruments	Periodic
	Use national strategy and planning for invasive alien species to achieve policy implementation	Periodic
	Support, fund and mobilize resources for innovation, research and environmentally sound technology	Ongoing
	Support information systems, infrastructures and open and equitable access to information on invasive alien species	Short
Research, information, and technology	Invest in information systems for invasive alien species for information-sharing within and across countries	Ongoing
	Maintain up-to-date information on necessary and enabling indicators	Ongoing
	Monitor policy and management effectiveness and resourcing levels	Ongoing
	Develop new solutions through research and technology	Ongoing

Short Periodic Ongoing

adequate resources to respond to the challenges of living with invasive alien species *(established but incomplete)* {1.6.7.2, 6.2.3.2, 6.2.3.5}.

D31 Open and interoperable information systems, supported by international cooperation, play a critical role in tackling biological invasions *(established but incomplete)* {6.2.3.1(3), 6.6.2.2, 6.7.2.6}. Strengthening existing open information systems can facilitate the management of biological invasions, including prioritization of actions, early detection and rapid response, and can improve the effectiveness of regulations *(established but incomplete)* {5.4.1, 6.6.2.3}. Open information systems can substantially reduce the costs of management by ensuring targeted and appropriate responses, avoiding duplication of efforts and facilitating the evaluation of the effectiveness of policy instruments using indicators **(Table SPM.2)** *(well established)* {6.6.2.4, 6.6.2.6, 6.6.3}. The "rate of invasive alien species establishment" headline indicator adopted for monitoring progress towards Target 6 of the Kunming-Montreal Global Biodiversity Framework provides opportunities to build on existing indicators of biological invasions **(Table SPM.A1)** {6.6.3}. Collaboration and networking among stakeholders and governments can ensure equitable knowledge access *(established but incomplete)* {6.2.3.3, 6.2.3.4} and improve understanding of the context-specific features of biological invasions. It can also improve the availability of data and knowledge across geographic regions, habitats and taxonomic groups and reduce the wide variation in response capability *(established but incomplete)* {6.2.3.3, 6.4.1, 6.7.2.6}. Through citizen science, information systems have the potential to engage people, raise awareness and increase the availability of data *(established but incomplete)* {6.6.2.1}.

D32 Existing evidence of the magnitude and extent of the impacts of invasive alien species supports immediate, strategic and sustained action to successfully address biological invasions *(well established)* {1.1, 2.2, 3.6.3, 4.3.1, 4.4.1, 4.5.1, 5.6.2.5, 6.7.2}. The available data and knowledge reviewed for this assessment vary across regions, units of analyses, taxonomic groups and time because of language barriers, lack of targeted policies and legislation, lack of resources, uneven research capacity, data accessibility and other factors **(Table SPM.A1)**, contributing to gaps in data and knowledge *(well established)* {2.7, 3.6.1, Box 3.12, Box 3.13, 4.7.2, 6.6, Table 6.10}. Nonetheless, filling knowledge and data gaps, particularly at local scales, can bring about important improvements in the cost-effectiveness and success of prevention and management actions *(well established)* {6.6.1, 6.6.2}. For example, it would be particularly beneficial to increase the availability of information on invasive alien invertebrates and microorganisms; improve knowledge of the impacts of invasive alien species in parts of Africa, Central Asia and Latin America; gain a better understanding of the role of indirect and interacting drivers; develop management options for invasive microorganisms and marine species; and establish the effectiveness of different policy instruments *(established but incomplete)* (see **Table SPM.A1** for a comprehensive presentation of knowledge gaps). Enhancing research capacity in some regions and collaboration between biological invasion experts in the developed and developing world and across knowledge systems could improve data and information availability as well as understanding of the context-specific features of invasive alien species and their impacts *(established but incomplete)* {6.2.4, 6.6.1.1(3)}. With political will, strategic long-term commitment and sufficient resources, management of biological invasions is an attainable goal *(well established)* {Boxes 5.2, 5.4, 5.5, 5.6, 5.7, 5.8, 5.9, 5.11, 5.12, 5.14, 5.15, 5.16, 5.17, 5.19, 5.21, 6.7.3}.

D33 Successfully addressing biological invasions can also strengthen the effectiveness of policies designed to respond to other drivers *(established but incomplete)* {5.6.1.3, 6.3, 6.7.2.2}. Mitigating the risks of invasive alien species will contribute to the effective delivery of the 2030 Agenda for Sustainable Development, including the Sustainable Development Goals, especially those addressing the conservation of marine (Goal 14) and terrestrial biodiversity (Goal 15 including, but not restricted to, Target 15.8), food security (Goal 2), sustainable economic growth (Goal 8), sustainable cities (Goal 11), climate change (Goal 13), and good health and well-being (Goal 3) *(established but incomplete)* {6.7}. An integrated governance approach that acknowledges the interactions between invasive alien species and other drivers, including climate change, direct exploitation of natural resources, pollution and land- and sea-use, alongside human, animal and plant health, can identify where to best direct policy alignment and mutually supportive efforts *(established but incomplete)* {3.1.5, 6.2.4, 6.7.2.1, 6.7.2.2, 6.7.2.5}. Evidence-based policy planning can reflect the interconnectedness of the drivers so that efforts to solve one problem do not exacerbate the magnitude of others and may even have multiple benefits *(established but incomplete)* {3.2.5, Box 3.9, 5.6.1.3, 6.2.4, 6.3.1.1(1), 6.7.2.2}.

APPENDICES

APPENDIX 1
Communication of the degree of confidence

Figure SPM A 1 **The four-box model for the qualitative communication of confidence.**

Confidence increases towards the top-right corner, as suggested by the increasing strength of shading. Source: IPBES (2016).[12] Further details of the approach are documented in the *IPBES Guide on the Production of Assessments*.[13]

In this assessment, the degree of confidence in each main finding is based on the quantity and quality of evidence and the level of agreement regarding that evidence **(Figure SPM.A1)**.

The evidence includes data, theory, models and expert judgement.

- **Well established:** there is a comprehensive meta-analysis or other synthesis or multiple independent studies that agree.
- **Established but incomplete:** there is general agreement, although only a limited number of studies exist; there is no comprehensive synthesis, and/or the studies that exist address the question imprecisely.
- **Unresolved:** multiple independent studies exist but their conclusions do not agree.
- **Inconclusive:** there is limited evidence and a recognition of major knowledge gaps.

APPENDIX 2
Synthesis of knowledge and data gaps

Table SPM A 1 **Table of knowledge and data gaps**

Synthesis of the most important knowledge and data gaps identified and collated through the assessment. Confidence levels in the summary for policymakers were allocated with full consideration of the gaps listed in the table; closing those gaps would strengthen the understanding of biological invasions. Experts have assessed the estimated cost and scientific challenge of closing these gaps, as well as the potential gain in increasing understanding of and successfully tackling biological invasions globally (from very low to very high). The listed gaps may not be relevant at local or regional scales.

CATEGORY	GAP	IMPLEMENTATION CHALLENGE		POTENTIAL GAIN	
		Estimated research cost	Estimated scientific challenge	For taking management action	For better understanding biological invasions
Gaps in biomes, units of analysis and species groups	Incomplete or lack of inventories of invasive alien species in marine, tropical and Arctic ecosystems {2.5.2.1, 2.5.2.4, 2.5.2.5, 2.5.4}	🟠	🟣	🟣	🟣
	Incomplete or lack of inventories of invasive alien microorganisms and invertebrates {2.3.1.11, 2.3.3.3}	🟣	🟣	🟣	🟣
	Lack of understanding of the drivers of change that facilitate biological invasion for some animal groups (notably invertebrates), fungi and microbes {3.6.1}	🟠	🟠	🟣	🟣
	Lack of understanding and synthesis of the impacts of invasive alien microbes {4.7.2}	🟠	🟠	🟣	🟣
	Poor understanding of drivers of change that facilitate biological invasions in aquatic and marine systems {3.6.1}	🟠	🟠	🟣	🟣
	Lack of data on successful restoration attempts in terrestrial and marine systems {5.5.6, 5.6.2.1}	🔵	🔵	🟣	🔵
Regional gaps in data and knowledge	Comparatively incomplete inventories of invasive alien species in Africa and Central Asia {2.4.2.5, 2.4.5.5}	🟠	🟣	🟣	🟣
	Comparative lack of understanding of the drivers of change that facilitate biological invasions in developing economies {Box 3.12}	🟠	🟠	🟣	🟣
	Lack of data and knowledge of the drivers of biological invasions in sub-Saharan Africa, tropical Asia and South America {3.6.1}	🟣	🟠	🟣	🟣
	Incomplete data on the impacts of invasive alien species across Africa and Central Asia {4.7.2}	🟠	🔵	🟣	🟣
Interoperable data for monitoring invasive alien species and effects of drivers of biodiversity change	Lack of standardization of terminology for invasive alien species monitoring {2.4.4.5, 6.6.2.3, 6.6.2.7}	🟢	🟢	🟠	🟠
	Lack of information on the role of indirect drivers, especially governance and sociocultural drivers, in affecting biological invasions {3.1.5, 3.6.1, Box 3.13}	🔵	🔵	🟣	🟣
	Lack of understanding of the net effects of multiple interacting drivers in shaping and promoting biological invasions {3.5, Box 3.10, 3.6.1, Box 3.13}	🟢	🟠	🟣	🟣
	Lack of knowledge on interactions and feedback across drivers in promoting invasions {3.1.5, 3.6.1}	🔵	🟠	🟣	🟣

CATEGORY	GAP	IMPLEMENTATION CHALLENGE		POTENTIAL GAIN	
		Estimated research cost	Estimated scientific challenge	For taking management action	For better understanding biological invasions
Interoperable data for monitoring invasive alien species and effects of drivers of biodiversity change	Lack of integration of impact data and knowledge sources across languages {4.7.2}	●	●	●	●
	Incomplete data to undertake risk management, cost-effective species-based surveillance and detection of fungi, microbes and marine pests {Table 5.11}	●	●	●	●
	Incomplete data to prioritize biological invasion management under climate, sea- and land-use change {5.6.1.3}	●	●	●	●
	Lack of inventories at fine scales and for specific taxon and biome contexts to support decision-makers in determining when to implement species-based or site-based management (or both) {5.6.2.1, 5.7}	●	●	●	●
	Incomplete data to develop pathway risk assessments and management for different taxonomic groups and biomes {Table 5.11, 5.6.2.5}	●	●	●	●
	Incomplete data and understanding of site-based and ecosystem-based management concepts {5.6.2.1}	●	●	●	●
	Incomplete data and understanding of the conditions that facilitate successful integration of policy developments into management plans {6.6.1.4}	●	●	●	●
	Lack of indicators of the various dimensions of biological invasion that are policy-relevant, sensitive, reliable, relevant at national and global scales, sustained for medium-to-long-term tracking of progress and part of a responsive policy environment {6.6.3}	●	●	●	●
Gaps in how invasive alien species affect nature's contributions to people	Incomplete data on impacts on nature's contributions to people and good quality of life {4.7.2}	●	●	●	●
Management and policy approaches	Lack of control options for marine invasive alien species and invasive alien microbial fungal pathogens of plants and animals {5.6.1.1}	●	●	●	●
	Lack of agreed-upon methods of supporting management decision-making for invasive alien species with both positive and negative impacts {5.6.1.2}	●	●	●	●
	Lack of methods of managing pathways for invasive alien species arriving as contaminants, or through shipping containers, e-commerce (legal/illegal), biofouling or ports, and across land borders and along trade supply chains {Table 5.11, 5.6.2.4}	●	●	●	●
	Lack of methods for adaptive management of invasive alien invertebrates and plants using alternative approaches given the declining number of chemical control options {5.6.2.5}	●	●	●	●
	Lack of eradication guidelines and strategies for generalist invasive alien invertebrates, diseases and hard-to-detect freshwater and marine invasive alien species {5.6.2.1, Table 5.11}	●	●	●	●
	Lack of scenarios and models of invasive alien species that consider interactions with other drivers of global change {2.6.5, 6.6.1.6}	●	●	●	●
	Missing information on the implementation of adaptive-collaborative governance for biological invasions and factors important to the success of that governance strategy {6.4.4.5}	●	●	●	●
	Incomplete data on the effectiveness of policies, management strategies and actions related to biological invasions {6.1.3, 6.6.3}	●	●	●	●

INTRODUCING BIOLOGICAL INVASIONS AND THE IPBES THEMATIC ASSESSMENT OF INVASIVE ALIEN SPECIES AND THEIR CONTROL

1.1 INTRODUCTION: THE IPBES THEMATIC ASSESSMENT OF INVASIVE ALIEN SPECIES AND THEIR CONTROL

Invasive alien species **(Figure 1.1)**, through the process of biological invasion, are widely recognized as a major threat to nature and nature's contributions to people, with important implications for good quality of life (IPBES, 2018e, 2018f, 2018g, 2018h, 2019; **Glossary**). Biological invasions are a consequence of human activities and invasive alien species are acknowledged as one of the major drivers of local species extinctions within terrestrial and inland water ecosystems (Bellard *et al.*, 2016; IPBES, 2019a; **Chapters 3** and **4**); they have dramatically altered habitats within terrestrial, marine, and freshwater ecosystems around the world (Cacabelos *et al.*, 2020; Liu *et al.*, 2020; **Chapter 4**; **Glossary**). Invasive alien species, alongside other drivers of change in nature, are considered to be one characteristic of a new epoch – the Anthropocene (Capinha *et al.*, 2015; Crutzen & Stoermer, 2000). While the problems associated with invasive alien species have increased over the past century (**Chapters 2** and **4**), considerable progress has been made toward understanding (**Chapters 2**, **3** and **4**) and developing strategies and actions to manage them (**Figure 1.2**; **Chapter 5**). The thematic assessment report on invasive alien species and their control of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES; hereafter termed the IPBES invasive alien species assessment) provides a timely synthesis of this complex but fascinating multidisciplinary field of research to underpin potential options for policy- and decision-making (**Chapter 6**).

Throughout the IPBES invasive alien species assessment, the term biological invasion is used to describe a process involving the transport of a native species outside of its natural range, intentionally or unintentionally, by human activities to new regions where it may become established and spread (Richardson *et al.*, 2010). The term invasive alien species refers to particular species within the context of the process of biological invasion; namely those that negatively impact (**Glossary**) nature and also, in some cases, nature's contributions to people, and good quality of life.

The rapidly growing threat that invasive alien species pose to nature, nature's contributions to people, and good quality of life remains underestimated and, in some cases, overlooked by policy and decision makers (IPBES, 2018a, 2019). However, concerns over the adverse impacts of invasive alien species have driven multiple efforts to establish regional and international initiatives (**Figure 1.2**; Clout & De Poorter, 2005) and policy goals **(Box 1.1)**. A pioneering initiative was the Scientific Committee on Problems of the Environment (SCOPE), which engaged scientists to document biological invasions and invasive alien species from a global perspective in 1982 (J. A. Drake *et al.*, 1989; Mooney *et al.*, 2005).

The overarching aim of the IPBES invasive alien species assessment is to critically evaluate available evidence on the severity of the threat of invasive alien species to inform potential options for decision-making. The need for sustained social-ecological (Kull *et al.*, 2018), interdisciplinary (Vaz *et al.*, 2017) and transdisciplinary approaches (Kapitza *et al.*, 2019), which are sensitive to differing knowledge systems, value perceptions and cultural attributes, is acknowledged throughout this assessment and will be critical in addressing the recently adopted goals of the Kunming-Montreal Global Biodiversity Framework (CBD, 2022).

While previous regional, global and thematic IPBES assessments have considered biological invasions and invasive alien species, an in-depth and quantitative and qualitative global analysis of them has not been conducted. Therefore, the IPBES invasive alien species assessment not only extends the findings of the previous IPBES assessments, including the IPBES Global Assessment Report on Biodiversity and Ecosystem Services (IPBES, 2019), but addresses important gaps in information. Ultimately, through the synthesis and harmonization of information at a global scale, the IPBES invasive alien species assessment examines the magnitude of the threat of invasive alien species to nature, nature's contributions to people, and good quality of life **(Box 1.2)**.

The term biological invasion describes the process involving the intentional or unintentional transport or movement of a species outside its natural range by human activities and its introduction to new regions, where it may become established and spread.[1]

Native species (synonym indigenous species) are taxa that have originated in a given area (their natural range) without human involvement, or that have arrived there without intentional or unintentional intervention of humans, from an area in which they are native. This definition excludes products of hybridization involving alien taxa since "human involvement", in this case, includes the introduction of an alien parent.[2] Some native species can spread or undergo rapid population increase and have harmful impacts. Despite their adverse effects, such native species are not considered invasive alien species.[3]

Alien species, as opposed to native species (synonyms exotic, introduced, non-indigenous, non-native), are those whose presence in a region is attributable to human actions, intentional or unintentional, that enable them to overcome biogeographical barriers.[1] Native species that expand their natural range without intentional or unintentional human involvement, for example in response to other anthropogenic drivers such as changes in land use and climate change, are not considered to be alien species.[4, 5] However, a species that spreads to new regions without direct human involvement from a region where it is alien is considered to be alien in the new region.[2]

Established (synonym naturalized) **alien species** produce self-sustaining and viable populations for a given period of time during which climatic extremes typical for the invaded region are experienced, without direct intervention by humans, or despite human intervention.[6, 2, 7]

"**Invasive alien species** are animals, plants or other organisms introduced directly or indirectly by people into places out of their natural range of distribution, where they have become established and dispersed, and generating a negative impact on local ecosystems and species".[8] Invasive alien species are a subset of established alien species that have negative impacts.

Impacts are changes to nature, nature's contributions to people and/or good quality of life.[9] Impacts can be observed or unobserved. Generally, negative impacts become more apparent and problematic when invasive alien species are well established, widespread and present for a long time. Along with their adverse effects, some invasive alien species may have positive impacts providing benefits to some people.

Drivers are factors that directly or indirectly facilitate biological invasions.

Figure 1 1 **Definitions of important terms used to describe the status of a species from native to invasive alien through the process of biological invasion.**

The definition of native species provides the context for the term natural range. Stages of the biological invasion process (transport, introduction, establishment and spread) are defined in **section 1.3**.

Box 1 1 International policy targets for biological invasions.

The setting of global policy goals and targets is often considered an effective and transparent way to motivate governments and other actors (Kanie & Biermann, 2017). In recent decades, the need for prevention and management (**Glossary**) of biological invasions has been widely recognized by the Conference of the Parties to the Convention on Biological Diversity (CBD), which adopted the Strategic Framework for Biodiversity 2011-2020 in 2010, including the Aichi Biodiversity Targets (United Nations, 1992) which adopted the Strategic Framework for Biodiversity 2011-2020 in 2010, including the Aichi Biodiversity Targets, and the United Nations General Assembly, which adopted the 2030 Agenda for Sustainable Development and its Sustainable Development Goals (SDGs) in 2015. More specifically, two international commitments were made:

> "By 2020, invasive alien species and pathways are identified and prioritized, priority species are controlled or eradicated and measures are in place to manage pathways to prevent their introduction and establishment." Aichi Biodiversity Target 9, Strategic Plan for Biodiversity 2011-2020 (CBD, 2010; **Glossary**).

> "By 2020, introduce measures to prevent the introduction and significantly reduce the impact of invasive alien species on land and water ecosystems and control or eradicate the priority species." Target 15.8, SDG15 (United Nations, 2020a).

These targets were mostly directed towards biodiversity and conservation. However, while the wording of these targets does not address good quality of life directly, they are framed within a broader policy context aimed at conserving biodiversity and ensuring its sustainable use by human communities, the equitable sharing of benefits from genetic resources (CBD, 2020), and the broader goal of achieving a better and more sustainable future for all (United Nations, 2020b). As such the 2020 targets recognized the current and future threats posed by invasive alien species to humanity.

None of the 20 Aichi Biodiversity Targets were achieved at the global level (Secretariat of the CBD, 2020). The Kunming-Montreal Global Biodiversity Framework was adopted in 2022 and includes a target on invasive alien species, Target 6:

> "Eliminate, minimize, reduce and or mitigate the impacts of invasive alien species on biodiversity and ecosystem services by identifying and managing pathways of the introduction of alien species, preventing the introduction and establishment of priority invasive alien species, reducing the rates of introduction and establishment of other known or potential invasive alien species by at least 50 per cent, by 2030, eradicating or controlling invasive alien species especially in priority sites, such as islands." Kunming-Montreal Global Biodiversity Framework (CBD, 2022).

Box 1 2 Overarching questions on biological invasions.

The IPBES invasive alien species assessment addresses 11 overarching questions (IPBES, 2018a).

a. What progress has been made in tackling the Aichi Biodiversity Targets of relevance to invasive alien species globally?

b. What global-level policy initiatives would assist in invasive alien species prevention and management?

c. What are the obstacles to the uptake of invasive alien species prevention and management measures?

d. What methods are available for prioritizing invasive alien species threats?

e. How can networks assist in the prevention and management of invasive alien species? What role can regional partnerships play?

f. Are there perverse policy drivers that unintentionally create risks in relation to invasive alien species?

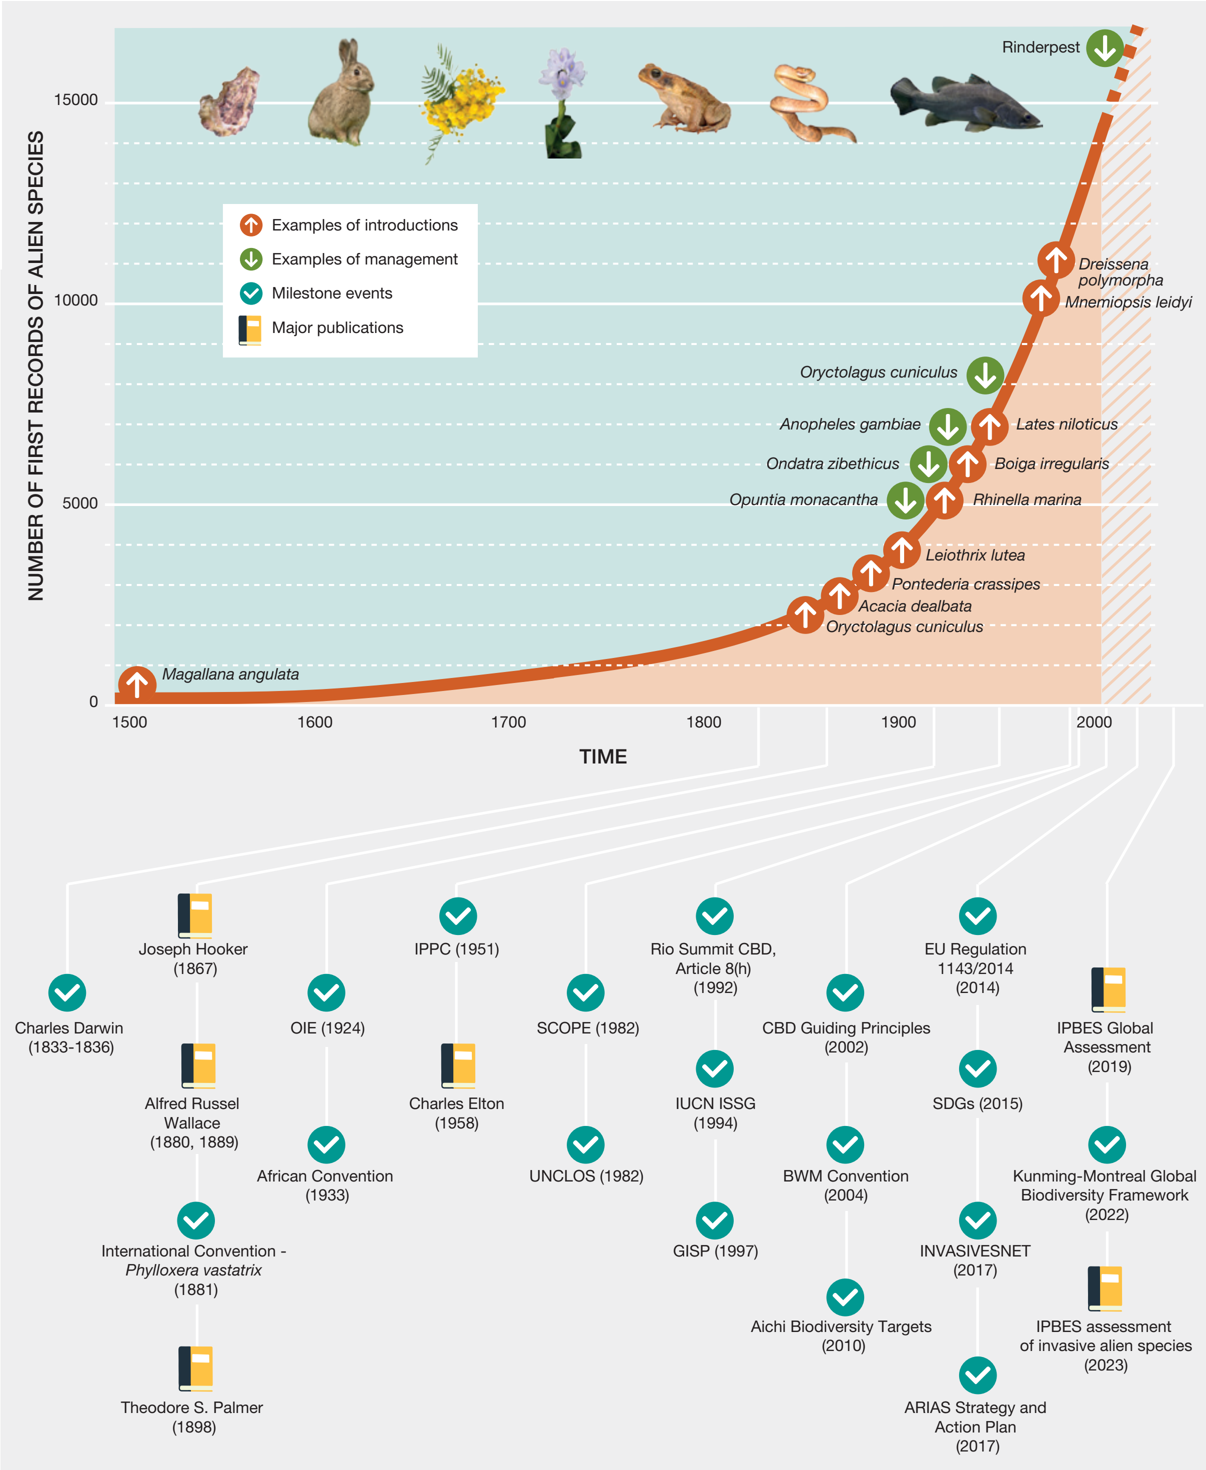
g. How can decision makers decide which issues to tackle first given limited resources?

h. Would there be value in developing a database of effective legislation, monitoring and response systems for invasive alien species, and of those countries and other stakeholders in need of capacity-building?

i. What are the impacts, risks and benefits of invasive alien species for biodiversity and ecosystem services, sustainable development and human well-being?

j. How might policy sectors, businesses, non-governmental organizations and other stakeholders benefit from better prevention and management of invasive alien species?

k. How does one prevent and manage invasive alien species that cause harm to biodiversity but contribute to economic activities?



↑	*Magallana angulata* (Portuguese oyster) was introduced in Europe in the 1500s
↑	*Oryctolagus cuniculus* (rabbit) was first recorded in Australia in 1859
↑	*Acacia dealbata* (acacia bernier) was first recorded in Sri Lanka in 1870
↑	*Pontederia crassipes* (water hyacinth) was first recorded in North America in 1884
↑	*Leiothrix lutea* (red-billed leiothrix) was first introduced in Europe in the late 1800s
↑	*Rhinella marina* (cane toad) was first recorded in Australia in 1935

- *Boiga irregularis* (brown tree snake) was first recorded in Guam in the late 1940s or early 1950s
- *Lates niloticus* (Nile perch) was first recorded in Lake Victoria in 1954
- *Dreissena polymorpha* (zebra mussel) was first recorded in North American Great Lakes in 1986
- *Mnemiopsis leidyi* (sea walnut) was first recorded in the Black Sea in 1982
- Control of *Opuntia monacantha* (common prickly pear) in South Africa (1913) and Australia (1914)
- Eradication of *Ondatra zibethicus* (muskrat) in the United Kingdom in 1939
- *Anopheles gambiae* (African malaria mosquito) was successfully managed in Brazil in the 1930s and early 1940s
- Control of *Oryctolagus cuniculus* (rabbits) in Australia in 1955
- Rinderpest is first wild animal disease to be eliminated globally in 2011
- Charles Darwin observed two European plants invading the pampas, Patagonia (1833-1836)

Figure 1 2 **Timeline of key strategic events and advances in the understanding of biological invasions.**

There has been considerable progress not only in understanding the process of biological invasions and invasive alien species but also in developing strategies and actions to manage them. The timeline shows milestone events relevant to biological invasions ( ), major publications on biological invasions ( ), examples of invasive alien species' first record ( ), and examples of successful management ( ), with the central line graph illustrating the global escalation in first records of alien species. Data management report available at: https://doi.org/10.5281/zenodo.7560099

1.2 ASSESSMENT STRUCTURE

The first assessment of biological invasions and invasive alien species that is global in scope, the IPBES invasive alien species assessment, is interdisciplinary, spanning environmental and social science as well as the humanities, and comprises six chapters written by experts from all regions of the world.

There are many links and several overarching cross-cutting and key issues across the six chapters **(Figure 1.3)**, but all the chapters can be read as standalone documents presenting syntheses of existing knowledge and highlighting gaps and priorities.

The assessment is composed of six chapters:

- **Chapter 1** introduces the concept of invasive alien species; the risks posed to marine, terrestrial and freshwater ecosystems; the IPBES conceptual framework; the cross-cutting themes (good quality of life, Indigenous and local knowledge, and scenarios and models), and common themes;
- **Chapter 2** assesses past, current and future trends in the spread, pathways, evolutionary change and distribution of invasive alien species;
- **Chapter 3** presents the direct and indirect drivers responsible for the introduction, spread, abundance and dynamics of invasive alien species;
- **Chapter 4** assesses the impacts of invasive alien species on nature and nature's contributions to people and good quality of life;
- **Chapter 5** evaluates the effectiveness of past and current programmes and tools for the global, national and local prevention and management of biological

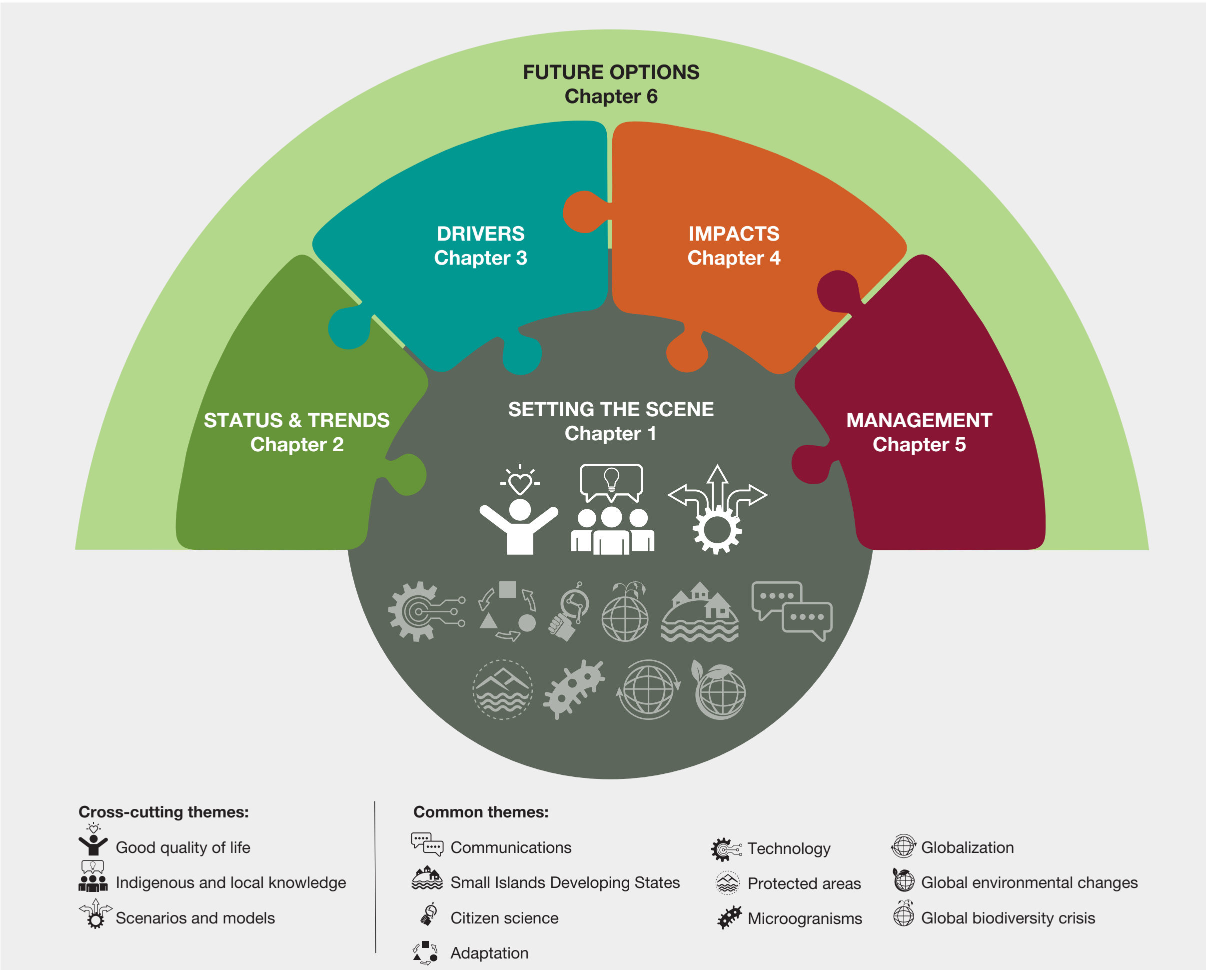

Figure 1 3 **Structure of the IPBES thematic assessment of invasive alien species and their control.**

invasions and invasive alien species and their impacts; and

- **Chapter 6** introduces future options for the prevention and management of biological invasions and invasive alien species and provides an analysis of possible policies and support tools for policy and decision makers.

Three cross-cutting themes – 1) Indigenous and local knowledge systems (**Glossary**), 2) good quality of life including human health, and 3) scenarios and modelling of trends (**Glossary**) and development of robust projections, are featured prominently throughout the IPBES invasive alien species assessment **(Figure 1.3)**. Several key issues, with relevance to two or more of the chapters, emerged during the assessment including globalization, adaptation, environmental change, the global biodiversity crisis, the role of technology, the role of communication, citizen (or community) science, the specific context of Small Island Developing States (SIDS), the role of protected areas (terrestrial, coastal, and marine) and of microorganisms. In many chapters these topics will appear as case studies. As this IPBES assessment will demonstrate, addressing invasive alien species, which are affecting many facets of the socioecological systems in which people live, can have far-reaching benefits for biodiversity and human health, and will shape the ability of future generations to live healthy, sustainable lives.

1.3 INVASIVE ALIEN SPECIES: WHAT THEY ARE AND WHY THEY MATTER

1.3.1 What are invasive alien species?

The term "alien" (synonyms: non-native, exotic, introduced, non-indigenous, allochthonous) species refers to species whose presence in a region is attributable to human actions, intentional or unintentional, that enable them to overcome biogeographical barriers (Essl *et al.*, 2018; Richardson *et al.*, 2010; Rojas-Sandoval & Acevedo-Rodríguez, 2015). It is widely acknowledged that some alien species (i.e., invasive alien species) can become established, spread (dispersed) and cause dramatic biotic and abiotic changes in the ecosystem to which they are introduced, resulting in the reduction in abundance or even extinction of native species, and/or major shifts in ecosystem functioning, and/or major adverse health, economic, social, or cultural impacts on human communities. Invasive alien species are defined in the scoping report for this assessment as "animals, plants or other organisms introduced directly or indirectly by people into places out of their natural range of distribution, where they have become established and dispersed, and generating an impact on local ecosystems and species" (IPBES, 2018e; **Figure 1.1** and **Glossary**). Although much of the focus of this assessment is on the negative impacts of invasive alien species, benefits are also discussed.

Invasive alien species can be introduced unintentionally or intentionally, and as these terms are more commonly used than directly or indirectly, they have been adopted throughout this assessment. Domestic or managed alien animals and plants are not considered to be invasive alien species while they remain in captivity or are managed by humans, but such species that establish feral or wild populations outside of captivity or cultivation would be termed invasive alien species. Furthermore, it is important to note that feral populations of domestic or managed animals (e.g., goats and fish) can have considerable adverse impacts prior to establishing sustained populations in the wild. Native species that expand their natural range without human involvement, for example in response to other anthropogenic drivers including land- and sea-use and climate change, are not considered to be alien species even though some of these range expansions result in dramatic ecosystem-level changes (**Figure 1.1**; Cannone *et al.*, 2022).

Invasive alien species are generally considered problematic because they cause environmental harm and also, in some cases, affect good quality of life. This standpoint is consistent with Article 8(h) of the CBD, which calls on the parties to "prevent the introduction of or control or eradicate those alien species that threaten ecosystems, habitats or species" **(Box 1.1)**. The term "invasive alien species" was adopted by the CBD Guiding Principles for the Prevention, Introduction and Mitigation of Impacts of Alien Species that Threaten Ecosystems, Habitats or Species (CBD, 2002; **Chapter 6**, **Table 6.3**) to define species whose introduction and spread threaten biological diversity. However, perceptions of invasive alien species may vary amongst stakeholders and Indigenous Peoples and local communities (**section 1.5.2**; see also **Chapter 5**, **section 5.6.1.2**) and it is therefore important to view invasive alien species not in isolation but within the context of the socioecological systems they are affecting (**section 1.5.2**).

It can take time for the negative impacts of some alien species to become apparent and so a precautionary approach (**Glossary**) is often adopted when categorizing an alien species as an invasive alien species (Coutts *et al.*, 2018). Generally authors do not consider the inclusion of impact within the definition of biological invasions, and instead their definition is based exclusively on ecological and biogeographical criteria (Blackburn, Pyšek, *et al.*, 2011; Occhipinti-Ambrogi & Galil, 2004; Pyšek *et al.*, 2004; Rojas-Sandoval & Acevedo-Rodríguez, 2015);

many of the datasets collated for alien species follow this approach (Pyšek *et al.*, 2017; 2020). The definition of invasive alien species, supported by the International Union for Conservation of Nature (IUCN), the CBD and the World Trade Organization (WTO), often used in policy discussions, explicitly assumes that invasive alien species cause adverse impacts on nature and also to the economy and good quality of life, including human health (IUCN, 2000). This IPBES invasive alien species assessment follows the definition of invasive alien species outlined within the scoping report (IPBES, 2018a) which includes the concept of impact on local ecosystems and species. Key terms within this definition are provided in **Figure 1.1**.

1.3.2 How many invasive alien species are there?

Patterns in the numbers of established alien species have been documented for all IPBES regions (**Chapter 2**, **section 2.4**; and specifically Bailey *et al.*, 2020; Genovesi *et al.*, 2009; Lambdon *et al.*, 2008; Turbelin *et al.*, 2017) and most taxonomic groups (**Chapter 2**, **section 2.3**; in particular Dawson *et al.*, 2017; Dyer *et al.*, 2017; van Kleunen *et al.*, 2015). However, as mentioned above, these datasets rarely distinguish those alien species which are invasive (Richardson *et al.*, 2010), and, as such, in this section the term alien species is used. Island and coastal mainland regions have higher alien species richness (i.e., total number of species) than mainland regions (Dawson *et al.*, 2017; **Figure 1.4**). Alien species richness is dependent on the number of different species introduced to a given location, often referred to as colonization pressure (Blackburn *et al.*, 2020; Lockwood *et al.*, 2009; **Glossary**).

Not all alien species transported beyond their natural ranges establish sustaining populations (Cassey *et al.*, 2018; Richardson *et al.*, 2010). Propagule pressure (**Glossary**) is a measure of introduction intensity comprising both the number of individuals introduced per introduction event (propagule size) and the frequency of introduction events (Cassey *et al.*, 2018; Colautti *et al.*, 2006; Lockwood *et al.*, 2005). Given suitable environmental conditions, the total number of individuals of a particular alien species that are introduced has been shown to be positively correlated with the establishment success of alien populations (Colautti *et al.*, 2006; Lockwood *et al.*, 2009). The more individuals released, the greater probability that the population will have sufficient genetic variation to adapt to local conditions and establish self-sustaining populations (Blackburn *et al.*, 2009).

Social and economic factors, including gross domestic product per capita and population density (**Chapter 3**, **sections 3.2.2** and **3.2.3**), are important in determining alien species richness globally (Dawson *et al.*, 2017). High trade and transport connectivity amongst regions which have similar environmental conditions can also be important in predicting the risk of invasive alien species (**Glossary**; Capinha *et al.*, 2014; Cope *et al.*, 2019; Early & Sax, 2014; Fitzpatrick *et al.*, 2007; Li *et al.*, 2014; Parravicini *et al.*, 2015) and describing global patterns of alien species richness (**Chapters 2** and **3**).

1.3.3 Drivers of change in nature affecting invasive alien species

Direct and indirect drivers of change refer to all external factors that affect nature and consequently nature's

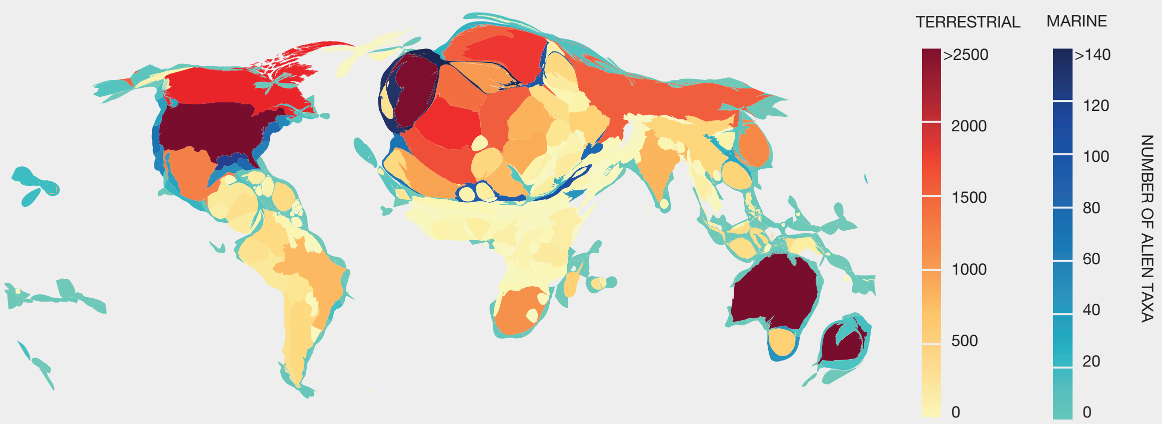

Figure 1 4 **Number of documented alien taxa in terrestrial (including freshwater) and marine environments.**

The size of regions is scaled proportionately by the number of documented alien taxa. Gaps for global alien species records are documented in **Chapter 2**. Data source: Seebens (2021).

contributions to people and good quality of life (Brondizio *et al.*, 2019). Direct drivers may be both human (anthropogenic) and non-human factors. Direct drivers affect nature directly in physical ways and include land or sea-use change, direct exploitation of natural resources, climate change, pollution, and invasive alien species. Indirect drivers are human actions that act on and alter direct drivers and other indirect drivers. Indirect drivers do not physically affect nature or nature's contributions to people, but they are the underlying cause of direct anthropogenic drivers. Indirect drivers include the role of institutions and governance (**Glossary**) systems, economic policies, and demographic, technological, and cultural influences.

The categories of indirect and direct drivers used throughout the IPBES invasive alien species assessment are based on the IPBES conceptual framework (Díaz *et al.*, 2015) with modifications specifically relevant to biological invasions and invasive alien species outlined in **Chapter 3**, **section 3.1.2**. The importance of interactions between invasive alien species and other drivers of change is acknowledged across the IPBES assessments (IPBES, 2018d, 2018e, 2018f, 2018g, 2019), and MacDougall & Turkington (2005) note that some invasive alien species may be considered passengers of global change because they only persist in an ecosystem through continued human disturbance. However, it is also important to recognize that alien species are themselves a component of biodiversity; they may be affected by other direct and indirect drivers while also interacting with native biodiversity and other alien species (**Chapter 3**, **section 3.3.5**).

Drivers may act alone or interact with each other to varying degrees, leading to additive or multiplicative effects (**Chapter 3**; Díaz *et al.*, 2018; Newbold *et al.*, 2015; Sala *et al.*, 2000) in which it is difficult to determine the relative importance of one driver over another (**Boxes 1.3** and **1.4**). For example, land-use changes are widely recognized as playing a role in promoting invasive alien species (IPBES, 2018c; Mooney & Hobbs, 2000). However, the role of indirect and direct drivers, and the complex interplay amongst them, will vary through the stages of the biological invasion process (**section 1.4**; **Glossary**). This complexity is rarely addressed within studies on invasive alien species but is increasingly recognized as an important consideration in understanding biological invasions and deriving solutions to mitigate or manage invasive alien species. It is important to recognize that drivers of change in nature such as land- and sea-use change, climate change and invasive alien species act at different temporal and spatial scales (**Chapter 3**; also **Figure 1.9** in **section 1.5**; Bonebrake *et al.*, 2019).

1.3.4 What are impacts in the context of invasive alien species?

For the purposes of this assessment, an impact is defined as a measurable change to nature, nature's contributions to people, and/or good quality of life (**Figure 1.1**; Ricciardi *et al.*, 2013; **Chapter 4**, **section 4.1.2**). It is useful to discriminate between measurable changes in physical or social parameters and value-laden decisions on whether such changes are beneficial or detrimental to humans or native species (Vimercati *et al.*, 2020). Invasive alien species can cause changes in physical, chemical, and/or biological properties, which can result in an increase or decrease in a parameter or an index. Such change may be considered as a harmful impact with respect to nature if whole ecosystems and communities are affected, or if other species are negatively (e.g., reduction in their performance and/or population size, or extinction) or positively (e.g., increase in their performance and/or population size, or establishment of new populations) affected. Impacts can also be considered as harmful (negative) or beneficial (positive) for humans if people suffer or gain from changes in nature's contributions to people or constituents of good quality of life

Box 1 3 Interactions between invasive alien species and climate change as drivers of biodiversity loss.

The IPBES-IPCC Co-Sponsored Workshop Report on Biodiversity and Climate Change (Pörtner *et al.*, 2021) recognized that climate change and biodiversity loss are interconnected and share common drivers through human activities. Although the outcomes of interactions between climate change and invasive alien species on community level processes is poorly understood (Robinson *et al.*, 2020), disproportionate changes in community composition across trophic levels are predicted to decrease species diversity and stability (Zarnetske *et al.*, 2012). As an example, climate change is anticipated to affect top predators more strongly than lower trophic levels, leading to an increase in herbivores and a decrease in plants (Zarnetske *et al.*, 2012). It is evident that the ongoing unprecedented changes in climate will alter the interactions between native and alien species (**section 1.6.8**). Interactions amongst drivers of change in nature, including climate change and invasive alien species but also other drivers, can generate complex feedback loops (Sinclair *et al.*, 2020; **Glossary**) with pronounced and unpredictable outcomes on evolutionary and ecosystem level processes (Pörtner *et al.*, 2021; **Chapter 3**, **section 3.5**).

Box 1 4 **Climate change, fire, and invasive alien plants.**

Many regions are experiencing unprecedented fire regimes because of human-driven ignition, coupled with intense droughts and record high temperatures associated with human-induced climate change (Bowman *et al.*, 2020; Kelly *et al.*, 2020). Undoubtedly, the increase in frequency and intensity of fires is threatening ecosystems and good quality of life in almost all parts of the world (Bowman *et al.*, 2011; **Figure 1.5**). Invasive alien species can worsen the situation by adding fire-prone fuel, which can increase not only the fuel quantity but also its flammability and its spatial continuity (Brooks *et al.*, 2004; Gaertner *et al.*, 2014). Studies have found that in several biomes, including tropical, temperate and Mediterranean regions, invasive alien plants may benefit from fires but can also act as promoters of more intense and frequent fire regimes, potentially causing more carbon release into the atmosphere (Nuñez *et al.*, 2021). In the Cerrado forest of Brazil, for example, *Melinis minutiflora* (molasses grass) and *Urochloa brizantha* (palisade grass) introduced in the 1800s are more prone to fire and although fire is a natural disturbance of this ecosystem, invasive alien grasses increase the frequency and intensity of fires (Damasceno & Fidelis, 2020). In Mediterranean climates and other semi-arid and arid ecosystems, some land-use practices, such as overgrazing, have resulted in significant increases in invasive alien European grasses such as *Bromus tectorum* (downy brome) that increase fuel load, continuity, and flammability. These conditions create a positive feedback loop between severe fires and the invasion of *Bromus tectorum* that results in multiple negative changes of natural grasslands and shrub steppe ecosystems and services (e.g., Western North America; see Pyke *et al.*, 2016). In areas with Mediterranean and temperate climates, especially in the southern hemisphere, shrubs and trees native to fire-prone ecosystems may cause extreme changes in fire regimes. In southern Africa and southern South America, Australian species of *Acacia* have shown to spread rapidly after fires and their biomass can fuel more intense fires (Le Maitre *et al.*, 2011). Similar positive feedback loops between invasive alien species and fires have been observed for *Pinus* across several ecosystems in the southern hemisphere (Cóbar-Carranza *et al.*, 2014; Franzese & Raffaele, 2017; Taylor *et al.*, 2017). Fire-prone invasive alien plants are likely to continue to spread under the more extreme climate scenarios and with the anticipated increase in conditions favourable to fire (Hurteau *et al.*, 2014). Consequently, these invasive alien plants are predicted to play a role in promoting more intense fire regimes with potential impacts on carbon cycling and further potential synergies with climate change.

Figure 1 5 **Invasive alien plants increase fire intensity and spread.**

(**Chapter 4**, **sections 4.1.3**, **4.4** and **4.5**; García-Llorente *et al.*, 2008; Pyšek & Richardson, 2010; F. Williams *et al.*, 2010). It is important to acknowledge that the outcomes of assessments of the benefits or positive impacts of invasive alien species should not be used to balance or offset the harmful or negative impacts, which may be irreversible including ecosystem transformation (Lockwood *et al.*, 2023; **Chapter 4**). Invasive alien species can have direct or indirect adverse impacts in their new environment even if their populations are not established or conversely can have negligible impacts even when established and widespread (**Glossary**; Jeschke *et al.*, 2013). While most literature on invasive alien species refers to the detrimental effects on ecological processes in terrestrial, freshwater and marine environments, new evidence is revealing the devastating effects on social (Bacher *et al.*, 2018; Gallardo *et al.*, 2019) and economic aspects (Diagne *et al.*, 2020). There is consensus among the scientific community that impacts of invasive alien species cannot be understood independently of other drivers of change in nature and that ecological, social, and economic aspects are also closely intertwined (Pyšek, Hulme, *et al.*, 2020; Shackleton, Shackleton, *et al.*, 2019).

Previous IPBES assessments have concluded that increased biotic homogenization (**Glossary**), or loss of biotic uniqueness, of biological communities is a major negative impact of invasive alien species which can result in the introduction and establishment of further alien species (IPBES, 2018d, 2018e, 2018f, 2018g, 2019). Local community assemblages are becoming more similar to each other on average, and this biotic homogenization (Finderup Nielsen *et al.*, 2019; McKinney & Lockwood, 1999; Yang *et al.*, 2021) has also been referred to as the "anthropogenic blender" (Olden, 2006). A recent review highlighted a consistent trend of decreasing taxonomic and phylogenetic diversity globally, providing strong evidence of widespread biotic homogenization (D. Li *et al.*, 2020). The consequences of biotic homogenization for ecosystem processes and nature's contributions to people can be substantial, but are often context specific, are hard to predict, and remain understudied. Ongoing environmental transformation is reducing the ability of ecosystems to withstand disturbance, including the arrival of invasive alien species, and so leading to decline in the resilience (**Glossary**) of natural systems (Dasgupta, 2021).

The introduction of one invasive alien species can facilitate invasion by another (**Chapter 3**, **section 3.3.5**; Simberloff & Von Holle, 1999). In some cases, this has led to an increasing rate of establishment and consequently communities of interacting invasive alien species are becoming increasingly common (Jackson, 2015; Simberloff & Von Holle, 1999). This facilitation is more likely to occur when a high number of species are introduced to an area (e.g., islands) or for alien species that are already known to interact with one another (e.g., species that co-occur within the native range or previously invaded ranges), such as pests and parasites. Indeed, parasites and pathogens are frequently introduced into new communities alongside invasive alien species and are implicated in altering the outcome of biological invasions by changing the strength of interactions between alien and native species (Dunn & Hatcher, 2015; **Box 1.14** in **section 1.6.7.2**). Co-occurring and interacting invasive alien species may amplify and exacerbate negative impacts. Indeed, biotic facilitation (**Glossary**), the synergistic interactions amongst different alien species within an invaded ecosystem, can lead to extreme adverse effects on ecosystem functions, which have been termed "invasional meltdown" (Simberloff, 2006; Simberloff & Von Holle, 1999; **Glossary**). However, in some cases interactions amongst invasive alien species can mitigate the adverse effects, for example when a predator is introduced and reduces the population of the prey of the invasive alien species (**Chapter 3**, **section 3.3.5**; Braga *et al.*, 2018; Facon *et al.*, 2006; Jackson, 2015).

The effects of an invasive alien species on an invaded biotic community will increase as the density of the invading organisms increases (Shea & Chesson, 2002). Effects on and responses of the resident species will in turn determine whether the community provides opportunities for invasive alien species (Parker *et al.*, 1999). However, while it is recognized that the outcome of biological invasions can be partially explained by the traits of alien species (invasiveness, i.e., the intrinsic biological characteristics of the species that result in the ability to invade a particular ecosystem) and characteristics of the recipient community (invasibility, i.e., susceptibility of an ecosystem to be invaded by one or multiple species), high levels of uncertainty (Leung *et al.*, 2012) are often a feature of predictions on the dynamics of invasive alien species (Facon *et al.*, 2006; Hui & Richardson, 2019). It is critical to integrate characteristics of the invading species alongside characteristics of the recipient habitats to account for the context within which the biological invasion is occurring (Foxcroft *et al.*, 2011).

Invasive alien species may reduce the phylogenetic distance among species within a community and, although in some cases they may increase the phylogenetic diversity within local sites, they can reduce phylogenetic diversity between sites (D. Li *et al.*, 2020). Ecosystem function is influenced by phylogenetic diversity (Cadotte *et al.*, 2012); ecosystems comprising community assemblages with higher phylogenetic diversity are considered to be more resilient to disturbance because they have the evolutionary potential to adapt to changing environmental conditions (D. Li *et al.*, 2020). The diversity and relative abundances (evenness) of species may strongly affect ecosystem function for community assemblages comprising combinations of functionally different species with low niche overlap (Cadotte *et al.*, 2012). While it is difficult to

Box 1 5 Role of invasive alien species within novel or emerging ecosystems.

Changes in the composition of communities as a consequence of invasive alien species will lead the emergence of new species combinations. Ecosystems containing these new species combinations are termed "novel ecosystems" or "emerging ecosystems" (Hobbs *et al.*, 2006). A broad range of examples document the emergence of novel ecosystems specifically in the context of biological invasions leading to new species combinations (Haram *et al.*, 2021; Lindenmayer *et al.*, 2008; Lugo, 2004; Mascaro *et al.*, 2008; Wilkinson, 2004). The adverse consequences of these changes include hybridization (e.g., between *Sporobolus maritimus* (small cordgrass) and *Sporobolus alterniflorus* (smooth cordgrass) leading to the emergence of the invasive alien *Sporobolus anglicus* (common cordgrass)), species declines (e.g., brown tree snake decimation of the forest bird species in Guam; Rodda & Savidge, 2007), or ecosystem-level change (e.g., changes in nutrient cycles, fire cycles or hydrology; Ehrenfeld, 2010; Ramakrishnan & Vitousek, 1989; Simberloff, 2011; Vilà *et al.*, 2011; Vitousek, 1986). However, novel ecosystems have shown to be beneficial in some contexts (Munishi & Ngondya, 2022) including, for example, by restoring ecosystem processes (Ewel & Putz, 2004; Lugo, 2004; C. E. Williams, 1997) or by providing nature-based solutions to mitigate environmental change (Munishi & Ngondya, 2022) although it is recognized that more evidence is needed for the latter (Turner *et al.*, 2022). Furthermore, context-specific adaptive governance (**Glossary**; **Chapter 6**, **Table 6.6**) coupled with pathway management (**Glossary**; **Chapter 5**, **section 5.4.3.1**) and understanding of drivers (**Chapter 3**) and more broadly the biology of alien species, including their interactions with native species, is considered critical to success of nature-based solutions for managing biological invasions (Munishi & Ngondya, 2022).

The formation of novel ecosystems that include invasive alien species has led to discussions about the implications of resulting compositional and ecological changes (e.g., Hobbs *et al.*, 2014; Murcia *et al.*, 2014). Perceptions (**section 1.5.2**) depend on many factors including concerns over environmental and societal impacts but also differing cultural values toward "nativeness" and "exoticism" and how such beliefs develop over time (Higgs, 2003). The range of perceptions may also be based on how effective the actions are likely to be in reversing the changes caused by invasive alien species. On one side of the spectrum, reversal of the novel state generated by alien species is viewed as a useful, morally necessary, and achievable goal (Hallett *et al.*, 2013; Hobbs *et al.*, 2006). On the other side of the same spectrum, the transition to a novel system due to alien species impacts is viewed as irreversible when a system has crossed an ecosystem restoration (**Glossary**) threshold (Hallett *et al.*, 2013; Hobbs *et al.*, 2006). The latter is the case for most marine biological invasions, where post-establishment management actions are mostly unsuccessful and invasive alien species can alter ecosystem functions and ultimately transform the entire landscape (E. Sala *et al.*, 2011). As an example, the snail *Littorina littorea* (common periwinkle), first recorded in the mid-1800s in the north-west Atlantic subsequently spread throughout the Atlantic coast of North America, altering the diversity, abundance and distribution of many benthic species on rocky and soft shores (Carlton, 1992).

Irreversible impacts are also likely to occur in scenarios where invasive alien species remain undetected for long periods of time. These historical biological invasions hamper our ability to recognize pre-existing native landscapes and ecosystems causing what is called "ecological mirages" (Bortolus *et al.*, 2015). The historical introduction of *Sporobolus alterniflorus* to the east coast of South America during the 1800s modified the pre-existing and extensive bare mudflats into vegetated salt marsh areas, leading to shifts in bird, fish and invertebrate biodiversity, with concomitant trophic cascades, but these changes were long overlooked (Bortolus *et al.*, 2015).

Acknowledging the uncertainty of outcomes of novel ecosystems and the potential for invasional meltdown (**Chapter 3**, **sections 3.1.3.2** and **3.3.5**), it is desirable to adopt a cautious and context-specific approach when considering the impacts of alien species and of the novel ecosystems they generate (Hobbs *et al.*, 2006), including the potential role of novel ecosystems as nature-based solutions to mitigating other drivers of change in nature (Seddon *et al.*, 2021). This uncertainty also highlights the value of pragmatism when recommending management strategies, and the benefits of engaging all stakeholders with available evidence to consider desirability, cost, and resource availability (**Chapters 5** and **6**; Hallett *et al.*, 2013; Miller & Bestelmeyer, 2016). There are many ways in which alien species interact with one another and with native species (Hui *et al.*, 2021). Novel mutualistic interactions (pollination, seed dispersal and plant-microbial symbioses) amongst alien species have been shown to facilitate other invasive alien species(Traveset & Richardson, 2014) leading to cascading effects that alter ecosystem functioning **(Box 1.11)**. Less attention has been given to interactions between alien and native species which lead to benefits, or indeed reductions in the magnitude of adverse impacts of interacting alien species (Liu *et al.*, 2018; Ross *et al.*, 2004), but it is acknowledged that beneficial interactions are also important in determining the outcomes of biological invasions on communities and consequently ecosystem function (Braga *et al.*, 2018; Halpern *et al.*, 2007; Viana *et al.*, 2019). The outcomes of species interactions are highly context-dependent (Lord *et al.*, 2017) and other drivers of change in nature will alter the population dynamics of alien and native species with consequences for eco-evolutionary and community-level processes which can be difficult to predict (Facon *et al.*, 2006; Robinson *et al.*, 2020).

quantify niche overlap and functional differences among multiple species, phylogenetic diversity can be used as a proxy of similarities and differences amongst species (Cavender-Bares *et al.*, 2009). Species-specific traits or human-mediated processes have been shown to be more important sources of variation in establishment and spread of invasive alien species than phylogenetic diversity (**Chapter 3**; Diez *et al.*, 2008). However, it is important to include multiple facets of biodiversity when assessing impacts, and phylogenetic diversity can be used as metric for predicting multifunctionality of ecosystems (Lishawa *et al.*, 2019). Innovative approaches integrating species distributions, traits, phylogenies, and interaction networks incorporating feedback loops will contribute to better understanding of biodiversity change (Pollock *et al.*, 2020) including predicting the outcomes of biological invasions (Hui & Richardson, 2019).

Since invasive alien species interact with resident species in evolving ecosystems **(Box 1.5)**, elucidating the complex adaptive networks these invasive alien and resident species form is critical to underpin understanding of the dynamics of invasive alien species and management of biological invasions. Network ecology embraces the multitude of biotic interactions within a framework of feedback loops which affect species persistence and coexistence (Borrett *et al.*, 2014; Hui *et al.*, 2016) and ultimately the functioning of ecosystems (Harvey *et al.*, 2017). Emerging insights in understanding the influence of human decisions, perceptions and management efforts within the context of ecological networks will improve forecasts on the response of networks to invasive alien species (Kueffer, 2017).

Ecological impacts of invasive alien species include adverse effects on biodiversity and also on nature's contributions to people (**Chapter 4**, **sections 4.3** and **4.4**). Invasive alien species can lead to extreme disruptions in the good quality of life of local communities (**Chapter 4**, **section 4.5**) either by indirect impacts on human health (e.g., introduced mosquitoes and disease; see **Box 1.14** in **section 1.6.7.2**), reduction of food security (e.g., invasive alien species as weeds in crop systems) or through degradation of habitats on which people depend (e.g., fire regime shifts caused by some invasive alien plants that are particularly flammable). As with any ecosystem change, there are cases where invasive alien species may provide opportunities for people to adapt and take advantage of the new conditions the species can provide. Production of firewood, new food sources and strengthening of aesthetic and cultural values have been recognized as beneficial outcomes of biological invasions (Shackleton, Shackleton, *et al.*, 2019). However, the overall impact on nature's contributions to people and good quality of life is hard to assess, as these species may have also disrupted the traditional and cultural ways of living of many Indigenous Peoples and local communities (**Chapter 4**, **section 4.6**).

1.4 BIOLOGICAL INVASION PROCESS

Over the past thirty years, different approaches to describe biological invasions have been developed (Colautti & MacIsaac, 2004; Leung *et al.*, 2012; Rejmanek & Richardson, 1996; Rojas-Sandoval & Acevedo-Rodríguez, 2015; Williamson, 1996; Williamson & Fitter, 1996). The unified framework for biological invasions **(Figure 1.6)** emerged from the integration of key features from across these commonly used frameworks and represents a single conceptual model that can be applied to all human-mediated biological invasions (Blackburn, Pyšek, *et al.*, 2011). This framework is used throughout the IPBES invasive alien species assessment.

The unified framework divides the biological invasion process into a series of stages (transport, introduction, establishment, and spread), recognizing the need for a species to overcome the barriers (geography, captivity or cultivation, survival, reproduction, dispersal, and environmental) that obstruct transition between each stage. Different factors may be advantageous in allowing species to pass through each stage **(Figure 1.6)**. The two barriers, survival and reproduction, recognize that the establishment stage is a population process, and establishment of a viable population requires self-sustaining populations encompassing multiple generations. **Chapter 4** provides a synthesis of the environmental, economic and social impacts which can occur throughout the biological invasion process. Evolutionary processes and mechanisms, including evolutionary history, founder effects, and hybridization, are also relevant (Dlugosch *et al.*, 2015; Estoup *et al.*, 2016; Facon *et al.*, 2006; Hufbauer *et al.*, 2012; Zenni *et al.*, 2017) and considered further within **Chapter 2**, **Box 2.3**.

1.4.1 Transport

Transport is the first stage in the biological invasion process (Williamson, 1996). Species have native geographic distributions with limits imposed by natural constraints, both biotic and abiotic. Human activities, such as shipping for trade, agricultural practices, and ornamental planting, can result in the movement of species beyond the barrier(s) that define these natural limits (**Chapter 3**). Humans can deliberately or inadvertently break down the natural barrier(s) which otherwise define these natural limits in the global distribution of species. This barrier is termed "geography" (Rojas-Sandoval & Acevedo-Rodríguez, 2015) in the unified framework as it is typically a physical feature (e.g., a mountain range or ocean) or a climatic barrier through which a species cannot normally disperse. However, the barrier may also be biogeographical, if distributional limits are imposed by biotic factors such as the presence

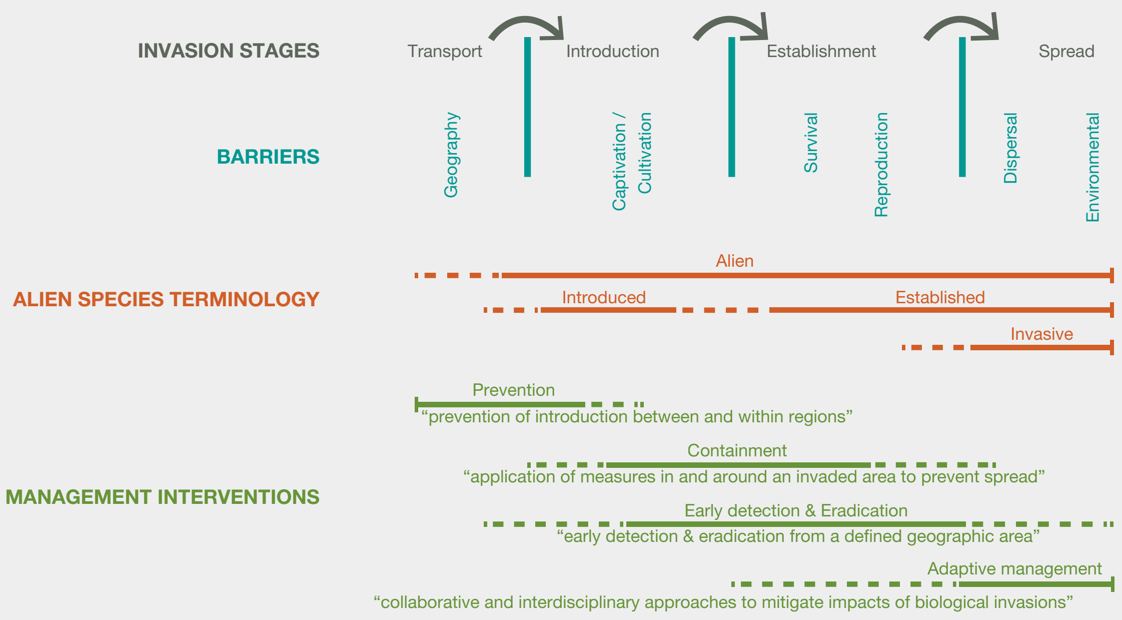

Figure 1 6 **The biological invasion process.**

Alien species terminology adopted throughout the assessment. The status of the species is reflected in the change in terminology and depends on the stage within the biological invasion process. Each stage is separated from the next by a barrier which a species must overcome in order to pass to the next stage. Alien species at different stages are associated with different management interventions. Solid horizontal lines represent the core application of the terminology, or management interventions and broken lines indicate extended application of the terminology in some contexts and where suitable management interventions may have some relevance. Box 1 6 Pathways of introduction of invasive alien species.

Pathways describe the many ways in which an alien species can be intentionally or unintentionally introduced through human activities from one geographical location to another (Hulme *et al.*, 2008; Pyšek *et al.*, 2011). Recognizing the importance of linking pathways to management or legislative options, a pathway scheme was developed by Hulme *et al.* (2008) that coupled policy options with the broad mechanisms by which alien species could be introduced to a region. The Conference of the Parties to the CBD subsequently adopted (and refined) the pathway scheme proposed by Hulme and colleagues (Hulme, 2014; Hulme *et al.*, 2008) to give a unified system for categorizing alien species pathways (CBD, 2014). The CBD Pathway Scheme distinguishes intentional and unintentional introductions, the six broad mechanisms of introduction (categories) and a number of corresponding subcategories. Furthermore, Saul *et al.* (2017) have published guidance for interpretation of the categories in introduction pathways, including for the six broad mechanisms of introduction:

Release in nature: intentional introduction of alien species for the purpose of human use in the natural environment;

Escape: unintentional movement of alien species from confinement (e.g., in zoos; aquaria; botanic gardens; agriculture; horticulture; aquaculture and mariculture facilities; scientific research or breeding programmes; or from keeping as pets) into the natural environment;

Transport-contaminant: unintentional movement of alien species as contaminants of a commodity that is intentionally transferred through international trade, development assistance, or emergency relief;

Transport-stowaway: unintentional movement of alien species attached to transporting vessels and associated equipment and media;

Corridor: unintentional movement of alien species into a new region following the construction of transport infrastructures in whose absence spread would not have been possible;

Unaided: secondary natural dispersal (**section 1.4.4**) of alien species that have been introduced by means of any of the foregoing pathways.

of competitors, predators, parasites and pathogens, or the absence of mutualists. Barriers to dispersal promote diversification by driving important evolutionary processes (e.g., speciation) and as such environmental conditions that prevent organisms from dispersing have far-reaching consequences for the organization of life on earth (Caplat *et al.*, 2016). The ways in which alien species are intentionally or unintentionally introduced through human activities from one geographical location to another are termed "pathways" (Hulme *et al.*, 2008; Pyšek *et al.*, 2011). An alien species may arrive within a new region through the importation of a commodity, arrival of a transport vector (physical means or agent, such as ship, train, aircraft, or other vehicle), which an alien species moves in or on (IUCN, 2017), and/or natural spread from a previously invaded region (Hulme *et al.*, 2008). These three mechanisms of arrival can be subdivided into six major pathways **(Box 1.6)**. It is evident that the pathways through which alien species are transported and introduced to new regions are changing over time (Essl *et al.*, 2015; Hulme *et al.*, 2008) and it is apparent that some of the most problematic invasive alien species arrive through multiple pathways (Essl *et al.*, 2015; Saul *et al.*, 2017) and repeated introductions (J. R. U. Wilson *et al.*, 2009). The movement of alien species may be facilitated by a broad range of human factors, or drivers of change, especially those related to the economy, human demography, and land-use (**Chapter 3**).

1.4.2 Introduction

A species may be moved to a location beyond its natural distributional limits but will only go on to invade an area if it is introduced beyond captivity and cultivation from that location (Williamson, 1996). To become introduced, individuals of that species must overcome the (sometimes literal) barriers imposed by captivity or cultivation (Rojas-Sandoval & Acevedo-Rodríguez, 2015). A deliberate (intentional introduction) act may be with the aim of establishing an alien species, for example if the species can be considered economically (e.g., game species) or environmentally (e.g., biological control agents, **Glossary**) or culturally (e.g., landscape gardening; van Kleunen *et al.*, 2018) beneficial. Over time, a wider understanding of the harm that invasive alien species can cause (Pyšek, Hulme, *et al.*, 2020) led to the conclusion that most introductions are not deliberate, but are unintentional. Important anthropogenic factors, or drivers, that may facilitate the introduction of invasive alien species include escape from captivity (e.g., pet animal escapes, seed spread from botanical gardens, larvae or adults that escape from aquaculture facilities) or escape by stowaways (e.g., organisms in ballast water), although some can result from intentional liberation of individuals into a novel environment (e.g., ceremonial release of animals) (Dyer *et al.*, 2017; Magellan, 2019; Pyšek, Hulme, *et al.*, 2020; Simberloff *et al.*, 2013; **Chapter 3**).

1.4.3 Establishment

Introduced species will fail to become invasive if they are unable to produce a self-sustaining and viable population in the new location, a process that is termed "establishment" (Williamson, 1996). This stage in the biological invasion process requires that introduced individuals both survive and reproduce in the new environment, and hence that barriers to survival and reproduction are overcome (Pyšek, Bacher, *et al.*, 2020; Rojas-Sandoval & Acevedo-Rodríguez, 2015). Therefore, as mentioned in **section 1.3.2**, biological invasions are a function of propagule pressure, colonization pressure, abiotic characteristics of the invaded ecosystem and biotic characteristics of the recipient community and invading species (Catford *et al.*, 2009; Lockwood *et al.*, 2009) including ecological and evolutionary change (Facon *et al.*, 2006).

The number of individuals introduced into a new environment has been the most consistently described and widespread correlate of establishment success of alien species (Blackburn, Prowse, *et al.*, 2011; Lockwood *et al.*, 2005). Indeed, propagule pressure is considered the most reliable predictor of biological invasion success (Colautti *et al.*, 2006). As already described, the term propagule pressure incorporates both the number of individuals released in one introduction event and the number of such events (Lockwood *et al.*, 2005). Small introduced populations, with a few notable exceptions (Briski *et al.*, 2018; Roman & Darling, 2007), are likely to fail to establish because of constraints of demography, genetics or environmental variation, even if the location is suitable for their survival and reproduction (as is also the case for small populations of threatened native species) (Cassey *et al.*, 2018; Duncan *et al.*, 2014; Lockwood *et al.*, 2005).

The outcome of a specific introduction and establishment is dependent on resource availability, interactions with other species including natural enemies (predators and parasites), and the abiotic environmental conditions (Catford *et al.*, 2009; Roy & Lawson Handley, 2012; Shea & Chesson, 2002). These factors all vary in time and space and can be modified by human influences or drivers of change in nature (**Chapter 3**) and natural disturbances (Catford *et al.*, 2012). The relative importance of these factors varies between species. As an alien species increases in population density, it will influence the invaded locality through interactions with other species within the community. The process of biological invasion is dynamic and specific outcomes of interactions vary over time and with context including the responses of humans to the invasive alien species, which can range from adaptation to management including eradication and ecosystem restoration **(Box 1.7)**.

The concept of invasibility, the susceptibility of a community to become invaded by one or several species, has been described as an intrinsic community and ecosystem attribute, but this view has been challenged because the lack of available information on species that have failed to establish makes it difficult to infer whether some species are more invasive or some habitats more invasible than others (Colautti *et al.*, 2006; Zenni & Nuñez, 2013). Furthermore, invasiveness of an alien species and the invasibility of the recipient ecological network are interlinked (Hui *et al.*, 2021); establishment success is a function of the interaction between traits or invasiveness of the species (e.g., behaviour, physiology, life history) and invasibility of the environment (e.g., climate, habitat) (Abramides *et al.*, 2011),

Box 1 7 Ecosystem restoration enhancing resilience to invasive alien species.

Ecosystem restoration is defined as any intentional activity that initiates or accelerates the recovery of an ecosystem from a degraded state (IPBES,[3] e.g., **Figure 1.7**) – i.e., assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed – and is often used to reinstate ecosystems that have been altered by invasive alien species. An exciting extra role for ecosystem restoration is to prevent the establishment and spread of invasive alien species in the first place. Indeed, there is increasing interest in using restoration to enhance ecosystem resilience to perturbations as environmental change accelerates.

Invasive alien species are recognized as one of five major drivers of change in nature, with adverse impacts on nature and also, in some cases, nature's contributions to people and good quality of life (**Chapter 4**). As such, management of biological invasions is critical to achieving ecosystem restoration (**Chapter 5**, **section 5.5.7**). However, there is also considerable evidence of invasive alien species as "passengers" of change (S. D. Wilson & Pinno, 2013). Restoring ecosystems to prevent the establishment and spread of invasive alien species is most obviously beneficial under the so-called "Passenger Model", under which invasive alien species are facilitated by anthropogenic environmental change – such as disturbance or eutrophication (**Chapter 3**, **sections 3.3.1** and **3.3.3**). In this case invasive alien species are "passengers" that benefit from the altered environment rather than themselves driving change (MacDougall & Turkington, 2005).

Invasive alien species are frequently a problem during ecosystem restoration, and much research focuses on how to control them. By contrast, studies of the ability of restored ecosystems to prevent the establishment and spread of invasive alien species are few, and most assess resistance during the early stages of ecosystem restoration. For example, Foster *et al.* (2015) found that following experimental additions of invasive alien species, including the highly invasive alien legume *Lespedeza cuneata* (sericea lespedeza), restored American prairie strongly limited invasive alien species compared to unrestored prairie. In general, a high native diversity might be expected to increase resistance to invasive alien species (Byun *et al.*, 2018). However, there is a lack of evidence about the ability of ecosystem restoration to limit biological invasions over the long-term and at large scales.

2021 marked the start of the United Nations-sponsored Decade on Ecosystem Restoration, acknowledging that ecosystem restoration could become central in efforts to resist and effectively prevent biological invasions. Ecosystem restoration has many other benefits, including the enhancement of ecosystem functions and benefits to people, the provision of habitat for native species, and resilience to ongoing environmental change.

3. IPBES glossary: https://ipbes.net/glossary

but crucially also depends on human actions (Duncan *et al.*, 2003; Redding *et al.*, 2019) and on many different and interacting drivers of change in nature (**Chapter 3**, **section 3.5**).

1.4.4 Spread

The next stage in the biological invasion process is known as spread, whereby individuals from an established population disperse across the new environment (Williamson, 1996), increasing the size of the geographic distribution of the alien species. An alien species can spread in various ways, such as through natural dispersal or transport alongside human activities (**section 1.4.1**). Spread requires the alien species to overcome a barrier imposed by limits to dispersal (e.g., the distance between suitable habitat patches), and a barrier imposed by environmental suitability (Rojas-Sandoval & Acevedo-Rodríguez, 2015), which will tend to increase with distance from its location of establishment (Lomolino *et al.*, 2010). Spread of an alien species is a sequence of population establishments, and so environmental suitability can be viewed as presenting barriers to survival and reproduction that must be overcome in each newly colonized location. Human factors, especially those related to disturbance and the creation of corridors, may act as drivers facilitating the spread of alien species within and beyond their non-native range (**Chapter 3**, **sections 3.3.1**, **3.4.2**). It is important to note that there are often time lags, sometimes of decades or more, between introduction, establishment, and spread (Essl *et al.*, 2011; Kowarik, 1995; Seebens *et al.*, 2017).

Introduced populations of alien species can also be a source of new introductions; this is referred to as secondary spread (Bertelsmeier & Keller, 2018). Patterns of spread of alien species have been widely documented (Ascunce *et al.*, 2011; Chapman *et al.*, 2020; Keller *et al.*, 2012; Lombaert *et al.*, 2010) and the mechanisms underpinning secondary spread have been the subject of many studies and some debate (Bertelsmeier & Keller, 2018). A single introduced population can be the source of many secondary introductions and so an alien species may spread rapidly even in the absence of further direct introductions from the native range. This has led to the hypothesis that adaptations for increased invasiveness could have occurred in introduced populations compared to native populations. The term "bridgehead population" or "bridgehead effect" has been used in reference to alien species establishing a stronghold or base population prior to further incursions to other environmentally suitable regions (Lombaert *et al.*, 2010). However, evidence for adaptive evolution within bridgehead populations of introduced alien species is lacking (Bertelsmeier & Keller, 2018) but evolution can play a role in the survival and establishment of introduced species through local adaptation to the novel conditions in the invaded range (Facon *et al.*, 2006; Hufbauer *et al.*, 2012). Introduced populations can reach higher densities than those in the native range, for example because of increased resource availability in the invaded range (Catford *et al.*, 2009). The resulting high abundance, alongside other factors including ongoing introductions from the native range, increases the probability of the alien species moving to new regions with human activities, including trade networks (Banks *et al.*, 2015), providing the necessary connectivity to facilitate the secondary spread (Chapman *et al.*, 2020).

1.4.5 The management-invasion continuum

The invasion curve (**Figure 1.8**; **Glossary**) diagrammatically presents the four stages of biological invasion over time. The curve can be contextually interpreted as number of alien species, area occupied or levels of impact over space and time. It was first developed for policymakers in Australia (Victorian Government, 2010), and is now widely used across government agencies in the United States, Canada, New Zealand and Japan and by some international organizations including the IUCN. As already stated, invasive alien species often have a lag-phase during establishment (Essl *et al.*, 2011; Kowarik, 1995; Seebens *et al.*, 2017). This is followed by a dispersal phase of variable duration during which there is often logarithmic growth, up until the point at which the invasive alien species occupies a large area and so is in the widespread phase when the biophysical or socioecological negative impacts are high and affect a large proportion of the landscape/seascape (**Chapter 4**). The invasion curve highlights the importance of preventative measures (**Figure 1.8**; **Chapter 5**, **section 5.5.2**) before an invasive alien species arrives, and retaining the ability to manage an invasive alien species in the early stages of invasion after arrival. It supports understanding and decision-making of management options along the management-invasion continuum (**Chapter 5**, **sections 5.2** and **5.3**). While the invasion curve is employed widely to understand the process of biological invasions, this assessment will also utilize the IPBES conceptual framework, which is described in **section 1.6.1**.

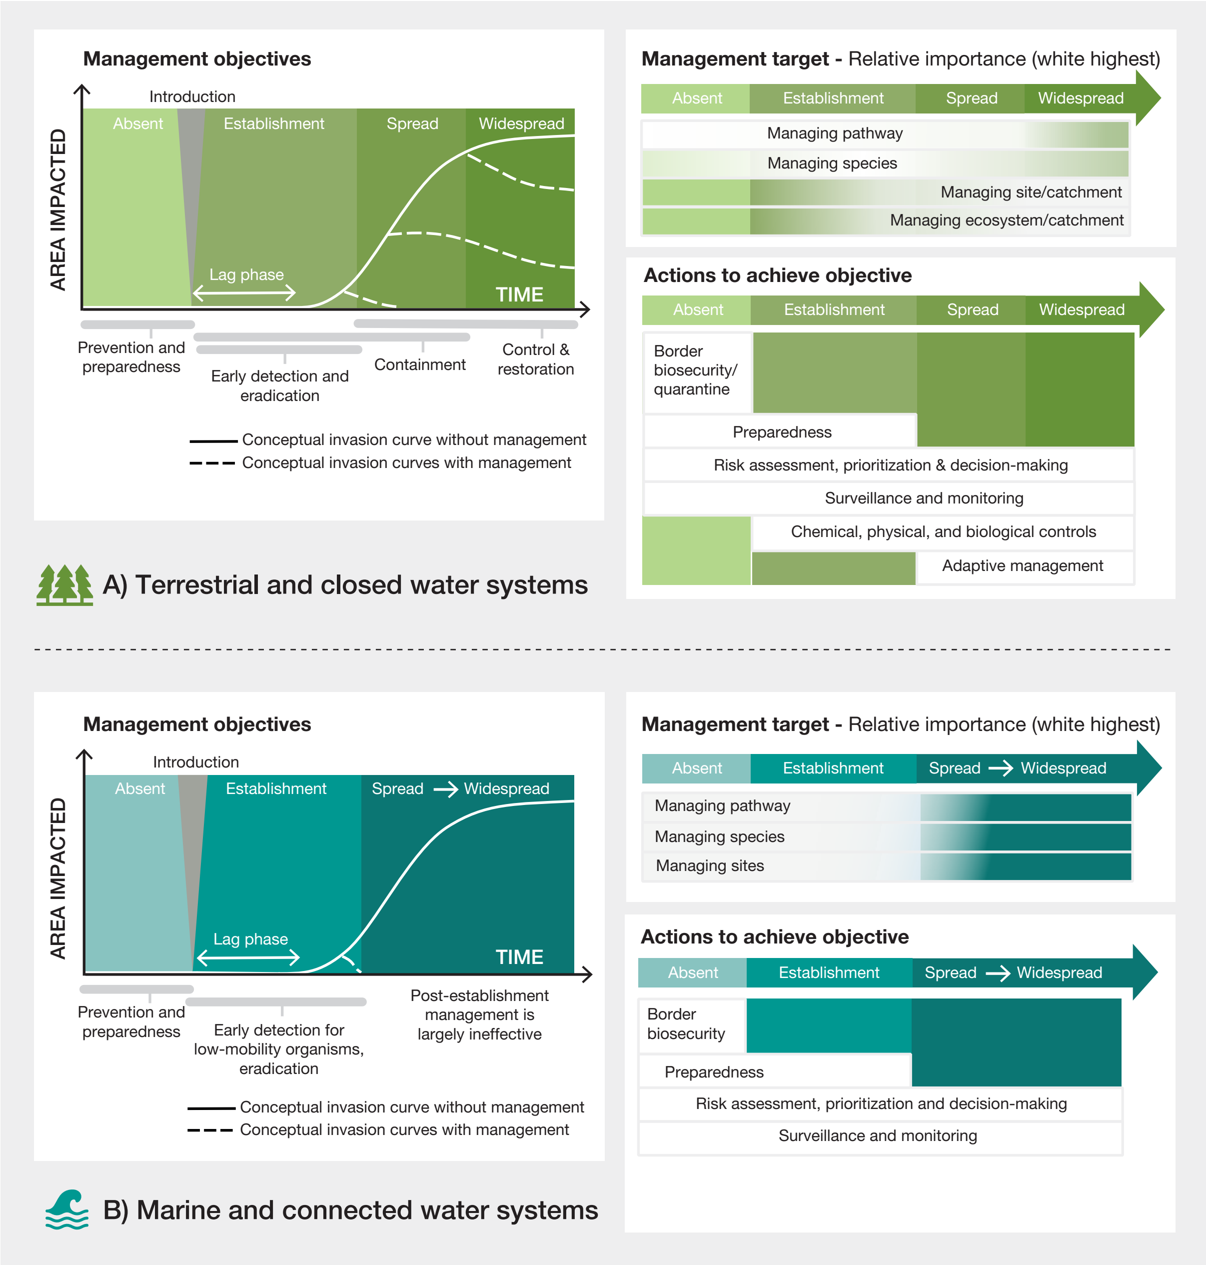

Figure 1 8 **Conceptual diagram of management-invasion continuum (see also Chapter 5, Figure 5.1).**

The generalized invasion curve without management and the expected changes in the invasion curve with appropriate management actions in **A)** terrestrial and closed water systems (including coastal systems and salt marshes) and in **B)** marine and connected water systems. White boxes indicate the optimal management objectives at each stage of the biological invasion process. Colour gradient of managing pathway, species, site and ecosystem boxes show how the relative focus generally changes as biological invasions progress. White boxes indicate typical management actions necessary to achieve each management objective. Post-establishment management actions are not shown under panel B since these are generally not achievable in these systems. In a management context, the first detection (introduction point), the lag phase (see **Glossary**) and the exponential spread phases are important points to design an early detection and rapid response management plan. This figure is conceptual, and the curves do not represent actual population dynamics of invasive alien species.

1.5 SOCIOECOLOGICAL CONTEXT

Increasing attention has been given to understanding the context dependency of biological invasions (Pyšek, Bacher, *et al.*, 2020; Sapsford *et al.*, 2020). Thus, the outcome of each biological invasion not only depends on the propagule pressure and traits of the species invading, but on the recipient ecosystem and its defining parameters within a specific time span and a specific spatial scale (Pauchard & Shea, 2006; **section 1.3.2**; **Figure 1.9**). This context dependency goes beyond ecological parameters as it is at least partly determined by human culture, incorporating behaviour, government policies and regulations, and other social components, including social differentiation and, at times, violent conflict (**Figure 1.9**; Howard, 2019; Kelsch *et al.*, 2020).

Modelling and predicting the spread and potential impacts of invasive alien species on biodiversity and human health and well-being are widely seen as critical to better curtail the harm they can cause to ecosystems and human communities (**Chapter 4**, **section 4.7.1**, and **Chapter 5**, **section 5.6.3.2**). Although there have been considerable advances in this regard, increasingly, scientists are recognizing the inherent difficulties of forecasting these processes in complex socioecological systems (Lenzner *et al.*, 2019). There are several reasons why this remains the case, despite progress in both the natural and social sciences in the study of biological invasions.

Invasive alien species respond to multiple natural and anthropogenic drivers (**Chapter 3**), which can also have synergistic effects on the outcomes of biological invasions. Pörtner *et al.* (2021) highlight the importance of recognizing the complex and multiple connections between climate and other drivers of change in nature. For example, positive feedback loops between plant invasions and more intense and frequent fires **(Box 1.4)** associated with climate change can completely shift fire regimes (Brooks *et al.*, 2004). The sphere of social interactions and human behaviour increases

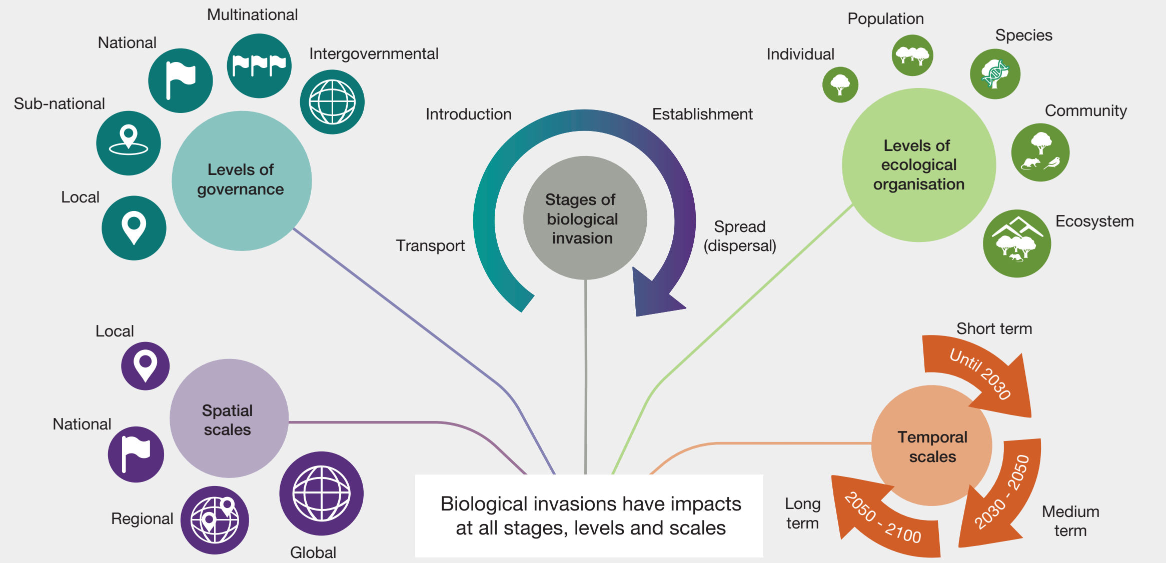

Figure 1.9 **Context dependency in biological invasions across multiple spatial and temporal scales, and governance and ecological levels.**

Underlying processes span various spatial (bottom-left: local to global) and temporal scales (bottom-right: short to long-term). Impacts of invasive alien species on nature, nature's contributions to people and good quality of life also vary across temporal and spatial scales and may differentially affect each level of ecological organization (top-right: from individuals to ecosystems). For some invasive alien species, the impacts are immediate and continue into the long-term (e.g., fast-spreading pathogens such as Zika virus, or fast-spreading predators such as lionfish) while for others there may be a considerable time lags, spanning decades in some cases, before the impacts are apparent (e.g., many invasive alien trees, see Kowarik, 1995). Some invasive alien species have local impacts (e.g., *Carassius auratus* (goldfish) released into small ponds by pet owners) while others impact globally (e.g., *Batrachochytrium dendrobatidis* (chytrid fungus)); and while many invasive alien species have impacts at the individual, population, or community level, others adversely impact entire ecosystems (e.g., eucalyptus and pine trees transforming native grasslands into shrub or wood land). Finally, different levels of governance (top-left: from local to inter-government) affect how biological invasions progress and are managed (e.g., local governance of invasive alien species may differ from national or international policies).

the complexity of mitigation efforts, which can be very difficult to communicate to policy- and decision-makers, to a wide variety of stakeholders, and to Indigenous Peoples and local communities. The effects of human caused fires (i.e., ignition) associated with a particular cultural behaviour have the potential to accelerate fire regime changes, and complicate management decisions alongside the outcomes from biotic and abiotic modelling. As another example, many aquatic invasive alien species are spread through recreational boating and if people who engage in this activity are unaware of the need to practice hull cleaning, and of the damage that invasive alien species can inflict on other recreational pastimes, they will be unlikely to take part in mitigation efforts.

Human responses to the threats posed by invasive alien species, including the introduction of alien species to achieve biological control and the use of chemicals or other agents in eradication programmes, can also affect the possibility of future biological invasions and the range of management responses and policy choices (**Chapters 5** and **6**). If people have begun to adapt to the presence of invasive alien species in a way that benefits them, then efforts to eradicate these species may not be seen as acceptable by some stakeholders (Howard, 2019), and there may also be resistance, on ethical grounds, to management methods that involve lethal responses.

Understanding the process of biological invasions within the context of varying spatial and temporal scales is important but can be challenging, because mechanisms underpinning the patterns are influenced by scale and the peculiarities of the phenomena being studied (Pauchard & Shea, 2006; Sapsford *et al.*, 2020). While patterns of biological invasions have now been documented at multiple spatial and temporal scales (**Chapter 2**), most studies have explored the mechanisms behind biological invasions only at small spatial scales because of the difficulties in experimental design and replicability. Furthermore, most mechanistic studies only look at short periods of time (i.e., a few years). Thus, there is still a critical gap in understanding the process of biological invasion over a range of scales. Simple scaling up is of limited value because processes and mechanisms vary at different scales and changes over time are rarely linear (Kowarik, 1995; Levin, 1992). However, in the last two decades and because of the accumulation of extensive observational datasets and the development of new analytical tools (Sagarin & Pauchard, 2012), macroecological studies are filling some of these gaps. It is now possible to consider invasive alien species on large temporal and spatial scales and therefore link patterns to processes and reveal underpinning mechanisms more robustly than was previously possible (e.g., Seebens *et al.*, 2015, 2021; **Chapter 2**). Indeed, the first estimates of future alien species projections, based on long-term alien species trends, are now available (Seebens *et al.*, 2021), indicating that past trends of invasive alien species will continue to accelerate for many taxonomic groups and regions. Multiscale solutions can help to address the threats posed to the natural world by multiple drivers of change in nature (Bonebrake *et al.*, 2019).

1.5.1 Characterizing stakeholders and biological invasion stages

Invasive alien species can variously affect, and be affected by, different categories of stakeholders across the stages of the biological invasion process **(Figure 1.10)**. A stakeholder refers both to those people who have the capacity to affect (influence) or are affected by (have interests in) biological invasion processes, outcomes, and policies. The IPBES invasive alien species assessment identifies three groups of stakeholders in relation to stages of the biological invasion process. They include "influencing stakeholders", who influence biological invasion processes, management or policies; "affected stakeholders", who are affected by biological invasions as "winners" or "losers"; and "contributing stakeholders" **(Figure 1.10)**, who contribute directly or indirectly to biological invasions without necessarily being influential or affected (Dandy *et al.*, 2017). Such groups are not mutually exclusive – both individuals and organizations can belong to several of these categories **(Figure 1.10)**.

Within the "influencing" and "affected" stakeholder groups, Dandy *et al.* (2017) identify several categories of stakeholders, described in **Table 1.1**.

1.5.2 Perceptions and values

Social and cultural dimensions of biological invasions encompass people's awareness, perceptions, values, attitudes, and interests **(Table 1.2)**. The study of these dimensions helps to better understand social conflicts, engagement and action or inaction throughout the biological invasion process described in **section 1.4**, and particularly in the context of the management of biological invasions and control of invasive alien species (Estévez *et al.*, 2015; Kueffer & Kull, 2017; Novoa *et al.*, 2017; Shackleton, Richardson, *et al.*, 2019). Some key literature from the environmental humanities has been critical in drawing attention to the entanglement of the ecological context and cultural values in biological invasions (Frawley & McCalman, 2014; Head, 2017; Tassin & Kull, 2015) and in showing that management of biological invasions depends on human decision making and behavioural change for success (Head *et al.*, 2005; McNeely, 2001).

Research activity on the social and cultural dimensions of biological invasions is slowly accelerating but is still in

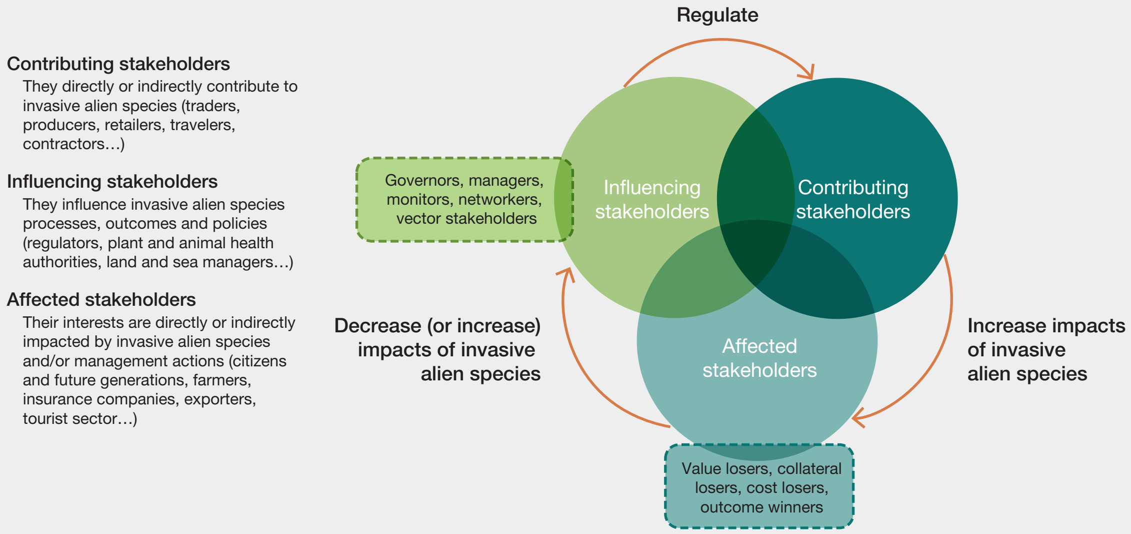

Figure 1 10 **Involvement of different stakeholder groups in the context of biological invasions.**

Table 1 1 **Groups and categories of stakeholders considered in the IPBES invasive alien species assessment.**

For a full description of the Stakeholder categories, please consult **Supplementary material 1.1.**

Stakeholder group	Stakeholder category	Description
Influencing stakeholders	Vector-stakeholders	Individuals or organizations whose activities, intentionally or unintentionally transport, introduce and/or spread invasive alien species
	Governors	Individuals or organizations who set formal and informal rules or establish norms that guide and drive management of biological invasions and adaptation, including prevention across all stages of the biological invasion process
	Monitors	Individuals or organizations who predict, identify, detect, conduct surveillance of and share information on invasive alien species across all stages of the biological invasion process
	Managers	Individuals or organizations who undertake “on-the-ground” responses to biological invasions across all stages of the biological invasion process
	Networkers	Individuals or organizations who disseminate information and key messages between actors relevant to biological invasions management, connecting other stakeholders with differing perspectives and operating at different scales
Affected stakeholders	Value losers	Individuals or organizations for whom nature’s contributions to people and good quality of life are reduced by invasive alien species or by management responses across all stages of the biological invasion process
	Cost losers	Individuals or organizations who bear the direct economic costs of responding to invasive alien species, such as paying for labour and materials required for eradication or containment, or for information dissemination across all stages of the biological invasion process. These direct costs can be incurred in addition to the loss of existing value (i.e., cost losers may often also be value losers)
	Collateral losers	Individuals or organizations who lose value indirectly as a consequence of the adverse impacts of invasive alien species or their management across all stages of the biological invasion process
	Outcome winners	Individuals or organizations for whom nature’s contributions to people and good quality of life are increased by invasive alien species or by their management responses across all stages of the biological invasion process. In some cases, invasive alien species provide additional nature’s contributions to people, in other cases, these stakeholders are able to turn harm into benefit
Contributing stakeholders	Individuals or organizations who directly or indirectly contribute to biological invasions	

Table 1 2 **Primary and underlying factors that shape people's perceptions of invasive alien species.**

Updated from Shackleton, Richardson, *et al.* (2019).

Primary factors driving perceptions of invasive alien species	Example sub-categories
Individual(s)	Demographic characteristics (gender, education, job, etc.) Experience of species and effects Knowledge systems Sense of place Social relationships and group membership Individual values and beliefs Livelihood strategies
Species	Introduction and species status (invasion status) Residence time Species traits Taxonomic/functional group Species charisma
Effects/Impacts (potential and realized) (beneficial and detrimental)	Economic Ecological Social, religious, and cultural Food security
Socio-cultural contexts	Land tenure system Management history Public and media discourse Socio-economic development Social and cultural institutions and value systems Relationship to the land Social memory Language used Livelihoods
Landscape context	Availability of alternative resources (e.g., from native species) Ecosystem type Land use and cover Landscape beauty/scenery or attractiveness Management history Ecosystem services
Institutional, governance and policy context	Historical processes Institutional frameworks International agreements Legislation, regulation, and enforcement Policy and governance strategy Scientific knowledge and understanding Power and responsibility

its infancy (Kapitza *et al.*, 2019; Vaz *et al.*, 2017). There have been important contributions to the understanding of biological invasions from the humanities **(Box 1.8)** and social sciences. However, a review of studies on biological invasions published between 1950 and 2014 revealed that contributions from the social sciences were limited to less than five per cent and that up to the 1990s interdisciplinary collaborations were largely confined to interactions between ecological and environmental sciences (Vaz *et al.*, 2017).

Kapitza *et al.* (2019) conducted a systematic review of studies on social perceptions of invasive alien species published before 2016. While the scope of this study was limited to the perception of invasive alien species themselves (thus excluding studies on perceptions of control or management of invasive alien species) it does reveal some important insights. First, most studies investigated perceptions of the general public (79 per cent), followed by decision-makers' (35 per cent) and scientists' (23 per cent) perspectives. Second, these studies reported a frequent use of quantitative methods using questionnaires, while only 14 per cent of the studies used qualitative methods such as interviews. Arguably, this indirectly led to a bias towards measuring perceived detrimental impacts of invasive alien species as these were more commonly included as items in questionnaires than the benefits of invasive alien species. Third, there were large biases in taxonomy (more than half of the studies (58 per cent) focused on plants), ecosystems (the majority of the studies (78 per cent) focused on terrestrial ecosystems), and geographical region (more than half of the studies were conducted in either North America (32 per cent) or Europe (28 per cent). This systematic review demonstrates the difficulty of ascertaining a clear picture of social perceptions

Box 1 8 Contributions to understanding of biological invasions from historical studies.

Since the emergence of the field of invasion biology in the 1980s, ecologists have increasingly recognized that the study of biological invasions involves significant ethical and cultural considerations that fall outside the purview of the biological sciences (Frawley & McCalman, 2014; Simberloff & Rejmanek, 2011). Historians have contributed to this research in three key ways: 1) by identifying the historical drivers of species migration; 2) by describing the emergence of narratives of biological invasion in scientific discourse and the impacts of invasive alien species control programmes; and 3) by deconstructing the language of prevalent biological invasions frameworks. They have shown that although species have always migrated across ecosystems, species movement accelerated from the eighteenth century onwards due to the mobilization of global agriculture, the extraction of biological matter for "exotic" horticulture, and land-use change (K. Thomas, 1984; Robbins, 2002; Ritvo, 2014; Bewell, 2017). Historians have described this advent of species movement "the Columbian exchange" (Crosby, 1972) and "ecological imperialism" (Crosby, 1986); few would disagree that the spread of commercial trade has been and continues to be the main driver facilitating species' introductions, including those now driven by climate change.

Legislation permitting the widespread control of certain plants and animals, unintentionally imported to colonial plantations, that had negative impacts on crops date back to the late eighteenth century. However, it wasn't until the late nineteenth century that some alien species were described as invasive. Historians have pointed to Charles Darwin, T.H. Huxley, his grandson Julian Huxley, and Charles Elton as key figures in the articulation of invasive alien species as a subject of scientific interest. This emergent narrative of biological invasion has been associated with xenophobia, successive wars, the start of the collapse of European empires, and early science fiction that addressed themes of alien invasion and scientific attempts to control it (Alt, 2010; Hovanec, 2018; Chang, 2019).

Historians and geographers have argued that neither "invasive" nor "native" are stable characteristics but are rather narratives of behaviours and interactions between species in ever-changing bio-cultural environments (Cronon, 1992; Smout, 2003; Frawley & McCalman, 2014). Such narratives often change over time (Hobbs *et al.*, 2006; Pawson & Christensen, 2014; Rangan & Kull, 2009; Ritvo, 2014). Some argue that "invasive" implies the previous existence of a static biota free from alien species when no such past exists (Rotherham & Lambert, 2013; Ritvo, 2014). Others have analysed the theory of "shifting baselines" — the way that each generation, without considering historical factors, bases science and policy decision-making around their own ecological circumstances (Dizard, 2010; Pauly, 1995; Vera, 2010).

Several critical studies have addressed the power of narratives about biological invasions in driving responses to changing environments such as eradication programmes (Smout, 2003; Trigger, 2008), and suggest that such stark binaries obscure the dynamism of changing environments (Head & Muir, 2004; Beinart & Wotshela, 2003; C. D. Thomas, 2017; Shah, 2020), including biodiversity gains and cultural losses. Failures to consider the diversity of rights-holders and stakeholders when addressing anthropogenic drivers of species loss in the past have enabled the continuation of colonial science in conservation decision-making (Grove, 1996; Griffiths & Robin, 1997; Caluya, 2014). Some historians urge that there is a need to emphasize the role of class and race in order to avoid deepening global inequalities (Nixon, 2011; Moore, 2016; Caluya, 2014). Researchers across the humanities are nevertheless in agreement that to solve the current and future interconnected problems of the global environmental crisis, we need to understand the complex interactions of ecologies, cultures, and societies of the past.

of biological invasions, despite their importance to the IPBES invasive alien species assessment.

An important aspect of perception is public awareness of invasive alien species. Public awareness is notoriously difficult to measure, but it is fundamental if preventive regimes (see **Glossary**) are to be adopted within communities. Schelhas *et al.* (2021) conducted an extensive review of public awareness and derived four important conclusions:

1. Knowledge of public awareness of invasive alien species is still quite limited and comes from either case study research or census studies. Case studies found that people are often generally aware of the existence of invasive alien species, but have limited knowledge about specific species, their impacts on biodiversity or the role of people in their introduction (e.g., García-Llorente *et al.*, 2008; Lindemann-Matthies, 2016; Verbrugge *et al.*, 2013, 2014). Findings from a survey on attitudes of citizens towards biodiversity show that, across Europe, introduced plants and animals are perceived as a lower threat to biodiversity compared to air and water pollution, human-made disasters, intensive farming, deforestation and over-fishing, climate change and conversion of natural areas to other uses (European Commission, 2013, 2015, 2019). However, in highly impacted locations, such as Hawai'i (Kalnicky, 2012) and in countries with a long history in plant and animal invasions, such as New Zealand (Hulme, 2020b), public interest and knowledge are often greater, as is support for management.

2. Invasive alien species are often viewed differently by the public than by scientists or policy makers. A mail

survey in the United States showed that members of the public ranked invasive alien species as 19 out of 24 ecological risk items, while professional risk assessors ranked them as ninth (Slimak & Dietz, 2006). A species' perceived harmfulness and human responsibility for its spread were the most important animating factors, while non-nativeness did not necessarily raise concerns (Qvenild *et al.*, 2014; Selge *et al.*, 2011). However, species' charisma (characteristics that positively affect the perceptions, attitudes, and behaviours of people towards them) can also have implications on public perceptions and consequently management interventions (Jarić *et al.*, 2020). Time also plays a role in shaping public perceptions, as people may be unaware of the origin of introduced species as they are regarded as normal or desirable in their natural surroundings (Genovart *et al.*, 2013) – this is sometimes also referred to as shifting baseline syndrome (Clavero, 2014).

3. It is suggested that the terminology employed to call attention to invasive alien species and their control should be chosen carefully (Clergeau & Nuñez, 2006; Janovsky & Larson, 2019; Larson, 2005; Verbrugge *et al.*, 2016). The use of metaphors or derogative language is common in both scientific and popular writing about biological invasions, but little is known about the effects on public values or opinions. How the issue-area is framed by officials, scientists, politicians, and other leaders will have an impact on subsequent policy development; biological invasions can be seen primarily as threats to biodiversity, national security, human health, trade, or even cultural homogeneity (Stoett, 2010).

4. Indigenous voices and values are under-represented in scholarly discourse about invasive alien species (e.g., Bhattacharyya & Larson, 2014). The IPBES invasive alien species assessment has attempted to be inclusive, but see Schelhas *et al.* (2021) for an elaborative view on the importance of considering Indigenous and local knowledge, unique cultural dimensions and engaging Indigenous Peoples and local communities in the management of biological invasions and the control of invasive alien species, using two examples from the United States to show how invasive alien species can either culturally impoverish or enrich Indigenous Peoples and local communities (see also Pfeiffer & Voeks, 2008). The social justice concerns related to Indigenous Peoples and local communities as they manage biological invasions should not be overlooked (Head & Atchison, 2015).

Perceptions of invasive alien species and support for management are thus influenced by a wide range of values (**Table 1.2**; **Boxes 1.9** and **1.10**; see also Carter *et al.*, (2021) who extend this overview with ethical considerations for including social perspectives in research planning and decision-making). Research in the past five years has become more diverse in terms of theoretical and methodological approaches, for example by analysing how socio-historical processes interact with biological invasions (Archibald *et al.*, 2020), developing "sense of place" as a concept to explain how place attachment can promote or impede action against invasive alien species, or reframing biological invasions as socioecological phenomena to enhance cross-fertilization across ecological sciences and social sciences (Gawith *et al.*, 2020; Vaz *et al.*, 2017). Encouragingly, collaborative knowledge platforms are being developed (e.g., Bennett & van Sittert, 2019; Udo *et al.*, 2019), but further efforts for realizing collaboration between natural and social sciences are much needed for a more holistic understanding of perceptions of invasive alien species and critical for developing adequate control and policy responses.

Box 1 9 **Human values and the invasive alien carp in North America.**

A group of invasive alien carps (cyprinid fishes) were brought from Eastern Asia to Arkansas, United States of America in the 1960s to serve as biological control agents in aquaculture ponds (Besek, 2019). Many escaped soon after their importation and have since been migrating up the Mississippi River watershed, adversely impacting both social and ecological systems along the way. Since the early 2000s, many stakeholders with an interest in the North American Great Lakes have been advocating for the construction of a hydrologic barrier to stop invasive alien carp from entering and impacting their fisheries. This proposed barrier, however, would drastically impact regional shipping and transportation, setting up a substantial political battle regarding how to best manage invasive alien carp spread. This contentious social context has significantly impacted the work of scientists trying to assess invasive alien carp migration, tying their work to local politics and human values in numerous ways. For instance, most scientists have refused to offer unqualified predictions about the future migration of invasive alien carp because the ecological processes involved are so complex, and many political actors have seized on this indeterminacy to publicly question science methodologies and laboratory techniques used to study invasive alien species. Some scientists have been requested to explain and defend their work in federal courtrooms. This heated political climate has in some ways given extra attention to detection techniques, improving their precision, but has also led many scientists to avoid working on invasive alien carp altogether.

Box 1 10 **Conceptual perspectives from the social sciences.**

Social science and humanities research on biological invasions has grown steadily since the 1990s (Vaz *et al.*, 2017). Some of this work addresses perceptions, attitudes, and behaviours with a perspective towards enabling management and control of invaders (Rotherham & Lambert, 2013; Shackleton, Richardson, *et al.*, 2019). Arguably, when social science is integrated with biological invasion science, it has followed an "ABC" framework, focusing primarily on attitudes, behaviour, and choice (Shove, 2010). Some researchers are leaning towards more explicitly "critical" approaches to biological invasion science (Head, 2017; Kull, 2018). By "critical", social scientists refer to approaches that question underlying processes and conceptual foundations, seeing knowledge as political and transformative.

Several factors inform a critical social science perspective. It is challenging to consider landscapes being invaded without looking at how they have been co-produced by humans in myriad ways (for instance, clearance, soil degradation and introductions), and in many cases the invasive alien species themselves (for instance, genetic selection for species that have been introduced). This focus shifts attention from dangerous invaders to human complicity in biological invasions (Kueffer, 2017). Second, the study of invasive alien species has a specific trajectory and social context that shapes the knowledge produced on biological invasions (Archibald *et al.*, 2020). The social-political context of the institutions that undertake biological invasion-related research and seek to manage biological invasions and control invasive alien species (state weed agencies, land managers), is relevant, as this determines the voices and knowledge systems that are heard. The IPBES conceptual framework is attentive to the need to examine a variety of knowledge systems (Díaz *et al.*, 2015). A third necessity is to investigate how knowledge about invasive alien species is used and implemented, and what the consequences are for people and landscapes (Kull, 2018). The establishment of lists of high risk invasive alien species, for quarantine systems, or for community weed-pulling days; sending rangers out to spray herbicides on invasive alien plants or lay poison traps for invasive alien animals; establishing major public works policies like South Africa's "Working for Water" programme – each of these actions has knock-on effects, creates winners and losers, and creates ripples in the system that are not entirely predictable nor agreed to by all parties (Atchison & Head, 2013; Bach *et al.*, 2019; Fall, 2013; Gallardo *et al.*, 2019; Head *et al.*, 2015).

1.5.3 Ethics and invasive alien species

The management of invasive alien species, in particular sentient animals, raises multiple ethical debates with regards to animal welfare and rights, and this is considered an under-addressed animal welfare issue in conservation (Carter *et al.*, 2021; Doherty & Russell, 2019; Hampton & Hyndman, 2019; **Chapter 5**, **section 5.6.2.1**).

There are philosophical differences between proponents of animal rights, who focus on the individual animal, and those who focus on conservation at a species or ecosystem level, with the former having an increasing influence on public opinion and legislation. The extension of legal rights to animals and nature imposes moral and legal limits on acceptable human uses of the environment, and if the legal personality (**Glossary**) of both ecosystems and individual animals is acknowledged, the interests of individual animals may conflict with interests of individual species, as can be the case with native and invasive alien species (Futhazar, 2020). Arguably, the rights of native species to exist need to be respected (hence the importance of prevention and adapting the precautionary principle) but once an invasive alien species is established, the picture is more complicated.

Deciding whether and how to control invasive alien species involves analysing risks, and considering international consensus principles for ethical wildlife control which are informed by social and cultural values in addition to scientific, technical, and practical information. As discussed above, there is a diverse range of perceptions of invasive alien species, both positive and negative (Shackleton, Richardson, *et al.*, 2019). Moral dilemmas posed by controlling invasive alien species can involve subjective judgements about the perceived ecological value of protected species *versus* the lack of importance of invasive alien species (Mankad *et al.*, 2019) or indeed the charisma of one species compared to another (Jarić *et al.*, 2020).

Different invasive alien species management methods can raise different ethical debates. Genome editing can pose ethical questions because of concerns about the risks and unknown consequences of releasing genetically modified plants or animals into the wild (**Chapter 5**, **section 5.4.4.2**) (Bertolino, 2020). Gene suppression-drives may pose risks to global populations of invasive alien species and so are being considered with caution (Thresher, 2020). There are several reports outlining the risks and opportunities of these technologies (**Chapter 5**, **section 5.4.4.2**; Invasive Species Advisory Committee (ISAC), 2017; Redford *et al.*, 2019). Biological control can pose potential social and environmental risks, but often brings benefits (Müller-Schärer *et al.*, 2020; Thomas & Willis, 1998), and evokes a normative debate (Mankad *et al.*, 2019). It is relevant to consider social values and emotional and cultural associations, in addition to stakeholder preferences, humaneness and effectiveness, when managing invasive alien species (Mankad *et al.*, 2019).

Lethal management methods can be particularly controversial and a framework for assessing the success and sustainability of a particular management decision that takes into account ecology, economic and ethics has been proposed (Warburton & Anderson, 2018). Prevention is often the "preferred option for managers and desirable and philosophically acceptable to animal rights advocates" (Perry & Perry, 2008). Furthermore, proponents of compassionate conservation state that humans should do no harm and consider that individual animals matter.

Given the range of values and management options, there are unique conceptual and governance challenges associated with invasive alien species (Stoett, 2007). The language used to describe invasive alien species has sometimes been labelled as nativist (Gbedomon *et al.*, 2020), and is predominantly negative. Inglis (2020) states that; "the invasive discourse is couched in language which immediately prejudices people against the animals. This leads to the killing of these animals being viewed as both morally acceptable and indeed necessary." Nevertheless, Shackelford *et al.* (2013) suggest finding middle-ground in the native/non-native debate that recognizes the merits of both sides when assessing management options. Furthermore, there is no globally accepted definition of animal welfare and interpretation of the concept of animal welfare evolves with advances in our understanding of animals (Dawkins, 2017; Harrop, 2013; Mellor *et al.*, 2020; White, 2013).

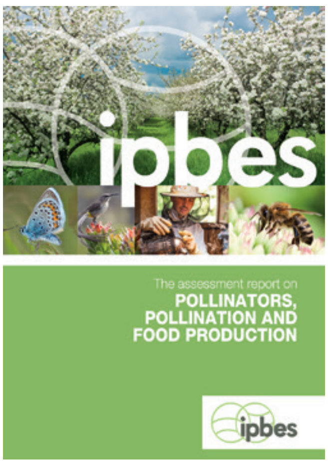
An eighteenth Sustainable Development Goal on animal health, welfare and rights has been suggested to ameliorate trade-offs between animal welfare and sustainability, with the management of invasive alien species noted as an example (Visseren-Hamakers, 2020). Accordingly, as discussed in **Chapter 6**, balancing values across multiple and interrelated stakeholder groups is an important consideration within invasive alien species management (Carter *et al.*, 2021).

1.6 CONCEPTUAL BASIS FOR THE INVASIVE ALIEN SPECIES ASSESSMENT

IPBES assessments aim to identify policy-relevant findings for decision-making in government, the private sector and civil society by synthesizing and critically evaluating peer-reviewed scientific literature, grey literature, and other available knowledge, such as Indigenous and local knowledge. Assessments do not generate new data, but seek to create new understanding through summary, sorting and synthesis using different methods to manage complexity.

The IPBES invasive alien species assessment builds upon several IPBES assessments, which include

Box 1 11 **Biological invasions and pollination processes.**



The IPBES Assessment Report on Pollinators, Pollination and Food Production (IPBES, 2016b) considered the outcomes of biological invasions on pollinator populations, diversity, network structure and pollination processes and confirmed that ecological and evolutionary contexts are important. Although predicting the consequences of the arrival of an invasive alien species within a pollinator network is difficult, because of the ecological complexity inherent with multiple interacting species, it is apparent that the trophic position (plant/herbivore/pollinator/predator) and degree of specialization of an invasive alien species can be informative. Invasive alien species can alter the function, structure and stability of plant-pollinator networks with adverse impacts on specific native pollinator species and, sometimes, reductions in overall pollinator abundance or diversity (Vilà *et al.*, 2009). In native pollination networks dominated by generalist plants and pollinators, invasive alien plant species are often readily integrated. Consequently, networks including alien plants are characterized by increased plant and pollinator richness and high values of nestedness (Stouffer *et al.*, 2014). As an example, alien species (plants and pollinators) comprised 56 percent of the total number of interactions within pollination networks on the Galápagos Islands. Alien insects within these pollination networks linked mostly to generalist plant species resulting in increased nestedness and network stability (Traveset *et al.*, 2015). Such changes to the community structure increase network cohesiveness but disrupt native ecological interactions (Traveset *et al.*, 2015). The impacts of invasive alien species on pollinators and pollination are likely to be further exacerbated when coupled with other threats including wildlife diseases, climate or land-use change (González-Varo *et al.*, 2013; Schweiger *et al.*, 2010; Sunny *et al.*, 2015; Vanbergen & Initiative, 2013).

thematic assessments of Pollinators, Pollination and Food Production (IPBES, 2016b; **Box 1.11**), Land Degradation and Restoration (IPBES, 2018c); Sustainable Use of Wild Species (IPBES, 2022c); Methodological Assessments of Scenarios and Models of Biodiversity and Ecosystem Services (IPBES, 2016c), and of the Diverse Values and Valuation of Nature (IPBES, 2022a); four regional assessments of Biodiversity and Ecosystem Services (IPBES, 2018d, 2018e, 2018f, 2018g); and the Global Assessment of Biodiversity and Ecosystem Services (IPBES, 2019).

1.6.1 The IPBES conceptual framework and its use in the invasive alien species assessment

The IPBES conceptual framework[4] aims to facilitate interdisciplinary collaboration and science-policy dialogues (Díaz *et al.*, 2015). It explicitly considers diverse disciplines, different stakeholders and Indigenous Peoples and local communities (**section 1.5.2**), and several knowledge systems (natural sciences, social sciences and humanities, Indigenous, local and practitioners' knowledge).

4. A full description of the IPBES conceptual framework, and associated definitions, is available in **Supplementary material 1.2**.

The IPBES conceptual framework includes six interlinked elements constituting a socioecological system that operates at various scales in time and space: nature; nature's contributions to people; anthropogenic assets; institutions and governance systems and other indirect drivers of change; direct drivers of change; and good quality of life.

The IPBES invasive alien species assessment falls within the IPBES conceptual framework, and uses it to understand how the major threat posed by invasive alien species can be reduced while those that are considered important components of nature and nature's contributions to people can be maintained in order to improve good quality of life. The assessment recognizes the importance of integrating this knowledge in the broader context of global change. By superimposing the specificities of the assessment over the IPBES conceptual framework, **Figure 1.11** shows the interactions between invasive alien species and the other elements of the IPBES conceptual framework. All these relationships are dynamic, changing over time, and different scenarios (i.e., trajectories for each component) are likely to lead to different outcomes. Socioecological contexts, including public awareness and stakeholder engagement levels, can also change according to the spatial scale under consideration (i.e., local, regional, global), thus affecting how invasive alien species are perceived and managed.

Box 1 12 Nature's contributions to people.

Nature's contributions to people are an integral part of the IPBES conceptual framework **(Figure 1.11)** and represent all the contributions, both positive and negative, of living nature (i.e., diversity of organisms, ecosystems, and their associated ecological and evolutionary processes) to the quality of life for people (Díaz *et al.*, 2018). Beneficial contributions from nature include such things as food provision, water purification, flood control, and artistic inspiration, whereas detrimental contributions include transmission of disease, particularly those affecting animal, plant, and human health **(Box 1.14)**, and other ways in which harm to people or their assets or community stability/resilience may occur as a consequence of invasive alien species. Many of nature's contributions to people may be perceived as beneficial or detrimental depending on the cultural, temporal, or spatial context (Díaz *et al.*, 2018; **sections 1.5.2**, **1.5.3**; **Chapter 4**, **section 4.1.3**). The concept of nature's contributions to people addresses the need to recognize the cultural and spiritual impacts of biodiversity, in ways that are not restricted to a discrete cultural ecosystem services category, but instead encompass diverse world views of human-nature relations (Mace, 2014).

The IPBES invasive alien species assessment adopts the 18 categories identified by IPBES for reporting nature's contributions to people (Díaz *et al.*, 2018). These 18 categories of nature's contributions to people are organized into three partially overlapping groups, according to the type of contribution they make to people's quality of life **(Figure 1.12)**:

Material nature's contributions to people: substances, objects, or other material elements from nature that directly sustain people's physical existence and material assets. They are typically physically consumed in the process of being experienced.

Non-material nature's contributions to people: nature's effects on subjective or psychological aspects underpinning people's quality of life, both individually and collectively.

Nature's regulating contributions to people: functional and structural aspects of organisms and ecosystems that modify the environmental conditions experienced by people, and/or sustain and/or regulate the generation of material and non-material contributions.

Box 1 12

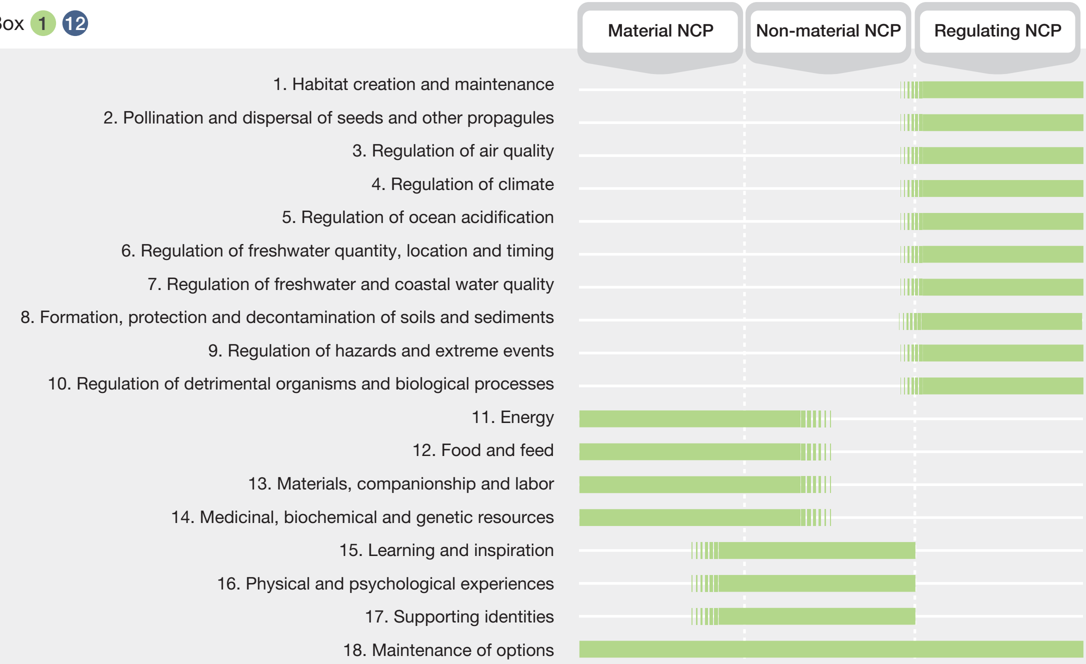


Figure 1 12 **Categories of nature's contributions to people (NCP).**

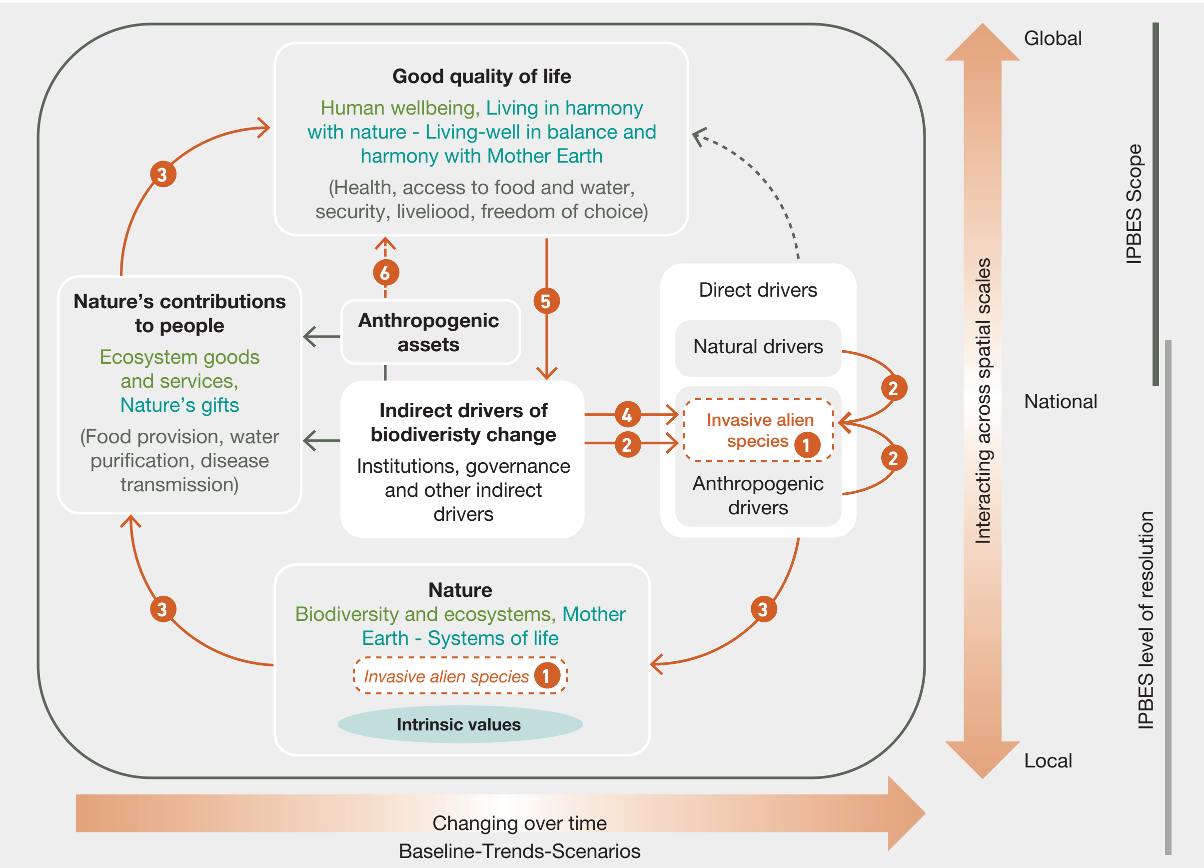
From Brondizio *et al.* (2019), https://doi.org/10.5281/zenodo.3831852, under license CC BY 4.0. These categories are used in this assessment of invasive alien species.



1 **Status and trends of invasive alien species:** invasive alien species are one of five major direct drivers of change, and at the same time are part of nature. This assessment captures both aspects, with their dynamics being addressed in **Chapter 2**.

2 **Synergies and interactions of invasive alien species with other drivers of change in nature:** the transport, introduction, establishment and spread of invasive alien species are facilitated, modified and amplified through interactions and synergies with other direct and indirect drivers of change in nature (e.g., climate change, economic drivers) as well as by natural hazards and biodiversity loss (addressed in **Chapter 3**).

3 **Impacts of invasive alien species on nature, nature's contributions to people and good quality of life:** invasive alien species impact nature in diverse ways, and often in ways that interact with other drivers of change in non-linear ways (synergistic, antagonistic) (addressed in **Chapter 4**). Changes to nature, including in ecosystem functions, underpin changes to nature's contributions to people (see **Box 1.12**), which can affect society in detrimental or, in some cases, beneficial ways (addressed in **Chapter 4**). The effects of invasive alien species on people and good quality of life (**section 1.6.7.2**) can be direct or through other components of the ecosystems (e.g., human health may be affected by parasites and contagious emergent diseases) (addressed in **Chapter 4**).

4 **Responses to biological invasions:** institutions, governance and other societal indirect drivers of change in nature can respond to biological invasions through direct management measures, including prevention and adaptation, restoration and policies (addressed in **Chapters 5** and **6**).

5 **Influence of people on responses to invasive alien species:** biological invasions' management and policies are driven by how people perceive and act in response to the threat of invasive alien species (addressed in **Chapters 1**, **5** and **6**).

6 **Adaptation to invasive alien species:** society can also adapt to invasive alien species and thus mitigate their adverse impacts on good quality of life; for example, invasive alien species can become new sources of food security (addressed in **Chapters 5** and **6**).

Figure 1 11 **The IPBES conceptual framework adapted to the IPBES invasive alien species assessment.**

Interactions amongst the components of the IPBES conceptual framework that are relevant to biological invasions are indicated in numbered arrows (boxes, arrows and numbers), with detailed descriptions provided in the lower panel of the figure. Unnumbered arrows represent the relationships between different components of the IPBES conceptual framework as defined in Díaz *et al.* (2015), that are not studied in this assessment. Adapted from Díaz *et al.* (2015), https://doi.org/10.1016/j.cosust.2014.11.002, under license CC BY-NC-SA 3.0.

1.6.2 Literature review

The IPBES invasive alien species assessment's findings emerge from systematic and transparent evaluations of available evidence to date[5] combined with experts' inputs, taking into account different worldviews and knowledge systems. Existing evidence encompasses published scientific and grey literature, including Indigenous and local knowledge, government publications, policy documents and briefs, technical reports and datasets, etc. This assessment also builds on previous IPBES assessments and other relevant global assessments such as the Global Biodiversity Outlook series, the United Nations Environment Programme (UNEP) Global Environment Outlook series, and the Millennium Ecosystem Assessment.

Authors were guided by the IPBES Data Management Policy (IPBES, 2020a), and the flexible protocol for systematic review that was first developed by the Global Assessment of Biodiversity and Ecosystem Services (Brondizio *et al.*, 2019; Collaboration for Environmental Evidence, 2013), which is critical to achieve scientific credibility and transparency of the assessment, following the FAIR (findable, accessible, interoperable, and reusable) data principles.

Authors sought to represent the most relevant and highest quality evidence, with the highest level of synthesis available as a priority; and provided supplemental material if necessary to fully cover and evaluate the topic, or to include the most up-to-date information. Methodologies and workflows for literature reviews usually include two practical steps: 1) concurrent database searches of different kinds of literature (e.g., peer reviewed and "grey" published literature, unpublished but openly available reports and databases) to minimize potential biases and 2) personal knowledge and experience of authors regarding key seminal resources or publications not appearing as an output from first step (if available).

Data and information have been compiled from many sources and domains spanning scales from local to global **(Figure 1.13)**. Throughout the chapters, following

5. The cut-off date for the inclusion of published sources was 15 December 2021, which corresponds to the start of the second external review (second draft of the chapters and first draft of the summary for policymakers). In line with IPBES procedures, additional citations were included passed this date when prompted by a comment made during the second external review (accessible at https://ipbes.net/ias) and when seen as relevant by experts.

extensive synthesis of available evidence, gaps in existing knowledge were revealed and documented with an overarching synthesis of gaps, and options for addressing them, provided within **Chapter 6**. The IPBES Regional Assessments of Biodiversity and Ecosystem Services all recognize gaps in data and information which are particularly pronounced in some regions and for many taxa (IPBES, 2018g, 2018f, 2018d, 2018e, 2018c). However, the growth in availability of datasets globally is encouraging (**Chapter 2**, **section 2.1.4**), although there remain lags in collating and sharing information on invasive alien species and consequently gaps in datasets across all regions.

The analysis of Indigenous Peoples and local communities' issues and knowledge also benefited from an "online call for contributions", which collected 30 references that were reviewed and selected to inform specific sections of the assessment. Three Indigenous and local knowledge dialogue workshops were also held throughout the timeframe of the assessment, which led to suggested literature and government reports being reviewed (**section 1.6.7.1**).

Authors documented their sources as well as their methodologies and workflows for literature reviews in data management reports, which are linked as footnotes, where appropriate. Across all chapters, references are cited within the text and the full reference is provided at the end of each chapter. The executive summaries of the chapters and the background text of the summary for policymakers include statements with traceability enclosed in curly brackets linking the statements to their underlying chapter subsections.

These systematic literature reviews, combined with expert-based critical opinions, are intended to enable the IPBES invasive alien species assessment to generate key findings and policy-relevant messages to support decision-makers in better understanding and tackling the complex issue of biological invasions and invasive alien species (**section 1.6.3**).

1.6.3 IPBES confidence framework

Confidence levels assist authors in the process of assessing and communicating the degree of uncertainty, or confidence, related to key findings. The evidence includes publications, data, theory, models and information **(Figure 1.14)** from multiple disciplines and knowledge

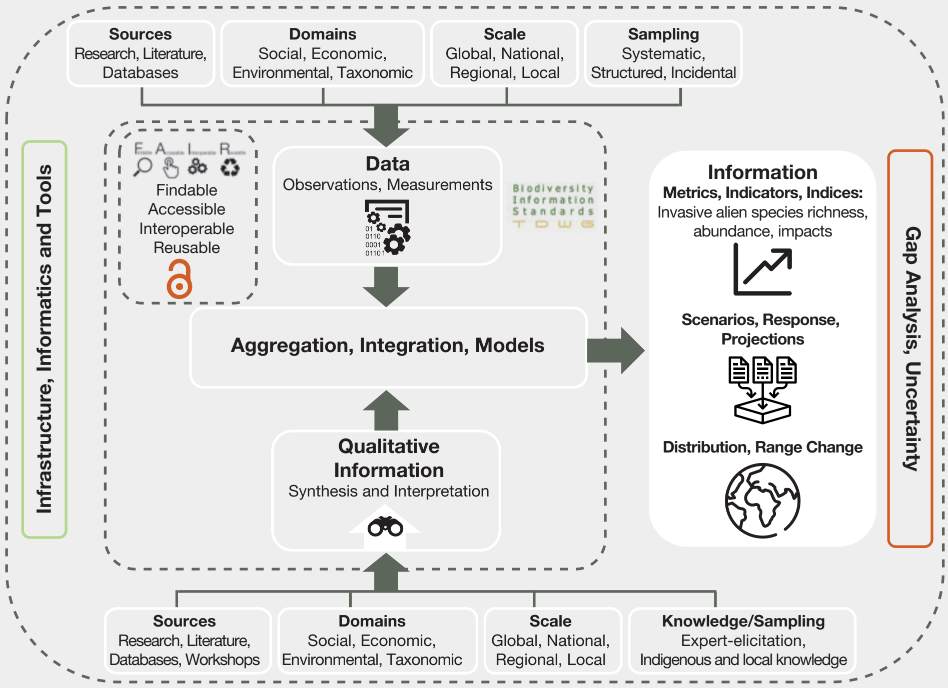


Figure 1 13 **Connections amongst types of evidence.**

Data and knowledge (**Chapter 2**) from many sources and domains spanning various scales and sampling techniques are combined to establish information in the form of metrics, indicators and indices which contributes knowledge on drivers (**Chapter 3**) and impacts (**Chapter 4**), ultimately informing management (**Chapter 5**) and future options (**Chapter 6**).

Figure 1 14 **The four-box model for the qualitative communication of confidence.**

Confidence increases towards the top-right corner as suggested by the increasing strength of shading. The four-box confidence framework developed for IPBES assessments is based on the quantity and quality of evidence assessed (x-axis) in combination with the level of agreement of experts using their judgment (y-axis). From IPBES (2016a), https://doi.org/10.5281/zenodo.2616458, under license CC BY 4.0.

systems. These confidence terms inform and communicate to decision-makers the degree of confidence that the assessment author teams associate to the key findings throughout the assessment and, importantly, highlight where further investigation is required to inform robust evidence-based decision making. Further details of the approach are documented in the IPBES Guide to the Production of Assessments (IPBES, 2018b).

The summary terms to describe the evidence are:

- **Well established:** There is a comprehensive meta-analysis or other syntheses/multiple independent studies that agree.
- **Established but incomplete:** There is general agreement although only a limited number of studies exist; there is no comprehensive synthesis, and/or the studies that exist address the question imprecisely.
- **Unresolved:** Multiple independent studies exist but their conclusions do not agree.
- **Inconclusive:** There is limited evidence and a recognition of major knowledge gaps.

1.6.4 IPBES regions and sub-regions

The IPBES invasive alien species assessment is global and encompasses alien species in terrestrial, freshwater and marine ecosystems across regions. It adopts the IPBES categorization of regions and sub-regions (**Figure 1.15**; IPBES technical support unit on knowledge and data, 2021) to structure its analysis (**Chapters 2, 3, 4, 5** and **6**). The IPBES technical support unit on knowledge and data (2021) also produced the dataset describing the IPBES regions and sub-regions and their corresponding countries or areas, in line with decision IPBES-3/1.

1.6.5 IPBES units of analysis

Each region and sub-region **(Figure 1.15)** are divided into multiple spatial units (biomes and ecosystems), spreading across borders. The invasive alien species assessment therefore adopts the 17 IPBES units of analysis (**Table 1.3**, see **Chapters 2, 3, 4, 5** and **6**) also used in previous IPBES assessments and defined by the IPBES Global Assessment (IPBES, 2019)[6] to support its analysis.

6. Definitions of the IPBES units of analysis available in **Supplementary material 1.3**

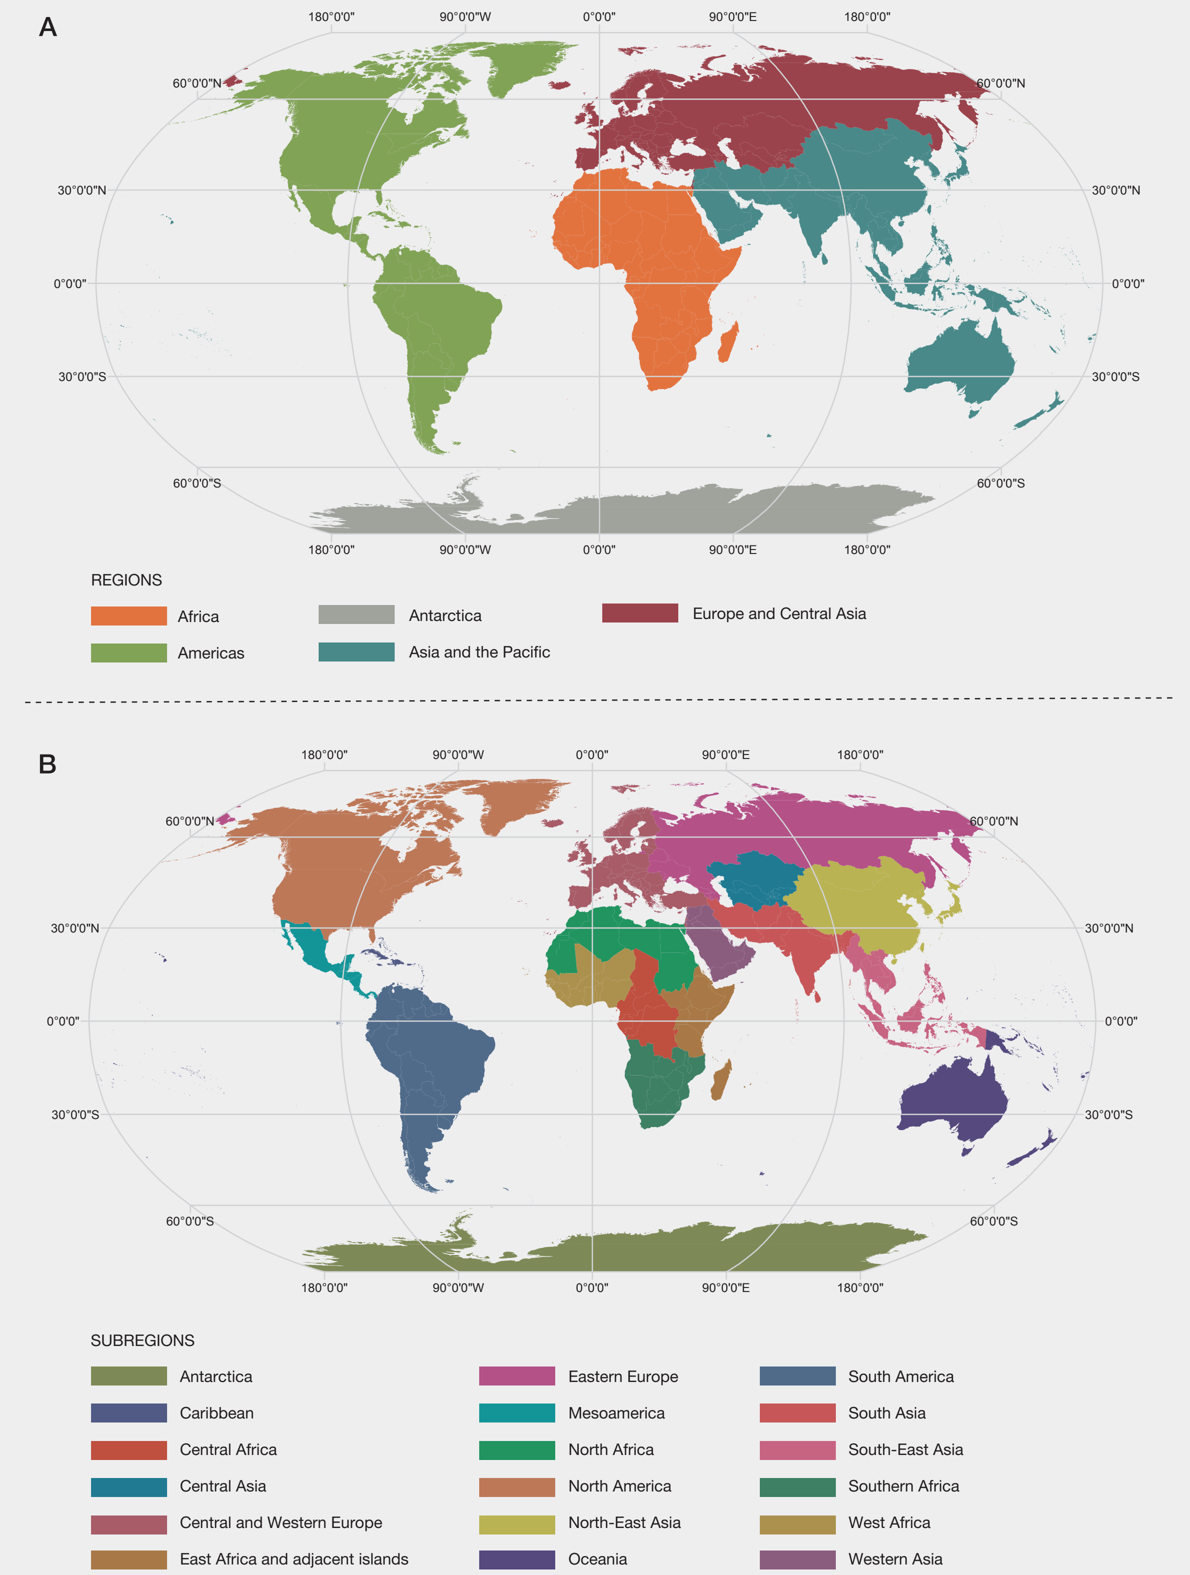

Figure 1 15 **IPBES regions (top) and sub-regions (bottom).**

Source: IPBES technical support unit on knowledge and data (2021), https://doi.org/10.5281/zenodo.5719431, under license CC BY 4.0.

Figure 1 16 **Photo montage of invasive alien species across regions and biomes.**

From top to bottom, left to right: *Pinus mugo* (mountain pine); *Passer domesticus* (house sparrow); *Rattus rattus* (black rat); *Vulpes vulpes* (red fox); *Vachellia nilotica* (gum arabic tree); *Aedes albopictus* (Asian tiger mosquito); *Undaria pinnatifida* (Asian kelp); *Lissachatina fulica* (giant African land snail); *Pontederia crassipes* (water hyacinth); *Solenopsis invicta* (red imported fire ant); *Procambarus clarkii* (red swamp crayfish); *Carcinus maenas* (European shore crab); *Caulerpa taxifolia* (killer algae); *Pterois miles* (lionfish); *Mustela vison* (American mink).

Table 1 3 **Examples of invasive alien species for each IPBES unit of analysis.**

The examples do not necessarily include the most widespread or harmful invasive alien species, but examples to provide representation of the diversity of species in each unit of analysis.

Unit	Biomes	Examples[7,8]- see Figure 1.16 for illustrations
1. Tropical and subtropical dry and humid forests	Terrestrial	*Cenchrus setaceus* (fountain grass) *Lissachatina fulica* (giant African land snail) *Cenchrus ciliaris* (buffel grass) *Homalodisca vitripennis* (glassy winged sharpshooter)
2. Temperate and boreal forests and woodlands	Terrestrial	*Lupinus polyphyllus* (garden lupin) *Lumbricus terrestris* (lob worm) *Pueraria montana* (kudzu) *Solenopsis invicta* (red imported fire ant)
3. Mediterranean forests, woodlands and scrub	Terrestrial	*Acacia longifolia* (golden wattle) *Pheidole megacephala* (big-headed ant) *Centaurea solstitialis* (yellow starthistle) *Aedes albopictus* (Asian tiger mosquito)
4. Tundra and high mountain habitats	Terrestrial	*Pinus mugo* (mountain pine) *Poa annua* (annual meadowgrass)
5. Tropical and subtropical savannas and grasslands	Terrestrial	*Prosopis glandulosa* (honey mesquite) *Felis catus* (cat) *Andropogon gayanus* (tambuki grass) *Bubalus bubalis* (Asian water buffalo)
6. Temperate grasslands	Terrestrial	*Pinus radiata* (radiata pine) *Pinus patula* (Mexican weeping pine) *Rattus rattus* (black rat) *Rattus norvegicus* (brown rat)
7. Deserts and xeric shrublands	Terrestrial	*Bromus tectorum* (downy brome) *Canis lupus dingo* (dingo) *Vachellia nilotica* (gum arabic tree) *Sus scrofa* (feral pig)
8. Wetlands – peatlands, mires, bogs	Freshwater	*Reynoutria japonica* (Japanese knotweed) *Mimosa pigra* (giant sensitive plant) *Procambarus clarkii* (red swamp crayfish) *Pomacea canaliculata* (golden apple snail)
9. Urban/Semi-urban	Human (anthrome)	*Parthenium hysterophorus* (parthenium weed) *Linepithema humile* (Argentine ant) *Lonicera tatarica* (Tatarian honeysuckle) *Aedes albopictus* (Asian tiger mosquito) *Passer domesticus* (house sparrow) *Sturnus vulgaris* (common starling) *Columba livia* (pigeons)

Table 1 3

Unit	Biomes	Examples[7,8]- see Figure 1.16 for illustrations
10. Cultivated areas (incl. cropping, intensive livestock farming, etc.)	Human (anthrome)	*Artemisia vulgaris* (mugwort) *Mustela vison* (American mink) *Acacia longifolia* (golden wattle) *Nosema bombi* (microsporidian parasite)
11. Cryosphere	Terrestrial, freshwater and marine	
12. Aquaculture areas	Human (anthrome)	*Undaria pinnatifida* (Asian kelp) *Magallana gigas* (Pacific oyster) *Carassius gibelio* (Prussian carp) *Pacifastacus leniusculus* (American signal crayfish)
13. Inland surface waters and water bodies/freshwater	Freshwater	*Potamogeton crispus* (curlyleaf pondweed) *Dreissena polymorpha* (zebra mussel) *Gambusia affinis* (western mosquitofish) *Myxobolus cerebralis* (whirling disease agent) *Phragmites australis* (common reed) *Pontederia crassipes* (water hyacinth)
14. Shelf ecosystems (neritic and intertidal/littoral zone)	Marine	*Sargassum muticum* (wire weed) *Carcinus maenas* (European shore crab) *Hemigrapsus sanguineus* (Asian shore crab) *Mytilus galloprovincialis* (Mediterranean mussel)
15. Open ocean pelagic systems (euphotic zone)	Marine	*Pterois volitans* (red lionfish) and *Pterois miles* (lionfish)
16. Deep sea	Marine	
17. Coastal areas intensively and multiply used by human	Marine	*Batillaria attramentaria* (Japanese false cerith) *Caulerpa racemosa* (green algae) *Caulerpa taxifolia* (killer algae) *Carcinus maenas* (European shore crab)

7. For more examples, see **Supplementary material 1.4**
8. Note that scientific names follow the taxonomy used in the original papers. Examples were chosen based on a systematic literature review. Data management report available at: https://doi.org/10.5281/zenodo.5518254

1.6.6 Nomenclature and taxonomy

The IPBES invasive alien species assessment generally follows the Global Biodiversity Information Facility (GBIF) Backbone taxonomy (GBIF, 2021), with a few exceptions for marine species, where authors have followed the World Register of Marine Species (WoRMS, 2022).

For increased accessibility where available, English common names, following the Centre for Agriculture and Bioscience International (CABI) Invasive Species Compendium (CABI, 2022) as the main reference source, are indicated alongside scientific names throughout the report.

The assessment acknowledges the diversity of common names across the globe, as well as their cultural importance (**section 1.6.7.1**). Common names are therefore sometimes included in the local language if pertinent to a specific case study, where such names are available and appropriate.

1.6.7 Cross-cutting themes

A number of cross-cutting themes have been acknowledged as important to IPBES assessments. In this assessment, three major cross-cutting themes are developed across chapters. 1) Indigenous Peoples and local communities are recognized as possessing detailed knowledge on biodiversity and ecosystems, and accordingly, IPBES is committed to promoting an enhanced recognition of and to working with Indigenous and local knowledge systems (Annex 1 of decision IPBES-7/1). 2) Good quality of life is included within the context of the IPBES conceptual framework and within the ongoing IPBES values assessment (IPBES, 2022a). 3) The Methodological Assessment of Scenarios and Models of Biodiversity and Ecosystem services (IPBES, 2016c) led to the commitment to continuing advanced work on scenarios and models of biodiversity and ecosystem functions. For each of the three cross-cutting themes, liaison groups were formed with representation of at least one expert from each of the chapters.

1.6.7.1 Indigenous and local knowledge

Engaging with Indigenous Peoples and local communities

Indigenous Peoples and local communities is a term used internationally by representatives, organizations, and conventions to refer to individuals and communities who either self-identify as Indigenous or as members of distinct local communities that maintain an inter-generational historical connection to place and nature through livelihoods, cultural identity, languages, worldviews, institutions, and ecological knowledge (IPBES, 2019). Indigenous Peoples and local communities are, typically, ethnic groups who are descended from and identify with the original inhabitants of a given region, in contrast to groups that have settled, occupied or colonized the area more recently (IPBES, 2019). At least a quarter of the global land area is traditionally owned, managed, used, or occupied by Indigenous Peoples, representing about 38 million km^2 (Garnett *et al.*, 2018). In addition, a diverse array of local communities, including farmers, fishers, herders, hunters, ranchers, and forest users, manage substantial areas under various property and access regimes (IPBES, 2019). Accordingly, Indigenous Peoples and local communities are stewards to an impressive diversity of nature's contributions to people (Brauman *et al.*, 2020; see **Chapter 2**, **Box 2.6**). However, these lands and waters may be increasingly impacted by invasive alien species (**Chapter 2**, **Box 2.6**; **Chapter 4**, **section 4.6**).

As a result of their close relationship with nature, and dynamic Indigenous and local knowledge systems, many Indigenous Peoples and local communities have developed new understandings and knowledge of biological invasions and invasive alien species (Howard, 2019; Jevon & Shackleton, 2015). They are observers to the introduction and spread of invasive alien species and their impacts on humans and biodiversity, often in environments where scientific monitoring (**Glossary**) and research are sparse or challenging. Many Indigenous Peoples and local communities have a good understanding of the often complex and interacting roles of drivers facilitating the introduction, establishment and spread of invasive alien species on their lands (**Chapter 3**, **Box 3.15**), and also employ their knowledge of the environment to develop responses or management strategies (**Chapter 5**) and are key, active participants in management and decision-making (**Chapter 6**, **section 6.4**; Fischer, 2007; Gratani *et al.*, 2011; Jagoret *et al.*, 2012). Indigenous Peoples and local communities are also in a position to judge trade-offs between beneficial and harmful impacts of invasive alien species both in terms of livelihoods and the environment, as they have to live with them or manage them in their lands and waters (S. J. Hall, 2009; Kannan *et al.*, 2016; Koichi *et al.*, 2012). For example, local authorities in Queensland, Australia, consulted with Girringun Aboriginal rangers and residents to better understand the extent of myrtle rust impacts on native plant species, and to design responses that align to the risk level posed, so as not to undermine local livelihoods (see also Grice *et al.*, 2012; Head & Atchison, 2015). Many Indigenous Peoples and local communities are therefore concerned that their knowledge, needs and views are not properly considered in both research and management of biological invasions (IPBES, 2020b, 2020b).

Working with Indigenous and local knowledge in the assessment

There is a clear need to work with Indigenous Peoples and local communities on assessments and activities related to biological invasions and invasive alien species. However, Indigenous and local knowledge is still often under-represented in research on biological invasion science, which represents a great loss to overall understanding and capacity to manage biological invasions and control invasive alien species. The IPBES invasive alien species assessment therefore aims to work with Indigenous and local knowledge, and to build its conclusions on the best available science and Indigenous and local knowledge. It recognizes that there are numerous barriers to effectively working with Indigenous and local knowledge in a global-scale assessment, including language, data and information flow, accessibility of information, representation of diverse groups within Indigenous communities, and differing understandings and conceptualizations of risk (e.g., Maclean *et al.*, 2021; Michán, 2011; Muller *et al.*, 2009). To overcome these issues as far as possible, the assessment follows the IPBES approach to recognizing and working with Indigenous and local knowledge (Decision IPBES-5/1, annex II), with the support of the IPBES task force and technical support unit on Indigenous and local knowledge. This work included convening three dedicated workshops[9] on Indigenous and local knowledge that brought together Indigenous Peoples and local communities and assessment authors (IPBES, 2020b, 2020b, 2022b), and the consideration of literature beyond the scientific journals

9. The first dialogue workshop took place in Montreal, Canada on 15-16 November 2019; the second dialogue workshop was held online from 21 September to 1 October 2020; and the third dialogue workshop was held online on 1-3 February 2022.

and major invasive alien species databases[10], including materials received through an online call for contributions for the assessment. Assessment authors also carried out an extensive cross-chapter review of literature on Indigenous and local knowledge. Consideration of free, prior and informed consent was key to this work.

The diversity of Indigenous Peoples and local communities' perspectives on invasive alien species

Indigenous Peoples and local communities' perspectives on invasive alien species often differ from scientific perspectives. Indigenous Peoples and local communities perceive invasive alien species in terms of both the particular ecological context and the cultural world views and traditions of their communities (Ellen, 2020). Science also brings its own set of value judgements relating to invasive alien species. This can lead to differences in understanding, responses, and management practices relating to biological invasions. Perspectives on any given invasive alien species will also vary within and between communities, as different community members may experience different impacts depending on gender, age, livelihood and a multitude of other factors (IPBES, 2022b). The great diversity of Indigenous Peoples and local communities' conceptions across species, places, cultures, livelihood systems and time periods, and consequential actions and responses to invasive alien species and the management of biological invasions, makes generalization almost impossible (IPBES, 2020b). Understanding these differing perceptions is therefore a key task for the assessment, and recognition of diverse perspectives is important if effective collaboration between scientists, policymakers, and Indigenous Peoples and local communities is to occur **(Box 1.13)**.

Many Indigenous Peoples and local communities emphasize the inter-relatedness of humans, the land, water, and other species (Barbour & Schlesinger, 2012), which can lead to acceptance of new species. For example, the Anishnaabe of the Great Lakes Region of North America explain the arrival of new plants or animals as a natural process of migration and must then determine why they have come and what their relationship with these migrants might be (Reo & Ogden, 2018). Thus, while some Anishnaabe support invasive alien species eradication, others argue: "…we're supposed to respect all of nature. To me having respect for nature is respecting the fact that it knows how to balance itself and stop trying to introduce different things to fix this and fix that…Respect nature and it will balance. I mean everything has its cycles, leave it alone for gosh sakes. Let it do its thing and quit playing God." (Reo & Ogden, 2018, quoting Kathy LeBlanc, a cultural leader and elder from the Bay Mills Indian Community).

In other cases, established invasive alien species have become a valued part of the socioecological system and are reflected in cosmology. Xeni Gwet'in and Tsilhqot'in of British Columbia now link their identity with *Equus caballus* (horses), describing them as relatives, individuals, or neighbours with family groups. As one elder put it, "The wild horses are like us. They've got routes they go to. They have plans… The mares are sort of the leaders, like in our culture the women have power. They are really respected and strong. So, the stud would protect the mares, but the mare would decide where to go, when to go. And it's quite interesting, in our culture it's the same" (Bhattacharyya & Slocombe, 2017).

Also, in some cases, the introduction of some invasive alien species occurred so long ago that these species can be perceived as native and now "belong to country" (Bach & Larson, 2017). Meanwhile, in many cases,[11] invasive alien species are perceived by Indigenous Peoples and local communities as "negative", often referred to as "weeds" or "pests", and "new" in contrast to "native species" often due to negative impacts on food systems, medicines, and livelihoods of Indigenous Peoples and local communities (IPBES, 2019b; **Chapter 4**, **section 4.6**). A further key issue can be that Indigenous Peoples and local communities' cosmologies or cultural world views may not have a place for these new species: invasive alien species may often be seen as a cultural and spiritual threat, as well as an ecological issue (Grenz, 2020; IPBES, 2020b, 2022b; Trauernicht *et al.*, 2013). For example, among the Māori of New Zealand, Peltzer *et al.* (2019) report that introduced predators have significantly challenged the key cultural concept of "whakapapa", which portrays the genealogical connections between the natural world, including humans, and the cosmological domain. Similarly, among some Australian Aboriginal groups, invasive alien species are a threat because they have no dreaming – no origins accounted for in the ancestral creation of the landscape – and thus no law or responsibilities assigned to families to care for and respect them (Crowley, 2014; Salmón, 2000). Some Indigenous Peoples and local communities explain dramatic and especially negative changes in the landscape, such as an invasive alien species, as a failure of humans to uphold their responsibilities: For example, the Soliga describe the establishment and spread of the invasive alien plant *Lantana camara* (lantana) in Southern India as the punishment of the Hindu Lord Shani for unknown moral infringements by the local communities (Puri, 2015; Thornton *et al.*, 2019).

10. Data management report available at: https://doi.org/10.5281/zenodo.5760266

11. Data management report available at: https://doi.org/10.5281/zenodo.5760266

Box 1 13 **Indigenous and local knowledge of invasive alien species in names, stories, and songs.**

Indigenous and local knowledge of invasive alien species may be embedded in stories, poetry, and songs. A poem from Ethiopia illustrates local understandings of the adverse impacts of invading *Prosopis juliflora* (mesquite, or woyane harar trees) on fodder resources and cattle grazing practices, and their interactions with other drivers of change in nature:

> "Cattle from upland, cattle from lowland
> Goats from here, sheep from there
> Are you [my camels] ever going to have the trees
> That you once had all for yourselves?
> In the summer, the floods
> In the winter the locusts
> In the upland the Christians
> On the lowland the sorghum fields
> In awash the woyane trees
> Where should I take you my heart [my she camel]?"
> (Balehegn, 2016)

Indigenous and local knowledge of biological invasions may also be embedded in specific names, which may also reveal much about how an invasive alien species is perceived. Most invasive alien species are given new names by Indigenous Peoples and local communities, which may indicate origin or foreignness as well as inclusion in a similar generic category, and can have political undertones. For example, the Kawaiwete of Brazil label the incoming, and more aggressive, hybrid African-European honey bee as a "honey wasp", in contrast to the benign local "honey bee" (Athayde *et al.*, 2016). In Kenya, the introduction of the invasive alien tree *Prosopis juliflora* is locally dubbed woyane harar after the Tigrinean People's Liberation Front (TPLF), which introduced the tree for land reclamation, fodder, and wood fuel (Berhanu & Tesfaye, 2006; Rettberg, 2010; Tessema, 2012). *Chromolaena odorata* (Siam weed) is known as rumput golkar or golkar grass in Timor after the ruling government party of Indonesia, as it overshadows competitive plants (McWilliam, 2000). Similarly, Congress grass refers to the poisonous *Parthenium hysterophorus* (parthenium weed) across India, said to have been inadvertently gifted to the nation in wheat that was imported for famine relief by Nehru's Congress Party in the mid-1950s (OpIndia, 2021). Invasive alien salmonids in the fresh waters of Argentinian Patagonia are known to the Mapuche as cosa de winka ("white man stuff"), associated with the arrival of settlers who introduced these environmentally damaging species for sport fishing; they are now considered as ill omens that disturb native fish populations and the sacred status of the waters and their inhabitants (Aigo & Ladio, 2016). More positively, *Prosopis juliflora* is welcomed by many in Jordan, despite acknowledging its negative impacts, as a source of vegetation cover, fodder, firewood, and charcoal, and is known as Al salam ("the peace"; Al-Assaf *et al.*, 2020).

As noted above, diversity in perception may also occur within communities. In Chitwan National Park, Nepal, Tharu household socioeconomic characteristics influence the perceived value of invasive alien *Mikania micrantha* (bitter vine). Those families that were more dependent on forest products incurred more of both the costs and the benefits associated with *Mikania micrantha* than less forest dependent families (Murphy *et al.*, 2013; Rai & Scarborough, 2015). *Sus scrofa* (feral pig) in Northern Australia is similarly either vilified for its negative impacts on vegetation, soils, other wild foods, cultural heritage sites, and because it increases the spread of invasive alien *Lantana camara* (lantana), or highly valued as an important food source for those with lower socioeconomic status (Koichi *et al.*, 2012). Likewise, there are diverging perspectives on *Bubalus bubalis* (Asian water buffalo) and *Equus caballus* (horses) in Northern Australia, with many worried about damage to sacred sites and wild foods, while others benefit from them directly or want financial returns from animals when they are controlled (Ens *et al.*, 2016; **Chapter 4**, **Box 4.14**). Underemployed or low income Māori have benefited from invasive alien species, such as products from possums and pacific rats, while other Māori see them as both ecological and cultural threats (Peltzer *et al.*, 2019). Similarly, Hawaiian cattle (Fischer, 2007), and *Camelus dromedarius* (camels) and *Bubalus bubalis* in Australia (Vaarzon-Morel, 2010; Weston *et al.*, 2012) have been viewed in mixed fashion. Overall, the different perceptions within and between communities, caused by gender, age, knowledge status, livelihoods, and spirituality, result in a diversity of viewpoints on management and policy options for biological invasions (**Chapters 5** and **6**).

1.6.7.2 Good quality of life

Invasive alien species not only affect biodiversity and the ecological processes underpinning nature's contributions to people, but they also directly or indirectly affect good quality of life (or human well-being). Good quality of life is the achievement of a fulfilled human life, a notion which varies strongly across different societies and groups within societies. It is a context-dependent state of individuals and human groups, comprising access to food, water, energy and livelihood security; health, good social relationships; equity, security, cultural identity; and freedom of choice and action **(Table 1.4)**. Much of this provision is a result of nature's contributions to people **(Figure 1.12**; **Box 1.12)**, but its fair distribution and progressive attainment relies principally on governance arrangements and social capital/infrastructure. Good quality of life and health encompass not just physical health, but psychological health, including the satisfaction created by cultural expression and stability, spiritual fulfilment, and reliable access to the resources necessary to thrive as a human being. Though people generally introduce alien species deliberately in order to improve their incomes, food security, or tangible material assets, invasive alien species can threaten good quality of life in various ways at both the individual and community level **(Box 1.9)**; but it can also be argued that efforts to manage invasive alien species can be seen in some cases as detrimental to good quality of life, especially if they involve the cessation of access to natural resources for some groups in society, or inappropriate use of hazardous chemicals. There are also clear cases where communities have adapted to invasive alien species (**Chapter 6**, **section 6.2.2.5**), sometimes because they lacked other options (IPBES, 2022a) and where this has enhanced local good quality of life. Although the preponderance of evidence suggests that invasive alien species are mainly viewed as threats and challenges to human communities, at least one recent study indicates that adaptation is a more dominant response than eradication efforts (Howard, 2019).

It follows that management techniques and policy development will likely benefit from taking into careful consideration the trade-offs among different constituents of good quality of life. For example, people might be willing to accept reductions in their resources, safety, health or lifestyle choices for what they consider a greater cause, such as community survival or national pride. Furthermore, communities will not necessarily be united in how they feel about the values of invasive alien species and associated detrimental or beneficial impacts (Kelsch *et al.*, 2020; Shackleton, Larson, *et al.*, 2019). Many citizens may feel quite neutral or are apathetic about the issue.

There is also the question of scale. While it is obvious that good quality of life encompasses individuals and small communities, it can also refer to national or even supranational identities, stability, survival and resilience. For example, framing invasive alien species as a local problem as opposed to a national security issue will have an impact on policy response options and levels of related resource allocation (Stoett, 2010). Ultimately, considering good quality of life across scales and linking levels of governance will improve the management of biological invasions (**Chapter 6**, **section 6.3.1.1**). **Table 1.4** below presents some examples of constituents of good quality of life which have been considered in the present assessment.

Another prominent element affecting good quality of life is the differentiation in status and access to resources related

Table 1 4 **Constituents of good quality of life and examples of their subcategories.**

The overarching premise for all constituents is the freedom of choice and action, that is, the opportunity to be able to achieve what a person values doing and being. Adapted from Bacher *et al.* (2018); Millennium Ecosystem Assessment (2005).

Constituents of human well-being	Examples
Safety – human security	Personal safety Gender equality Secure resource access Security from disasters Resilient communities
Material and non-material assets	Adequate livelihoods Sufficient nutritious food Shelter Access to goods Recreation
Health	Physical health Feeling well/psychological health Access to clean air and water Absence of infectious disease
Social, spiritual and cultural relations	Social, spiritual and cultural practice Social infrastructure and governance Environmental, social justice and equity Mutual respect Friendship Identity and autonomy
Freedom of choice and action	Control over events and actions

to gender. There is limited research on the interplay between gender relations and invasive alien species, but it is clear that women can be impacted differently in cases where they are expected to engage in many of the forms of labour that are most directly affected by invasive alien species, such as health care, firewood gathering, and the acquisition and use of water for cleaning, sanitation, or family consumption (Fish *et al.*, 2010; Shrestha, 2021). Women are often tasked with the difficult (and often futile) job of weeding by hand, which can take up valuable time better spent on other quality-of-life-related tasks and expose them to dangerous pesticides and herbicides (Terefe *et al.*, 2020). The sharp thorns of the invasive alien *Prosopis juliflora* (mesquite) shrub (native to Mexico, introduced in Ethiopia in 1999) harm the hands of women collecting fuel wood (Terefe *et al.*, 2020). It has also been suggested that personal safety can be compromised with the advent of invasive alien plants; for example, local reports of sexual assault under cover of dense stands of invasive alien *Acacia* spp. invasions have been made (Shackleton, Shackleton, *et al.*, 2019; de Neergaard *et al.*, 2005). More international research on the role of gender in invasive alien species identification, management, and monitoring is needed for a more nuanced perspective to emerge.

The succession of emerging zoonotic diseases in the early twenty-first century has led to the development of several holistic and interdisciplinary approaches to safeguard health. Current concepts such as Planetary Health, EcoHealth, and One Health (**Glossary**) stress the importance of understanding the links between human, animal, and environmental health, though with a strong emphasis on safeguarding the health of vertebrates (Lerner & Berg, 2017). The World Health Organization (WHO), the Food and Agriculture Organization of the United Nations (FAO), and the World Organisation for Animal Health (WOAH, founded as OIE) provide international standards for human health, plant health, and animal health, respectively. Working together with the UNEP through a One Health High-Level Expert Panel (OHHLEP), they have jointly defined One Health as "an integrated, unifying approach that aims to sustainably balance and optimize the health of people, animals and ecosystems. This approach recognizes that the health of humans, domestic and wild animals, plants, and the wider environment (including ecosystems) are closely linked and inter-dependent. It mobilizes multiple sectors, disciplines and communities at varying levels of society to work together to foster well-being and tackle threats

Box 1 14 The role of invasive alien species in zoonotic disease transmission.

The relationship between invasive alien species and human health, particularly pathogenic microbes, and emerging infectious diseases (Pyšek, Hulme, *et al.*, 2020) is especially relevant in a decade which began with a global coronavirus disease (COVID-19) pandemic that killed close to 20 million people (The Economist, 2022), ravaged the world economy, and exacerbated inequality and poverty (Ritchie *et al.*, 2020). Invasive alien species can have serious implications for human health (Lazzaro *et al.*, 2018; Pyšek & Richardson, 2010): alien species can act as a vector of pathogens (e.g., *Aedes albopictus* (Asian tiger mosquito) for dengue fever; Brady & Hay, 2020; Hulme, 2014); produce allergenic pollen (*Ambrosia artemisiifolia* (common ragweed); Richter *et al.*, 2013); and be poisonous (e.g., *Rhinella marina* (cane toad); Bacher *et al.*, 2018) or venomous (e.g., sea jellies; Kideys & Gücü, 1995). Indeed, the COVID-19 pandemic has demonstrated the catastrophic consequences of ongoing environmental transformation, wildlife exploitation, and the movement of organisms in a globalized world (IPBES, 2020c; Nuñez *et al.*, 2020).

Parasites (including pathogenic bacteria, fungi and viruses) can be introduced into an invaded range alongside an invasive alien species (Bojko *et al.*, 2021; Dasgupta, 2021; Daszak *et al.*, 2000; Evans, 2003; Roy *et al.*, 2017). Additionally both introduced and endemic parasites can change the strength of interactions between species and ultimately affect the outcome of a biological invasion (Amsellem *et al.*, 2017; Dunn & Hatcher, 2015). Pathogens causing emerging infectious diseases (WHO, 2014), which spread into new host populations or species, are rarely treated as invasive alien species, but it is widely recognized that the introduction of novel organisms (those without evolutionary analogues in the recipient environment) have the potential to be incredibly disruptive (Nuñez *et al.*, 2020; Saul & Jeschke, 2015; Vilà *et al.*, 2021).

The role of invasive alien species in the transmission dynamics of emerging zoonotic diseases is often overlooked (Nuñez *et al.*, 2020; Vilà *et al.*, 2021) despite the interlinkages between human health and biodiversity loss having now been explored in great detail by the scientific community (Estrada-Peña *et al.*, 2014; Jones *et al.*, 2008; UNEP *et al.*, 2015; Wolfe *et al.*, 2007). Integrated approaches that take into account the landscapes and seascapes in which socio-ecological systems, including their human dimensions, are embedded, could be part of an effective collective response to the threats posed by invasive alien species and related pathogenic diseases. Invasive alien species are part of these broader systems, and the harm to human health which results from their spread and from emerging infectious diseases share many characteristics **(Figure 1.17)**. Pathogenic microbes which cause human epidemics and pandemics are highly successful invasive alien species, transmitted by human behaviour. Integrated interdisciplinary approaches will contribute to increased understanding of the interplay amongst factors driving disease transmission whether in humans, other animals or plants (Vilà *et al.*, 2021).

to health and ecosystems, while addressing the collective need for clean water, energy and air, safe and nutritious food, taking action on climate change, and contributing to sustainable development" (UNEP, 2021). There have been previous efforts to integrate biological invasions within the One Health approach (Conn, 2014; Hulme, 2020a; F. A. B. Meyerson *et al.*, 2009; L. A. Meyerson *et al.*, 2002; L. A. Meyerson & Reaser, 2002, 2003). However, despite the critical role invasive alien species can play as reservoirs and vectors of zoonotic diseases (**Box 1.14**; Hulme, 2014; Roy *et al.*, 2017, 2023), Planetary Health, EcoHealth, and One Health approaches have yet to systematically integrate the threat and impacts of biological invasions into their analyses (IPBES, 2020c; Chinchio *et al.*, 2020; Bertelsmeier & Ollier, 2020; Nuñez *et al.*, 2020; Vilà *et al.*, 2021). The acceptance of the One Health approach as appropriate by many governments and international organizations might change this, however. A more biosecurity-focused approach has also been suggested: "One Biosecurity" would integrate the One Health framework with the practical necessities associated with the provision of biosecurity, including the prevention of all invasive alien species (Hulme, 2020b; **Glossary**). One Biosecurity could be informed through a streamlined approach to the prediction of emerging biosecurity risks (whether pathogens, pests, or weeds), a global network of surveillance (**Glossary**) and information sharing, and coordinated international responses to incursions of invasive alien species. Such an approach could be underpinned by a regulatory framework that parallels the International Health Regulations of the WHO (Hulme, 2021) (**Chapter 6**, **section 6.7.2.2**).

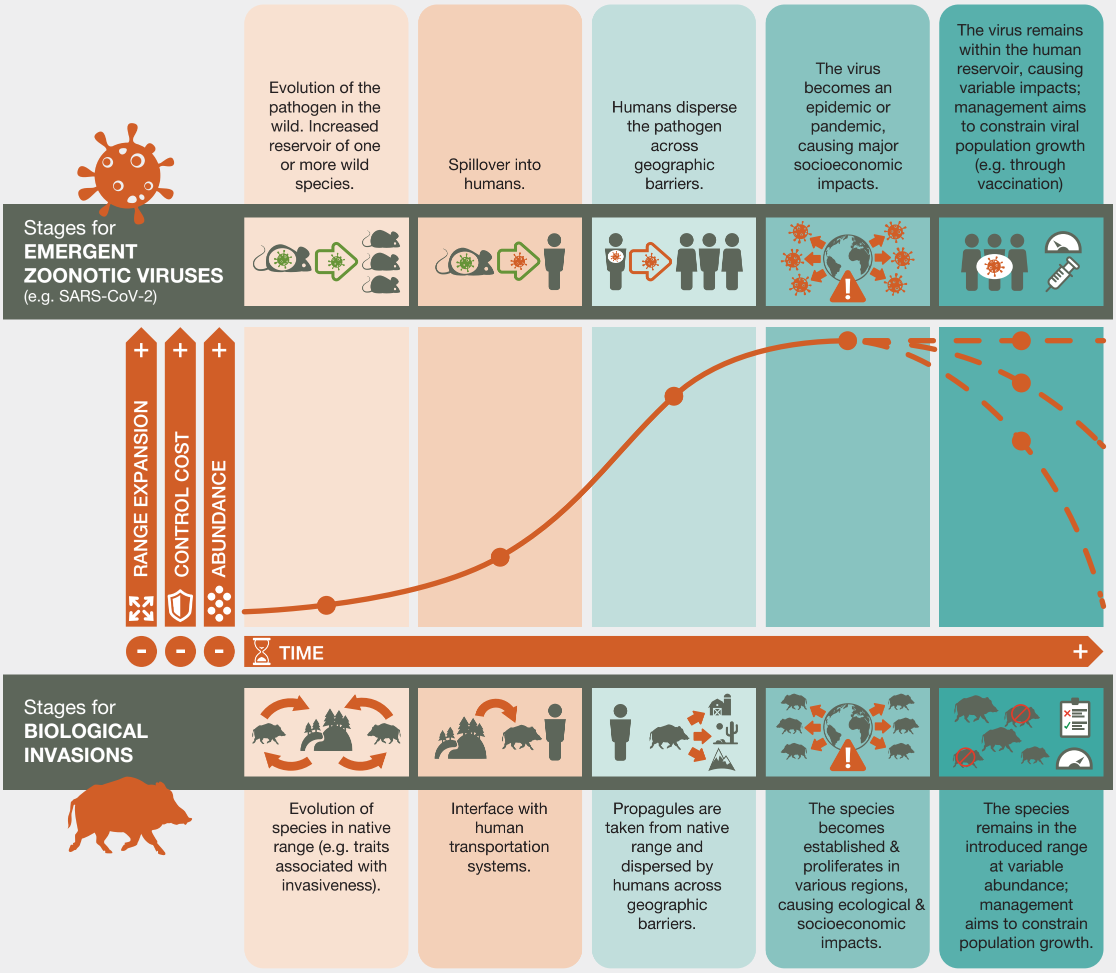

Figure 1 17 **Comparison of the stages of a zoonotic viral epidemic and those of a biological invasion.**

1.6.7.3 Scenarios and modelling

Understanding the drivers and patterns of invasive alien species dynamics is crucial for designing and implementing appropriate management and monitoring strategies (Brundu & Richardson, 2016). There is a growing need to reconstruct the routes of introduction of invasive alien species (Estoup & Guillemaud, 2010; Gautier *et al.*, 2022) to predict biological invasions and effectively support different types of intervention, from early detection to management of established invasive alien species (S. A. Hall *et al.*, 2021; Van Wilgen *et al.*, 2011). Indeed, the importance of model- and scenario-based prevention and early detection has been highlighted in several policies including the European Union Regulation 1143/2014 on invasive alien species (European Union, 2014). Modelling approaches have been used to define coarse climatic envelopes for invasive alien species (Brundu & Richardson, 2016; Pino *et al.*, 2005), and reconstructing routes of biological invasions (Gautier *et al.*, 2022). Fine-scale species distribution modelling and prediction requires information on local environmental and habitat factors (Vicente *et al.*, 2011), as well as linking correlative models to demographic variables or demography-based population models (Kueffer *et al.*, 2013; Vicente *et al.*, 2019). The prevention, early detection and management of biological invasions will consequently benefit from increased knowledge, more informative predictions, and accurate and plausible future scenarios (Chornesky *et al.*, 2005; Genovesi & Monaco, 2013; Roura-Pascual *et al.*, 2021).

For invasive alien species, scenarios and models have been applied to inform understanding of how spatial-temporal patterns emerge (**Chapter 2**, **section 2.6.5**; **Chapter 4**, **section 4.7.1**), of which processes are underlying these patterns, and of how ecological, economic, and societal drivers relate to the emergence of the observed patterns (**Chapter 3**, **Box 3.14**). Scenarios and models differ in their approach to investigate historic, current, and future patterns of alien species richness, abundance and distributions. While models aim to predict alien species patterns based on how environmental, economic or social variables relate to species occurrence or abundance, scenarios are based on alternative possible future states of those variables resulting in projections of potential future patterns of biological invasions (IPBES, 2016c; Lenzner *et al.*, 2019; Roura-Pascual *et al.*, 2021). In the section below, scenarios and models are briefly contrasted in terms of how patterns and dynamics are analysed, the methods used, their different uses, and the advantages and disadvantages of each approach. A systematic review was undertaken to assess the current use of scenarios and models within the context of biological invasions.[12]

12. Data management report available at https://doi.org/10.5281/zenodo.5706520

Models

Models can be defined as “qualitative or quantitative representations of key components of a system and of relationships between these components”.[13] There are four broad groups of model types (main model types) identified (IPBES, 2016c):

i. Expert-based models include any type of qualitative expert opinion (where experts are defined as a single person or group of people that hold specific knowledge of a process, species or system of interest). Experts may include scientists and other academics, relevant stakeholders and Indigenous Peoples and local communities (**section 1.6.7.1**).

ii. Correlative models (also called statistical models) use empirical data to estimate parameter values for processes that are implicit rather than explicit.

iii. Process-based models (also mechanistic models) explicitly integrate processes or mechanisms based on established scientific understanding.

iv. Hybrid models combine correlative and process-based modelling approaches.

Most papers identified through the systematic review used correlative models (57 per cent of 781 observations), followed by process-based models (33 per cent), hybrid models (8 per cent) and expert-based systems (1 per cent).

There are also interdisciplinary models and integrated assessment models (IPBES glossary[12]) that are used to describe the complex relationships between environmental, social and economic drivers (e.g., Havlík *et al.*, 2014) by integrating trans-disciplinary knowledge to capture large-scale dynamics, interactions and feedbacks of a specific system (Harfoot *et al.*, 2014). Integrated assessment models assess “wicked problems” which are highly complex, socioecological problems including many variables and actors (Termeer *et al.*, 2019). Currently, biological invasions are not included in existing global integrated assessment models, but such an integration would be highly beneficial (Lenzner *et al.*, 2019).

Further details, including opportunities and limitations, of these modelling approaches are provided in the data management report.

Scenarios

Scenarios are “representations of possible futures for one or more components of a system, particularly for drivers of change in nature and nature’s benefits, including

13. IPBES glossary: https://ipbes.net/glossary

alternative policy or management options".[14] Different types of scenarios can be identified and are applicable in specific contexts:

i. (Exploratory scenarios (also called "explorative scenarios" or "descriptive scenarios") examine a range of plausible futures, based on pre-defined drivers and their assumed future trajectories starting from the present conditions.

ii. Target-seeking scenarios (also called "goal-seeking scenarios" or "normative scenarios") have a clear objective or set of objectives for a point in time in the future (i.e., a specific target) and aim to describe plausible pathways to achieving this outcome. The procedure of developing such scenarios is called backcasting.

iii. Policy-screening scenarios aim to evaluate alternative policy or management options. They either follow a similar logic to target-seeking scenarios where a future policy goal is determined, or they can be developed through policy screenings (also called "ex-ante scenarios"). See the IPBES glossary and the methodological assessment report on scenarios and models of biodiversity and ecosystem services (IPBES, 2016c) for more detail.

Most of the papers identified through the systematic review focused on exploratory scenarios (87 per cent of papers), followed by policy-screening (7 per cent) and target-seeking scenarios (6 per cent). In most papers, scenarios were quantitative (82 per cent) as opposed to qualitative (9 per cent) or both quantitative and qualitative scenarios (8 per cent).

Overall, scenarios aim to provide a holistic view on global trends and processes and how they might shape the world's future under different assumptions. For many drivers of change in nature (e.g., climate; IPCC, 2014) and socioeconomic domains (e.g., demography, land-use; Hurtt *et al.*, 2011), such scenarios have already been developed. However, biological invasion scenarios have not been available until recently (Corrales *et al.*, 2018; Dehnen-Schmutz *et al.*, 2018; Ricciardi *et al.*, 2017). The need for scenarios for short (2030), mid (2030-2050), and long-term (2050-2100) trends in alien species richness and distribution at various scales to inform targets has been recognized (Bellard *et al.*, 2013; Roura-Pascual *et al.*, 2021). Increasing data availability and increased understanding of (historic) trends, distribution and impacts of invasive alien species globally and locally makes the development of scenarios for biological invasions feasible (Lenzner *et al.*, 2019). Recently, the first alternative futures for biological invasions were published (Roura-Pascual *et al.*, 2021). Roura-Pascual and colleagues developed 16 different qualitative scenarios storylines, which can be grouped into four archetypes based on their description of potential futures. The scenarios develop potential future trajectories of the world until 2050 with a special focus on drivers relevant for biological invasions (Essl *et al.*, 2020) and projected changes in alien species richness.

Moreover, recently IPBES has developed a framework for the creation of independent multiscale biodiversity scenarios for constructing pathways towards desirable futures for nature – the Nature Futures Framework (IPBES, 2022d). A distinguishing feature of the Nature Futures Framework, beyond classical environmental scenario frameworks, is the consideration of a plurality of perspectives and values towards nature within the scenarios, facilitating the assessment of different views on nature and ensuring the integration of these views through participatory approaches. While the Nature Futures Framework has not yet been applied in the context of biological invasions, it has considerable potential for exploring the role of invasive alien species in future biodiversity change across scales and contexts.

Scenarios and models in invasive alien species research

The scenarios and models' liaison group undertook a systematic review[15] including an initial set of 30,299 research papers of which 778 research papers were found to consider both the use of models and scenarios to evaluate the patterns and trends of invasive alien species. The search was restricted to indexed publications in English, ensuring a structured, systematic approach to the use of the terms "invasive alien species", "modelling" and "scenarios". A summary of the outcomes is provided here with further information available in the data management report.14 In some cases, a single paper focused on multiple categories (e.g., a model applied to both the United Kingdom and Portugal), and these are categorized as separate observations. The information is summarized as either a percentage of papers or of observations.

Patterns and trends

The Americas was the IPBES region with the highest proportion of observations across all papers, with 33 per cent of all observations (total number of observations: 1,153), followed by Europe and Central Asia (26 per cent), Asia and the Pacific (24 per cent), Africa (13 per cent) and finally Antarctica (2 per cent). In 3 per cent of the papers, the IPBES region was not stated. Most papers focused on only

14. IPBES glossary: https://ipbes.net/glossary

15. Data management report, including full output of the review, available at https://doi.org/10.5281/zenodo.5706520

one IPBES region (78 per cent of a total of 778 papers) and one country (70 per cent).

Most of the papers (63 per cent of all papers) were focused on only one invasive alien species with most focusing on invasive alien plants (including bryophytes; 40 per cent of observations from a total of 858 observations), followed by invertebrates (30 per cent), fishes (8 per cent), mammals (7 per cent), amphibians, birds and reptiles (3 per cent); and finally, fungi (2 per cent) or other invasive alien species taxa such as algae, bacteria, virus or protozoan (2 per cent). Furthermore, the majority of papers focused on only one particular IPBES unit of analysis (96 per cent of 778 papers), with the terrestrial environment dominating the literature extracted from the review with 75 per cent of observations (from a total of 813), followed by the freshwater (15 per cent) and the marine (8 per cent) environments. The impacts of invasive alien species were addressed in only 22 per cent of papers with most of these papers focusing on negative impacts (18 per cent of all papers). Invasive alien species pathways were considered in only 10 per cent of papers. Only 23 per cent of papers (n=182) considered invasive alien species management, and most papers focused on one (54 per cent) or two management strategies in combination (37 per cent).

The cross-cutting themes identified for the IPBES invasive alien species assessment were poorly represented in the papers with only 1 per cent considering Indigenous and local knowledge, 3 per cent considering good quality of life and 6 per cent including nature's contributions to people.

Further descriptive summaries and results from the review, including multidimensional scaling, illustrating the clustering of model and scenario features from across the papers, are available in the data management report.[16] Further specific detailed information from the review is included within the relevant chapters.

1.6.8 Key issues in the discussion of biological invasions

Throughout this assessment several key issues, some extant and some emerging, have been identified as critical to the discussion of biological invasions. The key issues identified within this assessment include the advent of **globalization**, the **impact of global environmental change** (and, in particular, the global biodiversity crisis), the **use of adaptation strategies**, the **role played by technology**, the **challenges for islands and protected areas**, and the **role micro-organisms play** in the broader understanding of invasive alien species.

16. Data management report available at https://doi.org/10.5281/zenodo.5706520

The most obvious issue is that of **globalization**, which has acted as an important overarching driver facilitating the unprecedented spread of invasive alien species that humans face today. There is a strong historical link between colonization by European powers and biological invasions, and the rise of global transport and trade has been a primary driver responsible not only for the transport and introduction of invasive alien species but also for the advent of biotic homogenization, which lowers resilience and increases vulnerability to further invasive alien species. Globalization is a catalyst exacerbating the problems of a human-dominated biosphere that has led to the Anthropocene, a world with biophysical systems profoundly shaped by human activity. The increasing levels of invasive alien species on a global scale are stark evidence of this era. At the same time, international instruments developed to prevent the spread of invasive alien species rely heavily on international organizations that are at least partially reflective of the process of globalization.

Another central key issue is the present and future **impact of global environmental change**, and the underlying direct and indirect anthropogenic drivers of change, not only on the spread and introduction success of invasive alien species but also on options for management (**Chapters 3** and **5**). Climate change and land and sea use, but also pollution (chemical, plastics, debris, etc.), ocean acidification, and other systems-level direct drivers of change in nature are currently shaping the Anthropocene, and driving, in particular, the loss of biodiversity (IPBES, 2019). Invasive alien species have long been identified as one of the primary drivers of this global biodiversity crisis, and they interact with other drivers of global environmental change to exacerbate it (**Chapters 3** and **4**).

The overarching issue of **human community adaptation** is noticeable as well: While invasive alien species can cause both harm and benefits, some human communities (at various scales, from rural areas to Indigenous Peoples and local communities to cities to regions) have in fact adapted to the presence of invasive alien species, and it is informative to see how, why, and in what forms this adaptation took place over time. This key issue, which is even more pertinent in the current era where climate change is forcing unprecedented adaptation and evolving survival strategies, is discussed more explicitly in **Chapter 6**, **section 6.2.2.5**. In some cases, the response to invasive alien species does not adequately deal with the threats they pose, and adaptation may be the only or the preferred policy response. It is important to note that prevention is an effective approach to managing invasive alien species and the costs of responding to biological invasions far outweigh the costs of prevention (Diagne *et al.*, 2021). However, in some cases, invasive alien species have become part of socio-ecological systems and are here to stay.

The evolving **role played by technology** is another key issue. The development of the steam engine enabled faster trans-ocean voyages involving ballast water usage, thus acting as a driver that accelerated pathways for

Box 1 15 The role of citizen (or community) science in monitoring invasive alien species.

Citizen science (also known as community science, participatory monitoring, community-based environmental monitoring, crowd science, crowd-sourced science, civic science, or volunteer monitoring) is a term that describes the diverse range of approaches in which scientific research is conducted, in whole or in part, by volunteers with varying levels of expertise (Gura, 2013; Pocock *et al.*, 2014, 2018). Citizen science is defined by the European Commission Green Paper as "general public engagement in scientific research activities where citizens actively contribute to science either with their intellectual effort, or surrounding knowledge, or their tools and resources" (Consortium, 2013; Follett & Strezov, 2015).

People contribute to biodiversity and ecosystem research through citizen science in diverse ways including providing data, raising new research questions, and communicating and disseminating findings. Citizen science can be broadly considered as contributory or collaborative (co-created). Within contributory citizen science, participants are primarily involved in data collection while through collaborative citizen science, participants are involved in various stages of the scientific process including identifying the scope and research questions through to interpreting and using the results. Citizen science not only results in scientific advances but is also known to increase public understanding of science by improving the scientific capacity of participants through skills acquisition and learning (MacPhail & Colla, 2020; Steven *et al.*, 2019).

There are many diverse approaches to surveillance and monitoring of invasive alien species. Citizen science is seen as particularly relevant for environmental monitoring and has a long history in many countries with some initiatives in Northern Europe and North America having been ongoing for more than a century (Allen, 1976; Miller-Rushing *et al.*, 2012; Pocock *et al.*, 2015). Many of the large-scale and long-term global biodiversity datasets have relied on contributions from volunteers. Indeed, citizen science is often used to engage people in scientific projects that may be impractical for individuals or small groups to conduct alone because of the need to gather or analyse "big data" (Willett *et al.*, 2013).

Volunteers have made substantial contributions to understanding biological invasions (Roy *et al.*, 2015) from documenting the arrival, establishment, and spread of alien species through to predicting potential new arrivals through horizon scanning (Roy *et al.*, 2020) and so contributing to early-warning. The breadth of expertise provided by taxonomic experts from volunteer biological recording communities is essential for horizon scanning. Prioritization of invasive alien species through horizon scanning can be used to inform mass participation approaches involving the public (or where relevant special interest groups such as anglers) in monitoring and surveillance underpinning early-warning.

The advent of mobile computing technologies in smartphones and tablets and the corresponding proliferation of mobile applications (apps) have greatly expanded the potential of citizen science for contributing to research on invasive alien species (Adriaens *et al.*, 2015). As mobile phones become increasingly ubiquitous (users now exceed 2.8 billion people worldwide; Alavi & Buttlar, 2019), citizen science is undergoing an unprecedented shift in the scale and quantity of available data (Silvertown, 2009; Teacher *et al.*, 2013). Popular biodiversity reporting apps like eBird (Sullivan *et al.*, 2014) and iNaturalist (Unger *et al.*, 2021) have user communities in the hundreds of thousands, generating enormous quantities of data for research (e.g., over 1 million records in iNaturalist in the first seven years; Pimm *et al.*, 2014). Invasive alien species reporting apps, which enable users to submit geotagged observations of invasive alien species, are an excellent new source of spatiotemporally explicit occurrence data for invasive alien species management and research, and seen as a major pathway to implementing surveillance and monitoring at national and global scales (Martinez *et al.*, 2020). The number of invasive alien species reporting apps available is steadily increasing, ranging from regional apps to those focused on particular taxa including aquatic organisms, insects, and plants (e.g., Goëau *et al.*, 2013; Laforest & Bargeron, 2011; Scanlon *et al.*, 2014; Wallace *et al.*, 2020).

Many mobile devices now include a variety of onboard sensors and instrumentation like barometers, gyroscopes, accelerometers, microphones, cameras and ambient light sensors, and the capability of storing data from these sensors and uploading it to online databases (Lane *et al.*, 2010). Onboard sensors are increasingly used to facilitate and even automate citizen science participation *via* invasive alien species apps, for example in bioacoustics surveys for invasive alien amphibians (Platenberg *et al.*, 2020). Artificial intelligence and machine learning, especially in image recognition, are further enhancing mobile app contributions to citizen science, by allowing for the automated identification of organisms in user-submitted images (Terry *et al.*, 2020). The steady improvement and increasing availability of online invasive alien species occurrence databases and their integration with mobile technology is another major and ongoing advance underpinning citizen science (Martinez *et al.*, 2020; Reaser *et al.*, 2020; Seebens *et al.*, 2020).

Science-society-policy interactions are developed through open and collaborative approaches amongst participants involved in citizen science (Powell & Colin, 2009; Gardiner & Roy, 2022). Collaborative research outcomes, resulting from open, networked and transdisciplinary citizen science approaches, can ultimately contribute to democratic decision-making.

the transport of invasive alien species (sailing ships also needed ballast but used soil, which itself carried invasive alien species but at slower delivery times) (**Chapter 3**, **section 3.2.3**). Modern technology (including genetics/genomics, informatics, and drone surveillance) is facilitating the transport of alien species around the globe *via* e-trade (**Chapter 3**, **sections 3.2.3** and **3.2.4**), but are also being used in new and inventive ways to discover, track, and manage invasive alien species and their impacts (**Chapter 5**). New online tools and technologies, particularly new data streams and data integration methods, will increase capacity to deliver a global monitoring and decision-support system for managing biological invasions (Martinez *et al.*, 2020; McGeoch & Jetz, 2019). Relatedly, communication strategies in the internet age have emerged as fundamental as people share new information about identifying and dealing with invasive alien species. Citizen science (**Glossary**), including approaches that encompass visual identification technologies and other innovations, has become a popular and valuable approach to underpin research and policy on biological invasions and invasive alien species (**Box 1.15**; Encarnação *et al.*, 2021; Roy *et al.*, 2015).

Insular environments, from oceanic islands and deep sea hydrothermal vents to freshwater systems and fragmented habitats, have provided insights into the relationships between geographic patterns and biological processes (D. R. Drake *et al.*, 2002). Such insular systems feature prominently in this assessment. Islands, especially SIDS, are considered particularly vulnerable to invasive alien species because of the difficulty of prevention where globalization, including mass tourism, has become deeply integrated into island economies. Invasive alien species on islands have been shown to have some of the most detrimental impacts compared to continental ecosystems, including the extinction of many endemic species (e.g., Bellard *et al.*, 2016; Pyšek, Blackburn, *et al.*, 2017). Indeed, invasive alien species are ranked as the leading cause of biodiversity loss on islands (Bellard *et al.*, 2016; Russell *et al.*, 2017). However, there are many examples whereby management of invasive alien species, including approaches to prevent arrival and eradication of specific taxa, has proven successful on islands (**Chapter 5**; Courchamp *et al.*, 2003; Russell *et al.*, 2017).

While most invasive alien species tend to thrive in anthropogenically disturbed ecosystems, some species are able to reach even the most remote and well conserved areas, including those formally declared as **protected areas** (Liu *et al.*, 2020; **Chapter 4**, **section 4.3.1.2**). Indeed, it is clear that the establishment of protected areas, in both terrestrial and marine environments, does not preclude the unintentional introduction and spread of invasive alien species, such as those associated with illegal wildlife trade and other activities such as fishing and recreation without high biosecurity standards. Indeed, there are concerns that biological invasions are insufficiently considered when devising management plans for marine protected areas in particular (Galil, 2017; Giakoumi *et al.*, 2016). Furthermore, historic or current intentional introductions such as through afforestation projects associated with climate change mitigation efforts can pose a threat to protected areas worldwide (Richardson, 1998), and ecosystem restoration projects also face similar concerns.

Another important key issue within biological invasions is the consideration of **microorganisms**, from virus to protozoa, including the links between invasive alien species and plant, animal, and human diseases including zoonotic diseases such as COVID-19, H1N1 flu (swine flu) and viral haemorrhagic fever (Ebola; **Box 1.14**). Such microorganisms have profound implications for good quality of life (Amsellem *et al.*, 2017) and biosecurity (Hulme, 2020a), and create space for further discussions of ecosystem-based and One Health approaches.

These key issues are relevant to natural science, social science, the humanities and policy developments, and will likely shape the evolution of our understanding of the biological invasion process in the years to come.

Chapter **2**

TRENDS AND STATUS OF ALIEN AND INVASIVE ALIEN SPECIES

EXECUTIVE SUMMARY

1 **At least 39,215 alien species and more than 37,000 established alien species have been recorded worldwide and occurrences of established alien species have been reported from all countries and all ecosystems globally *(established but incomplete)* {2.2.2}.** Among these, 5,256 species have been classified as invasive according to the database underlying this chapter *(established but incomplete)* {2.2.2}. The distribution of established alien species shows marked hotspots of high species numbers, mostly located in North America, Europe, and Australasia, but also in individual African and Asian countries *(established but incomplete)* {2.2.2}. However, low data availability, particularly in Africa and Central Asia, suggests that many more unrecorded established alien species are extant but not reported due to a lack of monitoring and data integration *(established but incomplete)* {2.1.3, 2.1.4, 2.7}. Thus, the reported numbers of alien, established alien, and invasive alien species are likely severely underestimated *(well established)* {2.1.3., 2.1.4}.

2 **The number of established alien species has risen at continuously accelerating rates for centuries, recently reaching the highest total number of established alien species and highest annual rate of new records *(established but incomplete)* {2.2.1}.** The rise in established alien species numbers has had periods of uniform increases and marked accelerations *(well established)* {2.1, 2.2.1}. Before 1800, the introduction of alien species was largely driven by European colonialism, while recently introductions for ornamental purposes or associated with international transport have become more important pathways *(well established)* {2.1, 2.1.2, 2.3.1.2, 2.3.1.6, 2.4.2.2, 2.4.5.2, Box 2.5}. Marked accelerations of alien species introductions were observed circa 1800 and post-1950, currently reaching the highest value yet; 37 per cent of documented alien species introductions over the last two centuries have occurred since 1970 *(established but incomplete)* {2.1}. In addition to total numbers, the rate of increase of newly recorded alien species, which later became established, has also continuously risen with approximately 200 new alien species now recorded annually worldwide *(established but incomplete)* {2.2.1}.

3 **In absolute values, the highest numbers of established alien species records have been reported for vascular plants, insects, fishes, fungi, and molluscs *(established but incomplete)* {2.2.2}.** The distribution of established alien species worldwide is similar across taxonomic groups, with hotspots located in North America, Europe, and Australasia *(established but incomplete)* {2.2.2}. Vascular plants and mammals are the most widespread invasive alien species *(well established)* {2.2.2}. Temporal trends of records revealed three main patterns: For vascular plants, the number of records and the rate of increase rose distinctly from the nineteenth century to the present *(well established)* {2.3.2.1}, while for invertebrates, algae, and microorganisms, numbers and rates showed a marked increase particularly after 1950, likely due to increasing trade *(established but incomplete)* {2.3.1.6; 2.3.1.8, 2.3.1.9, 2.3.2.3, 2.3.3}. Mammals represent the only taxonomic group where the rate of new annual records has consistently declined since 1950, likely as a result of stricter regulations. However, while declining, the rate is still positive resulting in additional new alien mammal records each year *(established but incomplete)* {2.3.1.1}.

4 **The total numbers of established alien species are similar in all IPBES regions except for Africa, ranging from 14,797 to 17,628 established alien species in the Americas, Europe and Central Asia, and Asia and the Pacific; total numbers are distinctly lower for Africa, which hosts a maximum of 6,484 established alien species *(established but incomplete)* {2.4.1, 2.4.2, 2.4.3, 2.4.4, 2.4.5}.** The lower number of established alien species in Africa likely results from a combination of reduced introduction effort and lower data availability; therefore, the true number of alien and invasive alien species is expected to be markedly higher in Africa than currently reported *(established but incomplete)* {2.4.1}. Likewise, rates of increase were similar among the Americas, Europe and Central Asia, and Asia and the Pacific, but lower for Africa where data are less complete *(established but incomplete)* {2.4.2, 2.4.3, 2.4.4, 2.4.5, 2.7}.

5 **The majority of established alien species have been reported from terrestrial ecoregions (75 per cent), while distinctly fewer established alien species were recorded in freshwater and marine ecosystems**

***(established but incomplete)* {2.5.1, 2.5.2, 2.5.3, 2.5.4}.** In part, this pattern reflects the natural distribution of species across ecosystems. However, aquatic habitats and marine systems in particular are less thoroughly sampled in comparison to terrestrial systems, suggesting that many more alien marine species have not been detected and recorded *(established but incomplete)* {2.5.2, 2.5.3, 2.5.4}.

6 The number of established alien species is expected to rise further with a predicted 36 per cent global increase by 2050, but with large variations by region and among groups of organisms; most existing established alien species are expected to expand their current ranges *(established but incomplete)* {2.6.1}. Annual rates of increase are predicted to rise further for invertebrates, such as insects and molluscs, likely as a consequence of anticipated increasing trade and transport, but to decline for mammals, probably due to efforts to prevent their introduction and spread *(established but incomplete)* {2.6.1}. However, models and scenarios to project biological invasion dynamics are scarce and underdeveloped, hindering a robust assessment of future dynamics *(well established)* {2.6.5}. Although some established alien species have reached their geographic range limits, most established alien species are likely to further expand their alien ranges in the near future *(established but incomplete)* {2.6.1}.

7 The number of established alien species is consistently lower on land managed by Indigenous Peoples *(established but incomplete)* {Box 2.6}. Indigenous Peoples' lands are often remote and host more natural habitats compared to other lands, but that has not protected them from alien species introductions. A total of 6,351 established alien species and 2,355 invasive alien species have been recorded worldwide on Indigenous Peoples' land *(established but incomplete)* {Box 2.6}. Hotspots of biological invasions on Indigenous lands with high numbers of established alien species are found on all inhabited continents but especially in Australasia, North America, and Europe *(established but incomplete)* {Box 2.6}, regions that have the highest established alien species numbers in general. Invasive alien species affect the livelihoods and good quality of life of Indigenous Peoples and local communities worldwide *(established but incomplete)* {Box 2.11}. However, most available studies on lands of Indigenous Peoples and local communities and on good quality of life focus on woody vascular plants, while much less information is available for the effects of other taxa, particularly microbes and insects *(established but incomplete)* {Boxes 2.6 and 2.11}.

8 Islands generally host high numbers of alien and invasive alien species *(well established)* {Box 2.5}. Compared to mainland areas, the number of established alien species on islands is often very high *(well established)* {Box 2.5}. For vascular plants, the numbers of established alien species exceed the total number of native species on many islands, doubling the plant species richness on those islands *(well established)* {Box 2.5}. Worldwide, widespread invasive alien species on islands include mammals such as *Rattus* spp. (rats), *Mus musculus* (house mouse), and *Felis catus* (cat), and plants such as *Leucaena leucocephala* (leucaena), *Lantana camara* (lantana), and *Ricinus communis* (castor bean) *(well established)* {Box 2.5}.

9 Research intensity and data availability documenting established alien species' occurrences have increased in recent decades, but information about alien species distributions remains incomplete, particularly for inconspicuous species such as invertebrates, microorganisms, and aquatic species *(well established)* {2.1.4, 2.2.2, 2.7}. Lists of established alien species occurrences are very likely incomplete in the vast majority of cases across in the world *(established but incomplete)* {2.1.3, 2.1.4}. There are, however, major critical gaps for many species groups in large parts of Africa and Central Asia, for invertebrates and microorganisms, and for marine and freshwater species worldwide *(well established)* {2.2.2, 2.3.1.11, 2.3.2.5, 2.3.3.3, 2.4.2.5, 2.4.5.5, 2.5.1}. Gaps in recording alien species occurrences result in incomplete alien species lists and prevent a fully comprehensive assessment of the trends and status of invasive alien species across all taxa and habitats *(established but incomplete)* {2.2.2}. Further uncertainty arises from time lags that can span several decades from species introductions to their first detection *(well established)* {2.2.1, 2.2.3}, very likely making the documented numbers of established alien species a severe underestimate of the true extent of biological invasions *(well established)* {2.2.1, 2.2.2}. Importantly, incomplete data does not preclude drawing robust conclusions about alien and invasive alien species *(well established)* {2.7}. By taking data uncertainty into account, experts can provide a complete, credible, and transparent assessment that can be updated as more information becomes available *(well established)* {2.7}.

10 A global assessment of biological invasions that covers the trends and status of regions and species groups equally can be achieved by a major increase in efforts to monitor alien and invasive alien species and by standardizing protocols for handling and sharing data at a global scale *(established but incomplete)* {2.7}. Closing knowledge gaps in all regions and species groups and improving understanding of biotic and abiotic interactions that influence how species respond to environmental changes can be achieved through consistent, repeatable, and comparable studies of alien species occurrences that are deposited into publicly available repositories *(established but incomplete)* {2.7}. Additional applications of technology (e.g., remotely sensed data, environmental DNA) applied at large spatial scales can also provide comprehensive coverage of alien and invasive alien species *(established but incomplete)* {2.7}. Engagement by and with policymakers, citizen scientists, and Indigenous Peoples and local communities worldwide is critical to close data and knowledge gaps *(established but incomplete)* {2.7}.

2.1 INTRODUCTION

Assessing current and future dynamics of biological invasions requires data and knowledge on the geographic extent of invasive alien species, which can be used to identify hotspots of invasive alien species (**Glossary**). Further, a more comprehensive assessment depends on information about temporal trends (**Glossary**) to evaluate past and potential future species spread and detailed information on alien species, which while not yet classified as invasive in certain regions could become invasive in the future. To achieve a comprehensive global assessment of biological invasions, this chapter includes information on temporal trends and spatial distributions of both **alien** and **invasive alien species** (a subset of alien species).

Humans have introduced species to regions outside of their native ranges (**Glossary**) for millennia, and throughout, these introductions have undergone different periods of acceleration. As early as approximately 8000 B.C., neolithic people unintentionally distributed plant seeds when transporting crops (e.g., Di Castri, 1989). The first evidence of agricultural crops being traded over long distances comes from the Pharaohs of ancient Egypt approximately 3,000 to 1,500 years ago (Janick, 2007) and from Mesoamerica around the same period (Sanchéz, 1997). While early reports are scarce and inaccessible, evidence of increasingly frequent species exchanges has accumulated. The intensity of biotic exchange is often related to the extent and power of a particular empire, such as the Romans, Greeks, Aztecs, Polynesians, or the Han Dynasty. All introduced a variety of species throughout their reigns that continue to survive in their new locations (P. A. Cox & Banack, 1991; Di Castri,

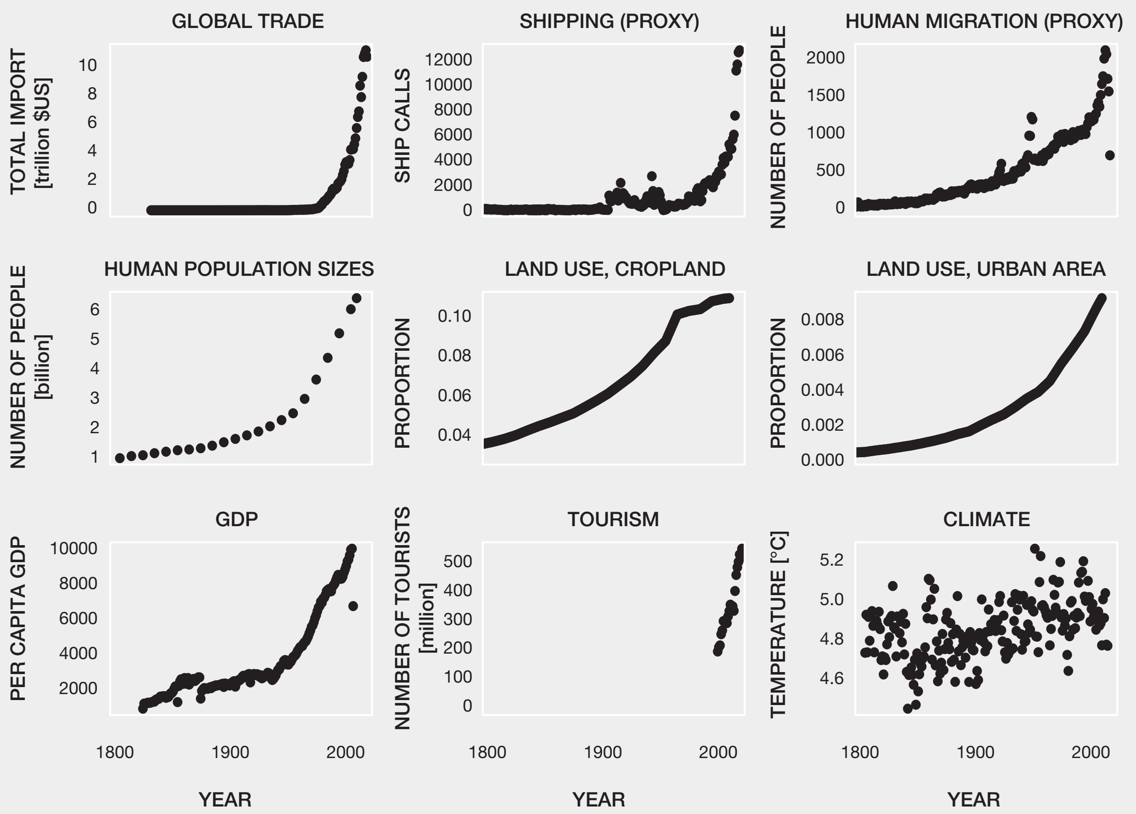

Figure 2 1 **Trends in drivers of change in nature and correlates of biological invasions.**

Panels show temporal trends of a selection of main drivers and correlates of biological invasions averaged globally. For "shipping" and "human migration" only proxy variables are shown due to the lack of more comprehensive data covering the full time period. Although these proxy variables represent only subsets of the full dynamics, they well indicate the overall temporal patterns of change. A data management report for this figure is available at https://doi.org/10.5281/zenodo.7615582

1989; Ma *et al.*, 2003; Sanchéz, 1997). As these empires expanded and the capacity of humans to travel long distances improved, there was a concomitant rise in the magnitude of alien species introductions.

The establishment of sea routes between Europe, the Americas, Africa, and Asia in the fifteenth century marked the onset of a truly global trade network that facilitated a continuously growing rise in alien species introductions (**Figure 2.1**; Di Castri, 1989) but the extent of increase varied considerably between taxonomic groups and geographic regions. Nonetheless, there has been a marked intensification of alien species exchanges across all taxonomic groups and regions in the last 200 years; the nineteenth century and post-1950s eras experienced especially high increases of new species introductions, i.e., 37 per cent of all documented established alien species introductions have occurred since 1970 (Bonnamour *et al.*, 2021; Seebens, Blackburn, *et al.*, 2017). Given the incomplete and inconsistent records of documented historic introductions, it is likely that past introduction rates were even higher (Seebens, Blackburn, *et al.*, 2017).

While many species have been unintentionally introduced, other introductions in the pre-historic, historic, and modern eras have been intentional, occurring for purposes including food, horticulture, sport hunting and fishing, the fur trade, the pet trade, and for nature's contributions to people such as erosion control and biological control (**Glossary**; e.g., Eviner *et al.*, 2012; Genovesi *et al.*, 2009; Luken & Thieret, 1997; R. M. Pringle, 2005; Reichard & White, 2001; Simberloff, 2012). The introduction pathways (**Glossary**) and the taxa introduced have varied over time **(Table 2.1; Figure 2.2)**.

The introduction of alien species is coupled with human activities and it is therefore unsurprising that invasion trends and human socio-economic activities are closely linked (Hulme, 2009; Levine & D'Antonio, 2003; X. Liu *et al.*, 2019; Meyerson & Mooney, 2007; Pyšek, Jarosik, *et al.*, 2010). Different drivers may affect invasion dynamics and become important during different stages of the biological invasion process (**Glossary**), such as the introduction and establishment stages. For instance, global trade and transport are well-known major drivers promoting the intentional or unintentional introduction of alien species (**Chapter 3**, **section 3.2.3**; and Hulme, 2009). Tourism is another important driver (**Chapter 3**, **section 3.2.3.4**), particularly on remote islands (Toral-Granda *et al.*, 2017). But interactions between introduction pathways and invasion stages also vary by taxonomic group (e.g., Bernery *et al.*, 2022). Anthropogenic disturbances such as habitat (**Glossary**) destruction (e.g., deforestation), degradation (e.g., eutrophication) and fragmentation, and climate change are strongly associated with increasing habitat vulnerability to invasions (Hierro *et al.*, 2006; Hulme, 2017; Pauchard & Alaback, 2004; J.-Z. Wan *et al.*, 2019). Thus, once introduced, alien species are more likely to establish in areas with high degrees of land use change, high human population density, and high gross domestic product (GDP) (Pyšek, Jarosik, *et al.*, 2010). All of these drivers have distinctly increased in the last decades (**Figure 2.1**; **Chapter 3**, **section 3.1.1**), paving the way for rising numbers of invasive alien species, and the establishment of alien species more generally.

2.1.1 Previous alien and invasive alien species assessments

Multiple recent regional and global scale assessments have highlighted biological invasions as having a significant influence on nature (**Glossary**), nature's contributions to people, good quality of life and on Indigenous Peoples and local communities (**Glossary**; IPBES, 2018a, 2018b, 2018c, 2019a). In general, these assessments have noted that while progress has been made in identifying pathways of alien species introductions and in invasive alien species eradication and management (**Glossary**; Secretariat of the CBD, 2020), successful prevention of biological invasions (**Glossary**) remains limited, in part due to ineffective border controls in some countries (Secretariat of the CBD, 2014). Global and regional assessment reports show that biological invasions are an increasing worldwide threat (Early *et al.*, 2016; Osipova *et al.*, 2017; WWF, 2018) exerting pressure on native biodiversity in concert with other global phenomena (IPBES, 2016; Secretariat of the CBD, 2020) resulting in consequences such as biotic homogenization and the extinction of native species (**Glossary**; Millennium Ecosystem Assessment, 2005). However, both positive and negative impacts (**Glossary**) associated with alien species have been documented (IPBES, 2016; Roué *et al.*, 2017). Nonetheless, large swathes of several regions remain understudied and report relatively little information regarding invasive alien species (IPBES, 2018b). In Europe, Central Asia, and in the Americas, biological invasions are severe due to extensive trade and transportation networks that are pathways for alien species introductions (IPBES, 2018b, 2018c) with more complete documentation in Europe and North America. In Central Asia, South America and mesoamerica, and in Africa, biological invasions tend to be less well-documented and few sources on the biogeographic details of invasive alien species trends are available across these regions (IPBES, 2018a, 2018b, 2018c). Further, invasive alien species are identified by Indigenous Peoples and local communities as one of the major drivers of change in nature as, for example, these species encroach on grazing lands and threaten agricultural systems (Forest Peoples Programme *et al.*, 2020; Roué *et al.*, 2017). Many invasive alien species do not have any cultural or economic value for Indigenous Peoples and local communities and some groups lack strategies to deal with biological invasions (Roué *et al.*, 2017).

2.1.2 Pathways of alien species introductions

Following standard frameworks (CBD, 2014; Hulme *et al.*, 2008), pathways describe the mechanisms that result in the introduction of alien species. Pathways usually focus on movements until a species reaches the border of an administrative unit, such as a country, although they are not restricted to this definition. Pathways are distinct from routes of introduction; pathways describe how and by what means a species has entered the new region; route of introduction refers to a geographic route between two locations. Pathways have been categorized into six major classes (release, escape, contaminant, stowaway, corridor, and unaided) and several sub-classes. Major classes of pathways are provided by the Convention on Biological Diversity (CBD; CBD, 2014; **Table 2.1**; **Chapter 1**, **Box 1.6**).

Alien species have been introduced through a variety of pathways that have varied in importance over time and among species groups (**Figure 2.2**; CBD, 2014; Faulkner *et al.*, 2016; Hulme *et al.*, 2008; Pyšek *et al.*, 2011). Intentional introduction pathways, such as release and escape, have played a major role for plant and vertebrate introductions, while unintentional introduction pathways, such as contaminant and stowaway, are highly relevant for introduced invertebrates, algae, and fungi (Saul *et al.*, 2017). In addition to variations among species groups, the relative importance of pathways for introducing alien species and the absolute number of alien species introduced through certain pathways has changed over time depending on the number of propagules being transported (van Kleunen *et al.*, 2018). Overall, the absolute number of established alien species has increased across nearly all pathways with particularly steep increases beginning circa 1800 and continuing until the present **(Figure 2.2)**. The main pathway recorded for most species was escape from confinement, followed by contaminant and stowaway, release in nature, and corridors. The relative importance of the escape pathway has declined slightly in recent decades, while the contaminant and stowaway pathways have increased in importance, possibly reflecting higher numbers of introductions through global trade and transport (Hulme, 2009). For detailed pathway classifications, seed contamination was the only pathway with declining absolute numbers, and particularly strong increases were observed for pet species and stowaways **(Figure 2.2)**. Overall, introductions for ornamental purposes remained highest in absolute numbers over the last 200 years. However, most (82 per cent of all available records in the pathway data set by Saul *et al.* (2017)) information on pathways is available for plants and vertebrates, while information on introduction pathways is often lacking for

Table 2 1 **Definition of major pathway classes.**

Definitions are published by the CBD (2014).

Pathway class	Definition
Release in nature	The intentional introduction of live alien organisms for the purpose of human use in the natural environment. Examples include biological control, erosion control, releases for fishing or hunting in the wild, landscape “improvement” and introductions of threatened organisms for conservation or religious purposes.
Escape from confinement	The movement of (potentially) invasive alien species from confinement (e.g., zoos, aquaria, botanic gardens, agriculture, horticulture, forestry, aquaculture and mariculture facilities, scientific research or breeding programmes, or escaped pets) into the natural environment. Through this pathway, organisms were purposefully imported or otherwise transported to confined conditions, but subsequently unintentionally escaped confinement.
Transport–Contaminant	The unintentional movement of live organisms as contaminants of a commodity that is intentionally transferred through international trade, development assistance, or emergency relief. This includes pests and diseases of food, seeds, timber, and other products of agriculture, forestry, and fisheries, as well as contaminants of other products.
Transport–Stowaway	The moving of live organisms attached to transporting vessels and associated equipment and media. The physical means of transport-stowaway include various conveyances, ballast water and sediments, biofouling of ships, boats, offshore oil and gas platforms and other water vessels, dredging, angling or fishing equipment, civil aviation, sea and air containers.
Corridor	The movement of alien organisms into a new region following the construction of transport infrastructure without which spread would not have occurred. Such trans-biogeographical corridors include international canals (connecting river catchments and seas) and transboundary tunnels linking mountain valleys or oceanic islands.
Unaided	The secondary natural dispersal of invasive alien species that have been introduced by means of any of the foregoing pathways.

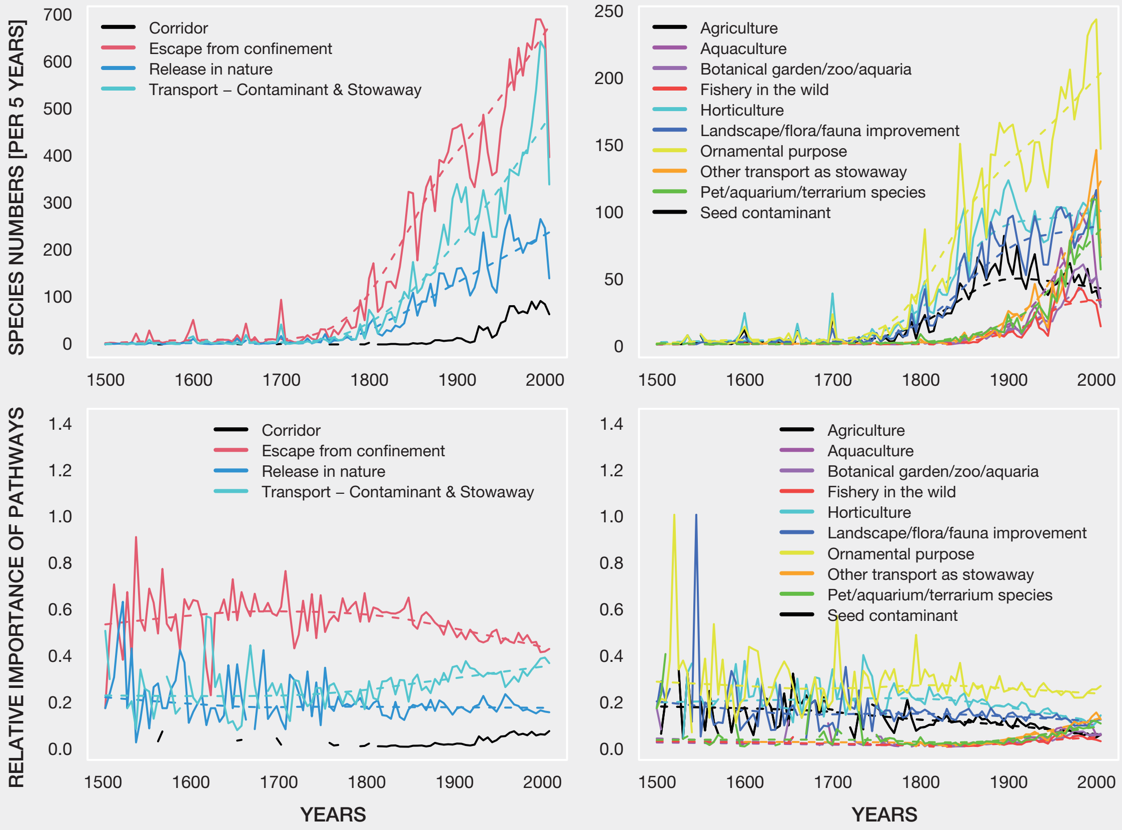

Figure 2 2 **Introductions of established alien species by pathway over time.**

The figure shows global absolute numbers (top) and relative importance (bottom) of established alien species introductions by pathway since 1500. Smoothed trends are indicated by dashed lines. Sudden drops at the end of the time series likely reflect a lack of recent records. Only the top ten pathway sub-categories are shown. A data management report for this figure is available at https://doi.org/10.5281/zenodo.7615582

other taxa. Therefore, the patterns and trends in pathway dynamics described above are likely biased towards pathways associated with plant and vertebrate introductions.

2.1.3 Chapter structure and content

Chapter 2 presents an overview of the current knowledge on the trends and status of alien species in general and invasive alien species. The logic underlying this chapter, the definitions of trends and status, and how the terms are used are presented in **Box 2.1**. Throughout the chapter, three distinct categories for species introduced to regions outside of their native ranges have been used: alien species, established alien species, and invasive alien species (**Chapter 1**, **Figure 1.1**, **Glossary**). These three status categories have been included because studies and databases vary in their definitions and details for these terms, some studies address only alien species without further specification, others focus on established alien species, while others distinguish among alien, established alien, and invasive alien species. It is critical to distinguish the status categories of species along the process of biological invasions for two main reasons, that is, because each term has a distinct meaning in invasion science and because the introduction dynamics, species distributions, and factors driving invasion patterns vary by taxa (Hejda *et al.*, 2009). The ability to clearly delimit invasive alien species from established alien species is impacted by a lack of standardized definitions systematically applied across studies and databases. Moreover, the status of a species introduced outside of its native range can change at any given time, further complicating assessments. Consequently, it remains difficult to consistently and comprehensively collate information on invasive alien species trends and status only; thus, alien and established alien species are also considered. This chapter does include one figure depicting temporal trends of invasive alien species numbers (**Figure 2.4**, in **section 2.2.1**) and multiple tables of the most widespread (**Glossary**) invasive alien species as provided by the Global Register of Introduced and Invasive Species (GRIIS; Pagad *et al.*, 2022). However, most available information and data are for established alien species. When known, the specific invasion status is therefore indicated throughout the chapter.

The structure of the chapter is depicted in **Figure 2.3**. This chapter reports on trends, status, and gaps consistently across all major sections. The major sections represent first a general introduction (**section 2.1**) and an overview of the global dynamics (**section 2.2**) followed by trends, status, and gaps by taxonomic group (**section 2.3**), IPBES regions and subregions (**section 2.4**), IPBES units of analysis (**section 2.5**), and future projections (**section 2.6**). While this structure creates some redundancies, it provides comprehensive and focused information for readers interested in a particular group, system, or region.

Box 2 1 Rationale of the chapter.

Chapter 2 reports on past and future temporal trends in alien species (including established and invasive alien species where possible) numbers, their current and future status, and data and knowledge gaps for taxonomic groups, Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) regions, and units of analysis (**Chapter 1**, **sections 1.6.4** and **1.6.5**). Temporal trends are long-term directional changes over long time periods (i.e., decades to centuries) in numbers of species, populations, or individuals introduced or in the spatial extent of colonization. Trends are presented as numbers of species (species richness) and rates of accumulation over time (i.e., numbers of newly recorded established alien species per unit time). Status is the current established alien species number and distributions in a certain area such as IPBES regions (**section 2.4**) or units of analysis (**section 2.5**) – and is indicated by established alien species number per spatial unit (global, regional, and biogeographic). Data and knowledge gaps describe missing or unavailable information or data for species or taxonomic species concepts, IPBES regions, or units of analysis.

Guiding questions:

- What is the status of alien species globally, regionally, by taxon and by unit of analysis?
- What are the trends for established alien species globally, regionally, by taxon, and by unit of analysis?
- What are the data and knowledge gaps for alien species-related data and how do they vary globally, regionally, by taxon and by unit of analysis?
- What are the eco-evolutionary dynamics of biological invasions?
- What are the methodological limitations and uncertainties in future dynamics in invasive alien species?

Keywords: alien species, established alien species, invasive alien species, distribution, status, trends, data gaps

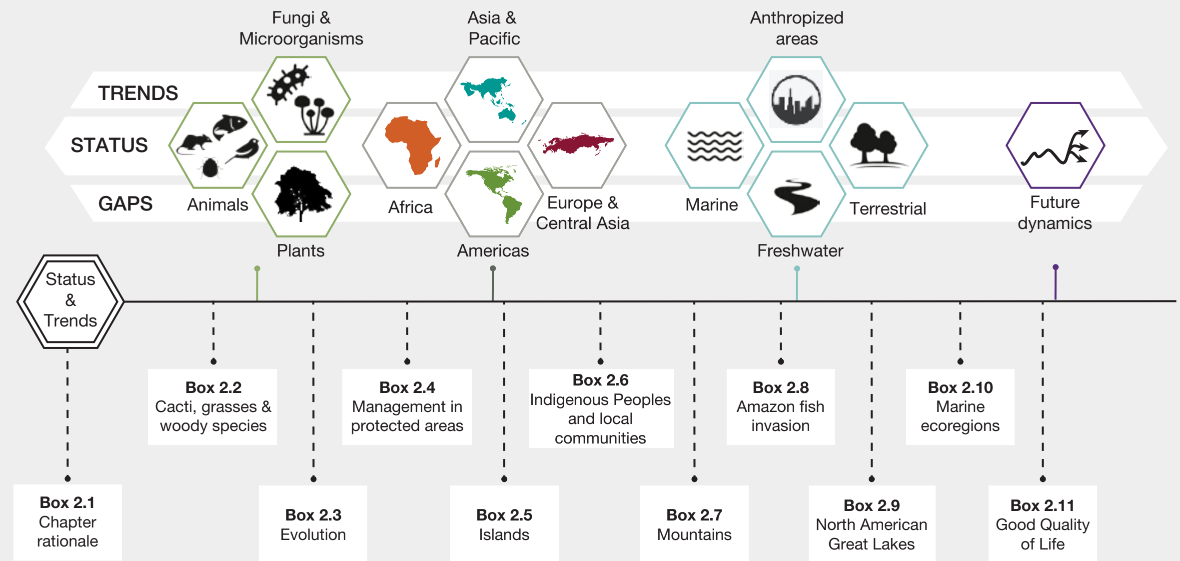

Figure 2 3 Overview of chapter structure.

Chapter 2 reports on temporal trends, the status of the current distributions of alien and invasive alien species, and the gaps in knowledge for taxonomic groups, IPBES regions, units of analysis, and future dynamics. Case studies and in-depth presentations are provided in boxes throughout the chapter.

In addition, particular emphasis was given to selected topics of overall importance in individual boxes. Throughout the chapter the term "species" is used for clarity, though it should be noted that individual populations of a species, not the entire species, are invasive. Where appropriate, the distinction has been made between major species groups, namely mammals, birds, fishes, reptiles, amphibians, insects, spiders, crustaceans, molluscs, other invertebrates, vascular plants, aquatic vascular plants, algae, bryophytes, fungi, Chromista, bacteria, and viruses.

The trends and status of alien species as presented here are based on a comprehensive review of the existing literature and databases, supplemented by knowledge from experts from all around the world and from multiple biological disciplines. The authors strove to provide a globally and taxonomically balanced and comprehensive assessment of the trends and status of alien, established alien, and invasive alien species based on available knowledge and data. However, the information residing in alien species records occurrences is scattered and patchy. A large number of records for alien species occurrences are missing for multiple reasons such as data not being publicly available, delays entering records into available databases, lack of such databases at all, or few or no monitoring activities (**Glossary**), which is particularly problematic for certain taxa such as microorganisms and sub-regions such as Central Africa. Consequently, the numbers presented in figures and tables inevitably underestimate the true numbers of alien species occurrences. However, incomplete data does not imply that inferred conclusions are flawed; instead, it means that conclusions should be drawn carefully while considering the availability and potential biases of information. In this assessment of trends and status of biological invasions, the uncertainty due to incomplete data to provide robust conclusions that are scientifically supported by currently available evidence has been included.

2.1.4 Generation of data underlying figures and tables in this chapter

Due to the use of inconsistent terminology and data processing steps, a direct comparison of individual studies of alien species occurrences is often difficult. Comprehensive global databases that allow direct comparisons of numbers across taxonomic groups and regions exist for a few well-investigated species groups. These global databases provide comprehensive information at least for individual species groups and form the basis for a database generated for this chapter.[2] All numbers presented in the tables and figures in this chapter are based on this single database compiled specifically for this chapter if not stated otherwise. Consequently, the textual descriptions of the chapter provide a more comprehensive assessment of the existing literature for the respective geographic unit or taxonomic group, while the figures and tables provide a basis for comparison across regions and taxa, which is inevitable based on a reduced number of records. The generation of the chapter database is described in detail below, and also provided in the data management report for this chapter.[2]

Generation of a database of regional checklists of alien species

The chapter database of alien species occurrences that provides the basis for figures and tables in this chapter[2] was established by integrating major global databases of alien species occurrences. These databases were selected because they are global, represent the most comprehensive databases in their field, and are published and freely accessible. Altogether, seven databases fulfilled these criteria **(Table 2.2)**: five databases with a focus on individual taxonomic groups, and two cross-taxa databases, one of which contains years of first records of alien species. The development of these databases is based on more than 4,000 individual sources of information including scientific publications, reports, and regional databases. That is, although only seven databases are included, the total number of considered publications and data sources is considerably larger. Nonetheless, it is likely that even for the species groups and content included in the databases, not all available reports and studies were considered, and records are missing for a variety of reasons. As a consequence, the numbers of species reported in figures and tables of this chapter are likely higher.

The seven global databases used as the basis for all figures and tables in this chapter differ in their spatial resolutions, terminologies, and taxonomies, impeding the direct integration of databases.[2] Assessment experts have therefore applied a workflow (i.e., a series of data transformation steps implemented in open-source computer scripts) to first standardize the spatial resolutions, terminologies, taxonomies, and the representation of years of first record. Synonyms were resolved according to the backbone taxonomy of the Global Biodiversity Information Facility (GBIF). Subsequently, the databases were combined, duplicated entries were removed, and conflicting entries, such as deviating first records, were resolved where possible. Conflicting entries that could not be resolved automatically, such as deviating invasion status, were kept as duplicated entries in the chapter database.[2] New workflows were developed to enable the identification of the biogeographical status of occurrence records using probabilistic frameworks (e.g., Arlé *et al.*, 2021).

2. The full workflow, including detailed descriptions and manuals, has been published (Seebens, 2021; Seebens *et al.*, 2020). Version 1.3.9 of the workflow (https://doi.org/10.5281/zenodo.5562840) has been applied to produce the final database version 2.4.1, which is used in this chapter (https://doi.org/10.5281/zenodo.5562892). The data management report is also available at https://doi.org/10.5281/zenodo.7615582

Table 2 2 **List of databases of alien and invasive alien species considered as a basis for figures and tables in this chapter.**

Database	Content used here	Citation and source
Global Naturalized Alien Flora (GloNAF)	Regional records of alien vascular plants	van Kleunen *et al.*, 2019 https://idata.idiv.de/DDM/Data/ShowData/257
Global Avian Invasions Atlas (GAVIA)	Regional records of alien birds	E. E. Dyer, Redding, *et al.*, 2017 https://doi.org/10.1038/sdata.2017.41
Distribution of Alien Mammals (DAMA)	Regional records of alien mammals	Biancolini *et al.*, 2021 https://doi.org/10.6084/m9.figshare.13014368
Alien amphibians and reptiles	Regional records of alien amphibians and reptiles	Capinha *et al.*, 2017 https://doi.org/10.1111/ddi.12617
MacroFungi	Regional records of alien macro fungi	Monteiro *et al.*, 2020 https://doi.org/10.15468/2qky1q
Alien Species First Records (FirstRecords)	First records of alien species in regions across taxonomic groups	Seebens, Blackburn, *et al.*, 2017 https://doi.org/10.5281/zenodo.4632335
GRIIS	Regional records of alien and invasive alien species across taxonomic groups	Pagad *et al.*, 2022 https://doi.org/10.5281/zenodo.6348164

The integration of the seven global databases as described above resulted in the largest single database of alien species distributions currently available, containing 175,980 records of 39,215 alien taxa from 264 locations worldwide. The term "location" mostly refers to countries, but the database also contains information about sub-national units such as islands or federal states in some cases. The database also includes populations with unconfirmed or "casual" (**Glossary**) status. Records of casual species are not reported in this chapter and therefore excluding casual alien species resulted in 37,591 established alien species and 5,260 invasive alien species as classified by the database GRIIS.

The databases underlying the chapter database differ in their terminology describing biological invasion status (i.e., introduced, established, invasive) of a population (Groom *et al.*, 2019). However, invasion status is often difficult to determine due to the lack of protocols for a standardized determination. Some databases, such as GloNAF, have a more rigorous and conservative approach to classifying established alien species, while other databases such as GRIIS included more species in this category. Consequently, the total numbers of established alien species vary among databases. Comprehensive global databases exist for mammals, birds, and vascular plants. These underwent a thorough assessment of invasion status and thus usually report lower numbers relative to cross-taxonomic databases such as the GRIIS or FirstRecords. To account for this variation in this assessment, total numbers of established alien species were provided as ranges for these taxonomic groups to emphasize the variation that exists in the published material. However, the spatial variations of the taxonomic databases are highly correlated with the variation in the GRIIS: The Pearson correlation coefficients, r, of total established alien species per region between GRIIS and GloNAF (r=0.92), Global Avian Invasions Atlas (GAVIA) (r=0.76) and Distribution of Alien Mammals (DAMA) database (r=0.82) were all high and significant. Thus, the spatial and temporal patterns as shown in this chapter do not distinctly differ among databases except in the overall levels of species numbers. This chapter therefore shows the total numbers of established alien species, including all databases in maps and time series, and provides ranges in tables of established alien species numbers.

Generation of a database of local occurrence records

The database used in this chapter provides information on alien species occurrences in so-called checklists representing lists of species for countries, large islands or other sub-national regions. This is inconvenient when it comes to the analysis of the distribution of alien species at other delineations such as units of analysis or marine ecoregions. To obtain information about alien species occurrences at different levels of spatial organization and scale, a freely available workflow to downscale regional checklists of alien species occurrences was applied (Seebens & Kaplan, 2022b). Using this workflow, coordinates of species occurrences as reported in the chapter database were obtained from GBIF and the Ocean Biodiversity Information System (OBIS). For each species in the chapter database, coordinates of records (marine or terrestrial) were obtained from the aforementioned online platforms and identified as representing alien populations based on the chapter database. Various steps of data cleaning and testing were included to avoid false entries. In this way, more than 35 million records of alien populations of 17,424 established alien species with coordinate-based records were gathered. These point-wise occurrence records were then aggregated to obtain total established alien species numbers per terrestrial region, marine ecoregion (see next paragraph for details, see also **Chapter 1**, **section 1.6.4** for a description of IPBES regions and sub-regions used in the IPBES invasive alien species assessment), and land managed by Indigenous Peoples (**Box 2.6** in **section 2.4.1**). The full database of coordinates is open access (Seebens & Kaplan, 2022a), and includes a manual for data generation and digital object identifiers for GBIF requests to ensure reproducibility and transparency.

Marine records

Comprehensive information about the global occurrence of marine alien species was largely lacking when work on this chapter was initiated. Since then, two important developments have taken place, namely the publication of a worldwide study on marine alien species distributions (Bailey *et al.*, 2020) and the publication of the World Register of Introduced Marine Species (WRiMS; M. J. Costello *et al.*, 2021). In both cases, records of marine alien species have been validated by experts in the field. A total number of 1,442 marine alien species were recorded by Bailey *et al.* (2020), while 2,714 species were reported by M. J. Costello *et al.* (2021). Both are likely underestimates of the true extent of marine alien species. Due to the lack of more detailed data and/or available expertise to check individual records and regions, the studies cover either only approximately half of the world's marine ecoregions or provide information on comparatively large spatial units rendering a comparison of marine ecoregions difficult. To provide an alternative way of gathering information, this assessment used the database of local occurrence records of established alien species as described in the previous paragraph, which is based on regional checklists of established alien species and records from GBIF and Ocean Biodiversity Information System (OBIS) as described in the published workflow (Seebens & Kaplan, 2022b). The coordinate-based records were then assigned to the marine ecoregion as presented by Spalding *et al.* (2007). The spatial representation is still biased towards well-investigated regions and records are not cross-checked by experts, but the generated data do provide an overview across nearly all marine ecoregions worldwide. To consider the published data validated by experts, the information provided in Bailey *et al.* (2020) has been used where possible and filled in missing regional information by the aforementioned data generation methods.

Quantification of data gaps

The lack of information on alien and invasive alien species occurrences means that regional lists (i.e., checklists) of established alien species are often incomplete, producing data gaps. The degree of incompleteness varies by taxonomic group, region, and time period (Pyšek *et al.*, 2008). To assess the influence of data gaps on the trends and status presented in this chapter, this assessment attempted to quantify the degree of incompleteness. As little research has been done previously to assess incompleteness, three different indicators of data gaps were tested:

1. The number of studies available per region in the chapter database was used as a proxy measure for research intensity and should negatively relate to data gaps.

2. To measure data gaps across taxonomic groups, the number of widespread phyla for which no information was available for a particular region was counted. A widespread phylum is defined as one with more than 500 records in the chapter database. Seven phyla were determined to be widespread: Ascomycota, Annelida, Basidiomycota, Mollusca, Chordata, Arthropoda, and Tracheophyta. Different cut-off values (other than 500 records) for selecting taxonomic groups were tested but did not change the overall patterns. The number of these phyla with less than five records per region was then counted. By applying this approach, experts assumed that at least five established alien species per selected phylum (i.e., at least five species of Tracheophyta per region, five established alien species of Arthropoda, etc.) should be found in each region as defined in the chapter database. This is likely true, particularly for large regions, but might be critical for very small regions and small islands. Different versions of this indicator were tested using different cut-off values (e.g., at least one, three, or ten records) but all versions revealed similar spatial patterns of research intensity and data gaps (**Figure 2.5** for a spatial representation of indicators 1 and 2).

3. A third indicator was used to describe spatial variation of data gaps for individual taxonomic groups by comparing the number of available first records of established alien species for a region with the total number of species recorded for the same region. This analysis provided information on the proportion of available first records per region and can be used to assess the robustness of temporal trends and provide indications about the general availability of information for the respective taxonomic group. As the biases known for first records largely reflect data and knowledge gaps in general, the proportion of available temporal information is used as a proxy for data completeness.

Although none of these indicators are ideal, they can be considered for context when interpretating the trends and status of biological invasions.

2.2 GLOBAL TRENDS AND STATUS OF ALIEN AND INVASIVE ALIEN SPECIES

This section describes an assessment of the temporal trends and status of the distribution of alien and invasive alien species globally for all taxonomic groups combined.

2.2.1 Trends

Overall, studies on the introduction of alien species over time have reported a continuous global increase in the number of established alien species consistent across taxonomic groups, particularly since the early nineteenth century (Aukema *et al.*, 2010; C. Chen *et al.*, 2017; E. E. Dyer, Cassey, *et al.*, 2017; S. Henderson *et al.*, 2006; Peck *et al.*, 1998; Pyšek *et al.*, 2012; Roy, Preston, *et al.*, 2014; Sandvik, Dolmen, *et al.*, 2019; Sax & Gaines, 2008; Verloove, 2006; Wilson *et al.*, 2007). Indeed, there is no study reporting a decline in established alien species numbers except for a few islands where eradication programmes or stringent biosecurity (**Glossary**) measures have been applied (Simberloff *et al.*, 2013). Distinct increases in established alien species numbers are often reported post-1950 (Huang *et al.*, 2011; Peck *et al.*, 1998; Pyšek *et al.*, 2012; Sandvik, Hilmo, *et al.*, 2019), while a few other reports indicate earlier acceleration in the nineteenth century (mostly for vascular plants; C. Chen *et al.*, 2017; S. Henderson *et al.*, 2006; Seebens, Blackburn, *et al.*, 2017; Wilson *et al.*, 2007) or continuous increases without periods of acceleration over 200 years (mostly for insects; Aukema *et al.*, 2010; Nahrung & Carnegie, 2020) and birds (Blackburn *et al.*, 2015). In addition to the rise in cumulative established alien species numbers, many studies also report rising rates of increase over time (Blackburn *et al.*, 2015; Seebens, Blackburn, *et al.*, 2017). Recently, the highest global emergence rates of new established alien species were reported with approximately 200 new alien species, which later became established, recorded annually (Seebens, Blackburn, *et al.*, 2017). Declining rates of new records of terrestrial alien species were observed only for vascular plants in North America (Seebens, Blackburn, *et al.*, 2017), insects in Australia (Nahrung & Carnegie, 2020) and mammals worldwide (Seebens, Blackburn, *et al.*, 2017). As shown in the GRIIS database, numbers of invasive alien species show very similar trends over time, but with lower numbers in comparison to established alien species (**Figure 2.4**; Seebens, 2021).

Most studies on selected taxonomic groups, specific regions, or global analyses show systematic and constant increases in established alien animal species across taxonomic groups (e.g., Aukema *et al.*, 2010; Bailey *et al.*, 2020; E. E. Dyer, Redding, *et al.*, 2017; Fuentes *et al.*, 2020; Seebens, Blackburn, *et al.*, 2017). For example, bird and mammal introductions mostly occurred in three distinct phases: first, historically with the discovery and colonization of new lands by Europeans from about 1500 to 1700; second, mainly through acclimatization societies (i.e., associations that encouraged the introduction of alien species), particularly *via* European colonialism from 1700 to 1900 (e.g., Pipek *et al.*, 2015); and since the 1950s, mostly *via* global trade (Biancolini *et al.*, 2021; Cassey *et al.*, 2015; E. E. Dyer, Redding, *et al.*, 2017; Hulme, 2021; Turbelin *et al.*, 2017). In contrast to alien homoeotherms, the pet trade is the primary cause of herpetofaunal introductions, a recently spreading group (Capinha *et al.*, 2017). For insects, there are two distinct waves of accelerated introduction rates, one between 1820-1914 and one from 1969 to present, likely due to intensifying global trade and transport (Bonnamour *et al.*, 2021; Roques *et al.*, 2016). Horticulture in general including the trade for ornamental purposes represents an important pathway for the introduction of vascular plants and their pathogens (**Figure 2.2**; Hulme, 2011; van Kleunen *et al.*, 2018). In addition to the total number of introduced alien species, the rate of species accumulation also continuously increased for most taxonomic groups in recent decades (see below), indicating a long-lasting intensification of introductions. Mammals represent the only exception, showing declines in species accumulation rates since about 1950, likely a consequence of stricter regulations on animal trade and husbandry and limited source pools (Seebens *et al.*, 2018; Simberloff *et al.*, 2013).

Once established in a new location, alien species are likely to spread to new areas within the introduced range either by natural dispersal or by means of human-mediated transportation. Approximately 90 per cent of all species introduced before 1700 are found today in more than one region, indicating further spread or multiple introduction events (Seebens, Blackburn, *et al.*, 2021). Spread of an alien species usually lasts for decades to centuries (Gassó *et al.*, 2010; Roques *et al.*, 2016). Rates of inter-regional spread were already high in the nineteenth century for many taxonomic groups, and peaked at that time for vascular plants, but increased further for other taxa, particularly for birds and invertebrates (Seebens, Blackburn, *et al.*, 2021). While spread appears to be slowing for a few already widespread alien species, it is likely that the vast majority of established alien species found currently in only a few sites (Pyšek, Pergl, *et al.*, 2017; Seebens, Blackburn, *et al.*, 2021) will spread also without human assistance in the near future.

The increase in numbers of established alien species is consistent among IPBES regions **(Figure 2.4)**. Before 1800, numbers of established alien species rose more rapidly in Europe and Central Asia, although Europe by far has the most records of first year of observations. The differences in early records between Europe and Central Asia and

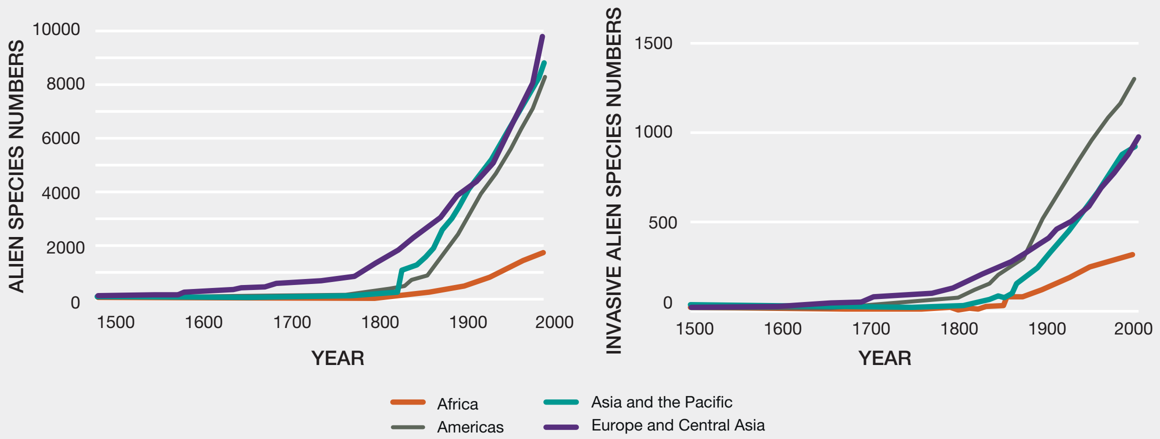

Figure 2 4 **Trends in numbers of established alien species and invasive alien species.**

Total numbers of established alien species (left) and invasive alien species (right) are shown for IPBES regions for 1500-2005. Numbers underestimate the true extent of alien species occurrences due to a lack of data (**section 2.1.4** for further details about data processing). A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

other IPBES regions are likely due to different sampling intensities (Seebens, Blackburn, *et al.*, 2017). In addition, due to time lags (lag phase in the **Glossary**), the rapid increase in researchers studying biological invasions and their impacts, and the subtlety of some impacts, the number of established alien species, and invasive alien species is almost certainly underestimated (Bellard & Jeschke, 2016). The steepest increases in established alien species were observed from post-1850 to the present, particularly for the Americas and the Asia-Pacific regions. These two IPBES regions followed similar trajectories of increases from about 1950 onwards resulting in similar total species numbers in 2005, between 7,000 and 8,000 established alien species for the Americas and the Asia-Pacific regions respectively. Note that the total number of recorded established alien species is higher than shown in the time series due to missing years of first records for most taxa and regions. The number of established alien species for Africa is notably low and markedly different from other regions. This is a general pattern that also holds when species numbers in particular taxonomic groups in Africa are plotted separately (Pyšek, Hulme, *et al.*, 2020). It is not fully understood why numbers are so much lower in Africa, but it is most likely due to Africa having lower imports than other regions, a lack of information on the year of first records of established alien species in Africa, and because the continent is generally understudied in terms of biological invasions (Pyšek *et al.*, 2008; **section 2.4.2**). As classified by GRIIS, numbers of invasive alien species show very similar dynamics though at a lower number, with correlation coefficients of times series over 0.95 for all IPBES regions **(Figure 2.4)**. The high correlation between the distribution of established alien species and invasive alien species, which has also been reported in other studies (Pyšek, Pergl, *et al.*, 2017), makes it very likely that trends and status of invasive alien species resemble those of established alien species, noting there are less invasive than established alien species.

2.2.2 Status

According to the chapter database underlying the figures and tables in this chapter, at least 39,215 alien species have been recorded worldwide. As the database does not contain all records of alien species (**section 2.1.4**), the true number is likely much higher. Of those alien species, 37,215 are recorded as having established alien populations, while 5,256 are classified as invasive alien species (**section 2.1.4**). Note that the total number of invasive alien species deviates from the number provided in **Chapter 4** due to different approaches and data sources. As the number of alien species recorded is unequally distributed across the globe **(Figure 2.5)**, because the detectable patterns depend upon available data, and because large data gaps remain (**section 2.2.3**), it is in some cases difficult to distinguish data biases and artifacts from true biological patterns. However, with continued research effort, the gaps are gradually shrinking. In the terrestrial and marine realms and consistent across taxonomic groups, the highest numbers of established alien species are found in Europe (particularly western Europe), North America, and Australasia (Dawson *et al.*, 2017). However, total numbers are higher than shown in **Figure 2.4** where only available global databases were included. For many regions, particularly several countries in Africa, Central Asia and many islands, data are scarce and available lists are incomplete. For many marine ecoregions (white areas), alien species occurrence data are lacking or not yet integrated into larger databases **(Figure 2.5)**.

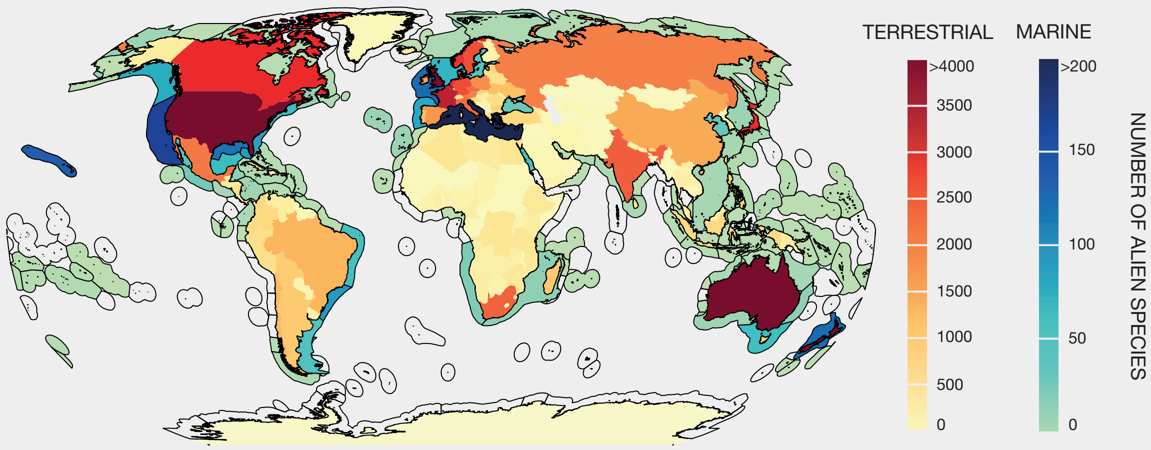

Figure 2 5 **Numbers of established alien species per region.**

The total number of established alien taxa per mainland region (terrestrial and freshwater) and marine ecoregion (marine) is indicated by colour separately. White denotes missing information. Note that marine records were available on different geographic delineations and thus marine ecoregions differ in sizes in this figure. Note that numbers may deviate from those reported in the text due to variation among data sources. See **section 2.1.4** for further details about data sources and data processing. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Global patterns of established alien species distributions were consistently assessed only for selected groups such as ants, spiders, amphibians, reptiles, freshwater fishes, birds, mammals and vascular plants for 186 islands and 423 mainland regions by Dawson *et al.* (2017). This study showed that established alien species from these groups are unevenly distributed, with some regions (particularly Europe, North America, and Australasia) harbouring more species than other regions. Although Dawson *et al.* (2017) previously provided the most comprehensive representation of established alien species distributions across taxonomic groups, their assessment included only two invertebrate groups (ants and spiders) and no marine species were included because of the lack of comprehensive information. The analysis by Dawson *et al.* (2017) based on the seven animal groups revealed two major commonalities: islands and coastal areas have greater proportions of established alien species in regional faunas, and high numbers of established alien species are associated with indicators of human activities such as land-use intensity and trade. The distribution of established alien species varies by taxonomic group. For example, biological invasion hotspots of ants are found in South America, equatorial Africa, and Southeast Asia (Bertelsmeier *et al.*, 2015), while bird and mammal invasions are concentrated in North America, western Europe, South Africa, Japan, Australia, and New Zealand (Biancolini *et al.*, 2021; E. E. Dyer, Cassey, *et al.*, 2017). Numbers of established alien species show latitudinal trends: alien bird species are greatest at mid-latitudes and reflect concomitant variations in human activity, most notably the number of species introduced to a particular location (E. E. Dyer, Redding, *et al.*, 2017). Below, overviews and examples of established alien species are provided for different taxonomic groups **(Tables 2.2, 2.3)**.

The worldwide distribution of established alien species shows a marked latitudinal gradient with the highest species numbers reported at mid-latitudes, such as the temperate regions of the Northern and Southern Hemispheres, with lower numbers in the tropics (Q. Guo *et al.*, 2021; Sax, 2001). The mechanisms that drive this pattern are not yet fully understood but may be positively correlated with invasive alien plant density, the human development index, and the location of most of well-developed countries in temperate regions (Weber & Li, 2008). Greater resistance to biological invasions, faster recovery after disturbance due to higher diversity, lack of life history traits that confer shade tolerance and lower colonization, high predation pressure, and propagule pressures (**Glossary**) are proposed, but not proven, to be major causes of lower alien richness in tropical continental regions compared to non-tropical regions (Fine, 2002; Freestone *et al.*, 2011; Isbell *et al.*, 2015; Rejmanek & Richardson, 1996). However, on islands the pattern is very different, with tropical islands harbouring very high numbers established alien species (Moser *et al.*, 2018; Rejmanek & Richardson, 1996). Thus, it seems unlikely that tropical regions have a greater resistance to biological invasions compared to non-tropical regions as they lack the characteristics to make them less vulnerable (Chong *et al.*, 2021). However, one explanation for lower numbers of established alien species in tropical regions is lower levels of propagule pressure (i.e., fewer introductions and/or smaller introduction size) due to factors such as low import volumes. In addition, reduced sampling intensities due to

Table 2 3 **Numbers of established alien species for various taxonomic groups worldwide.**

Species numbers can vary depending on data sources. Note numbers in this table may deviate from those reported in the text due to variation among data sources. For mammals, birds, and vascular plants, ranges of values indicate variation among databases (**section 2.1.4** for further details about data sources and data processing). A data management report for the data underlying this table is available at https://doi.org/10.5281/zenodo.7615582

Taxonomic group	Number of species
Mammals	197-368
Birds	495-877
Fishes	1,451
Reptiles	411
Amphibians	135
Insects	6,795
Arachnids	500
Molluscs	826
Crustaceans	661
Vascular plants	13,081-18,543
Algae	734
Bryophytes	88
Fungi	1,149
Oomycetes	70
Bacteria and protozoans	38

Table 2 4 **Top 10 most widespread invasive alien species worldwide.**

The number of regions where a species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien species and not their impacts, covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Organism group	Taxon	Number of regions
Vascular plant	*Pontederia crassipes* (water hyacinth)	74
Vascular plant	*Lantana camara* (lantana)	69
Mammal	*Rattus rattus* (black rat)	60
Vascular plant	*Leucaena leucocephala* (leucaena)	55
Mammal	*Mus musculus* (house mouse)	49
Mammal	*Rattus norvegicus* (brown rat)	48
Vascular plant	*Ricinus communis* (castor bean)	47
Vascular plant	*Ailanthus altissima* (tree-of-heaven)	46
Vascular plant	*Robinia pseudoacacia* (black locust)	45
Vascular plant	*Chromolaena odorata* (Siam weed)	43

lower research efforts and fewer monitoring programmes also likely contribute to the lower numbers recorded in the tropics (Chong *et al.*, 2021).

Comprehensive overviews of the global distribution of individual taxonomic groups exist mostly for vascular plants (E. J. Jones *et al.*, 2019; Pyšek, Pergl, *et al.*, 2017) and vertebrates (mammals, birds, amphibians, reptiles and fishes) (Capinha *et al.*, 2017; Dawson *et al.*, 2017; E. E. Dyer, Cassey, *et al.*, 2017; Pyšek, Hulme, *et al.*, 2020), with the exception of a few invertebrate groups such as spiders and ants (Dawson *et al.*, 2017) and land snails (Capinha *et al.*, 2015), and bryophytes (Essl *et al.*, 2013). Patterns of spatial distribution were similar across most taxonomic groups with particularly large numbers of terrestrial alien species in Europe, North America, and Australasia (Dawson *et al.*, 2017). As an exception, there are large numbers of alien fern species in the tropical regions of South America and Asia (E. J. Jones *et al.*, 2019). Common explanations for the variations observed in the spatial distribution of terrestrial alien species include variation in drivers such as trade and transport, GDP, high human population densities, and the degree of disturbance (Capinha *et al.*, 2017; Dawson *et al.*, 2017; E. E. Dyer, Cassey, *et al.*, 2017). Often alien species originate from neighbouring regions or regions connected through trade over long distances (D. S. Chapman *et al.*, 2017; L. Henderson, 2006; Pyšek *et al.*, 2012). High numbers of terrestrial alien species were often found on islands compared to mainlands, with remote islands often showing particularly large alien species numbers (Blackburn *et al.*, 2008; Moser *et al.*, 2018). While it is unknown whether these high numbers can be explained by high propagule and colonization pressures (**Glossary**) due to human activities, or instead are a result of the traits of the native communities, both factors likely interact to affect the outcome of invasions on islands.

2.2.3 Data and knowledge gaps

Perceptions of the distribution of alien species are highly influenced by an unequal global sampling of information on alien species occurrences. For example, hotspots (**Glossary**) of alien species occurrences (i.e., areas of high alien species richness relative to other regions with similar biogeographic characteristics; Dawson *et al.*, 2017) are well-known to coincide with global hotspots of data availability and study sites (L. J. Martin *et al.*, 2012; C. Meyer *et al.*, 2015), shaping knowledge of species distributions (A. C. Hughes *et al.*, 2021). This conclusion is confirmed by the information provided in this chapter: mapping of the number of available studies, which were used to generate the underlying database of this chapter (**section 2.1.4** for further details on the data generation), revealed that regions with high level of information on alien species occurrences **(Figure 2.6)** match the hotspots of established alien species occurrences **(Figure 2.5)**. Hence, knowledge of invasive alien species occurrences is biased towards well-sampled regions such as Europe and North America and taxonomic groups such as vertebrates and plants with the majority of studies conducted in recent decades (Bellard & Jeschke, 2016; Jeschke *et al.*, 2012; Pyšek *et al.*, 2008). It remains unclear how much of the distributions of alien species and documented hotspots is affected by spatial variation in research intensity. The investigation of data availability as described in **section 2.1.4** showed extensive data gaps, particularly in large parts of Africa, Central Asia and on islands worldwide **(Figure 2.6)**.

In addition to regional biases, research intensities vary across taxonomic groups. There is considerably more information available on the distribution of alien and invasive alien species for vertebrates, particularly mammals (**section 2.3.1.1**), birds (**section 2.3.1.2**), and vascular plants (**section 2.3.2.1**) than for other taxa. In general, there are large data and knowledge gaps for invertebrates and microorganisms. While most information about invertebrates is available for insects, crustaceans, and molluscs, these data are still incomplete for many regions of the world (**sections 2.3.1.6**, **2.3.1.8**, **2.3.1.9**). Information for other invertebrate groups is extremely scarce. Globally little information is available for alien microorganisms and recorded distributions are often biased towards individual studies. Across realms, the greatest amount of information is available for terrestrial habitats (**section 2.5.1**), while information for aquatic (marine, freshwater and brackish) alien species is often lacking (**sections 2.5.2**, **2.5.3**). Consequently, the lists of alien species for individual regions are, in most cases, incomplete, even for well-sampled regions due to the lack of information about microorganisms and invertebrates, for example, and the degree of incompleteness varies highly among regions globally.

Most of the information about alien species occurrences is available at the national scale for whole countries, while information on sub-national units such as federal states, provinces, protected areas, or private land is usually lacking. Information about occurrences is particularly scarce for lands and waters managed by Indigenous Peoples and local communities **(Box 2.6)**. Furthermore, information about abundances and changes in abundances of alien populations is available only in a few cases and is not consistently recorded across regions and taxa. Additional uncertainty in the records of alien and invasive alien species occurrences arises from time delays frequently observed between the actual species introduction and its first record as a new population outside its native range (Crooks, 2005). For vascular plants, these time lags have been estimated to be on average 20 years (Seebens *et al.*, 2015), while for individual cases time delays of up to 150 years have been recorded (Kowarik, 1995b).

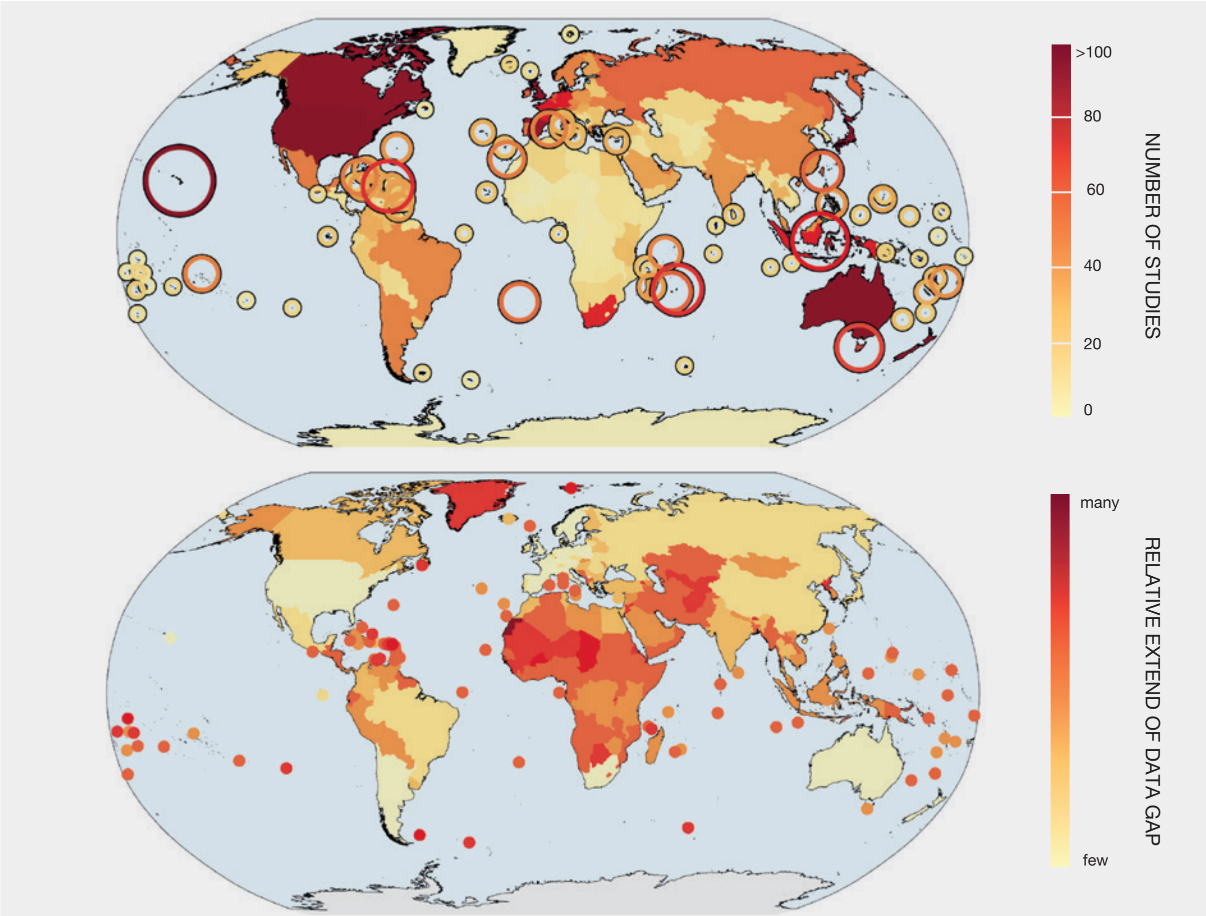

Figure 2 6 **Research intensity and data gaps for global established alien species distribution records.**

Research intensity (top) is indicated by the number of studies available in the chapter database. Data gaps (bottom) were determined as the lack of information for the seven most common phyla as recorded in the chapter database per region. Largest data gaps are apparent in Africa, Central Asia, and for many islands (**section 2.1.4** for further details about data sources and data processing for further details of the analysis). Islands are indicated by dots and circles, respectively. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

2.3 GLOBAL TRENDS AND STATUS OF ALIEN AND INVASIVE ALIEN SPECIES BY TAXONOMIC GROUPS

2.3.1 Animals

This section reports on the temporal trends and status of the distribution of alien and invasive alien animal species for various animal groups, namely mammals (**section 2.3.1.1**), birds (**section 2.3.1.2**), fishes (**section 2.3.1.3**), reptiles (**section 2.3.1.4**), amphibians (**section 2.3.1.5**), insects (**section 2.3.1.6**), arachnids (**section 2.3.1.7**), molluscs (**section 2.3.1.8**), crustaceans (**section 2.3.1.9**), and other invertebrates (**section 2.3.1.10**), as well as data and knowledge gaps (**section 2.3.1.11**).

2.3.1.1 Mammals

Trends

Because they were useful, mammals were among the first species introduced by humans, and the first records of introduced alien mammals date back thousands of years (Genovesi *et al.*, 2012). For example, mammals have been used as pack animals, for meat and fur, ornamentals, biocontrol agents, and pets since the expansion of humans from Africa to other continents (Clout & Russell, 2008; Long, 2003; Simberloff & Rejmanek, 2011). During prehistoric and historic human migration, humans transported mammals to new areas to create wild populations for settlers to hunt (Clout & Russell, 2008; Long, 2003; Simberloff & Rejmanek, 2011), peaking with European colonization. As a consequence, there were high numbers of alien mammals as early as 500-200 years ago (**Figure 2.7**). During the

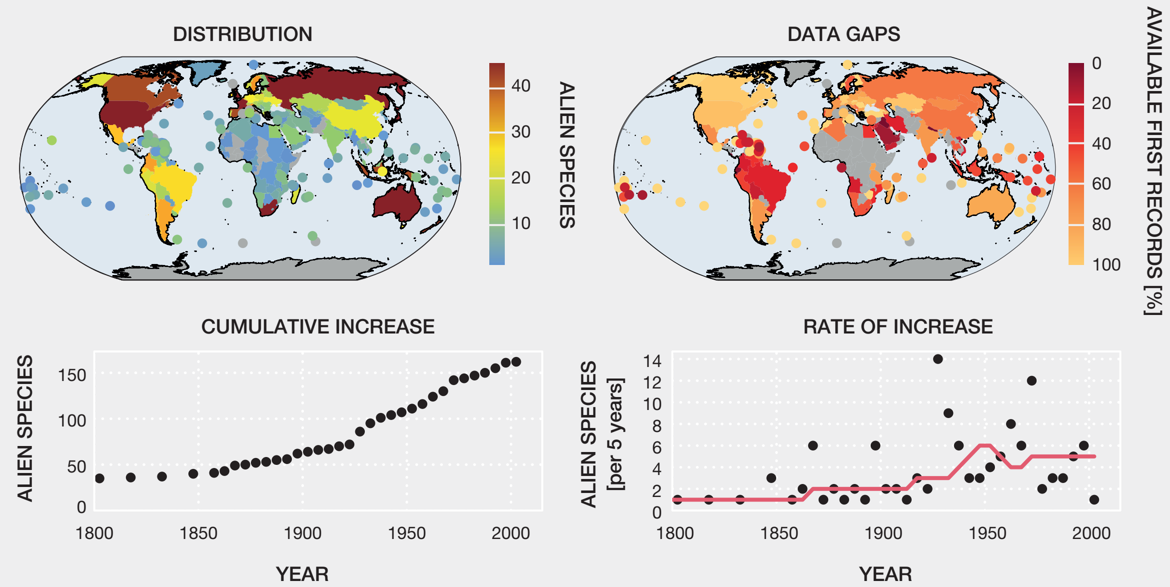

Figure 2 7 **Status, trends, and data gaps for established alien mammals.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted to aid visualization and do not indicate species numbers. Trends are shown in lower panels as cumulative numbers and as a rate of increase (i.e., numbers of alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

nineteenth century, a further acceleration of new records occurred (Biancolini *et al.*, 2021) when specific organizations (i.e., acclimatization societies) focused on alien species release to aesthetically "improve" the landscape and local fauna of colonial territories (Osborne, 2000; Simberloff & Rejmanek, 2011). In recent decades, the dominant pathways of mammal introductions have shifted from hunting and "faunal improvement" to the pet trade likely due to stricter regulations targeting alien mammals (Simberloff *et al.*, 2013). Many mammal introductions outside of their native ranges were also carried out for conservation, and to protect mammal species from overhunting, habitat loss, and invasive alien predators (Biancolini *et al.*, 2021; Seddon *et al.*, 2015; Woinarski *et al.*, 2015).

Status

The biological invasion history and status of mammals are among the best documented of alien animal taxa (Biancolini *et al.*, 2021; Blackburn *et al.*, 2017; Clout & Russell, 2008; Long, 2003). At present, 241 mammal species have established alien populations globally, causing many and diverse environmental impacts, especially on insular ecosystems (**Glossary**; Biancolini *et al.*, 2021; Blackburn *et al.*, 2017; Clout & Russell, 2008; **Chapter 4**, **section 4.3.1.1**). If the few records of unsuccessful and unconfirmed introductions are included, at least 274 mammal species have been introduced by humans to new locations (Blackburn *et al.*, 2017; Zenni & Nuñez, 2013).

According to the global Distribution of Alien Mammals database (DAMA), Asia has the highest number of established alien mammals (95), followed by North America (79), Europe (76), Australia (54), Africa (52), Oceania (50), and South America (42) (Biancolini *et al.*, 2021). The major global donors of alien mammal species are Asia (91 established alien species) and Europe (34), Australia (32), North America (31), Africa (30), and South America (23 alien species). An outgoing species flow directed to other continents is predominant for Europe and Asia, while an intracontinental flow (i.e., alien species introduced to other parts of their native continent) is common for Australia (74 per cent of all alien Australian mammals), North America (61 per cent), South America (5 per cent), and Africa (56 per cent). Other countries of Oceania received species only from other continents (Biancolini *et al.*, 2021).

Globally, the vast majority (81 per cent) of alien mammal records are found on islands (Biancolini *et al.*, 2021), most likely due to the higher vulnerability to biological invasions of insular ecosystems and greater propagule and colonization pressure on islands relative to mainland systems (Dawson *et al.*, 2017; Moser *et al.*, 2018). Moreover, alien mammals occur on 97 per cent of islands that harbour highly

Table 2 5 **Top 10 most widespread invasive alien mammal species worldwide.**

The number of regions where a species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien mammal species, not impacts which are covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Taxon	No. of regions	Taxon	No. of regions
Rattus rattus **(black rat)**	60	*Capra hircus* (goats)	30
Mus musculus **(house mouse)**	49	*Myocastor coypus* (coypu)	21
Rattus norvegicus **(brown rat)**	48	*Oryctolagus cuniculus* (rabbits)	20
Felis catus **(cat)**	38	*Mustela vison* (American mink)	18
Sus scrofa **(feral pig)**	32	*Canis lupus familiaris* (dogs)	15

threatened vertebrate species (Spatz *et al.*, 2017). Among the orders richest in alien mammals, the highest per centage globally is for Rodentia (58 species, 25 per cent), Cetartiodactyla (49 species, 21 per cent), Carnivora (30 species, 13 per cent), Diprotodontia (28 species, 12 per cent) and Primates (26 species, 11 per cent) (Biancolini *et al.*, 2021). Some alien mammals such as *Rattus* spp. (rats), *Mus musculus* (house mouse) and *Felis catus* (cat) are so common that they are often not recognized as invasive alien species in mainland regions (Long, 2003; Loss & Marra, 2017), and thus are missing from lists of alien species. Several of these mammals have lived in close proximity to humans for a very long time resulting in long-lasting commensalisms (Puckett *et al.*, 2020) and in the spread of these species globally.

Many of the most widespread invasive alien mammals worldwide **(Table 2.5)**, such as feral domestic species and commensal stowaways, can exploit human-disturbed environments (Biancolini *et al.*, 2021; Long, 2003). On islands and in Australia, where invasive alien mammals are the main cause of extinction and native species declines (Courchamp *et al.*, 2003; Woinarski *et al.*, 2015), they are subject to many control and eradication measures (DIISE, 2020; H. P. Jones *et al.*, 2016; Parkes *et al.*, 2017; Russell *et al.*, 2015, 2016). Other notorious global invasive mammals include *Herpestes javanicus auropunctatus* (small Indian mongoose), *Oryctolagus cuniculus* (rabbits), *Lepus europaeus* (European hare), *Dama dama* (fallow deer), *Camelus dromedarius* (dromedary camel), *Ondatra zibethicus* (muskrat), *Mustela vison* (American mink), *Myocastor coypus* (coypu), Procyon lotor (raccoon), *Nyctereutes procyonoides* (raccoon dog), *Vulpes vulpes* (red fox), *Sus scrofa* (feral pig), *Capra hircus* (goats), *Ovis aries* (sheep), *Equus asinus* (donkeys), *Equus caballus* (horse), *Bos taurus* (cattle), and *Canis lupus familiaris* (dogs) (Biancolini *et al.*, 2021; Blackburn *et al.*, 2017; Clout & Russell, 2008; Long, 2003; Louppe *et al.*, 2020). Mammals are the most widespread group of invasive alien animal species in terms of the number of regions invaded **(Table 2.5)**.

2.3.1.2 Birds

Trends

Birds have been introduced for thousands of years, but a notable acceleration of introductions occurred in the mid-nineteenth century arising from increasing European colonial expansion and an acclimatization of alien species considered to be beneficial. The origins and introduction sites of alien birds during this period reflects the geography of colonialism, and the locations of former British colonies (E. E. Dyer, Cassey, *et al.*, 2017), and especially hotspots such as New Zealand, Australia, Hawaii, and the Mascarenes. In this period, alien species were mainly deliberately introduced for game or ornamentation such as gallinaceous birds, wildfowl, and pigeons (E. E. Dyer, Cassey, *et al.*, 2017). Other alien species were introduced for biocontrol of agricultural insect pests such as *Acridotheres tristis* (common myna) introduced from India to Mauritius to control *Nomadacris septemfasciata* (red locust) in 1762 (Shaanker & Ganeshaiah, 1992; Simmonds *et al.*, 1976).

Introduction rates again accelerated in the mid-twentieth century most likely due to increasing trade volumes, particularly for birds imported and exported for the pet trade **(Figure 2.8)**. Most recent introductions, reflected in the taxonomic composition, stem from unintentional escapes or releases from the caged bird trade. Commonly introduced species are parrots, estrildid finches, mynas, and starlings (E. E. Dyer, Cassey, *et al.*, 2017).

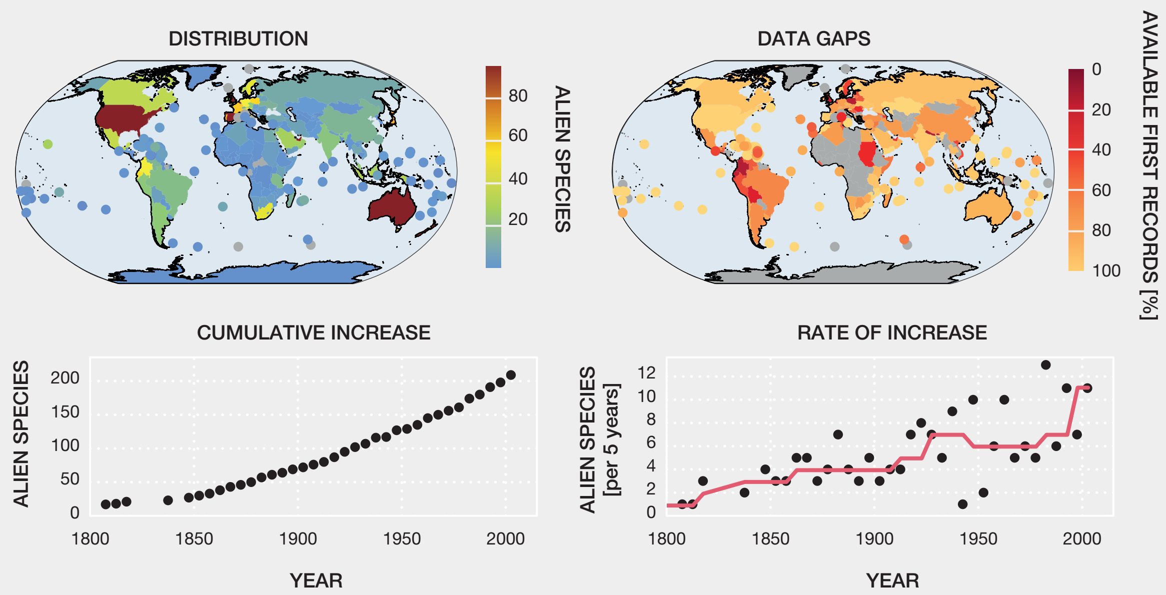

Figure 2 8 **Status, trends, and data gaps for established alien birds.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Status

Alien birds have been introduced to nearly all regions worldwide including many small islands (E. E. Dyer, Cassey, *et al.*, 2017; Evans, 2021). Global patterns of established alien bird species richness show relatively low numbers of alien birds in most parts of the world (though local numbers can be very high, e.g., more than 90 species in Hawaii), but very few regions without established alien bird species (Dawson *et al.*, 2017). E. E. Dyer, Cassey, *et al.* (2017) showed that colonization pressure (and to a smaller extent, distance from an historic port) was the key driver related to alien bird species richness, and that accounting for these factors, alien bird richness was also higher in areas with high native bird species richness. Thus, a range of environmental, life history, and anthropogenic factors determine areas with high alien bird richness.

A global analysis of historical data on bird introductions showed that environmental conditions at introduction sites are the primary determinants of successful establishment (Redding *et al.*, 2019). While climatic suitability is particularly important, the presence of other alien species can lead to an accumulation of alien species in "hotspots" potentially facilitating the establishment of additional species (termed "invasional meltdown"; **Glossary** and **Chapter 1**, **section 1.3.4**). Establishment of alien species is also more likely when extreme weather events do not occur in the decade following an introduction, suggesting that environmental stochasticity is important to the persistence of small populations (Redding *et al.*, 2019). Species-level traits, notably generalist species and founding population size, exert important secondary effects on success (Redding *et al.*, 2019). Generalist species are more likely to establish self-sustaining populations, as are species introduced in greater numbers (Cassey *et al.*, 2018; Redding *et al.*, 2019). Birds are strong dispersers, a trait that facilitates biological invasion success post-introduction (Cassey *et al.*, 2015). For example, of about 60 pairs of birds first introduced before the twentieth century to Central Park, New York City, *Sturnus vulgaris* (common starling) now numbers approximately 200 million individuals in the United States of America (Linz *et al.*, 2007).

Globally, particularly problematic invasive alien birds include *Anas platyrhynchos* (mallard), *Acridotheres tristis* (common myna), *Pycnonotus jocosus* (red-whiskered bulbul) (Martin-Albarracin *et al.*, 2015), *Nesoenas picturatus* (Madagascar turtle dove), *Pitangus sulphuratus* (great kiskadee), *Tyto novaehollandiae* (Australian masked owl), *Tyto alba* (barn owl), and *Bubo virginianus* (great horned owl) (Evans *et al.*, 2016). The 10 most widespread species are listed in **Table 2.6**.

Table 2 6 **Top 10 most widespread invasive alien bird species worldwide.**

The number of regions where the respective species has been recorded and classified as being invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien bird species, not impacts, which are covered in **Chapter 4** (see **section 2.1.4** for further details on data sources and processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Taxon	No. of regions	Taxon	No. of regions
Acridotheres tristis **(common myna)**	22	*Branta canadensis* (Canada goose)	9
Columba livia **(pigeons)**	20	*Alopochen aegyptiaca* (Egyptian goose)	8
Corvus splendens **(house crow)**	17	*Sturnus vulgaris* (common starling)	8
Passer domesticus **(house sparrow)**	14	*Myiopsitta monachus* (monk parakeet)	7
Psittacula krameri **(rose-ringed parakeet)**	13	*Phasianus colchicus* (common pheasant)	6

2.3.1.3 Fishes

Trends

Freshwater fish invasions are one of the best documented biological invasions among animal taxa with considerable information available on invasive alien fish traits, invaded regions, and invasion pathways (Bernery *et al.*, 2022). Information for marine fish invasions is much more fragmented (e.g., Arndt *et al.*, 2018; Vignon & Sasal, 2010). Globally, the number of invasive alien fishes accelerated in the twentieth century **(Figure 2.9)**. Although one might conclude that saturation has been reached based on the figure displaying the number of established alien species per five-year intervals, the lag between species introduction, reports of the introduction in the literature, and the cumulative numbers worldwide for this taxonomic group suggest that this is not the case (Seebens, Blackburn, *et al.*, 2017). Even though introductions of fish outside their natural ranges worldwide increased substantially at the onset of the industrial revolution, first records of alien fish introductions date back at least to the Roman Empire in Europe (first and second century; Balon, 1995).

Currently, the rate of newly established alien fish species is still very high, higher than for most other taxa (Seebens, Blackburn, *et al.*, 2017), partially explaining why fish are among the most widespread invasive alien taxonomic group (Gozlan, 2008). Globally, many fish species have been and are often still introduced intentionally, although unintentional introductions also occur. Due to widespread intentional introductions, alien freshwater fish species occur in all biogeographic regions (Leprieur *et al.*, 2008). Due to the compounding effects of increased global maritime transportation, canal construction, and climate change, the number of alien marine fish also rose dramatically in the twentieth and twenty-first centuries. These same three factors may also further promote biological invasions of fish in the future (Castellanos-Galindo *et al.*, 2020; Cohen, 2006; Muirhead *et al.*, 2015; Ruiz *et al.*, 2006).

Status

The most widespread alien fish species are listed in **Table 2.7** demonstrating the very high number of regions invaded by this group, second only to mammals in terms of distribution.

Dawson *et al.* (2017) showed that alien freshwater fish were distributed in six global biological invasion hotspots where established alien species constituted over 25 per cent of total species richness. When considering within country introductions, which are frequently not included in global analyses, the number of alien fishes increased for large countries such as Brazil, the People's Republic of China, and the United States (Vitule *et al.*, 2019). Pathways of fish biological invasions vary and include inter-oceanic canals, ballast water, intentional introductions for fishing or fisheries stocking, ornamental purposes, and escapes from aquaculture. For example, many alien populations of salmonids, tilapias, and carps originated from aquaculture escapes (Froese & Pauly, 2015). The Center for Food Safety reported about 26 million escaped fish worldwide between 1996 and 2012 (CFS, 2012). Similarly, D. Jackson *et al.* (2015) reported almost 9 million escapees in six European countries over a 3-year period. Estimates suggest that in Chile more than 1 million salmonids escape annually from the net pens of salmon farms (Sepúlveda *et al.*, 2013; Thorstad *et al.*, 2008). Marine waters are also inhabited by many alien fishes. The opening of the Suez Canal has enabled the migration of species from the Red Sea into the Mediterranean Sea (known as Lessepsian/Erythraean invasion), which has caused the influx of more

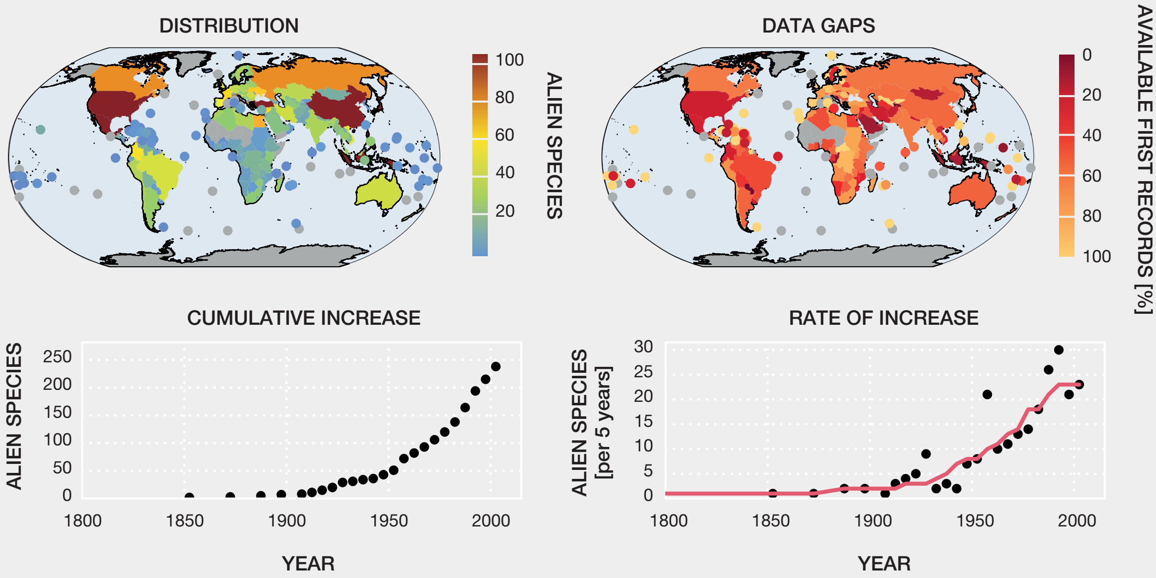

Figure 2 9 **Status, trends, and data gaps for established alien fishes.**

than 400 Indo-Pacific species into the Mediterranean Sea, including over 100 (118 by latest tally, unpublished) fish species (Bariche & Fricke, 2020; Çinar *et al.*, 2021; Galil *et al.*, 2021b), resulting in considerable changes to fish communities and fisheries, particularly in the Levant basin to date (Arndt *et al.*, 2018; Arndt & Schembri, 2015; Galil *et al.*, 2007). Both *Pterois volitans* (red lionfish) and *Pterois miles* (lionfish) have invaded large areas of the north-western Atlantic imposing large impacts on prey populations of native species and local fisheries (Côté *et al.*, 2013), and *Pterois miles* is now spreading within the Mediterranean Sea (Poursanidis *et al.*, 2020). Species of peacock basses

(genus *Cichla*), native to South America, have been introduced to tropical and sub-tropical regions worldwide for fisheries (Franco *et al.*, 2022).

2.3.1.4 Reptiles

Trends

The introduction of alien reptiles has a long history associated with the movement of humans and trade routes. For example, introduced species such as *Tarentola mauritanica* (common wall gecko) and *Vipera aspis* (asp viper) in the Mediterranean Basin can be traced back to the fourth century B.C. and the fifth century, respectively (Masseti & Zuffi, 2011; Mateo *et al.*, 2011; Pleguezuelos, 2002). Since 1800, the number of first records of alien reptiles globally has been rising steadily, accelerating since 1950 (Capinha *et al.*, 2017; Kraus, 2009). Similar trends have also been reported at local and regional scales (Krysko *et al.*, 2011, 2016; Mateo *et al.*, 2011; Perella & Behm, 2020; Powell *et al.*, 2011; Toomes *et al.*, 2020). Most alien reptile introductions through the end of the twentieth century were due to the unintentional transport of species as stowaways or contaminants (Kraus, 2009; Lever, 2003). This pathway remains important, but the pet trade has also emerged as a significant source of alien reptiles in recent decades (É. Fonseca *et al.*, 2019; Lockwood *et al.*, 2019; Perella & Behm, 2020; Stringham & Lockwood, 2018; Van Wilgen *et al.*, 2010).

Contemporary trends **(Figure 2.10)**, the expected increase in pet trade as a source of new species, and model-based projections of future distributions all indicate that both the number of alien reptiles and the number of invaded areas will continue to increase (Chapple *et al.*, 2016; da Rosa *et al.*, 2018; Filz *et al.*, 2018; Gippet & Bertelsmeier, 2021; X. Li *et al.*, 2016; X. Liu *et al.*, 2014; Seebens, Blackburn, *et al.*, 2017). Alien reptiles are fast becoming an important group of alien vertebrates alongside other taxa such as birds and mammals. In Australia, alien reptiles have been the dominant group of alien terrestrial vertebrates intercepted and detected at large since 1999 (Toomes *et al.*, 2020).

Status

Established populations of alien reptiles are found in all the IPBES regions except for the polar areas (Capinha *et al.*, 2017; Kraus, 2009). Islands and areas with relatively warm climates and high economic and human activity tend to host more alien reptiles than other places (Capinha *et al.*, 2017; É. Fonseca *et al.*, 2019; Moser *et al.*, 2018; Silva-Rocha *et al.*, 2019). Of the top five global hotspots for alien

A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Table 2 8 **Top 10 most widespread invasive alien reptile species worldwide.**

The table shows the number of regions where the species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table refers only to the distribution of invasive alien species, not their impacts which are covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species	No. of regions	Species	No. of regions
***Trachemys scripta elegans* (red-eared slider)**	15	*Chelydra serpentina* (common snapping turtle)	4
***Hemidactylus frenatus* (common house gecko)**	12	*Anolis cristatellus* (Puerto Rican crested anole)	4
***Hemidactylus mabouia* (tropical house gecko)**	12	*Anolis porcatus* (Cuban green anole)	3
***Iguana iguana* (iguana)**	8	*Hemidactylus turcicus* (Mediterranean house gecko)	3
***Anolis sagrei* (brown anole)**	5	*Pelodiscus sinensis* (Chinese soft-shelled turtle)	3

reptiles, the top three are in North America (Florida, Hawaii, and California), Europe (Balearic Islands, Spain), and Japan (Capinha *et al.*, 2017; Krysko *et al.*, 2011, 2016; Mateo *et al.*, 2011; Meshaka, 2011; Silva-Rocha *et al.*, 2015).

At least 198 reptile species belonging to three major reptile orders (Squamata, Crocodilia, and Testudines) have established alien populations worldwide (Capinha *et al.*, 2017). Of the top five most commonly established alien reptiles, four species (*Indotyphlops braminus* (brahminy blind snake), *Hemidactylus frenatus* (common house gecko), *Hemidactylus mabouia* (tropical house gecko), and *Hemidactylus turcicus* (Mediterranean house gecko)) have been transported unintentionally, and one (*Trachemys scripta* (pond slider)) is common in the pet trade (Capinha *et al.*, 2017; García-Díaz *et al.*, 2015; Kraus, 2009; Masin *et al.*, 2014). Some of the above species are among the 10 most widespread of all invasive alien reptiles worldwide **(Table 2.8)**. The establishment success and spread rates of alien reptiles are associated with high propagule pressure, the degree of climate matching between native and recipient regions, presence of congenerics, and high reproductive output (W. L. Allen *et al.*, 2017; Bomford *et al.*, 2009; X. Liu *et al.*, 2014; Mahoney *et al.*, 2014; Tingley *et al.*, 2016; Van Wilgen & Richardson, 2012). As examples, *Python bivittatus* (Burmese python) is spreading in the Florida Everglades, preying upon many species including the apex native predator *Alligator mississippiensis* (American alligator; Dorcas *et al.*, 2012). Invasive alien *Boiga irregularis* (brown tree snake) has reached iconic status as one of the most impactful invasive alien species worldwide. Fewer than 10 individuals were unintentionally introduced from the United States into the Pacific Island of Guam following World War II (Richmond *et al.*, 2015). This species has since colonized all habitats on Guam, from grasslands to forests, with peak densities as high as 10,000 individuals per km^2 (Rodda *et al.*, 1992). Several lesser known and potentially invasive alien reptiles are emerging including *Varanus niloticus* (Nile monitor) in Florida, *Lampropeltis getula* (common kingsnake) in the Canary Islands, *Boa constrictor* (boa constrictor) on Aruba, and several giant constrictor snakes in Puerto Rico (Reed & Kraus, 2010).

2.3.1.5 Amphibians

Trends

Alien amphibian introductions are not a new phenomenon. For instance, the introduction of *Bufotes balearicus* (Balearic green toad) to the Balearic Islands, Spain, is assumed to have occurred around the second century B.C. (Mateo *et al.*, 2011; Pleguezuelos, 2002). However, the accumulation of first records of alien amphibians shows a global rise since 1800 with a slightly more pronounced increase after the 1950s (Capinha *et al.*, 2017; Kraus, 2009, 2011). Similar patterns of relative increases in both the number of new alien species and the number of records of alien amphibians have been reported regionally and locally (Krysko *et al.*, 2011, 2016; Mateo *et al.*, 2011; Powell *et al.*, 2011; Toomes *et al.*, 2020). Nevertheless, the implementation of biosecurity and rapid response activities in countries such as New Zealand and Australia has likely prevented new introductions and establishment of alien amphibians (Chapple *et al.*, 2016; García-Díaz *et al.*, 2017; Toomes *et al.*, 2020). The United States appears to be an outlier in terms of new introductions; both the number of alien amphibian species

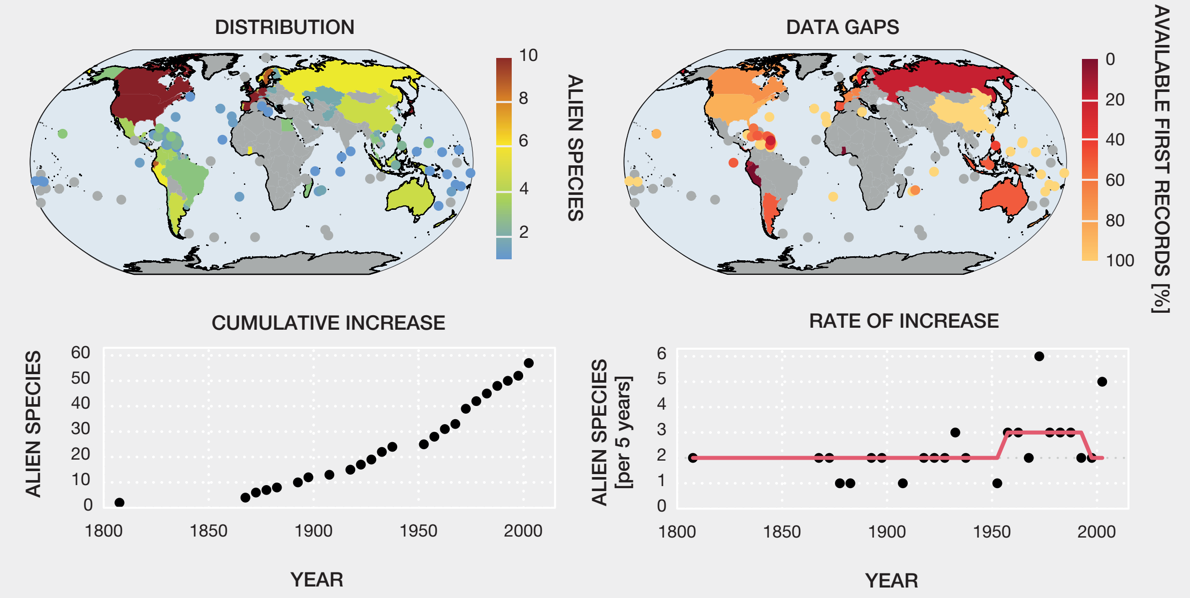

Figure 2 11 **Status, trends, and data gaps for established alien amphibians.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization purposes and do not indicate species numbers. The trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend line is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

reported annually and the number of records per year have remained relatively stable since around the mid-twentieth century (Mangiante *et al.*, 2018). It is important to note that in 2016 the United States Fish and Wildlife Service published an interim rule listing 201 salamander species as injurious wildlife under the Lacey Act to prevent the arrival of *Batrachochytrium salamandrivorans* (chytrid fungus) carried by alien species in the trade. Similarly, in 2017, Canada restricted salamander importation for the same reason (Yap *et al.*, 2017).

Status

Intentional and unintentional pathways are virtually equivalent contributors to the current distribution and status of alien amphibians worldwide, but their role varies by region and period (Kraus, 2009; Lever, 2003). For example, individuals of several toad species (family Bufonidae), such as *Rhinella marina* (cane toad) and *Sclerophrys gutturalis* (guttural toad), were deliberately released as biocontrol agents in the Indo-Pacific and Caribbean islands during the first half of the twentieth century (Kraus, 2009; Lever, 2003; Powell *et al.*, 2011; Shine, 2018; Telford *et al.*, 2019). More recently, *Duttaphrynus melanostictus* (Asian common toad) has been unintentionally transported to many areas in the Indo-Pacific region (Mo, 2017; Moore *et al.*, 2015; Tingley *et al.*, 2018; Vences *et al.*, 2017). The two most widespread alien amphibians in the world, *Lithobates catesbeianus* (American bullfrog) and *Rhinella marina*, have been introduced as a source of food and for biocontrol purposes, respectively (Capinha *et al.*, 2017; Kraus, 2009; X. Liu *et al.*, 2012, 2015; Shine, 2018). In Australia, almost twice the number of alien amphibians was found introduced through the pet trade compared to the stowaway pathway (71 and 38, respectively), yet the latter is a more important pathway when considering the total number of individuals moved rather than the number of species (García-Díaz & Cassey, 2014; Toomes *et al.*, 2020). Unintentional pathways are responsible for 12 out of 13 alien amphibians present in Guam (Christy, Clark, *et al.*, 2007). The pet trade is expected to remain a prominent source of new alien amphibian introductions in the near and medium-term (Lockwood *et al.*, 2019; Mohanty & Measey, 2019; Stringham & Lockwood, 2018).

The diversity of transport pathways responsible for the introduction of alien amphibians has resulted in established alien amphibian populations in all IPBES regions except for polar areas (**Figure 2.11**; Capinha *et al.*, 2017; Christy, Savidge, *et al.*, 2007; É. Fonseca *et al.*, 2019; García-Díaz

Table 2 9 **Top 10 most widespread invasive alien amphibian species worldwide.**

The table shows the number of regions where the respective species has been recorded and classified as being invasive based on GRIIS (Pagad *et al.*, 2022). Note that this table only refers to the distribution of invasive alien species rather than their impacts, which is covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species	No. of regions	Species	No. of regions
***Lithobates catesbeianus* (American bullfrog)**	24	*Pelophylax ridibundus* (Eurasian marsh frog)	3
***Rhinella marina* (cane toad)**	14	*Duttaphrynus melanostictus* (Asian common toad)	2
***Xenopus laevis* (African clawed frog)**	9	*Eleutherodactylus coqui* (Caribbean tree frog)	2
***Triturus carnifex* (Italian crested newt)**	3	*Eleutherodactylus planirostris* (greenhouse frog)	2
***Eleutherodactylus johnstonei* (whistling frog)**	3	*Andrias davidianus* (Chinese giant salamander)	1

& Cassey, 2014; Kraus, 2009; Measey *et al.*, 2017; Rago *et al.*, 2012; Tingley *et al.*, 2010). The United Kingdom, and California, Hawaii, and Puerto Rico (United States) are the top-four global hotspots of alien amphibians, each with more than five species established (Capinha *et al.*, 2017; Kraus, 2009; Powell *et al.*, 2011). Alien amphibian richness tends to be higher on islands and in places with high precipitation, high potential evapotranspiration, and high levels of economic activity (Capinha *et al.*, 2017; É. Fonseca *et al.*, 2019; Poessel *et al.*, 2012). High propagule pressure, the presence of congeneric species, life-history traits related to rapid growth and reproduction, and environmental similarity between the recipient and the native ranges are associated with the establishment success and invasion rates of alien amphibians (W. L. Allen *et al.*, 2017; Bomford *et al.*, 2009; Ferreira *et al.*, 2012; K. Li *et al.*, 2016; X. Liu *et al.*, 2014; Poessel *et al.*, 2012; Rago *et al.*, 2012; Tingley *et al.*, 2010, 2011; Van Wilgen & Richardson, 2012). It is interesting to note that many species native to Southern Africa have been introduced elsewhere, while few alien amphibians are reported for Southern Africa due to a very low trade involving these animals (Measey *et al.*, 2017).

The reported trajectories, combined with invasive alien amphibian niche shifts and the increase in pet trade, point to future increases in both the number of new alien amphibians and the number of regions occupied (Capinha *et al.*, 2017; Chapple *et al.*, 2016; da Rosa *et al.*, 2018; Mohanty *et al.*, 2021; Mohanty & Measey, 2019; Pili *et al.*, 2020; Toomes *et al.*, 2020). Additionally, invasion debts (i.e., the additional area an invasive alien species is likely occupy in the future; **Glossary**) mean that the accelerating trends in introductions described above could lead to established populations unless rapid response management actions are taken (Chapple *et al.*, 2016; M. J. Spear *et al.*, 2021).

Notorious invasive amphibians include *Rhinella marina* (cane toad), a large and toxic toad native to Mesoamerica and introduced worldwide into sugar cane producing regions to control beetles causing crop damage (Shanmuganathan *et al.*, 2010). *Xenopus laevis* (African clawed frog) is among the most commonly used laboratory animals (e.g., basic biology and formerly for pregnancy testing); many populations originating from laboratories have become invasive in regions with a Mediterranean climate. **Table 2.9** lists the 10 most widespread invasive alien amphibians and the number of regions each has invaded.

2.3.1.6 Insects

Trends

Since Insecta is the largest animal class it comes as no surprise that global numbers of alien insect species vastly exceed numbers for all other animal taxa combined by 1.7 times (Seebens, Blackburn, *et al.*, 2017). Yet, their biological invasions are still likely underreported as insects are less studied relative to other organisms such as vertebrates.

While there are a few rare documented cases of natural intercontinental insect spread (e.g., *via* wind) (Hoffmann & Courchamp, 2016), the long-distant spread of alien insects has risen steeply due to the facilitation by recent human activities (Gippet *et al.*, 2019; Meurisse *et al.*, 2019). Early exploration and colonial settlements facilitated the global range extension of several insect species, but higher rates of alien species establishment did not begin until approximately 1820 and lasted until 1914. This was followed by a second wave of accelerated establishment post-1960 (Bonnamour *et al.*, 2021). These periods coincided with the industrial revolution; increased global trade and travel facilitated accidental movement of insects with plants, plant products,

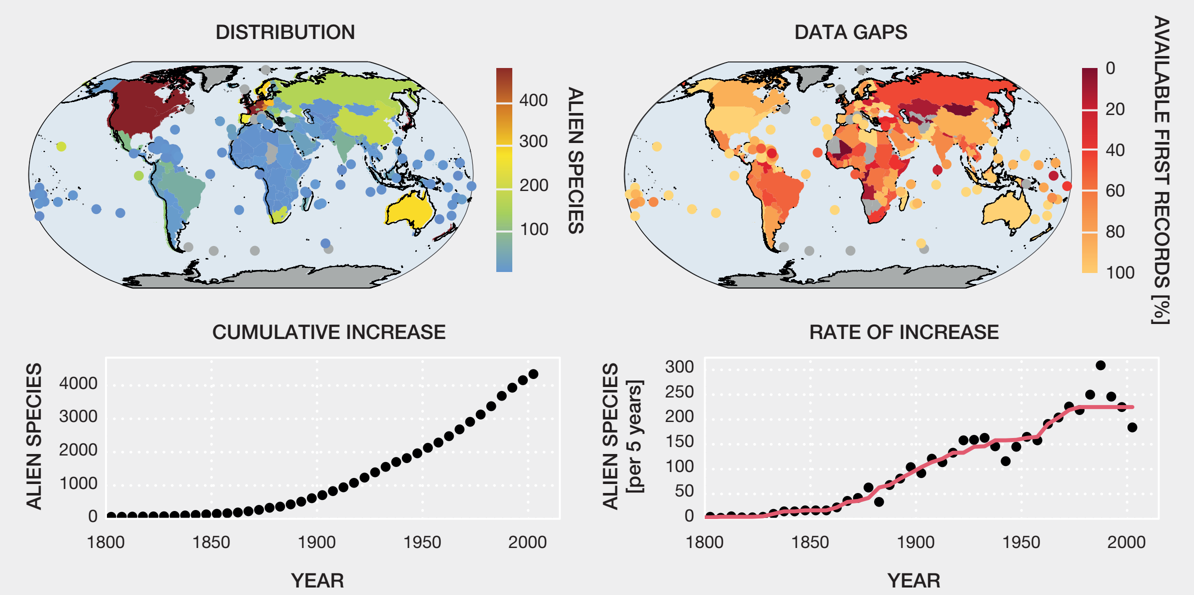

Figure 2 12 **Status, trends, and data gaps for established alien insects.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization purposes and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

general cargo, and baggage (Bertelsmeier *et al.*, 2017; Bonnamour *et al.*, 2021). Much of the global distribution of alien insects is driven by plant biological invasions (**Chapter 3**, **section 3.3.5.1**); many insects are dependent on individual plant species or genera, so establishment of alien plant species provides necessary resources that facilitate insect establishment (Liebhold *et al.*, 2018). Some evidence indicates that the recent implementation of biosecurity practices has reduced the proportion of imports contaminated with insects (Leung *et al.*, 2014; Liebhold & Griffin, 2016), but imports have also simultaneously and massively increased at the same time. While insects are such a large group that some specific variation may be masked, the resulting trend is a net increase. Indeed, as a group, they have even exponentially increased since the start of the nineteenth century, both in terms of cumulative numbers and number of established alien species per five-year intervals **(Figure 2.12)**, and still show no sign of saturation (Bonnamour *et al.*, 2021; Seebens, Blackburn, *et al.*, 2017). The continued increase of global trade and climate change will likely further accelerate for these easily transported and climate-sensitive organisms (Bellard, Thuiller, *et al.*, 2013). Additional factors could contribute to further spread (e.g., large infrastructure projects; Galil, Boero, Campbell, *et al.*, 2015; X. Liu *et al.*, 2019; Muirhead *et al.*, 2015) or establishment (e.g., industrial rearing of insects for food; Bang & Courchamp, 2021) of both existing and new invasive alien insects.

Status

Global estimates of the total number of alien insects are not available but likely exceed 10,000 species with more than 3,500 species established in North America alone (Yamanaka *et al.*, 2015). Actual numbers are likely much higher since many established species remain undiscovered or unreported. Global hotspots of insect biological invasions appear to be related to historical patterns of urbanization and industrialization (Branco *et al.*, 2019; Huang *et al.*, 2011) and the transport of species between Europe, East Asia, and North America reflecting trade and travel patterns (Kenis *et al.*, 2007; Mattson *et al.*, 2007). As global connectivity increases, regions such as Africa and South America are likely to be increasingly important as both recipients and donors of invasive alien insects.

Many invasive alien insects are highly problematic around the world, with coleopterans, lepidopterans, dipterans, and hymenopterans being among the most notorious (e.g., Kenis *et al.*, 2009). For example, alien ant species are often considered among the worst invasive alien species (Holway *et al.*, 2002; Pyšek *et al.*, 2008). Three ants are among the 10 most widespread invasive insects **(Table 2.10)** and five are among the "100 of the world's worst invasive alien species", the only family to have so many species listed. Ants are easily transported by humans because of their generalist nesting habits and their small size

(Wetterer *et al.*, 2009). When intercepted at ports of entry, alien ant species are frequently detected on commercial ornamental plants (Lester, 2005; Suarez *et al.*, 2005; Ward *et al.*, 2006). Globally, more than 200 species have established populations outside their native distributions (Wetterer *et al.*, 2009), but over 600 species have likely been introduced outside their native ranges (Miravete *et al.*, 2014). This makes ants the most represented insect family and particularly notorious ant species include *Linepithema humile* (Argentine ant), *Anoplolepis gracilipes* (yellow crazy ant), *Wasmannia auropunctata* (little fire ant), *Solenopsis invicta* (red imported fire ant), and *Pheidole megacephala* (big-headed ant). In addition, a recent study predicted that 13 other species with similar ecological traits could also become invasive should they be introduced outside their native ranges (Fournier *et al.*, 2019). To date, few studies are available on the biology and ecology of these invasive alien ants, except for *Linepithema humile* and *Solenopsis invicta* (Bertelsmeier *et al.*, 2016; Pyšek *et al.*, 2008). These two ant species from South America have invaded many countries by separate multiple introductions from their native ranges and subsequent secondary spread from invaded ranges (Ascunce *et al.*, 2011; Giraud *et al.*, 2002). Secondary introduction seems to be common for ants: 76 per cent of interception events of alien ants at the border of the United States and 88 per cent of those intercepted at the New Zealand border did not come from their country of origin but from previously invaded countries (Bertelsmeier *et al.*, 2018).

Many alien insects are invasive in most parts of the world making it difficult to define the most important while remaining concise, but the 10 most widespread species provide good examples **(Table 2.10)**. *Ceratitis capitata* (Mediterranean fruit fly) and *Bemisia tabaci* (tobacco whitefly) affect agriculture in numerous countries, while insect-borne diseases are spread by the invasions of several mosquito species, such as *Aedes albopictus* (Asian tiger mosquito), *Aedes aegypti* (yellow fever mosquito), and *Anopheles quadrimaculatus* (common malaria mosquito). *Harmonia axyridis* (harlequin ladybird) was introduced to North America and Europe to control aphids, subsequently leading to the decline of native ladybirds through predation (Roy *et al.*, 2012). *Icerya purchasi* (cottony cushion scale) is found in most regions, where it feeds on more than 80 families of woody plants, particularly citrus crops. *Brontispa longissima* (coconut hispine beetle) feeds on young leaves of coconut palms throughout the Pacific region. *Bemisia tabaci* thrives in tropical and subtropical (and to a lesser degree temperate) regions, where it feeds on many plants but also facilitates the spread of plant viruses. Although not among the 10 most widespread, some other insects are among the best known of all invasive alien species. For example, North American forests have been deeply damaged by the invasions of *Agrilus planipennis* (emerald ash borer; Herms & McCullough, 2014; Poland & McCullough, 2006; Valenta *et al.*, 2017), *Anoplophora glabripennis* (Asian longhorned beetle; Dodds & Orwig, 2011; Kappel *et al.*, 2017; Nowak *et al.*, 2001), and *Lymantria dispar* (gypsy moth; C. B. Davidson *et al.*, 1999; Tobin *et al.*, 2012). *Drosophila suzukii* (spotted wing drosophila), a vinegar fly of Asian origin, has emerged as a devastating pest of small and stone fruits throughout North America, Europe and South America (L. A. dos Santos *et al.*, 2017). *Coptotermes formosanus* (Formosan subterranean termite) affects infrastructure and *Trogoderma granarium* (khapra beetle) destroys grain and seed reserves throughout the world. It is noteworthy that bees (Apis (honey bee), *Bombus* (bumble bee) or *Megachile* (leaf-cutter bees), among others; e.g., Bartomeus *et al.*, 2013; Goulson, 2003; Morales *et al.*, 2017) and wasps (*Vespa, Vespula*, gall and parasitoid wasps, among others; e.g.,

Table 2 10 **Top 10 most widespread invasive alien insect species worldwide.**

The number of regions where the species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table refers only to the distribution of invasive alien species, not their impacts which are covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). Species	No. of regions	Species	No. of regions
***Icerya purchasi* (cottony cushion scale)**	29	*Harmonia axyridis* (harlequin ladybird)	14
Tapinoma melanocephalum (ghost ant)	28	*Ceratitis capitata* (Mediterranean fruit fly)	14
Pheidole megacephala (big-headed ant)	24	*Brontispa longissima* (coconut hispine beetle)	13
Aedes albopictus (Asian tiger mosquito)	24	*Bemisia tabaci* (tobacco whitefly)	13
Solenopsis geminata (tropical fire ant)	19	*Cameraria ohridella* (horsechestnut leafminer)	13

Beggs *et al.*, 2011; Lester & Beggs, 2019) excepting *Apis mellifera scutellata* (Africanized bee), hybrid of several European honey bee subspecies and the East African honey bee, are the source of considerable revenue and rarely viewed as invasive despite outcompeting native pollinators (IPBES, 2016; Moritz *et al.*, 2005).

2.3.1.7 Arachnids

Trends

The number of recorded alien spiders has been increasing continuously (**Figure 2.13**; Nentwig, 2015; Seebens, Blackburn, *et al.*, 2017). An accelerated increase is observed after 1950 similar to those in many other invertebrate groups and likely as a consequence of increasing global trade and transport. In addition to the total number of alien spiders, the rate of annual new records has increased until the present reaching about 30 new records per five years (i.e., 6 new records annually; **Figure 2.13**).

Status

Worldwide, 285 alien spider species (0.57 per cent of all described spider species) have been recorded outside of their native range. Most alien spiders are known from only a few records, from a few regions, but some species are so widespread that they are alien to several continents **(Table 2.11)**. The 28 most widespread species (10 per cent of all alien spiders) are known from more than 30 invaded regions (often from all or most continents) and represent 50 per cent of all records. Major trade routes, at least past routes, connect areas of origin to invaded regions: 29 per cent of all globally spread spider species are native to Europe (while Europe is home to only 10 per cent of all spider species), 25 per cent from the Americas, 20 per cent from Asia, 17 per cent from Africa, 10 per cent from Australasia and the Pacific. Most spiders alien to Europe were unintentionally introduced either as stowaways, in or on transport vectors (i.e., the physical means or agent that transports a species; **Glossary**), or as contaminants (Nentwig, 2015). Horticulture is a major source of introduced spiders, followed by fruit and vegetable shipments, containers, and packaging materials. Imported classic cars and used sport cars often contained *Latrodectus mactans* (black widow spider) and cocoons in high numbers (Van Keer, 2010). For many areas in the world, no reliable species inventories are available. The top 10 most widespread invasive alien arachnids as recorded by GRIIS are shown in **Table 2.12**.

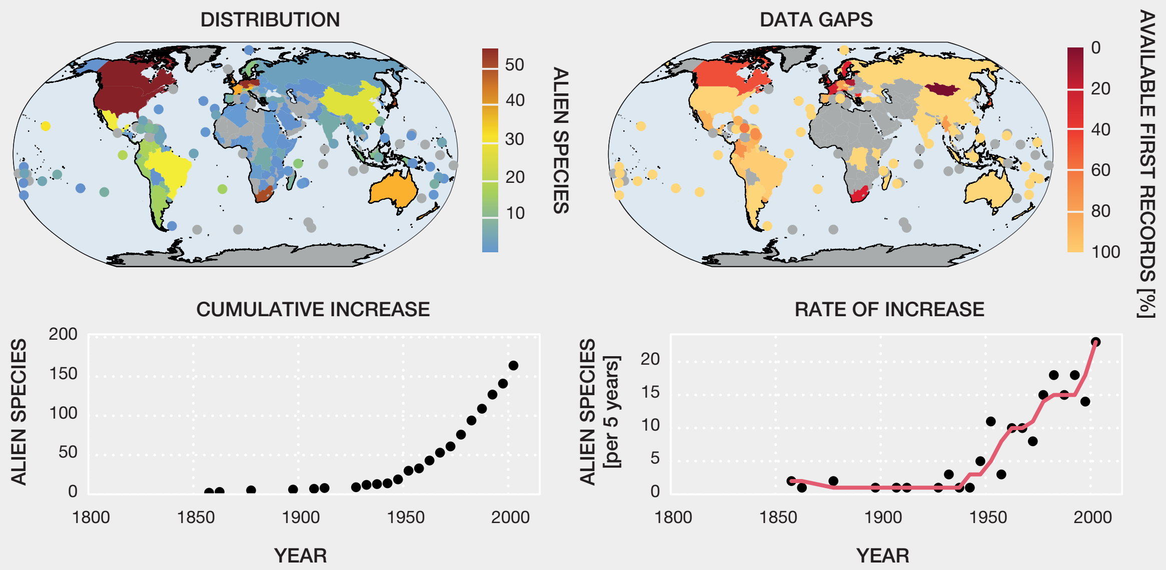

Figure 2 13 **Status, trends, and data gaps for established alien arachnids.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Table 2 11 **The most common established alien spider families and species.**

Based on 12 arachnid families with the most widely distributed established alien species, this family-wise presentation is of those species known to occur in more than 30 regions outside their native ranges. Families are ordered alphabetically, species according to frequency in the invaded area. Data from the World Spider Catalog (2017).

Family	No. of established alien species	Most widespread species	Alien range
Agelenidae **(funnel web spiders)**	8	*Tegenaria domestica* *Eratigena agrestis*	Europe Europe
Araneidae **(orb weavers)**	23	*Neoscona nautica* *Argiope trifasciata*	Pacific North America
Cheiracanthiidae **(yellow sac spiders)**	3	*Cheiracanthium mildei*	Europe
Dysderidae **(woodlouse hunters)**	2	*Dysdera crocata*	Pacific Europe North America
Oonopidae **(goblin spiders)**	19	*Triaeris stenaspis* *Brignolia parumpunctata* *Ischnothyreus peltifer* *Opopaea concolor*	Africa Tropical Asia Tropical Asia Africa
Pholcidae **(daddy-long-legs)**	15	*Pholcus phalangioides* *Micropholcus fauroti* *Artema atlanta* *Smeringopus pallidus* *Spermophora senoculata*	Temperate Asia Temperate Asia Africa Africa Temperate Asia
Salticidae **(jumping spiders)**	34	*Plexippus paykulli* *Hasarius adansoni* *Menemerus bivittatus*	Africa Africa Africa
Scytodidae **(spitting spiders)**	8	*Scytodes thoracica*	Europe
Oecobiidae **(disk web spiders)**	9	*Oecobius navus*	Africa
Sicariidae **(six-eyed spiders)**	1	*Loxosceles rufescens*	North America Europe Australia Asia
Sparassidae **(giant crab spiders)**	3	*Heteropoda venatoria*	Tropical Asia
Theridiidae **(cobweb or combfooted spiders)**	47	*Parasteatoda tepidariorum* *Steatoda grossa* *Steatoda triangulosa* *Latrodectus geometricus*	South America Europe Europe Africa

Table 2 12 **Top 10 most widespread invasive alien arachnids worldwide.**

The number of regions where the species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien species rather than their impacts which is covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. Mermessus trilobatus **(trilobate dwarf weaver)**	2	*Aculops lycopersici* (tomato russet mite)	1

2.3.1.8 Molluscs

Trends

Overall, molluscs have mostly been introduced unintentionally with numbers of introductions starting to increase at the end of 1800s **(Figure 2.14)**. Similar to crustaceans, marine species introductions started when transoceanic voyages began around 1500 but were rarely documented (Carlton, 1999b). During the second half of the twentieth century, increases in shipping, aquaculture, and the aquarium trade facilitated the introductions of both marine and freshwater molluscs (Carlton, 1999a; Cianfanelli *et al.*, 2016; Cowie, 2005; Darrigran *et al.*, 2020; De Silva, 2012; X. Guo, 2009; Katsanevakis *et al.*, 2013; Ojaveer *et al.*, 2018; R. Sousa *et al.*, 2014). A similar pattern is observed for terrestrial molluscs; they are almost exclusively moved as contaminants through agriculture and horticulture and their introductions began in ancient times (Herbert, 2010). Since 1600, European colonists have introduced many species to new areas (Herbert, 2010). With the increasing trade, introductions rates grew from the 1950s onward (Cowie, 2005; Herbert, 2010; Hutchinson *et al.*, 2014).

Status

Established alien molluscs have been reported from all over the world (Capinha *et al.*, 2015; R. Sousa *et al.*, 2009). However, despite their status as widespread alien species and extensive work by malacologists in terrestrial and marine ecosystems **(Figure 2.14)** their distribution and spread has received comparatively little attention except for species such as *Dreissena* spp. (zebra and quagga mussels), *Corbicula fluminea* (Asian clam), and *Magallana gigas* (Pacific oyster) (Dölle & Kurzmann, 2020; Orlova *et al.*, 2005; Ruesink *et al.*, 2005; A. Sousa *et al.*, 2009; Strayer *et al.*, 2019). For bivalves, R. Sousa *et al.* (2009) listed examples of 35 established alien species in marine and freshwater systems of all continents, 24 of which have sufficient information about distribution or effects reported. However, the number of established alien bivalves is likely much higher than reported. Recently, *Mytilus* cf. *platensis* (mussel) was discovered in Antarctic waters (Cárdenas *et al.*, 2020), further demonstrating that molluscs are transported in intercontinental transfers. Invasive bivalves often occur at very high densities becoming a major proportion of the benthic fauna (e.g., *Arcuatula senhousia* (Asian date mussel; Crooks & Khim, 1999), *Mytilus galloprovincialis* (Mediterranean mussel; Branch & Steffani,

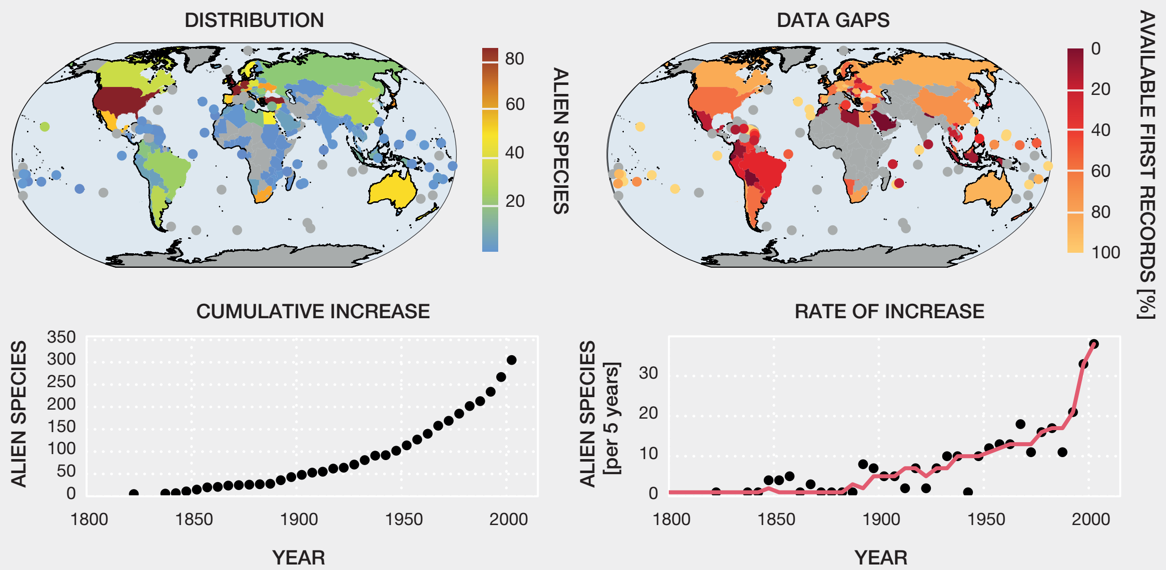

Figure 2 14 **Status, trends, and data gaps for established alien molluscs.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. The trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

2004), *Limnoperna fortunei* (golden mussel; Boltovskoy *et al.*, 2006), *Perna viridis* (Asian green mussel; Rajagopal *et al.*, 2006), and *Ensis leei* (American jack-knife clam; Raybaud *et al.*, 2015)).

Marine bivalves (oysters, mussels, clams) have long been widely introduced for cultivation and harvesting in many regions of the world. Some were introduced to replace depleted or diseased stocks of commercially valuable indigenous species, for example, *Magallana gigas* (Pacific oyster) and *Ruditapes philippinarum* (Japanese carpet shell) in Europe to diversify local marine farming, and *Mytilus edulis* (common blue mussel) in Canada and China (Tang *et al.*, 2002). These alien species cause negative impacts in their introduced habitats by forming reefs on hard and soft bottoms and effecting large structural changes in littoral communities (**Chapter 4**, **section 4.3.2.3**).

Though of small size, some invasive alien molluscs attain high densities and cause remarkable impacts. *Littorina littorea* (common periwinkle) occurs at densities of up to 600 individuals per m^2 (Carlson *et al.*, 2006), reduces algal canopies, and controls rocky intertidal community structure and species diversity (Bertness, 1984; Lubchenco, 1978; Petraitis, 1987; Yamada & Mansour, 1987). *Crepidula fornicata* (American slipper limpet) was introduced from the North American Atlantic coast to the Pacific coast and to Europe with *Crassostrea virginica* (eastern oyster). It forms dense conglomerations of live specimens, shells and pseudofaeces, transforming the physical and chemical composition of the sediment, which adversely affects the endobenthic community and reduces the area of flatfish habitat. When it fouls *Mytilus edulis* (common blue mussel), *Crepidula fornicata* increases mussel mortality by four to eight times, but also reduces mussel predation by *Asterias rubens* (common starfish; Blanchard, 2009; Kostecki *et al.*, 2011; Thieltges, 2005a, 2005b). The easternmost Mediterranean is the region with the highest reported number of marine alien molluscs (over 160 species along 180 kms of Israeli and Palestine coast alone), most introduced through the Suez Canal (Galil *et al.*, 2021b).

Alien snails and slugs have become established in most parts of the world, including on many islands. For example, 38 alien terrestrial snails and slugs are established in Hawaii (Cowie *et al.*, 2008). Cowie *et al.* (2009) listed 46 species spanning 18 families for priority quarantine from the United States. *Lissachatina fulica* (giant African land snail) is one of the largest land snails in the world, reaching up to 19 cm in length, and is recognized as one of the world's most damaging invasive alien species because of its omnivorous nature and because it is a vector of at least two human diseases (W. M. Meyer *et al.*, 2008; **Chapter 4**, **section 4.5.1.3**). *Euglandina rosea* (rosy predator snail) was originally introduced to control *Lissachatina fulica*. Not only did it fail to control it, but *Euglandina rosea* caused the extinction of many endemic snails on the islands of Hawaii, Tahiti, Moorea, and other Pacific islands (Davis-Berg, 2012; **Chapter 4**, **section 4.3.1**). Other widespread alien species include *Pomacea canaliculata* (golden apple snail; Q.-Q. Yang *et al.*, 2018), *Arion ater* (european black slug; Zemanova *et al.*, 2018), *Cepaea nemoralis* (grove snail), *Cornu aspersum* (common garden snail), *Limax maximus* (leopard slug), *Cernuella virgata* (vineyard snail), *Theba pisana* (white garden snail) and *Arion vulgaris* (Spanish slug). **Table 2.13** lists the 10 most widespread alien mollusc species invasive in most regions.

Table 2 13 **Top 10 most widespread invasive alien mollusc species worldwide.**

The number of regions where the species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien mollusc species rather than their impacts which are covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species	No. of regions	Species	No. of regions
***Lissachatina fulica* (giant African land snail)**	31	*Pomacea canaliculata* (golden apple snail)	13

***Dreissena polymorpha* (zebra mussel)**	20	*Melanoides tuberculata* (red-rimmed melania)	10
***Magallana gigas* (Pacific oyster)**	15	*Corbicula fluminalis* (Asian clam)	9
***Potamopyrgus antipodarum* (New Zealand mudsnail)**	15	*Dreissena rostriformis bugensis* (quagga mussel)	9

2.3.1.9 Crustaceans

Trends

Unintentional introductions of marine crustaceans probably began in the 1500s when transoceanic voyages were first undertaken (Carlton, 2011), but no data are available. The first records of alien crustaceans were reported between the 1800s and the beginning of 1900s (Carlton, 2011; **Figure 2.15**). Like those of other alien marine species, crustacean introductions have risen in recent decades due to increased shipping, fisheries, aquaculture, and aquarium trade (Fernández de Alaiza García Madrigal *et al.*, 2018; Hänfling *et al.*, 2011; Katsanevakis *et al.*, 2013; Ojaveer *et al.*, 2018). For example, the Suez Canal allowed the entry of alien crustaceans into the Mediterranean Sea for the entire twentieth century with an increase from 1990 facilitated by climate warming (Galil, 2011). The unintentional introduction of freshwater species started with global shipping and the construction of artificial canals (e.g., in Central and Western Europe), increasing after the 1950s. Overall, crustaceans were one of the most frequently introduced groups in recent decades in the Baltic Sea, California Bay, and the Laurentian Great Lakes (Hänfling *et al.*, 2011). On the other hand, crayfish have been intentionally introduced as a food source since the end of 1800s (Hänfling *et al.*, 2011), but global increases of crayfish production starting in the 1970s boosted introductions (Haubrock *et al.*, 2021; Lodge *et al.*, 2012).

Status

Crustaceans are frequently found among lists of marine and freshwater alien species (Galil *et al.*, 2011; Hänfling *et al.*, 2011; Simões *et al.*, 2021). As an example, the Mediterranean, North East Atlantic, Black and Baltic Seas host some of the highest species numbers, with 1,411 established alien species reported (Tsiamis *et al.*, 2018), a noteworthy proportion of which includes crustaceans (Tsiamis *et al.*, 2020). Owing to human activities, many marine crustacean species have achieved global distributions (e.g., barnacles *Balanus glandula* (Kerckhof *et al.*, 2018), *Amphibalanus improvisus* (bay barnacle), and *Amphibalanus eburneus* (ivory barnacle); isopods *Synidotea laevidorsalis* (J. W. Chapman & Carlton, 1991) and *Ianiropsis serricaudis*; amphipod *Caprella mutica* (Japanese skeleton shrimp); shrimp *Palaemon macrodactylus* (oriental shrimp); additional shrimp and many crab species; many copepods and mysids; and several more).

Hemigrapsus sanguineus (Asian shore crab) is now the dominant crab in rocky intertidal habitats along much of the north-eastern coast of the United States and the

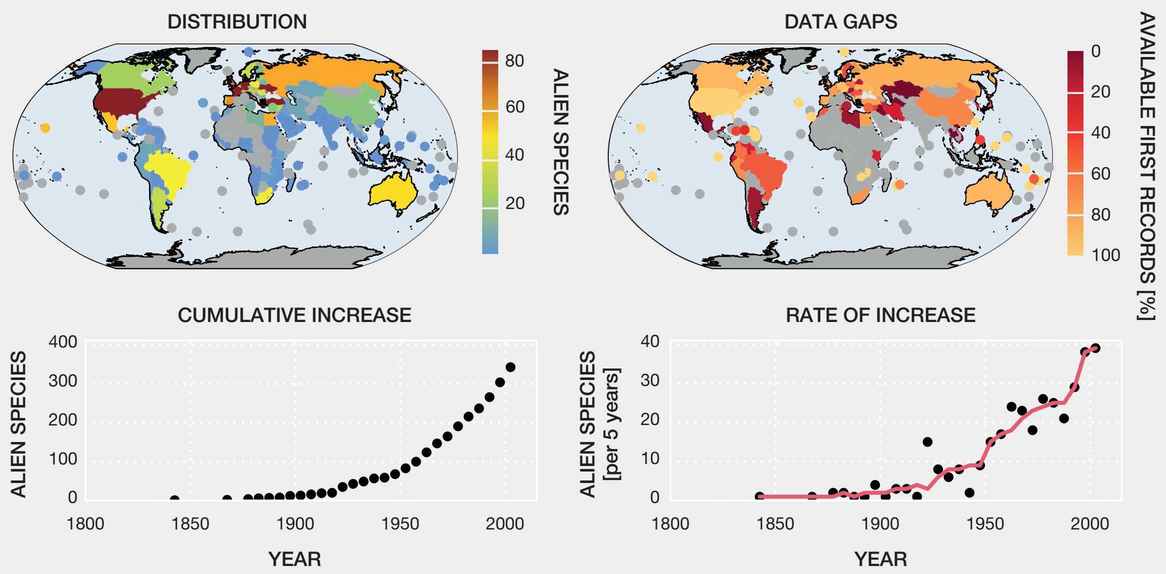

Figure 2 15 **Status, trends, and data gaps for established alien crustaceans.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. The trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend line is calculated as running median (**section 2.1.4** for further details about data sources and data processing). European Atlantic coast where it has been introduced and displaces resident crab species (Blakeslee *et al.*, 2017; Epifanio, 2013). The literature on the Asian shore crab is limited in comparison to that of better-known global marine invasive established crabs like *Carcinus maenas* (European shore crab), *Carcinus aestuarii* (Mediterranean green crab) (Cosham *et al.*, 2016; Leignel *et al.*, 2014), and *Eriocheir sinensis* (Chinese mitten crab; Dittel & Epifanio, 2009). **Table 2.14** lists the 10 most widespread invasive alien crustacean species and the number of regions each has invaded.

Crustaceans also comprise major proportions of alien animals established in large freshwater ecosystems; their rate of discovery, along with that of other freshwater invertebrates, is increasing in these habitats (Ricciardi, 2015). According to Gherardi (2010), 28 crayfish species have been introduced into a new biogeographic region and/or translocated within their native biogeographic region. In Europe, most crayfish species are alien (at least 10 alien, five native), with significantly higher abundances and severe impacts caused by alien crayfish, especially the transmission of crayfish plague, a disease lethal to native species (Kouba *et al.*, 2014; **Chapter 4**, **section 4.3.2.2**). There is increasing recognition of their severe impacts, notably the displacement of native species (Gherardi, Aquiloni, *et al.*, 2011; South *et al.*, 2020). In Africa, five out of nine introduced crayfish species established populations in at least six countries, causing substantial ecological and economic damage (Madzivanzira *et al.*, 2021). Genetic divergence between European and North American lineages of freshwater cladocerans suggests that the current rate of invasion by European species in North America is ca. 50,000 times higher than prehistoric levels (Hebert & Cristescu, 2002). Invasions of the Laurentian Great Lakes **(Box 2.11)** by two cladocerans, *Cercopagis pengoi* (fishhook waterflea), and *Bythotrephes longimanus* (spiny waterflea), have caused concern for freshwater biodiversity and regional fisheries (Pichlová-Ptáčníková & Vanderploeg, 2009). *Dikerogammarus villosus* (killer shrimp) is a physiologically tolerant and adaptable amphipod of Ponto-Caspian origin that has colonized most of the major European inland waterways in only two decades, replacing many local amphipod species. Its continued range expansion, as well as its potential to reach freshwaters of other continents (particularly North America and its Great Lakes), is a major conservation concern (Rewicz *et al.*, 2014). *Hemimysis anomala* (bloody-red shrimp) was one of several Ponto-Caspian species to invade the Great Lakes in recent decades through transoceanic shipping (Audzijonyte *et al.*, 2007).

2.3.1.10 Other invertebrates

Other invertebrates cover those invertebrate species that are not addressed in previous sections and include the phyla Acanthocephala, Annelida, Brachiopoda, Bryozoa, Chaetognatha, Cnidaria, Ctenophora, Echinodermata, Kamptozoa, Nematoda, Nemertea, Onychophora, Phoronida, Platyhelminthes, Porifera, Rotifera, Sipuncula and Xenacoelomorpha.

Trends

There is a paucity of data on molluscs, and crustaceans, but there is nothing to suggest that the trends for these animals differ from the better documented groups. In fact, data on the trends in both cumulative numbers and number of established alien species per five-year intervals show that animals other than the aforementioned vertebrates and invertebrates follow the same dramatic global increases since ca. 1850 **(Figure 2.16)**. For example, jellyfish populations appear to be increasing post-1950 in coastal ecosystems worldwide, mostly due to increasing populations of invasive alien species (Brotz *et al.*, 2012; importantly, note that Brotz *et al.* (2012) defined "jellyfish" as including three separate phyla of marine invertebrates – Cnidaria, Ctenophora, and Chordata). The increase has accelerated in recent decades and climate change is likely playing a role in facilitating increased survival and growth, and access to previously unfavourable waters. The depletion of predators and food competitors due to overfishing was also important (A. J. Richardson *et al.*, 2009). Notably, several comb jelly species (ctenophores) often survive ballast-water exchange, and their populations have been found to expand in over-fished areas that provide favorable conditions (Daskalov *et al.*, 2007). The invasion of the Black, Caspian, Baltic, and North Seas by the comb jelly *Mnemiopsis leidyi* (sea walnut) in the recent decades is a good illustration (Boersma *et al.*, 2007; Daskalov & Mamedov, 2007; Haslob *et al.*, 2007; Zaitsev, 1992). The increase of invasive alien jellyfish and comb jellies is predicted to continue accelerating (A. J. Richardson *et al.*, 2009). Other marine species, such as *Anemonia alicemartinae* (sea anemone), are considered invasive along the coast of Chile, and historical records show a rapid expansion towards the south, extending its distribution (Castilla *et al.*, 2005; Castilla & Neill, 2009; Häussermann & Försterra, 2001).

Status

Comprehensive studies for invertebrates, other than those reported above, are often lacking and detailed knowledge is usually available for only a few species. *Asterias amurensis* (northern Pacific seastar) is considered one of the most serious marine pests in Australia (MPSC, 2018). The same concern arises for *Centrostephanus rodgersii* (long-spined sea urchin). Its invasion from mainland Australia to Tasmania has already caused ecosystem shifts from kelp-dominated to a macroalgal-free habitat resulting in localized losses of about 150 taxa that associate with seaweed beds (Ling *et al.*, 2009). Among ctenophores, a prominent representative is the previously mentioned *Mnemiopsis leidyi* (sea walnut), first introduced from the North American east coast to the Black Sea in ship ballast water. The species subsequently spread throughout the Ponto-Caspian basin and the Mediterranean Sea, ultimately spreading across most

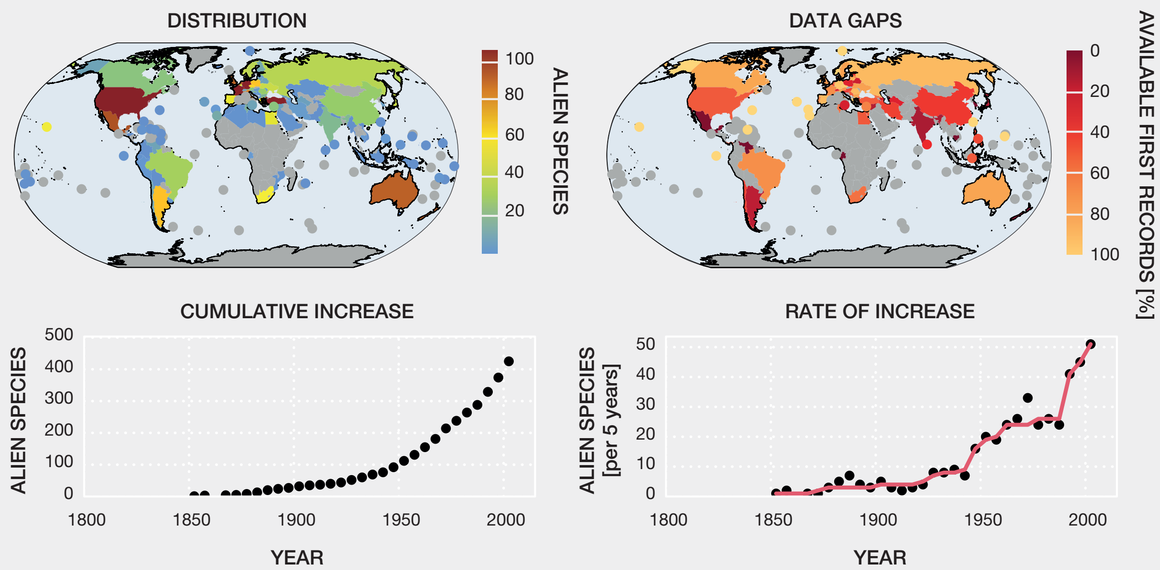

Figure 2 16 **Status, trends and data gaps for other established alien invertebrates.**

Other established alien invertebrates refer to animal groups, which are not covered in the previous sections. The names of the taxonomic groups are listed at the beginning of **section 2.3.1.10**. The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

European seas due to a climate-driven range expansion rather than a human-mediated introduction (Shiganova *et al.*, 2019).

Many earthworm species can be regarded as "ecosystem engineers", that is they play a pronounced role in the creation, modification and maintenance of the upper horizons of the soil habit (Eijsackers, 2011; C. G. Jones *et al.*, 1994; Ponge, 2021). The potential for modifying the soil environment means that earthworms can have a disproportionate impact on the communities that they invade (Hendrix *et al.*, 2008). This is especially true in circumstances where earthworms invade soils that previously had an absent or impoverished earthworm fauna (Frelich *et al.*, 2019). Globally, more than 100 alien earthworm species are documented (Hendrix, 2006) but have mostly been neglected until very recently. For example, earthworm invasions in North America date back to the first European settlers, but because they live underground, they have remained mostly unnoticed (Migge-Kleian *et al.*, 2006). Ongoing invasions of European earthworms into the Upper Midwest of the United States are relatively well documented (Hale *et al.*, 2005) compared to the invasion in the Northeast (Stoscheck *et al.*, 2012; Suárez *et al.*, 2006). Alien earthworms can often be found spreading into habitats where few or no native earthworms exist, such as in North America which has been depauperate in native earthworms since the last glaciation (McCay & Scull, 2019). Similar patterns are believed to exist in the taiga region in Russia and the coniferous forests of Scandinavia (Hendrix, 2006). The earthworm fauna of the North American northeast now includes a few native species (Csuzdi *et al.*, 2017), many alien species from Europe, and a rapidly rising number of species from Asia (Addison, 2009; McCay & Scull, 2019). The tropical earthworm *Pontoscolex corethrurus*, originally native to Guyana, was introduced to tropical and sub-tropical regions worldwide (S. Taheri *et al.*, 2018). *Platydemus manokwari* (New Guinea flatworm) was both unintentionally and deliberately introduced into the soils of many countries and islands, where it leads gregarious attacks on large earthworms and land snails (Sugiura, 2010; Sugiura & Yamaura, 2009). Another flatworm, *Obama nungara* from South America, has been introduced to France (Justine *et al.*, 2020). *Arthurdendyus triangulatus* (New Zealand flatworm) can now be found in Great Britain where it causes declines in native earthworm populations (Murchie & Gordon, 2013).

There is a growing recognition of the influence of alien earthworms in tropical environments as well (Marichal *et al.*, 2012; Ortíz-Ceballos *et al.*, 2019; Potapov *et al.*, 2021; S. Taheri *et al.*, 2018). Earthworm communities in tropical agricultural environments often consist of both native and invasive alien species; however, it is not always clear what role these species are playing, though, without doubt, deforestation, the spread of plantations, landscaping and an expansion of human activity may serve as drivers that facilitate further invasion (Potapov *et al.*, 2021).

Along the south-eastern Pacific coast, there are records for six introduced species of polychaete worms from the families Spionidae and Sabellidae (Fuentes *et al.*, 2020; Moreno *et al.*, 2006). The species *Polydora rickettsi*, *Polydora hoplura* and *Terebrasabella heterouncinata* were accidentally introduced. There is no information regarding the type of introduction for *Boccardia tricuspa*, *Polydora bioccipitalis* and *Dipolydora giardi* (Fuentes *et al.*, 2020). All of them compete with the native species. These introductions also cause negative economic impacts in the aquaculture industry by boring and infesting the shells of cultured molluscs (Fuentes *et al.*, 2020; Moreno *et al.*, 2006; **Chapter 4**, **Box 4.13**).

2.3.1.11 Data and knowledge gaps

Global analyses on invasion trends and status for animals are limited to some taxonomic groups, such as mammals, birds, reptiles, amphibians, fish, land snails, spiders, crustaceans and ants. Many case studies exist on species of other groups, but they provide substantially less information on general patterns.

Data and knowledge gaps are pervasive across all taxonomic groups and geographical levels (**Figure 2.6**; Pyšek *et al.*, 2008; Troudet *et al.*, 2017). Charismatic species such as birds and mammals tend to be more studied while other taxa, such as herpetofauna and invertebrates, have weaker sampling efforts and hence more data gaps (Pyšek *et al.*, 2008; Rocha-Ortega *et al.*, 2021; Troudet *et al.*, 2017). However, even the most intensively studied taxa may not be fully documented at the global scale resulting in geographic biases mainly driven by economic development (Dawson *et al.*, 2017) and linguistic barriers (Angulo *et al.*, 2021; Nuñez & Amano, 2021). The data gaps comprising both taxonomic groups and geographical regions in the marine realm are particularly apparent. Unlike terrestrial and freshwater alien species, marine alien species are mostly unintentionally introduced, and most records are either confined to economically impactful species, or to (relatively) large-sized sessile taxa inhabiting the intertidal or the shallow shelf. Even for these taxa, surveys have not been conducted along region-wide coastlines, leaving most alien taxa undetected and unrecognized. This presents an enormous challenge for understanding the dynamics of these biological invasions and prioritizing conservation and research aims for marine ecosystems (Ojaveer *et al.*, 2015, 2018).

Comprehensive analyses of data and knowledge gaps of alien species occurrences are largely lacking on a global scale. The few global systematic reviews of alien species distributions available for well-studied taxonomic groups such as mammals (Biancolini *et al.*, 2021), birds (E. E. Dyer, Cassey, *et al.*, 2017), reptiles and amphibians (Capinha *et al.*, 2017) indicate large geographic areas of incomplete information. For example, global systematic reviews of studies of first record data for alien amphibians and reptiles (N. J. van Wilgen *et al.*, 2018; **Figures 2.10** and **2.11**) using model-based estimates of the number of alien turtles expected to be introduced but not detected worldwide (García-Díaz *et al.*, 2015), showed consistent spatial gaps. Alien reptiles and amphibians have been understudied in Africa and parts of Asia, whereas the knowledge of alien amphibians and reptiles in Meso- and South America varies by country. These spatial patterns broadly mirror those of native reptiles and amphibians assessed as data-deficient in global International Union for Conservation of Nature (IUCN) Red List of threatened species assessments (Böhm *et al.*, 2013; Stuart *et al.*, 2008) and are very similar for other taxonomic groups.

In some cases, even though large regions are indicated as invaded due to country-level reporting, it is likely that only certain areas of these countries are actually invaded. This coarse scale reporting may cause distorted understanding of global distribution maps of these species by assigning very large territories to invasions while in fact, only smaller areas might be concerned. When numbers of invasive alien species are compiled, large countries are more likely to be tallied as containing species, even if their distributions are not greater than in smaller countries, thus contributing to this bias. Also, species introduced to new parts of a country where they did not previously exist are often not reported as being alien, and therefore, total numbers of alien species are frequently underestimated.

Data documenting invertebrate invasions are grossly incomplete. Earthworms are understudied compared to the impact they have on invaded ecosystems (Hendrix, 2006; Porco *et al.*, 2013). Many invertebrates are small and inconspicuous, and so large numbers of alien invertebrates remain undetected. For example, many Hymenoptera parasitoids have likely invaded regions without being detected likely due to a lack of available expertise and monitoring. The Asian parasitic wasp species *Gryon japonicum* (samurai wasp) was being evaluated for introduction as a biological control agent of *Halyomorpha halys* (brown marmorated stink bug) in North America when researchers discovered that it was already present (Talamas *et al.*, 2015). Addressing this problem not only requires increased survey effort, but also requires increased taxonomic research, since many insect species remain undescribed.

Research efforts are also driven by the actual, perceived, or projected impacts of invasive alien species, with highest-impact species being the most studied (e.g., bivalves, a small number of ants, a few other insects, some crustaceans, most vertebrates), while those causing less conspicuous damage are sometimes neglected (Pyšek *et al.*, 2008). For example, of the 19 highly invasive ant species, only two are extensively studied (over 350 studies each in Web of Science), three are much less covered, and the remaining species are almost entirely ignored (more than 3 per cent of all studies for the 14 other species cumulatively; Bertelsmeier *et al.*, 2016). Such disparities reflect presumed impacts and can potentially bias studies towards species with high expected impacts, but they also reflect the low number of biological invasion researchers and managers relative to the number of insect invasions.

Other factors contributing to data and knowledge gaps include taxonomic uncertainties, inadequate historical records, lack of data mobilization (i.e., making data available and accessible), sharing, and insufficiently applied expertise. Many ecosystems – especially freshwater and marine systems – harbour species that cannot be categorized as either alien or native with any high degree of certainty. In other cases, alien species are wrongly and erroneously assumed to be native and to have a natural cosmopolitan distribution (Carlton, 2009; Jarić *et al.*, 2019). The problem is most severe for small-bodied invertebrates (Marchini & Cardeccia, 2017; Ruiz & Carlton, 2003). Freshwater examples include bryozoans and rotifers, which are ubiquitous in lakes and rivers and have resting stages that are common and abundant in the ballast water of some transoceanic ships (Kipp *et al.*, 2010), but are rarely reported as alien species even in highly invaded aquatic systems (Pociecha *et al.*, 2016; Ricciardi, 2015).

In addition to information on the occurrence of alien populations, the dates of first introduction are unknown for most taxa except for avian and mammalian species (Biancolini *et al.*, 2021; E. E. Dyer, Redding, *et al.*, 2017). In general, more of this temporal information exists for Europe, especially for mammals and birds, while large gaps are found in Central Africa and South Asia. However, in most cases, the proportion of species with available temporal information is far below 50 per cent (Seebens *et al.*, 2020), often including well-studied regions like North America and Europe. Furthermore, there is a severe gap in temporal information for invertebrates all over the world.

More work to address the current knowledge gaps remains to be done. In particular, further genetic research including environmental deoxyribonucleic acid (DNA; Herder *et al.*, 2014; Hunter *et al.*, 2015; Tingley *et al.*, 2019) will contribute to resolving the alien or native status of some species and to uncovering cryptic and unrecognized introductions (Cogălniceanu *et al.*, 2014; Silva-Rocha *et al.*, 2012; Telford *et al.*, 2019).

2.3.2 Plants

This section reports on the temporal trends and status of the distribution of alien and invasive alien plant species for vascular plants (**section 2.3.2.1**), aquatic plants (**section 2.3.2.2**), algae (**section 2.3.2.3**) and bryophytes (**section 2.3.2.4**) as well as data and knowledge gaps (**section 2.3.2.5**).

2.3.2.1 Vascular plants

Trends

The total number of alien plant species established outside of their native ranges worldwide has increased continuously for centuries **(Figure 2.17)**, and first records of alien plants dating back more than one thousand years exist from all over the world (van Kleunen *et al.*, 2019; Wijesundara, 2010). As with many other taxonomic groups, the rate of accumulation for plants rose dramatically in the second half of the nineteenth century, tapering off in the early twentieth century, but increasing steeply after ca. 1970. Indeed, 28 per cent of all established plant records worldwide were recorded for the first time after 1970 **(Figure 2.17)**.

The number of alien plant species introduced is particularly important because plant introductions (whether intentional or unintentional) are a pathway for other invasive alien species introductions such as forest pests and pathogens, microbes, and other hitchhikers (Hulme *et al.*, 2008). The historical flow of alien plant species among continents shows that Europe and temperate Asia are the major donors of established alien plant species to other parts of the world (Drake *et al.*, 1989; van Kleunen *et al.*, 2015). The number of species native to Europe that have been established elsewhere is almost three times higher than expected (van Kleunen *et al.*, 2015). North America is also over-represented, with 57 per cent more species donated than expected based on native continental richness. In contrast, the continents in the Southern Hemisphere are all under-represented as donors of alien species. This suggests that, at least for plants, the "Old World *versus* New World" dichotomy (a classical concept in biological invasions suggesting that "Old World" biota were more likely to invade other parts of the globe due to traits they developed in close association with humans in their native ranges; Di Castri, 1989) needs to be replaced by a Northern Hemisphere *versus* Southern Hemisphere dichotomy for the donor continents of established alien plants (van Kleunen *et al.*, 2015).

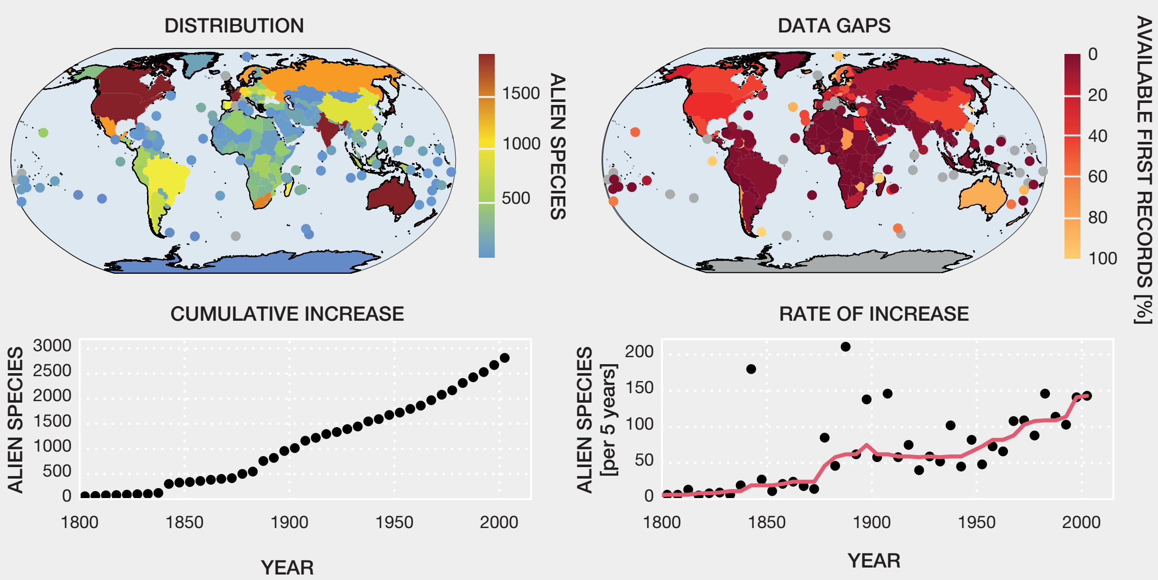

Figure 2 17 **Status, trends, and data gaps for established alien vascular plants.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

While North America has accumulated the greatest number of established alien species, the Pacific islands show the fastest increase in species numbers with respect to land area suggesting that Pacific islands have the highest vulnerability to invasions of all areas globally. Oceanic islands harbour more established alien plant species than similarly sized mainland regions, a phenomenon traditionally attributed to the niche space being unsaturated by native species or to a greater frequency of introductions (Moser *et al.*, 2018; van Kleunen *et al.*, 2015). Given the high concentration of endemic species on most oceanic islands, the large numbers of established alien species constitute a serious threat to global biodiversity (Fernández-Llamazares *et al.*, 2021; Pyšek, Blackburn, *et al.*, 2017; van Kleunen *et al.*, 2015).

Status

Currently, the total number of established alien plant species (13,939 species; van Kleunen *et al.*, 2019) indicates that at least 4 per cent of all known vascular plant species (337,137 species; The Plant List, 2015) have become established outside their natural ranges because of human activity. In total, 12,345 established alien species are reported from mainland regions globally and 8,019 from islands (Pyšek, Pergl, *et al.*, 2017).

The cool temperate forest and woodland regions have the highest richness of established alien plant species (6,586 species), followed by tropical (equatorial 4,690 species, and savanna 4,843 species), and warm temperate regions (4,649 species). In total, temperate regions harbour 9,036 established alien species relative to 6,774 for tropical zones, 3,280 in the Mediterranean regions, 3,057 in subtropical regions, and 321 in Arctic regions. When the total number of established alien species is standardized to the area of each region by comparing species accumulation rates with area, it appears that colder temperate and Mediterranean regions are more heavily colonized by alien species while more arid regions have fewer (**Figure 2.17**; Pyšek, Pergl, *et al.*, 2017).

Hotspots of relative alien species richness (i.e., the per cent of established alien species in the total regional flora) appear on both the western and eastern coasts of North America, north-western Europe, South Africa, south-eastern Australia, New Zealand, and India. South Africa, India, California (United States), Cuba, Florida (United States), Queensland (Australia) and Japan have the highest absolute values of established alien species (Essl *et al.*, 2019; Pyšek, Pergl, *et al.*, 2017). The mainland regions with the highest numbers of established alien species include several Australian states (New South Wales is highest in established alien richness on this continent) and several North American regions such as California, which has 1,753 established alien plant species. High levels of island colonization by established alien plants are concentrated in the Pacific region, but also occur on individual islands across all oceans. About one quarter (26 per cent) of the islands investigated by Essl *et al.* (2019) now have more established alien species than native species. England, Japan, New Zealand, and the Hawaiian archipelago harbour most established alien plants among islands or island groups (Pyšek, Pergl, *et al.*, 2017). Numbers of established alien species are closely correlated with those of native species and also with those of invasive alien species. There is also a faster increase in the numbers of established alien species with area on islands than in mainland regions, indicating a greater vulnerability of islands to alien species establishment (Essl *et al.*, 2019; Pyšek, Pergl, *et al.*, 2017).

Among vascular plants, the introduction of alien ferns is certainly less investigated and only one global assessment for alien ferns exists (E. J. Jones *et al.*, 2019). This study lists 157 alien ferns which are found in all climatic zones except the Arctic and Antarctic and on all continents. High numbers of alien ferns were reported for New Zealand, Hawaii, India and Europe.

In terms of plant families, rankings by absolute numbers of established alien species reveal that Asteraceae (1,343 species), Poaceae (1,267) and Fabaceae (1,189) contribute most to the global established alien flora. Comparing the number of established alien species in a family to its total global richness reveals that some of the large species-rich families are over-represented among established alien species (e.g., Poaceae, Fabaceae, Rosaceae, Amaranthaceae, Pinaceae), some under-represented (e.g., Euphorbiaceae, Rubiaceae), whereas Asteraceae, which has the highest richness of established alien species, reaches an expected value based on its global species richness. A significant phylogenetic signal indicates that some plant families have a higher potential for species to establish (Pyšek, Pergl, *et al.*, 2017). *Solanum* (112 species), *Euphorbia* (108) and *Carex* (106) are the richest genera in terms of established alien species. Some families are disproportionately over-represented by alien species on islands (i.e., Arecaceae, Araceae, Acanthaceae, Amaryllidaceae, Asparagaceae, Convolvulaceae, Rubiaceae, Malvaceae), but significantly fewer families are over-represented on mainlands (e.g., Brassicaceae, Caryophyllaceae, Boraginaceae). On islands, the genera *Cotoneaster*, *Juncus*, *Eucalyptus*, *Salix*, *Hypericum*, *Geranium*, and *Persicaria* are over-represented, while on the mainland *Atriplex*, *Opuntia* (pricklypear), *Oenothera*, *Artemisia*, *Vicia*, *Galium*, and *Rosa* are relatively richer in established alien species (Pyšek, Pergl, *et al.*, 2017).

The 10 most widely distributed established alien plants globally occur in at least 35 per cent of the world's regions. Other species such as *Sonchus oleraceus* (common sowthistle) occur in 48 per cent of the regions corresponding to 42 per cent of the globe. Additional widely distributed established alien species are *Oxalis corniculata* (creeping woodsorrel), *Portulaca oleracea* (purslane), *Eleusine indica* (goose grass), *Chenopodium album* (fat hen), *Capsella bursa-pastoris* (shepherd's purse), *Stellaria media* (common chickweed), *Bidens pilosa* (blackjack), *Datura stramonium* (jimsonweed), and *Echinochloa crus-galli* (barnyard grass). However, the ranking for invasive alien species differs among global databases because the data differ depending on the source used. The GloNAF database highlights *Lantana camara* (lantana,120/349 regions for which data on invasive status are known), *Calotropis procera* (apple of sodom, 118), *Pontederia crassipes* (water hyacinth, 113), *Sonchus oleraceus* (108) and *Leucaena leucocephala* (leucaena, 103) as the most distributed invasive alien species (Pyšek, Pergl, *et al.*, 2017), while GRIIS (Pagad *et al.*, 2022) provides a different ranking **(Table 2.15)**.

Table 2 15 **Top 10 most widespread invasive alien vascular plant species worldwide.**

The number of regions where the species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien vascular plant species rather than their impacts which are covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species	No. of regions	Species	No. of regions
***Pontederia crassipes* (water hyacinth)**	74	*Robinia pseudoacacia* (black locust)	45
***Lantana camara* (lantana)**	69	*Chromolaena odorata* (Siam weed)	43
***Leucaena leucocephala* (leucaena)**	55	*Pistia stratiotes* (water lettuce)	41
***Ricinus communis* (castor bean)**	47	*Erigeron canadensis* (Canadian fleabane)	38
***Ailanthus altissima* (tree-of-heaven)**	46	*Cyperus rotundus* (purple nutsedge)	37

Box 2 2 **Cacti, grasses and woody species: A global assessment of trends and status of alien and invasive alien species.**

Cacti (Cactaceae, about 1,922 species), grasses (Poaceae, about 11,000 species) and woody species are among the most studied species from a plant invasion perspective.

Cacti, native to the Americas, were among the first plants brought back by European explorers from the Americas in the fifteenth century. Most cacti (about 1,600 species, 81 per cent of the family) have been introduced outside their native ranges *via* the horticultural trade, especially recently due to higher volumes of e-commerce (**Glossary**; Novoa *et al.*, 2017), rapidly increasing the number of established alien cactus species **(Figure 2.18)**. However, only 3 per cent of species in Cactaceae (57 species) are currently considered as invasive alien species (Novoa *et al.*, 2015), with *Opuntia ficus-indica* (prickly pear) being the most widespread **(Figure 2.19)**. Although countries such as France, India or the United States support many established alien cacti **(Figure 2.20)**, there are three main hotspots for invasive alien cacti globally: South Africa (35 species recorded), Australia (26 species) and Spain (24 species). Most invasive alien cacti are native to Argentina, Mexico, and North America, which are roughly bioclimatically similar to the invaded regions. Other large regions, such as China, North- and South-East Asia, and Central Africa that are not intensively invaded by cacti have suitable climates for invasive cacti and therefore are at risk of future invasions (**Glossary**; Novoa *et al.*, 2015).

Grasses have been introduced outside their native ranges for horticulture, soil stabilization, as food and fodder, as biofuel, or as raw materials. Most remarkably, forage grasses have been a major focus of plant introduction programmes across large areas (Visser *et al.*, 2016). Perhaps as a result of such large introduction events, the number of established alien grass species has been intermittently increasing since the nineteenth century **(Figure 2.18)**. Currently, 1,226 alien grass species are reported as established globally (Pyšek, Pergl, *et al.*, 2017).

Box 2 2

Regions with the highest numbers of established alien grasses are Indonesia, Hawaii, Madagascar, New Zealand, tropical Africa, tropical South America and the southern United States **(Figure 2.20)**. Among all grasses, tall-statured grasses (defined as grass species that maintain a self-supporting height taller than or equal to 2 meters; 929 species) are 2–4 times more likely to establish than shorter grasses (Canavan *et al.*, 2019). This is due in part to their rapid growth rates and capacity to accumulate biomass. Tropical Africa (especially islands in the Western Indian Ocean) is the main hotspot of established alien tall statured grasses, with this group accounting for 30 to 70 per cent of all established alien grasses. The Caribbean is another such hotspot (Canavan *et al.*, 2019). Overall, 80.6 per cent of all tall statured grasses are woody bamboos, of which *Bambusa vulgaris* (common bamboo) is the most widespread species **(Figure 2.20)**.

Many **woody species** (shrubs and trees) are among the most widespread and damaging invasive plants (D. M. Richardson & Rejmánek, 2011). While there is no precise data available on the number of established woody species, D.M. Richardson and Rejmánek (2013; 2011) compiled a global database of 751 invasive alien woody species, comprised of 434 trees and 317 shrubs in 90 plant families and 286 genera. These alien species were introduced outside of their native ranges through many pathways including horticulture (62 per cent of invasive woody species: 196 trees and 187 shrubs), forestry (13 per cent), food (10 per cent), and agroforestry (7 per cent). Regions with the largest numbers of woody invasive alien species are North America (212), Pacific Islands (208), Australia (203), Southern Africa (178), Europe (134), and Indian Ocean Islands (126). Taxa within the genera *Acacia* and *Pinus* (Pine) comprise a large portion of the woody invasive alien species globally. In particular, *Pinus* (comprising 111 tree and shrub species, only one of which has its natural range confined to the Northern Hemisphere) have been widely introduced and planted in many areas well outside their native range and are among the most widely used forestry species worldwide (D. M. Richardson *et al.*, 1994). At least 30 *Pinus* species are known to be established alien species and 21 invasive alien species (D. M. Richardson, 2006). *Pinus contorta* (lodgepole pine) is one of the most invasive plantation trees **(Figure 2.19)**. Native to northwest North America, it is established in Great Britain, Ireland, and Russia, and is an invasive alien species in Argentina, Australia, Chile, New Zealand, and Sweden (Langdon *et al.*, 2010). *Pinus* invasions were first recorded in South Africa in 1855, in New Zealand in 1880 and in Australia in the 1950s (20-30 years after the first large plantations were established), and most research on *Pinus* invasions has been done in those countries (Simberloff *et al.*, 2009). However, because of a recent increase in commercial *Pinus* plantations in South America (Argentina, Brazil, Chile, and Uruguay are the countries having the greatest area of planted *Pinus*), *Pinus* invasions are currently an emerging problem on the continent and are predicted to increase rapidly in the next few decades (D. M. Richardson *et al.*, 2008). *Acacias* (about 1,350 species), especially Australian acacias (species within the genus *Acacia* that are native to Australia, about 1,012 species), have also been widely introduced outside their native ranges for centuries (D. M. Richardson *et al.*, 2011). At least 386 Australian acacias have been introduced outside Australia, of which 71 are recorded as established alien species and 23 as invasive alien species. The extent of Australian acacia invasions is likely to increase in the future, given that climatic models have suggested that a third of the world's terrestrial surface is climatically suitable. For example, *Acacia dealbata* (acacia bernier; **Figure 2.19**) is currently recorded as an invasive alien species in seven countries (D. M. Richardson & Rejmánek, 2011). Since it has been introduced widely outside of Australia, further accounts of its invasion are likely.

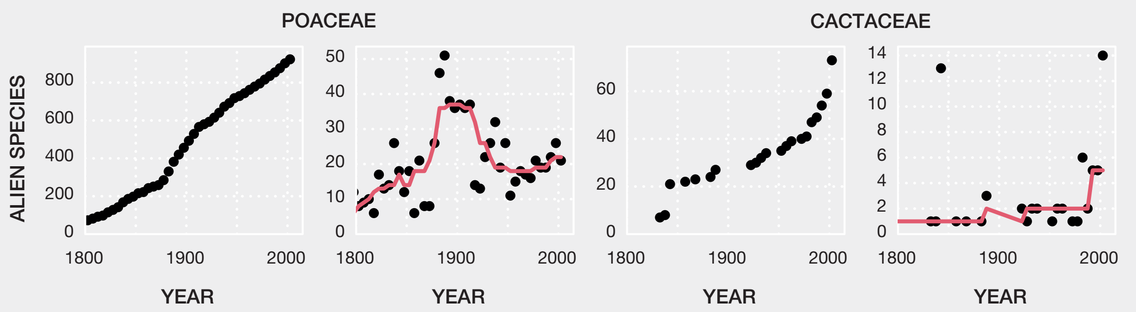

Figure 2 18 **Trends in numbers of established alien species for Poaceae and Cactaceae.**

Cumulative numbers (left panels) and number of established alien species per five-year intervals (right panels). Numbers shown underestimate the true extent of alien species occurrences due to a lack of data. Smoothed trends (line) are calculated as running medians (**section 2.1.4** for further details about data sources and data processing). A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Box 2 2

Figure 2 19 **Examples of the most widespread invasive cacti, grasses and woody species.**

Opuntia ficus-indica (prickly pear; top left) is the most commercially important cactus and is recorded as invasive in 26 countries worldwide. *Bambusa vulgaris* (common bamboo; top right) is the most widely cultivated bamboo and recorded as invasive in 5 countries. *Pinus contorta* (lodgepole pine; bottom left) is one of the most invasive plantation trees and it is recorded as invasive in 5 countries. *Acacia dealbata* (acacia bernier; bottom right) was introduced to many regions for multiple purposes and is now a widespread invasive alien species in 7 countries. Photo credit: Nicole Pankalla, Pixabay – under license CC BY 4.0 (top left) / Bishnu Sarangi, Pixabay – CC BY 4.0 (top right) / Walter Siegmund – CC BY 4.0 (bottom left) / Ulrike Leone, Pixabay – CC BY 4.0 (bottom right).

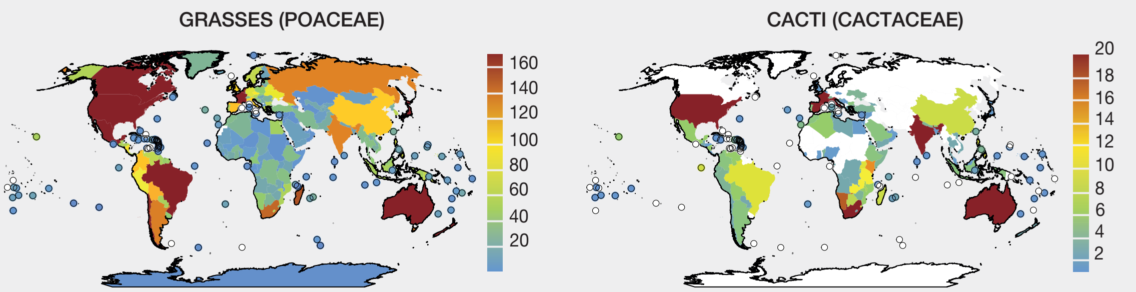

Figure 2 20 **Numbers of established alien grasses and cacti worldwide.**

Colours indicate established alien species of the families Poaceae and Cactaceae per region, including terrestrial, freshwater and marine species. For islands, numbers are shown as dots for visualization. White areas on land denote that information is lacking. Note that the legend scale varies among panels (**section 2.1.4** for further details about data sources and data processing). A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

2.3.2.2 Aquatic plants

Trends

The first records of alien aquatic plants date back to the eighteenth century, becoming more numerous by the early 1900s (Brundu, 2015b; Chomchalow, 2011; Gettys, 2019; M. P. Hill *et al.*, 2020; Hussner *et al.*, 2010). As modelled by Seebens, Bacher, *et al.* (2021), the rate of first records for alien aquatic plants increased post-1950, especially after 1980 when the ornamental plant trade increased (Hrivnák *et al.*, 2019; Hussner *et al.*, 2010; Nunes *et al.*, 2015), and again after 2008 when aquatic detection improved with the development of environmental DNA technology. Both the numbers and rates of established alien aquatic plants are projected to continue to increase until 2050 (Seebens, Bacher, *et al.*, 2021).

Status

Of the 13,168 established alien plant species reported in the GloNAF database, less than 1 per cent are aquatic (Pyšek, Pergl, *et al.*, 2017). However, comprehensive assessments of aquatic alien plants globally are lacking. Still, some aquatic plant species are prominent invasive alien species. Originally from the tropical zone of South America, *Pontederia crassipes* (water hyacinth), is one of the world's most prevalent invasive alien aquatic plants. This free-floating vascular plant has invaded freshwater systems in 62 countries, from 40°N to 40°S (Pan *et al.*, 2011) and, according to recent climate change models, its distribution may expand into higher latitudes as temperatures rise. It is prevalent in tropical and subtropical waterbodies where nutrient concentrations are often high due to agricultural runoff, deforestation, and insufficient wastewater treatment. There are no records of *Pontederia crassipes* first introductions, but many populations are well established and persistent despite control efforts (Coetzee *et al.*, 2017; Villamagna & Murphy, 2010). Sheppard *et al.* (2006) provide an evaluation of several aquatic invasive alien plant species distributions and status in Europe. For example, *Azolla filiculoides* (water fern), a small annual floating fern (hydrophyte), became established in slow moving and still water in ponds, canals, dikes and lakes, following escape from aquaria and botanical gardens in the mid-nineteenth century. The plant is now widespread in Central and Western Europe, South Africa, China and Australasia. Species from the Americas such as *Ludwigia grandiflora* (water primrose), *Ludwigia peploides* (water primrose), and aquatic perennial herbs (hydro-hemicryptophytes) are classified as invasive alien species in Europe. *Crassula helmsii* (Australian swamp stonecrop), originally from Australia and New Zealand, arrived in the United Kingdom in the 1950s and is known as an invasive alien species in the United Kingdom and the Kingdom of the Netherlands. *Elodea canadensis* (Canadian pondweed) and *Elodea nuttallii* (Nuttall's waterweed), both native to North America, are the most widespread alien aquatic plants in Europe. Introduced in the mid-1800s, *Elodea canadensis* spread along river systems throughout Europe in the latter half of the century and now occurs in many other countries worldwide. In the early twentieth century, *Elodea canadensis* was replaced by *Elodea nuttallii* in many regions. *Elodea nuttallii* may in turn begin to be replaced by another invasive alien hydrocharitacean species, *Lagarosiphon major* (African elodea), in the United Kingdom (Brundu, 2015a). *Myriophyllum aquaticum* (parrot's feather), from tropical and subtropical South America, is the dominant invasive alien aquatic plant in Europe. First introduced into France (1880) and then Portugal (1935) as an aquarium escapee, *Myriophyllum aquaticum* is also present in the United Kingdom and the Kingdom of the Netherlands and is probably more widespread as it was sold as an "oxygenating plant" until 2016. It is also a major weed in the United States, Australasia, Southern Africa, and Asia.

Among marine vascular plants, the seagrass *Zostera japonica* (dwarf eelgrass) was introduced to the Pacific Northwest in the mid-1900s likely *via* oyster aquaculture and has since spread and negatively impacted native *Zostera marina* (eelgrass) and ecosystem processes (Shafer *et al.*, 2014). Additionally, *Halophila stipulacea* (halophila seagrass) was introduced to the Mediterranean Sea through the Suez Canal where it is now widespread (Willette *et al.*, 2014). More recently, *Halophila stipulacea* was introduced to the Caribbean Sea where it is spreading and is described as the world's first globally invasive marine angiosperm (Willette *et al.*, 2014; Winters *et al.*, 2020).

2.3.2.3 Algae

In this section, algae are comprised of taxa of the phyla Rhodophyta, Chlorophyta, Charophyta, Cryptophyta, Euglenozoa, Haptophyta, Foraminifera, Ciliophora, Ochrophyta, Myzozoa and Cercozoa. Other groups of microorganisms are covered in **section 2.3.3**.

Trends

Globally, many alien green, brown, and red marine algae have been reported, with steep increases **(Figure 2.21)** in reports of large macroalgae invaders since the mid-twentieth century (Carlton & Eldredge, 2009; Fuentes *et al.*, 2020; Ribera & Boudouresque, 1995; J. E. Smith, 2011; Vaz-Pinto *et al.*, 2014; Villaseñor-Parada *et al.*, 2018; S. L. Williams & Smith, 2007). The high rate of increase since this time likely reflects increased global shipping after the invention of containerized transport in 1956. A study on the global distribution of 97 marine algae with known invasion histories revealed that hotspots of future occurrences are in East Asian and European waters, largely reflecting high shipping intensities of enclosed seas (Seebens *et al.*, 2016).

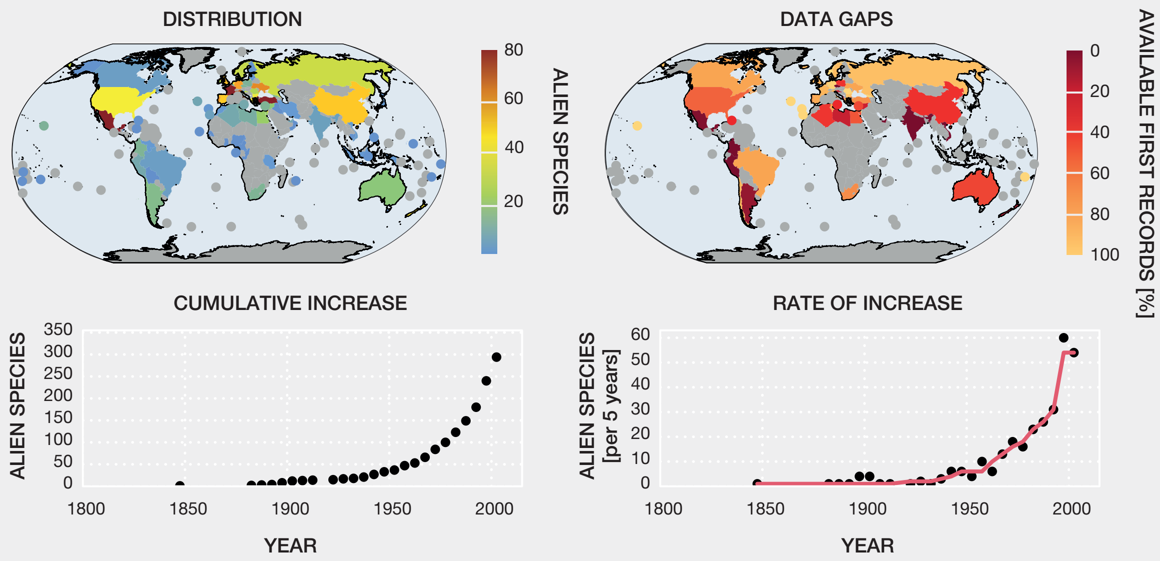

Figure 2 21 **Status, trends, and data gaps for established alien algae.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

The unresolved tensions between using alien species for aquaculture and their potential ecological impacts are well-represented in the history of seaweed invasions. In the 1970s, a suite of alien seaweeds was introduced to the Hawaiian Islands for mariculture, including *Kappaphycus striatus* (Indo-Pacific red algae) and *Gracilaria salicornia* (red alga), and the tropical Atlantic *Hypnea musciformis* (hypnea). In subsequent decades, these algae spread across the Hawaiian Islands. *Kappaphycus* (red alga) is reported to achieve over 50 per cent cover on some Hawaiian coral reefs. Efforts to remove alien seaweeds from Hawaiian reefs are ongoing.

Status

Examples of significant algal invasions with well-documented ecological and economic impacts include a variety of alien species native to Asia, such as *Sargassum muticum* (wire weed), *Codium fragile* (dead man's fingers), *Grateloupia turuturu* (devil's tongue weed), *Gracilaria vermiculophylla* (black wart weed), and *Asparagopsis armata* (Harpoon weed) – all now found on many continental margins around the world. Less widely distributed but even more notorious is *Caulerpa taxifolia* (killer algae), toxic to certain herbivores. More broadly distributed alien macroalgae are not necessarily more likely to succeed in new regions than more narrowly distributed species (S. L. Williams & Smith, 2007). For example, the genus *Capreolia* (red algae), considered endemic to Australasia, has been found on the coast of central Chile, based on molecular and morphological analysis (Boo *et al.*, 2014). *Pyropia koreana* (red algae) described previously from Korea, has been reported in the Mediterranean Sea (Vergés *et al.*, 2013) and New Zealand (Nelson *et al.*, 2014) and was detected using molecular analysis. Finally, *Chondracanthus chamissoi* (yuyo), considered endemic to the south-central coast of Chile, has been reported, through molecular analysis, in France, Japan, and Korea, where it shows important morphological variations (M. Y. Yang *et al.*, 2015; **Table 2.16**).

The cultivation of algae has facilitated the transfer of native species within country borders but still outside its historical range of distribution. For example, the macroalga *Gracilaria chilensis* (red seaweed), native to the south-central coast of Chile, has been extensively cultivated more than 640 km from its northern limit of distribution (Guillemin *et al.*, 2008; Santelices, 1989), resulting in established alien populations from the escape of vegetative propagules from aquaculture facilities (Castilla & Neill, 2009; Guillemin *et al.*, 2008; Villaseñor-Parada & Neill, 2011). Moreover, alien mollusc aquaculture has been identified as an introduction vector for many invasive macroalgae (Ribera Siguan, 2003; S. L. Williams & Smith, 2007). Indirect evidence suggests that

Table 2 16 **Top 10 most widespread invasive alien algae species worldwide.**

The number of regions where the species is recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien algae species rather than their impacts which are covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species	No. of regions	Species	No. of regions
Undaria pinnatifida **(Asian kelp)**	9	*Gracilaria vermiculophylla* (black wart weed)	5
Sargassum muticum **(wire weed)**	8	*Coscinodiscus wailesii* (diatom)	5
Caulerpa taxifolia **(killer algae)**	7	*Dasysiphonia japonica* (siphoned Japan weed)	5
Caulerpa cylindracea **(green algae)**	6	*Alexandrium tamarense* (dinoflagellate)	4
Codium fragile **(dead man's fingers)**	6	*Alexandrium minutum* (dinoflagellate)	4

several species of alien macroalgae have been introduced by aquaculture of *Magallana gigas* (Pacific oyster) in Europe (Krueger-Hadfield *et al.*, 2017; Lang & Buschbaum, 2010; Mineur *et al.*, 2007), North America (Mathieson *et al.*, 2003) and South America (D. E. Bustamante & Ramírez, 2009; Croce & Parodi, 2014). Filamentous alien species such as *Polysiphonia morrowii*, or alien species with filamentous stages in their life cycle, such as the "*Falkenbergia* phase" of *Asparagopsis armata* (Harpoon weed) or the "*Vaucheroid* phase" of *Codium fragile* (dead man's fingers), benefit from the rugosities in the shell of *Magallana gigas* where they can pass unobserved.

Alien macroalgae species themselves can serve as an introduction vector for other alien species that live as epiphytes in the thallus. For example, in many ecosystems where *Codium fragile* (dead man's fingers) has been introduced, its most conspicuous epiphyte is the Asian macroalgae *Melanothamnus harveyi* (Harvey's siphon weed; e.g., González & Santelices, 2004; E. Jones & Thornber, 2010; Schmidt & Scheibling, 2006; Villaseñor-Parada & Neill, 2011). Apparently, *Melanothamnus harveyi* is a secondary introduction associated with *Codium fragile*. Native species may also play an important role in the spread of alien species. For example, *Schottera nicaeensis* (red algae) and *Asparagopsis armata* (Harpoon weed) are invasive alien species in the Pacific southeast coast, and they have been found as epiphytes in drifting thalluses of the buoyant macroalgae *Durvillaea antarctica* (cochayuyo), becoming a potential dispersal mechanism for these species (Macaya *et al.*, 2016). For example, the release of reproductive fragments adrift has been identified as alternative dispersal strategies in *Codium fragile* (Villaseñor-Parada *et al.*, 2013) and *Mastocarpus latissimus* (Oróstica *et al.*, 2012).

2.3.2.4 Bryophytes

Trends

Cumulative numbers of first records grew slowly until 1950 and have since increased rapidly worldwide **(Figure 2.22)**, particularly in Oceania and Europe (Essl *et al.*, 2013).

Status

The most comprehensive assessment of alien bryophytes compiled data from 82 locations on five continents in both hemispheres (Essl *et al.*, 2013). To date, 139 species of bryophytes are considered alien in at least one of the regions studied, of which 79 are established, 19 are casual and 41 are cryptogenic (of uncertain origin; **Glossary**) occurrences. Of these, 106 are mosses, 28 liverworts, and 5 hornworts. Only 18 species (i.e., 13 per cent) are recorded as alien from at least five regions, with the most widespread being *Campylopus introflexus* (heath star moss; the best documented invasion, introduced to the United Kingdom in 1941 and coastal Europe in 1954 and currently extending to Russia in the east and the Mediterranean in the south), *Kindbergia praelonga* (common feather moss), *Lunularia cruciata* (crescent-cup liverwort), *Orthodontium lineare* (cape thread-moss), and *Pseudoscleropodium purum* (neat-feather moss). The two most important pathways for bryophyte introductions are unintentional imports as hitchhikers on ships and planes and as epiphytes on ornamental plants and other horticultural supplies with 34 and 27 species, respectively. Most alien bryophytes occur in human-made habitats, such as ruderal sites, roadsides, and lawns, while only a few natural ecosystems such as forests and rocky outcrops regularly harbour alien bryophytes (Essl *et al.*, 2013).

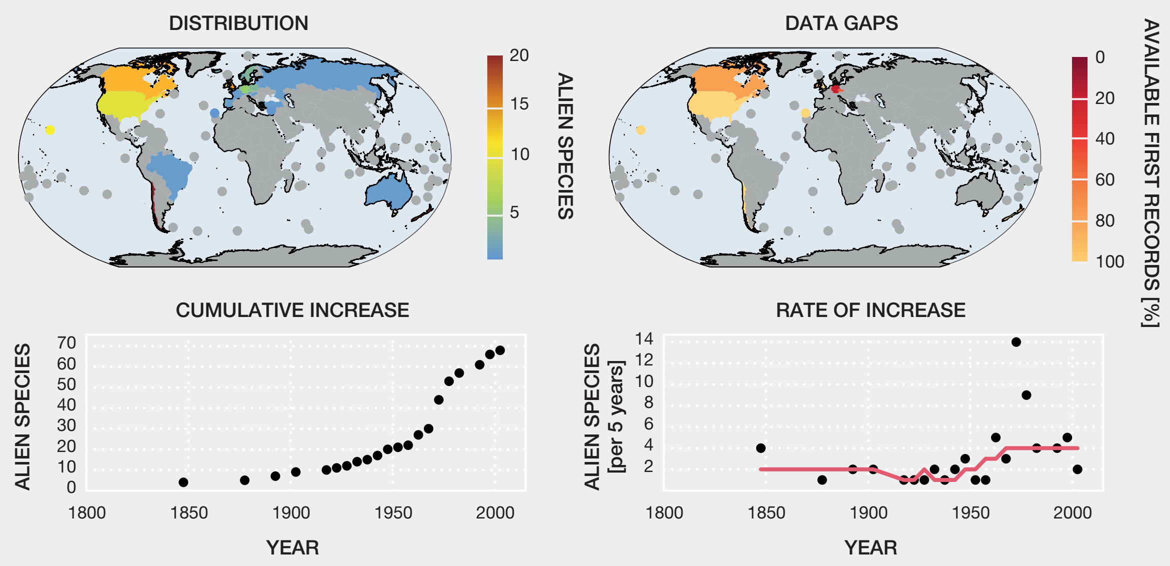

Figure 2 22 **Status, trends, and data gaps for established alien bryophytes.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend line is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Among locations of the Northern Hemisphere, the highest numbers of alien bryophytes are recorded for the Hawaiian Islands, United States and United Kingdom (22 species), followed by British Columbia, Canada (13 species), Ireland (11 species), California, United States (10 species) and France (10 species). In the Southern Hemisphere, most alien bryophyte species are recorded on islands (South and North Islands of New Zealand, 27 species each; St. Helena, 22 species). Continental South America, Asia and Africa have much lower numbers of alien bryophytes, from three to six species (Essl *et al.*, 2013). In general, islands are more invaded by alien (and cryptogenic) bryophytes than continental regions (Essl *et al.*, 2013). For invasive alien bryophytes, GRIIS (Pagad *et al.*, 2022) lists only two species that occur in more than one region, *Campylopus introflexus* (heath star moss) and *Orthodontium lineare* (cape thread-moss), each occurring in two regions.

2.3.2.5 Data and knowledge gaps

The GloNAF database and associated analyses (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2015, 2019) make it possible to quantify the proportion of a continental area for which data on established alien vascular plants are available (e.g., **Box 2.2**). GloNAF 1.1 covers more than 83 per cent of the world's ice-free terrestrial surface in terms of regions (n = 843) for which alien floras are available, but there is great variation in the geographic coverage among the continents defined by the Biodiversity Information Standards (TDWG, 2021). There is nearly complete data coverage, in terms of the proportion of individual regions having data on their alien floras, for Australasia (99.5 per cent of regions at the country, state, district or island level have information on alien flora), Africa (98.6 per cent), North America (95.9 per cent), South America (95.8 per cent) and Antarctica (90.2 per cent). The continents with lower coverage are tropical Asia (68.5 per cent), and particularly temperate Asia (54.8 per cent), where data are missing primarily for parts of Russia. The lack of data on alien floras for some regions of the European part of Russia also results in rather low coverage for Europe as a whole (63.8 per cent of the continent area). Data on alien plants are available for about half of the total area of the Pacific islands (49.1 per cent). However, good geographical coverage does not mean the information on the alien plants for a given region is complete; there can be data gaps even for well-studied regions (Pyšek *et al.*, 2008), as well uncertainties about a species status. Notably, identification of alien species is challenging for taxa with a distribution over more than one continent, for which no global identification key is available, and especially when the origin of the alien plant is unknown, such as for Cyperaceae, *Hydrocotyle* or *Myriophyllum*. The quality and completeness of individual datasets also vary greatly, as does the assessment of the status of alien species, habitat affiliations, first records and pathways **(Figure 2.22)**.

Ideally, records of alien plants occurrences would be collected following broadly accepted standards that reflect the research infrastructure and resources (Latombe *et al.*, 2017; **Chapter 6**, **section 6.6.2.3**).

Similarly, comprehensive databases such as the GloNAF database are not available for bryophytes or algae, severely limiting the potential for a thorough assessment of the trends and status for these groups. While alien bryophytes in Central and Western Europe and North America are well-documented, data on alien bryophytes on all other continents, and particularly in the tropics, are rarely available (Essl *et al.*, 2013). The number of algal invasions worldwide is poorly known due to low research efforts. In addition, comparatively high taxonomic uncertainty makes it difficult to compare species identities among studies. Many hundreds of seaweed species bear the same name around the world but are regarded as naturally distributed. These species doubtless represent a mixture of species complexes peppered with many overlooked invasions. Furthermore, the original native ranges are often unknown, making it impossible to determine whether populations are native or alien in that region. As a consequence, many populations of algae and bryophytes species can only be classified as cryptogenic and a comprehensive assessment of the current status of their alien distributions remains elusive.

Finally, the aforementioned databases provide regional lists of alien taxa without information on their precise spatial distributions. In large countries it is especially common that a reported species occurs in only part of the country. Occurrence datasets like the GBIF hold such spatially explicit data but to date report only incomplete information on the biogeographic status of taxa, that is, whether a species is native or alien (C. Meyer *et al.*, 2016). Additionally, like all global databases, GBIF records for plants are biased in terms of taxonomy, space, and time (A. C. Hughes *et al.*, 2021; C. Meyer *et al.*, 2016; Troudet *et al.*, 2017). However, new methods are emerging that allow the use of probabilistic tools to estimate the biogeographic status of occurrence records (Arlé *et al.*, 2021).

2.3.3 Fungi and microorganisms

This section reports on the temporal trends and status of the distribution of alien and invasive alien species for fungi (**section 2.3.3.1**) and the group of Chromista, bacteria and viruses (**section 2.3.3.2**) as well as data and knowledge gaps (**section 2.3.3.3**). In this chapter the group of microorganisms is split into "fungi" (**section 2.3.3.1**) with the phyla Ascomycota, Chytridiomycota, Basidiomycota, Microsporidia, and Zygomycota, and "Chromista, bacteria and viruses" (**section 2.3.3.2**) with the taxonomic groups Oomycota, Actinobacteria, Chlamydiae, Cyanobacteria, Firmicutes, Proteobacteria, and viruses. Other groups of microorganisms are covered in **section 2.3.2.3**. Note that there can be a high degree of uncertainty about to the status of microorganisms as native or alien.

2.3.3.1 Fungi

Trends

Fungi comprise an immensely diverse biological kingdom that forms complex interactions at multiple ecological levels. Fungal invasions are increasingly recognized as key drivers of wildlife mortality and population declines for amphibians, bats, bees, soft coral, and other organisms (Fisher *et al.*, 2012). Introduction of undesirable alien fungi such as those producing repellent smells or toxic compounds, is also problematic (Parent *et al.*, 2000; A. Pringle & Vellinga, 2006). Negative impacts of plant diseases caused by fungal invasions have resulted in widespread ecosystem disruptions that indirectly impact the function of forests, streams, and other natural environments (Anderson *et al.*, 2004; Scott *et al.*, 2019; **Chapter 4**, **section 4.3.1**) such as *Hymenoscyphus fraxineus* (ash dieback; **Table 2.17**) causing ash dieback in Europe. In addition, alien fungal pathogens have severe negative impacts on agricultural crops (**Chapter 4**, **section 4.4.1**). Examples include *Phytophthora ramorum* (sudden oak death; Thakur *et al.*, 2019), *Phyllosticta citricarpa* (citrus black spot; Guarnaccia *et al.*, 2019), *Phakopsora pachyrhizi* (soybean rust; Dean *et al.*, 2012) or *Pyricularia oryzae* (rice blast disease; Fones *et al.*, 2020).

With an increasingly connected world, the rate at which alien fungi are recorded is accelerating (Bebber *et al.*, 2013; Desprez-Loustau, 2009; Fisher *et al.*, 2012). First reports **(Figure 2.23)** of alien fungi have increased consistently since the mid-1800s (Bebber *et al.*, 2013; Fisher *et al.*, 2012; Monteiro *et al.*, 2020; Santini *et al.*, 2013), with approximately 25 per cent of all dated records reported since 2000 (Monteiro *et al.*, 2020). New species discovery for fungi has risen from 1,000-1,500 per year in the mid-2000s, to a peak of more than 2,500 species in 2016 and over 2,000 new species discovered in 2019 (Cheek *et al.*, 2020). Nonetheless, reports of new occurrences are almost certainly underestimated (Bebber *et al.*, 2019). In addition, with rising temperatures and more frequent extreme weather events, fungi are not only able to invade novel geographical areas, but some potentially pathogenic species are also beginning to evolve levels of thermotolerance that could allow them to breach the thermal barriers that have long protected mammals from fungal infections, representing a further threat to human health and wellbeing (Nnadi & Carter, 2021).

Status

Fungi are widely dispersed by humans, often unintentionally or as stowaways, *via* transport through the trade of goods such as plants, seed, wood, shipping containers and other materials (Desprez-Loustau, 2009). Fungi are also dispersed across long and short distances in the atmosphere by wind or water and weather disruptions can play a significant role in spreading fungi into new regions (Anderson *et al.*, 2004; J. K. M. Brown & Hovmøller, 2002). Fungi are being recorded on all continents, including Antarctica **(Figure 2.23)**.

The fungi comprise an immensely diverse biological kingdom that forms complex interactions at multiple ecological levels. Their inconspicuous nature and dispersal

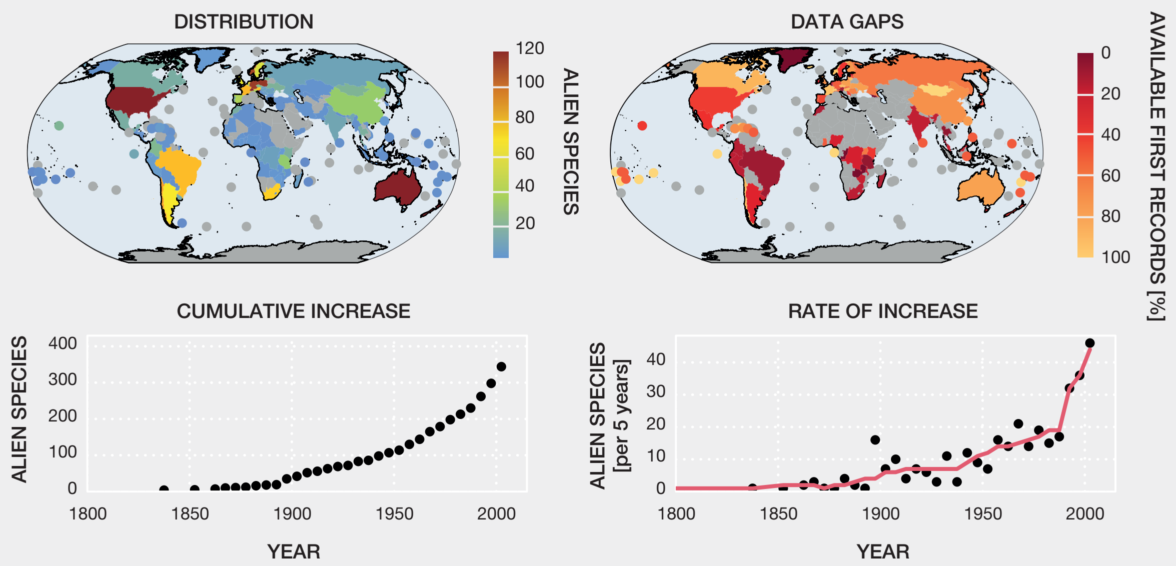

Figure 2 23 **Status, trends, and data gaps for established alien fungi.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note that presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Table 2 17 **Top 10 most widespread invasive alien fungi worldwide.**

The number of regions where the species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien species rather than their impacts which are covered in **Chapter 4** (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species	No. of regions	Species	No. of regions
***Ophiostoma novo-ulmi* (Dutch elm disease)**	10	*Ophiostoma ulmi* (Dutch elm disease)	4
***Batrachochytrium dendrobatidis* (chytrid fungus)**	9	*Erysiphe alphitoides* (oak mildew)	3
***Cryphonectria parasitica* (blight of chestnut)**	5	*Melampsoridium hiratsukanum* (alder rust)	3
***Hymenoscyphus fraxineus* (ash dieback)**	5	*Clathrus archeri* (devil's fingers)	2
Pyrrhoderma noxium	5	*Cronartium ribicola* (white pine blister rust)	2

by small, often long-lived spores make the spread of fungi to new locations difficult to control and easy to overlook. Fungal size, particularly the size of the fungal spore-bearing structures, greatly influences how invasive alien fungi are recognized and studied (Desprez-Loustau *et al.*, 2010). The "microfungi," so called because their spore-bearing structures are microscopic, are the most important fungi associated with plant diseases. In contrast, the "macrofungi", which produce large and sometimes vividly coloured spore-bearing structures (e.g., mushrooms), are mostly saprophytes and ectomycorrhizal fungi. Although the distinction between macro and microfungi is artificial, fungal size alone does influence the assessment of invasion dynamics of invasive alien fungi.

About 650 species of macrofungi have been recorded outside their native ranges (Monteiro *et al.*, 2020). Most belong to the orders Agaricales (44 per cent) and Boletales (29 per cent); slightly more than half are ectomycorrhizal, and the remainder are saprotrophic (Monteiro *et al.*, 2020). The most widely distributed alien macrofungi include *Amanita muscaria* (fly agaric), *Amanita phalloides* (death cap), *Phellinus noxius* (brown tea root disease), *Suillus granulatus* (weeping bolete mushroom), and *Suillus luteus* (ectomycorrhizal fungus of pine) (Monteiro *et al.*, 2020). The highest known diversity of macrofungal alien species is in the Southern Hemisphere in countries such as Argentina, Brazil, Chile, New Zealand, and South Africa, and in several European countries, including France, Germany, and the United Kingdom (Monteiro *et al.*, 2020; Vellinga *et al.*, 2009).

Invasive alien fungal symbionts have been co-introduced with their hosts, as in the case of the ectomycorrhizal fungus *Amanita phalloides* (death cap), a native of Europe introduced to Australia and North and South America, probably in soils as consequence of the plant trade (A. Pringle *et al.*, 2009; Vellinga *et al.*, 2009; A. Pringle & Vellinga, 2006). According to Vellinga *et al.* (2009), about 200 species of ectomycorrhizal fungi (including ascomycetes and basidiomycetes) have been introduced into novel habitats due to the transport of *Eucalyptus* and *Pinus* spp. (Pine).

Dung fungi that have accompanied their herbivore partners introduced to the Caribbean islands are a good example (M. J. Richardson, 2008). Commercial use of "biofertilizers" based on arbuscular mycorrhizal fungi is another example. This has led to a global spread of these species (Thomsen & Hart, 2018). Although they can have long-term effects on ecosystems, such alien species tend to go unnoticed (Velásquez *et al.*, 2018) or, in the case of "biofertilizers", unrecognized as an invasion. Some unnoticed alien fungal species may be mutualists associated with only one symbiont species, for example as a plant endobiont. If that symbiont is itself an invasive alien species, a case can be made that the unnoticed mutualist too is behaving invasively by contributing to the success of its associated invasive alien plant. Therefore, an as yet unknown number of additional fungal invasive alien species may remain undetected.

Most parasitic fungi affect plants (Anderson *et al.*, 2004). Examples of invasive alien species include *Cryphonectria parasitica* (blight of chestnut; Gruenwald, 2012), *Ophiostoma* spp. including *Ophiostoma novo-ulmi* (Dutch elm disease; Brasier & Kirk, 2000), *Cronartium ribicola* (white pine blister rust), *Austropuccinia psidii* (myrtle rust), and *Discula destructiva* (dogwood anthracnose). More aggressive genotypes of known plant pathogenic fungi may also arrive as alien species and later become invasive (Arenz *et al.*, 2011). Also important are invasive alien oomycetes such as *Phytophthora pinifolia* causing needle disease in *Pinus radiata* (radiata pine) in Chile (Durán *et al.*, 2008) and hybridization of oomycetes in the genus *Phytophthora* that can cause serious damage to agriculture, horticulture, and forestry (Érsek & Nagy, 2008).

Alien and invasive alien fungi that are pathogenic to animals include *Batrachochytrium dendrobatidis* (chytrid fungi) and *Batrachochytrium salamandrivorans* (chytrid fungi) which are the agents of chytridiomycosis, a disease spread by trade and causing massive global amphibian declines (Berger *et al.*, 2016; Weldon *et al.*, 2004), and *Pseudogymnoascus destructans* (white-nose syndrome fungus) in bats (Hendrix & Bohlen, 2002; Hovmøller *et al.*, 2016; Sikes *et al.*, 2018; Thakur *et al.*, 2019).

2.3.3.2 Chromista, bacteria, protozoans, and viruses

Chromista and other eukaryotic protists constitute several biological kingdoms independent of those for animals, fungi, and plants. Their underlying phylogeny remains poorly understood, with classifications frequently and often radically changing as molecular evidence becomes available. Chromista includes major groups of ecologically highly significant organisms, including many marine algae, diatoms and oomycetes. Note that some groups of Chromista, which are usually considered algae, are addressed in section "Algae" (**section 2.2.2.3**). Here, taxa of the groups Oomycota, Actinobacteria, Chlamydiae, Cyanobacteria, Firmicutes, Proteobacteria and viruses are included.

Along with the true fungi, the Oomycota (with few exceptions including Phytophthora) have rarely been analysed within the context of biological invasions. Recent advances in molecular analyses, however, have shown that at least some of these species have defined natural distributions and can be considered alien if introduced by humans beyond the native range. The emergence of microbial invasive alien species, pathogenic or not, is thus a global phenomenon and a major threat in invasion ecology

(Jack *et al.*, 2021; Litchman, 2010; Mawarda *et al.*, 2020; Ricciardi *et al.*, 2017; Thakur *et al.*, 2019).

Trends

The numbers of alien oomycetes have risen continuously since 1900 (**Figure 2.24**; Santini *et al.*, 2013), as has the numbers for other alien microorganisms as well **(Figure 2.25)**. The new arrivals include some species which are causal agents of serious plant diseases (Blehert *et al.*, 2009; Fisher *et al.*, 2009; Robert *et al.*, 2012; Singh *et al.*, 2008). Global trade is a major driver of oomycete invasions as they are usually unintentionally introduced on their hosts or as contaminants of goods (Sikes *et al.*, 2018). In particular, plants transported with intact root systems, and particularly with soil, are likely to host potentially alien oomycete species, both beneficial and pathogenic.

Historically, there have been several oomycete invasions that have had huge impacts on humans. The most prominent is *Phytophthora infestans* (Phytophthora blight) introduced in the 1800s from North America to Europe. The dispersal of *Phytophthora infestans* is well documented with multiple periods of intense spread over the past 200 years (Fry, 2008). It was the main cause of repeated total potato crop failures resulting in massive famines with millions of deaths and a huge wave of emigration by hundreds of thousands of Europeans (Woodham-Smith, 1962; Yoshida *et al.*, 2013). Importantly, *Phytophthora* species can hybridize, attain greater vigour, and potentially infect a wider host range relative to parent species thereby creating a serious threat to managed and natural systems (Van Poucke *et al.*, 2021).

Status

Well-documented microbial invaders are typically pathogenic organisms which are detected because of their devastating impacts. Anderson *et al.* (2004) provided a list of emerging infectious diseases including *Phytophthora ramorum* (sudden oak death; Gruenwald, 2012).

Biological invasions caused by viruses are also extremely relevant in the context of plants as they account for almost 50 per cent of their emerging infectious diseases (Anderson *et al.*, 2004). In many cases they are transmitted by an invasive alien host species such as *Bemisia tabaci* (tocacco whitefly), which can transmit over 114 virus species (D. R. Jones, 2003). Despite its tropical origin, there have been outbreaks of *Ralstonia solanacearum* biovar 2 (brown potato rot) in Europe where it survives the winter in waterways in association with endemic plants (Stevens & van Elsas, 2010). Many pathogenic microbes are thought to be alien species in the areas in which they were found (Rúa *et al.*, 2011).

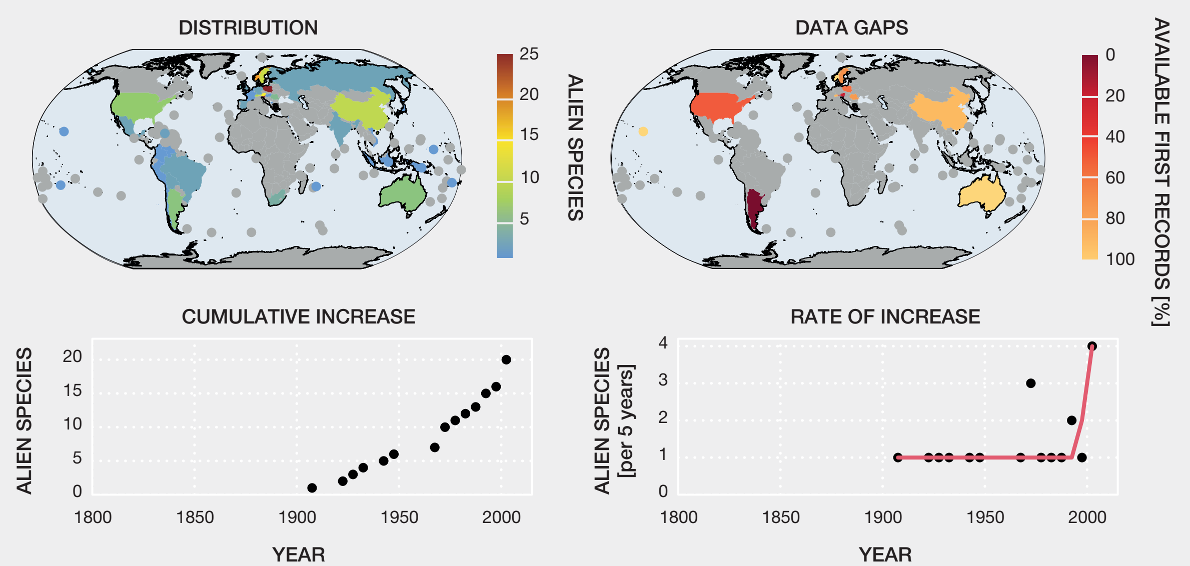

Figure 2 24 **Status, trends, and data gaps for established alien oomycetes.**

The number of established alien species per region (upper left) and the amount of available data (upper right) are indicated by colour. The amount of available data is estimated by the proportion of available first records among all records available for that region (**section 2.1.4** for further details). Grey regions denote areas with lacking data. Oceans are tinted for visualization and do not indicate species numbers. Trends are shown in lower panels for cumulative numbers and as a rate of increase (i.e., numbers of established alien species per five years). Smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Detection of non-pathogenic microbial species is more difficult because their impacts can be more subtle and do not result in mortality or disease and are therefore harder to quantify unless previously identified impacts are specifically looked for. Co-invasion of non-pathogenic microbes with plants has been detected in California, United States where genomic analyses revealed that *Ensifer medicae*, a bacterial symbiont associated with the legume *Medicago polymorpha* (bur clover), was introduced from Europe (Porter *et al.*, 2018). Similarly, colonization of New Zealand

Yersinia pestis **(black death)**	4	*Phytophthora plurivora* (oomycetes)	2

by European *Lotus corniculatus* (bird's-foot trefoil) coincides with the introduction of its symbiotic partner, the bacterium *Mesorhizobium loti* (Sullivan *et al.*, 1995, 1996).

In most cases, it is unknown whether these introductions spread to other hosts in the introduced habitats which might potentially lead to the displacement of native symbiotic species. Although most known microbial introductions have been reported from Europe, South America, Australia, and New Zealand, these data might be biased by the number of papers published from each country (Vellinga *et al.*, 2009). **Table 2.18** lists the 10 most widespread invasive alien Chromista and bacteria and the number of regions each has invaded.

2.3.3.3 Data and knowledge gaps

Data and knowledge gaps for fungi are vast. Fungi are frequently unnoticed or unreported, particularly in regions where scientific infrastructure is minimal (Desprez-Loustau *et al.*, 2010). Information about alien fungi in different regions can vary tremendously, with biases associated with available scientific infrastructure, taxonomic expertise, crop production, and trade routes (Desprez-Loustau *et al.*, 2010; Lofgren & Stajich, 2021). There are generally far fewer records of fungi than for animals and plants, even from areas with a strong tradition of fieldwork. There are several estimates of the total number of fungal species, with values ranging from 2.2 to 5.1 million, to as many as 11.7 to 13.2 million species (Lofgren & Stajich, 2021). These millions of predicted fungal species greatly eclipse the 146,155 species that are so far discovered and named (Kirk, 2021) and indicate that as many as 98.8 per cent of all fungal species await discovery. Although the rate of new species discoveries has accelerated since the advent of DNA technologies, at the current rate of about 2,000 new fungal species described each year (Cheek *et al.*, 2020), it will be at least a thousand years before a comprehensive inventory of fungal diversity is made.

The continued paucity of rapidly accessible and reliable information for fungi remains a major hurdle for identifying new fungal invasive alien species, particularly cryptogenic fungi, as their initial establishment phase, which is the only stage at which effective countermeasures are feasible, often remains unnoticed until major damage is done (McMullan *et al.*, 2018). Another important knowledge gap is an insufficient understanding of the taxonomic limits of fungal species. This hinders effective quarantine of animal and plant pathogens. Using molecular phylogenetics, several disease-causing microfungi were found to belong to species complexes, and incorrect identifications have led to confusion (Coleman, 2016; X. Lin & Heitman, 2006; Thines & Choi, 2016).

As with fungi, only 10 per cent of all probable oomycete species are estimated to be known and described (Thines, 2014), a large knowledge gap. Information about non-terrestrial species is similarly limited, although several invasions by aquatic algae have been documented (Acosta *et al.*, 2015), including the *Prymnesium parvum* (golden algae) which has successfully established in freshwater ecosystems in several locations in the United States (Roelke *et al.*, 2016; see also **section 2.2.2** including Algae).

Box 2 3 **Evolution during biological invasions.**

Biological invasions have been instrumental in demonstrating that evolution can be rapid enough to contribute to contemporary ecological dynamics and that feedback between ecology and evolution can occur within a few generations (so-called "eco-evolutionary dynamics"; Carroll *et al.*, 2007; Hendry, 2020). Evolution can influence the trends and status of biological invasions by enhancing dispersal rates that lead to species range expansion, improving alien species' performance, and increasing adaptation to novel environments (Suarez & Tsutsui, 2008; Vellend *et al.*, 2007). Indeed, approximately half of the investigated plants and animals show increased size and fecundity in their new range (Parker *et al.*, 2013); many of these differences are likely to have a genetic basis. Adaptive evolution (i.e., evolutionary changes that increase the chance of survival and reproduction) is thought to be common for alien species, especially alien plants (Hodgins *et al.*, 2009). A well-known animal example is *Rhinella marina* (cane toad), which has evolved longer legs and faster movement as its alien range has expanded across Australia (Phillips *et al.*, 2006).

Observations of evolution during invasion initially presented researchers with a paradox. Newly introduced populations tend to be small and are therefore expected to contain low genetic diversity, thereby limiting the population's ability to respond to selection (Sakai *et al.*, 2001). However, some populations that undergo founder effects and genetic bottlenecks can evolve rapidly (Dlugosch & Parker, 2008). In fact, low genetic variation can facilitate invasive behaviour. For example, loss of genetic variation may have reduced intraspecific aggression among alien populations of *Linepithema humile* (Argentine ant), leading to the formation of competitively dominant "supercolonies" (Tsutsui *et al.*, 2000). Other successful invasive alien species have been introduced multiple times and in high numbers (i.e., high propagule pressure), offsetting founder effects and limiting genetic bottlenecks (Roman & Darling, 2007). Indeed, introductions of individuals from different parts of a species' native range can create genetic admixtures (a mixture of previously distinct genetic lineages), boosting levels of standing genetic variation

Box 2 3

in the new range (Meyerson & Cronin, 2013) and potentially providing fitness advantages through hybrid vigour and increased variation, on which selection can act (S. R. Keller & Taylor, 2010). The contribution of novel mutations in large invasive alien populations also cannot be discounted (Colautti & Lau, 2015).

Hybridization and introgression

Genetic variation can also be enhanced during invasion by hybridization among species and interbreeding between native and introduced genotypes (Meyerson *et al.*, 2010; Meyerson & Cronin, 2013); these mechanisms occur commonly and can play an important role during invasion (Hovick & Whitney, 2014; Largiadèr, 2008). Hybridization can facilitate successful invasions if it is beneficial and increases fitness (Bossdorf *et al.*, 2005; Ellstrand & Schierenbeck, 2000; Meyerson *et al.*, 2010; Rius & Darling, 2014); and may help a species overcome Allee effects associated with small sizes of introduced populations (Yamaguchi *et al.*, 2019). For example, hybridization between *Sporobolus alterniflorus* (smooth cordgrass), which was deliberately introduced to the North American Pacific coast from its Atlantic-coast native range, and native *Sporobolus foliosus* (California cordgrass) have generated highly invasive hybrid populations (Daehler & Strong, 1997). Particularly in plants, polyploidy (i.e., genome duplication), sometimes in association with hybridization (Strong & Ayres, 2013), is linked with the success of some alien species through several mechanisms, including enhanced genetic variability (Suda *et al.*, 2015; te Beest *et al.*, 2011). Nonetheless, how frequently the benefits of hybridization outweigh the negative effects is still poorly understood (Hodgins *et al.*, 2018).

Plasticity and adaptation

Invasive alien populations with low genetic variation can also respond to environmental variation in a new range through phenotypic plasticity (Torchyk & Jeschke, 2018). Through plasticity, a single genotype can undergo physiological, phenological, and morphologic changes in response to environmental conditions, which can have significant evolutionary implications (Schlichting, 1986). While it is expected that plasticity will support the establishment and spread of alien species introduced to novel environments (Richards *et al.*, 2006), support for the hypothesis that invasive alien species display greater plasticity than native or non-invasive alien species is mixed (A. M. Davidson *et al.*, 2011; Meyerson *et al.*, 2020; Palacio-López & Gianoli, 2011; Torchyk & Jeschke, 2018). Phenotypic variation can also be generated during invasions through epigenetic mechanisms, that is heritable DNA modifications without changes in the genetic code (Bossdorf *et al.*, 2008). While epigenetic variation has been associated with some successful invasions (C. Liu *et al.*, 2020; Richards *et al.*, 2012), it is too early to generalize about the importance of this mechanism for invasions (Bock *et al.*, 2015). Invasive alien species can also adapt to environmental conditions in their new range and increase their abundance, though few empirical studies have quantified these links (Hodgins *et al.*, 2018). For example, *Lythrum salicaria* (purple loosestrife) in North America has experienced demographic benefits of adaptation estimated to be equivalent to those that the species enjoys from natural enemy release (Colautti & Barrett, 2013).

Data and knowledge gaps

A key uncertainty is how much evolution favours or hinders the outcome of a biological invasion, for example, by making the difference between invasion success and failure (Bock *et al.*, 2015). To this end, perspectives from ecology and evolution could be further integrated by combining genomic tools with more classical experimental and comparative studies to test the mechanisms and consequences of evolution during invasion (Holman *et al.*, 2019; McCartney *et al.*, 2019). Another critical question is to what extent evolution allows alien species to colonize environments that are outside of their native-range ecological niches (Moran & Alexander, 2014; Pearman *et al.*, 2008). Settling this question is important for commonly used tools such as species distribution models to forecast potential distributions of alien species (Pearman *et al.*, 2008). Finally, studies of invasions have shown that some species can rapidly adapt to changing environments (Colautti & Lau, 2015; Hodgins *et al.*, 2018). Alien species may be exceptionally responsive to interacting global-change drivers (Moran & Alexander, 2014), such as climate change or land-use change, a topic warranting further research (**Chapter 3**, **sections 3.5** and **3.6.1**).

Linking evolution and molecular tools to invasive alien species impacts and management

Just as alien species adapt to their novel environments, so too have native species evolved in response to the novel selection pressures posed by alien species. Evolutionary responses to exposure to alien competitors appear to be widespread in plants (Oduor, 2013). Thus, evolution may partially mitigate the negative impacts of invasive alien species on native communities (Carroll, 2011). This understanding also points to ways in which genetic tools and evolutionary principles may help to mitigate some of the impacts of invasive alien species (Chown *et al.*, 2015; Lankau *et al.*, 2011).

Information about the evolutionary/phylogeographic history of alien species obtained by using molecular markers and up-to-date statistical methods can also have several practical benefits for alien species monitoring and management (Lankau *et al.*, 2011). Such knowledge can improve the efficacy of biocontrol programmes by targeting biocontrol agents from within the source region of a given invasive alien species (Chown *et al.*, 2015) and provide better delimitation of source regions and introduction pathways, which can be obtained using high-resolution genomic tools (Hudson *et al.*, 2021, 2022). While it is widely recognized that biological

Box 2 3

invasions constitute a natural experimental framework for the study of contemporary evolution, a good understanding of source regions and introduction pathways (i.e., routes of invasion/introduction) is essential. Knowledge of those routes makes it possible to precisely compare introduced populations to their original source population(s) and thus determine whether the invaders have, for example, undergone an adaptive change that has favoured them in their new living environment. This change may result from the selection of genetic variants that are rare in the original source population(s) but favoured in the new environment. The reconstruction of routes of invasion/introduction is, therefore, crucial to define and test different hypotheses concerning the environmental and evolutionary factors underlying biological invasions and their success (Estoup & Guillemaud, 2010; S. R. Keller & Taylor, 2008). Bulk screening by using metabarcoding approaches may be used to flag recognized invaders at ports of entry and so prevent the introduction of harmful species (or new genotypes of already introduced species). The potential for molecular instruments to detect the spread of invasive alien species is important, although many challenges remain (Handley, 2015).

2.4 TRENDS AND STATUS OF ALIEN AND INVASIVE ALIEN SPECIES BY IPBES REGIONS

This section reports on the temporal trends and status of the distribution of alien and invasive alien species across IPBES regions (**section 2.4.1**), and for the individual IPBES regions Africa (**section 2.4.2**), the Americas (**section 2.4.3**), Asia and the Pacific (**section 2.4.4**), and Europe and Central Asia (**section 2.4.5**), and their respective sub-regions. A description of IPBES regions and sub-regions including a spatial representation is provided online (IPBES Technical Support Unit On Knowledge And Data, 2021) and in **Chapter 1**, **section 1.6.4**. For each IPBES region, dynamics on islands and data and knowledge gaps are provided as well. A global synthesis on the dynamics on islands and in protected areas is provided in boxes (**Boxes 2.4** and **2.5**).

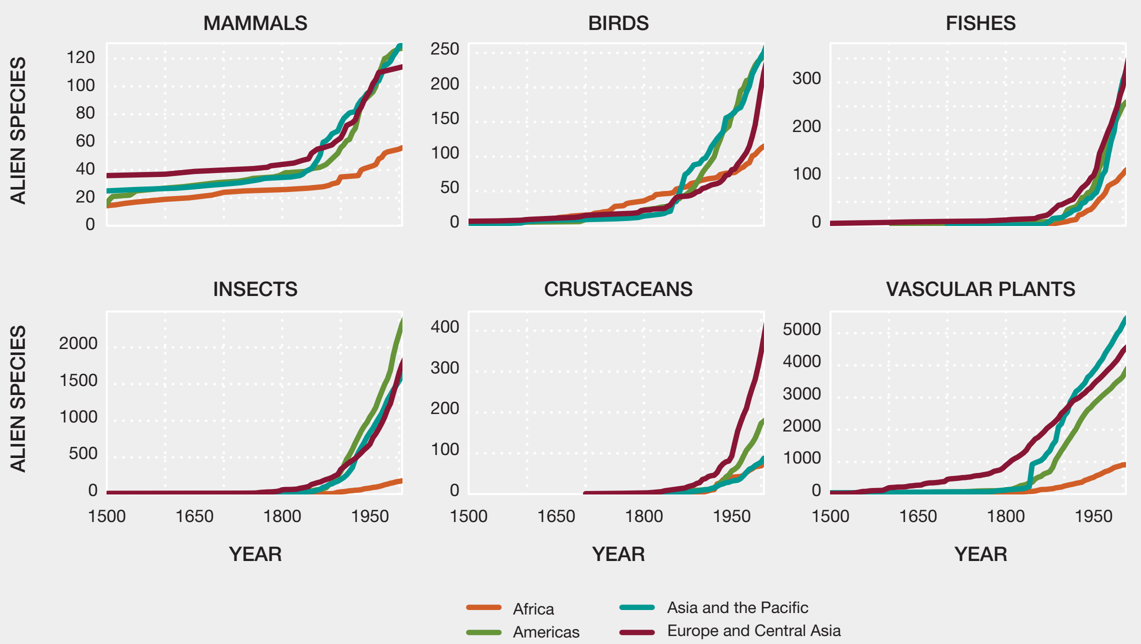

Figure 2 26 **Trends in numbers of established alien species across IPBES regions.**

The panels show cumulative numbers of established alien species for different taxonomic groups. Numbers shown underestimate the actual extent of established alien species occurrences due to a lack of data (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

2.4.1 Overview of trends and status by IPBES regions

Trends

The number of established alien species records has increased for all taxonomic groups and for all IPBES regions since 1500 with particularly steep escalations observed after 1800 **(Figure 2.26)**. Before 1800, the number of records is particularly low for insects and crustaceans. However, this is likely because of the lack of data, which is particularly common for invertebrate groups (**section 2.3.1.11**). Likewise, the comparatively high numbers of established alien species observed for Europe and Central Asia is likely influenced by the higher availability of records for Europe and biases in the underlying database. Nonetheless, no saturation of established alien species is observed for any region (Seebens, Essl, *et al.*, 2017).

Status

Across taxonomic groups, vascular plants provide the by far largest contribution to global established alien species numbers, followed by insects and fishes **(Table 2.19)**. For many taxonomic groups, all IPBES regions except Africa report similar numbers of established alien species **(Table 2.19)**. For instance, the numbers of alien vascular plant species reported for the Americas, Asia and the Pacific, Europe and Central Asia are comparable in their range, while the numbers for Africa are much lower. Similar patterns are observed for alien bird and fish species. On the other hand, algae show a different pattern with Europe and Central Asia harbouring the highest established alien species numbers, followed by the Americas, Asia and the Pacific, and Africa. However, this pattern may be influenced by variation in research intensity around the world. **Box 2.6** also presents an overview of alien and invasive alien species on land managed by Indigenous Peoples and local communities.

Table 2 19 **Numbers of established alien species across IPBES regions.**

Numbers of established alien species can vary depending on data sources. For mammals, birds, and vascular plants, ranges of values indicate variation among databases (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this table is available at https://doi.org/10.5281/zenodo.7615582

	Africa	Americas	Asia and the Pacific	Europe and Central Asia	Total
Mammals	30-80	83-164	97-163	72-164	197-368
Birds	121-133	249-287	287-336	221-630	495-877

Box 2 4 Protected areas: A global assessment of trends and status of alien and invasive alien species.

Protected areas around the world are crucial for preserving and sustaining biodiversity, ecosystem processes and human well-being (Gaston *et al.*, 2008; Naughton-Treves *et al.*, 2005). Increasingly, these areas are being threatened by numerous drivers of change in nature that are challenging the effective management of over 200 thousand protected areas globally (Osipova *et al.*, 2017; UNEP-WCMC *et al.*, 2021). Biological invasions constitute a major threat to protected areas (Goodman, 2003; Osipova *et al.*, 2017; Pyšek, Hulme, *et al.*, 2020; Schulze *et al.*, 2018), a concern that dates back to the 1860s (Foxcroft *et al.*, 2017).

Seminal work on invasions in terrestrial protected areas carried out during the Scientific Committee on Problems of the Environment (SCOPE) project in the 1980s found that all 24 studied terrestrial protected areas faced challenges from invasive alien species and that invasions were not only an issue within disturbed sites (Mooney *et al.*, 2005; Usher, 1988), but also in relatively undisturbed nature reserves. The SCOPE report also found that islands faced higher threats than mainland areas, that there was an inverse relationship between protected area size and the number of introduced species in arid land and chaparral biomes, and that there was positive correlation between number of human visitors and the presence of invasive alien species (Usher, 1988). In a study that revisited 21 of the originally studied protected areas and compared how the status of biological invasions has changed over the last 30 years, Shackleton *et al.* (2020) found that of all the taxa analyzed, invasive plants pose the greatest continued threat, and their numbers have increased in 31 per cent of the protected areas. Mammal invasions now represent a lesser threat due to effective management in many protected areas, with fewer invasive alien mammals now listed in 43per cent of protected areas. Invasions by amphibians, reptiles, and fish have remained fairly stable over the past three decades (R. T. Shackleton, Foxcroft, *et al.*, 2020). The limited number of study sites included were biased towards mainland United States and Africa making regional comparisons and trends hard to meaningfully assess. More comprehensive global assessments using similar methods would address a major knowledge gap and better evaluate status and change globally providing important information for international policy (**Glossary**) mandates.

The subsequent uptake of coordinated global academic projects on protected areas has been limited, particularly for marine systems leaving many knowledge gaps on the status of invasive alien species in protected areas and the broad-scale status trends. According to Shackelton *et al.* (2020) there is a lack of data on freshwater invertebrates, marine species, and other taxa creating a taxonomic bias in invasion science. However, some review and synthesis work (e.g., Foxcroft *et al.*, 2013, 2017; X. Liu *et al.*, 2020; R. T. Shackleton, Bertzky, *et al.*, 2020; R. T. Shackleton, Foxcroft, *et al.*, 2020; see above) has strengthened information on the current status and key trends of invasive alien species in protected areas globally, but each effort has limitations and greater coordination on taxa and management is needed.

In "Plant invasion in Protected Areas", Foxcroft *et al.* (2013) identified and illustrated key impacts of invasive alien species and outlined some mechanisms of invasion in protected areas and contributed to assessing management interventions, helping to synthesize and outline both the status of invasive alien species in protected areas and key knowledge gaps. Drawing on 14 case studies from around the world that included information from over 135 protected areas globally, the authors detailed assessments and baseline information and elucidated regional patterns and threats. One surprising result was that while intentional introductions of invasive alien species into protected areas have been assumed to be low, this is not the case. This point is further supported by Foxcroft *et al.* (2008) and Toral-Granda *et al.* (2017). Authors show that even Arctic regions now face challenges from invasive alien species (Shaw, 2013). Very few protected areas globally have good baseline information and only a handful of well-studied protected areas have robust invasive alien species lists available. Regionally there are also large differences in monitoring and information. The United States, Oceania, and some parts of Europe have more information than other regions. For example, J. A. Allen *et al.* (2009) highlight that there are over 7.3 million ha of invasions in 218 protected areas in the United States, with over 20,300 distinct invasion clusters by over 3,750 invasive alien species. In Central and Western Europe, Braun *et al.* (2016) collected and collated data on 53 invasive plant species in 46 large, protected areas finding that in 86 per cent of protected areas at least one of the 46 target invasive plants was present, and that 80 per cent of protected areas did conduct some form of management. The mean number of invasive plants was 11.2 per protected area, however, most of them only managed a mean 4.3 species accounting for around 3 per cent of park budgets. Interestingly, park size and age had no effect on invasive alien species presence or management.

A review on plant invasion science research in protected areas (Foxcroft *et al.*, 2017) yielded some important information on trends and status highlighting key advances in invasion science in protected areas, important policies starting with the Convention Relative to the Preservation of Fauna and Flora in their Natural State in 1933, the twelfth meeting of the Conference of the Contracting Parties to the Ramsar Convention on Wetlands in 2015, and 13 other important policy support mechanisms in-between. This review also identified 59 of the most common invasive plants in protected areas: eight species (*Arundo donax* (giant reed), *Pontederia crassipes* (water hyacinth), *Lantana camara* (lantana), *Melia azedarach* (Chinaberry), *Poa annua* (annual meadowgrass), *Psidium guajava* (guava), *Robinia pseudoacacia* (black locust), and *Rumex acetosella* (sheep's sorrel)) occur in more than

Box 2 4

150 protected areas globally. The review showed that North America and Europe dominate work on plant invasions in protected areas globally, followed by Africa and Oceania, with very limited knowledge from other world regions, particularly in South America and Asia.

More recently, key syntheses have assessed the trends and status of invasions in terrestrial and inland waters protected areas globally (e.g., X. Liu *et al.*, 2020; R. T. Shackleton, Bertzky, *et al.*, 2020). X. Liu *et al.* (2020) assessed the establishment of 894 terrestrial alien vertebrates and invertebrates in almost 200 thousand protected areas globally and found that very few (over 10 per cent) of protected areas harbour established alien animals, but the majority (89–99 per cent) have an established population of at least one alien animal species within 10-100 km from their borders. There are 520 alien animal species in protected areas globally, the most common being birds (4.7 per cent of the protected areas, 252 species), followed by mammals (3.7 per cent, 91 species), invertebrates (2.2 per cent, 63 species), amphibians (0.5 per cent, 48 species) and reptiles (0.4 per cent, 66 species) (X. Liu *et al.*, 2020). X. Liu *et al.* (2020) highlight that larger protected areas, those more recently inscribed, and those with a higher protection status were surprisingly more prone to a higher richness of alien animals. Furthermore, X. Liu *et al.* (2020) found that globally, protected areas in some regions and biomes are more at risk from alien animals, including birds, mammals, invertebrates, amphibian and reptiles; particularly in (sub)tropical Pacific and Caribbean Islands and New Zealand, as well as temperate mixed forests, savannas, and grasslands in the United States, western Europe, and Australia. Additionally, X. Liu *et al.* (2020) highlight that Africa and Asia are most often donors of alien animal species with North America and Europe being key recipient areas **(Figure 2.27)**.

Shackleton, Bertzky, *et al.* (2020) assessed the status of biological invasions and their management in 241 natural and mixed World Heritage Sites globally and found that just over half (53 per cent) were explicitely or implicitly reported to be threatened by invasive alien species through formal IUCN/ United Nations Educational, Scientific, and Cultural Organization (UNESCO) monitoring initiatives. It is suspected that this number is much higher. Almost 300 different invasive alien species were reported to be invading World Heritage Sites. However, detailed information through UNESCO and IUCN monitoring programmes yielded limited and inconstant information so broad-scale trends were hard to assess. To overcome this a seven-step monitoring and reporting framework was developed to better collate data moving forward. This includes: (i) evaluating pathways, (ii) compiling inventories of species, (iii) identifying current impacts, (iv) reporting on management, (v) predicting future threats and management needs, (vi) identifying knowledge gaps, and (vii) assigning an overall threat level. This framework could easily be used in all categories of protected areas and could be a priority moving forward to improve monitoring and understanding.

Marine protected areas *"… as oases of biodiversity, serve as the last rampart against these invasive alien species"* (Francour *et al.*, 2010). Alas, this is a wishful premise and biological invasions are having a large impact on marine protected areas worldwide. Large-scale global syntheses on the topic of marine invasions and protected areas are lacking, however, research on certain areas and species has provided important insights which are summarized here. Generally, European oceans and seas, as well as northern Atlantic and Pacific oceans, are most at threat from marine invasive alien species (M. J. Costello *et al.*, 2021). More specifically, 53 marine alien species, nearly all newly reported or newly recognized as introduced, were recently documented in the Galápagos Marine Reserve, which is a large, biologically diverse and remote protected area (Carlton *et al.*, 2019). Surveys of rocky reef fish assemblages conducted since 2000 in Mediterranean marine protected areas showed no differences in invasive fish density and biomass as compared to adjacent unprotected areas. In the south and eastern Mediterranean Sea invasive alien species have higher species richness and biomass as compared to local fish biota (D'Amen & Azzurro, 2020; Galil, 2017; Giakoumi *et al.*, 2019; Guidetti *et al.*, 2014). Indeed, a recent assessment in protected areas along the Mediterranean coast of Turkey identified 289 alien vertebrates, invertebrates and algae (Bilecenoğlu & Çınar, 2021). The reduction of protected areas to nursery sites for certain invasive alien species is most acute in the South-eastern Mediterranean but occurs throughout the sea and in the adjacent Atlantic (Blanco *et al.*, 2020; Cacabelos *et al.*, 2020; Mazaris & Katsanevakis, 2018; Wangensteen *et al.*, 2018). From a species point of view, the spread of the venomous Indo-Pacific lionfish, *Pterois volitans* (red lionfish) and *Pterois miles* (lionfish), across the tropical western Atlantic and the Caribbean Sea was swift, not sparing marine protected areas, including large, established, well-cared for and remote ones (e.g., Florida Keys National Marine Sanctuary, United States; Flower Garden Banks National Marine Sanctuary, United States; The Parque Nacional Arrecife Alacranes, Mexico) (Johnston *et al.*, 2013; López-Gómez *et al.*, 2014; Ruttenberg *et al.*, 2012), illustrating the threat that invasive marine species pose to conservation. Poor management and the lack of effective policies have been nullifying conservation goals in marine protected areas in regions exposed to biological invasions (Bilecenoğlu & Çınar, 2021; B. Galil, 2017; Mazaris & Katsanevakis, 2018; **Chapters 5** and **6**).

Foxcroft *et al.* (2017) mention three key needs to better understand the current status of biological invasions and their management in protected areas globally and to better assess key trends. These include (i) establish a global working group to better coordinate research, (ii) develop standardized protocols and tools for large-scale and long-term monitoring of invasive alien species in protected areas globally, and (iii) better account for and respond to different socioecological contexts in research and management. Importantly, many regions of the world have limited baseline and empirical evidence concerning biological invasions and their management making this fundamental research crucial.

Box 2 4

The collection of baseline data is increasingly being conducted in data poor areas (e.g., Bhatta *et al.*, 2020; Foxcroft *et al.*, 2017; Padmanaba *et al.*, 2017), but more is needed. Furthermore, improved monitoring and assessment globally is important to answer long-standing and disputed questions relating to invasions in protected areas. For example, whether or not protected areas impose biotic resistance (**Glossary**) against invasions (Meiners & Pickett, 2013). Some evidence suggests protected areas act as a barrier, or refuge, against invasions (Ackerman *et al.*, 2017; Foxcroft, Jarošík, *et al.*, 2010; Gallardo *et al.*, 2017), but other studies show the contrary (Byers, 2005; Holenstein *et al.*, 2021; Klinger *et al.*, 2006). Further work drawing on a multitude of taxa in different socioecological systems is needed to fully understand the role of protected areas in invasions, which is likely to differ by taxa and environmental settings.

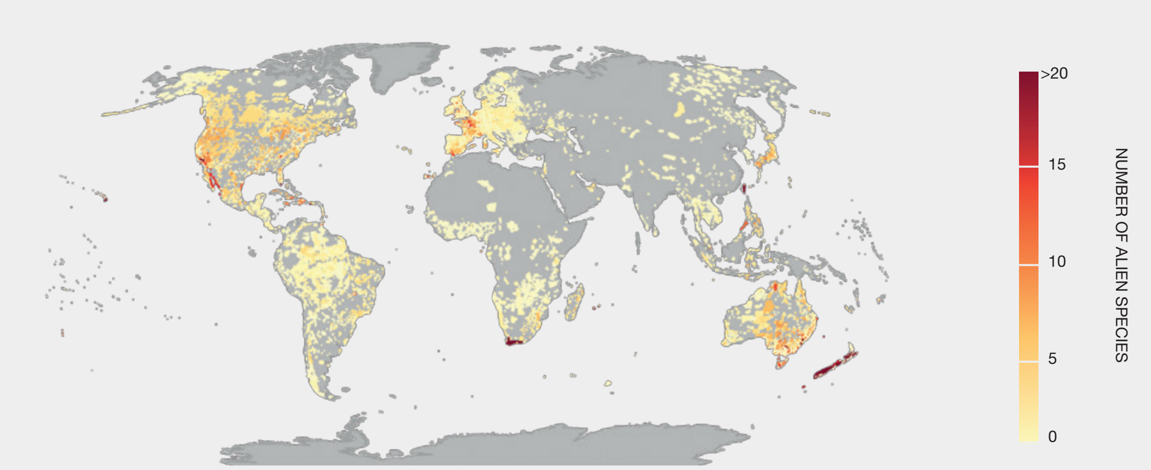

Figure 2 27 **Numbers of established alien vertebrate species per terrestrial protected area.**

Among the top 50 protected areas, 32 per cent are located in New Zealand, 26 per cent in Taiwan, Province of China, 16 per cent in the United States (mostly on Hawaii), 12 per cent in Great Britain and 6 per cent on Réunion. Adapted from X. Liu *et al.* (2020), https://doi.org/10.1038/s41467-020-16719-2, under license CC BY 4.0.

Box 2 5 **Islands: A global assessment of trends and status of alien and invasive alien species.**

One-quarter of the countries in the world are islands or groups of islands, and over two-thirds of all countries include islands (Russell & Kueffer, 2019). Taken together, the Earth's islands represent 5.3 per cent of the total land surface (Global Islands Network, 2021; Tershy *et al.*, 2015). Because of their very high rates of endemism (9.5 and 8.1 times higher than continents for vascular plants and vertebrates, respectively), and with over 20 per cent of the world's terrestrial species, islands are considered centres of biodiversity (Kier *et al.*, 2009). As a result, 10 of the 35 world's biodiversity hotspots (i.e., regions where biodiversity is both the richest and the most threatened (Mittermeier *et al.*, 2011) are entirely, or largely consist of, islands (Bellard *et al.*, 2014). Globally, islands represent concentrated regions of biodiversity loss in the past and present, and this trend is predicted to continue in the future (Russell & Kueffer, 2019; Whittaker & Fernández-Palacios, 2006).

Islands harbour some of the highest numbers of established alien species (Dawson *et al.*, 2017; Essl *et al.*, 2019), particularly small and remote tropical and sub-tropical islands with high numbers of invasive alien plants per unit of surface (Pyšek, Pergl, *et al.*, 2017), a pattern that holds across taxonomic groups (Moser *et al.*, 2018; Turbelin *et al.*, 2017). This is especially acute in former European island colonies with long histories of repeated species introductions (Turbelin *et al.*, 2017). Furthermore, nearly 50 per cent of all species at risk (**Glossary**) of extinction on the IUCN Red List are found on islands and species on islands are more likely to be threatened by biological invasions (almost three-quarters of threatened species; Leclerc *et al.*, 2018). While all threats interact on islands to cause declines in native species abundance, biological invasions consistently lead to the extinction of insular populations, particularly through predation and disease (Russell & Kueffer, 2019; **Chapter 4**, **section 4.3.1.1**). However,

Box 2 5

particularly independent small island developing states (SIDS) and island territories with dependencies on larger continental economies (Blackburn *et al.*, 2016; Meyerson & Reaser, 2003; Reaser & Meyerson, 2003; Russell *et al.*, 2017) have few resources for invasive alien species research, management, cooperation, and capacity-building (Reaser & Meyerson, 2003; Veitch *et al.*, 2019).

Trends

Temporal trends of biological invasions on islands can be classified into three distinct periods with contrasting dynamics; first contact (Indigenous Peoples and local communities), modern history (1500), and the contemporary twentieth century onwards era (Keppel *et al.*, 2014; Russell & Kueffer, 2019; **Figure 2.28**). In the first period, island syndromes (Wroe *et al.*, 2006) and the lack of refugia on small islands made insular species more vulnerable to biological invasions than continental species (Wroe *et al.*, 2006). The second period corresponds to the “Age of Discovery”, the timing of which in different parts of the world coincided with colonization of islands by Europeans (Russell & Kueffer, 2019). During this period, unintentional and intentional (and sometimes repeated) introductions of many animals and plants were facilitated by the establishment of regular shipping lines (Seebens *et al.*, 2013). This led to successful invasions by a large number of species on many islands of various ecosystem types (Russell & Kueffer, 2019). The third period is associated with globalization that included a distinct increase in world trade, migration, and tourism, all of which affected islands worldwide. The emergence and rise of rapid international transit increased substantially both the diversity of introduction vectors and pathways (Hulme, 2009, 2021; Meyerson & Mooney, 2007), and the associated number of these introductions (van Kleunen *et al.*, 2015). The number, frequency, and geographic origin of biological invasions to and among islands also increased with time, following the growth of human populations on these islands (both residents and tourists), as exemplified by the Galapagos (Toral-Granda *et al.*, 2017). At the same time, awareness was rising, and more research was underway to detect and report new species. Other important predictors for established alien species on islands are the existence of military bases or paved airfields (Denslow *et al.*, 2009).

Most introduced species on islands today only occupy a small portion of their final predicted range and are thus likely to expand further (M. J. B. Dyer *et al.*, 2018; Trueman *et al.*, 2010). In addition, more species from both the existing pool of alien species and those species not currently introduced outside their native range will continue to colonize and establish on islands in the future (Bellard *et al.*, 2017). Islands are also disproportionately vulnerable to climate change which may increase the rate of establishment and spread of many invasive alien species on islands (X. Li *et al.*, 2020). More frequent climate-induced disturbances (e.g., flooding, treefall, and landslides caused by tropical cyclones) and/or droughts increase the invasibility of native ecosystems affecting, for instance, the structure of island forests (Boehmer, 2011; Ehbrecht *et al.*, 2021; Pouteau & Birnbaum, 2016; Wyse *et al.*, 2018).

The accumulation rate of established alien species on islands is not slowing and the future invasive alien species will differ in type from species that have invaded islands in the past. These emerging invasive alien species include groups such as microorganisms and pathogens, as well as reptiles from the pet trade (Apanius *et al.*, 2000; Russell & Kueffer, 2019), which will likely lead to new species interactions with both direct and indirect ecological consequences (Forey *et al.*, 2021; J.-Y. Meyer *et al.*, 2021). In the future, the vectors and pathways of biological invasions are predicted to further evolve and to keep interacting with other drivers of change in nature, such as climate change (Russell *et al.*, 2017), and will continue to be of great concern for biodiversity conservation (Lenzner *et al.*, 2020; S. Taylor & Kumar, 2016). For instance, climate-induced forest decline is likely to increase the vulnerability of Pacific Island rainforests to invasive alien plants (Boehmer, 2011; Mertelmeyer *et al.*, 2019) and facilitate invasional meltdowns (Minden *et al.*, 2010).

Status

Most islands are affected by biological invasions with insular ecosystems being the recipients of 80 per cent of documented bird and mammal introductions (Ebenhard, 1988). At least 65 major island groups have been invaded by *Felis catus* (cat) (Atkinson, 1989) and over 80 per cent of all major island groups have also been invaded by *Rattus* spp. (rat) (Atkinson, 1985). If plants and invertebrates are included in assessments, biodiversity is most severely affected by biological invasions in the Pacific and Atlantic insular regions (Leclerc *et al.*, 2018). For plants, 26 per cent (82 islands) of islands covered in the GloNAF database harbour more established alien than native species (Essl *et al.*, 2019). The identity of invasive alien species and their impacts differ by region, island type, and associated ecosystems, but the cumulative pattern of impacts is consistent across world regions (Leclerc *et al.*, 2020).

Across SIDS, 8,668 presence records for 2,034 potential invasive alien species have been registered, 76 per cent of which are plants, 23 per cent animals, and 1 per cent fungi, chromists, viruses, bacteria, and protozoa (Russell *et al.*, 2017). Over half (53 per cent) of these species were identified as invasive alien species on at least one SIDS, while information was often lacking for the remaining species (Lenz *et al.*, 2021). Long-distance transportation by ship and plane dominates invasive alien species pathways to islands, distinguishing islands from continents and natural colonization in rate and type (Hulme *et al.*, 2008), such as for *Anolis* spp. (anole lizards) on Caribbean islands (Helmus *et al.*, 2014). Only one study has focused on plant invasions in urban environments of SIDS (Lowry *et al.*, 2020). Given rapid changes expected in Pacific country urban areas in coming decades, it is a critical to fill this gap (ADB, 2012).

Box 2 5

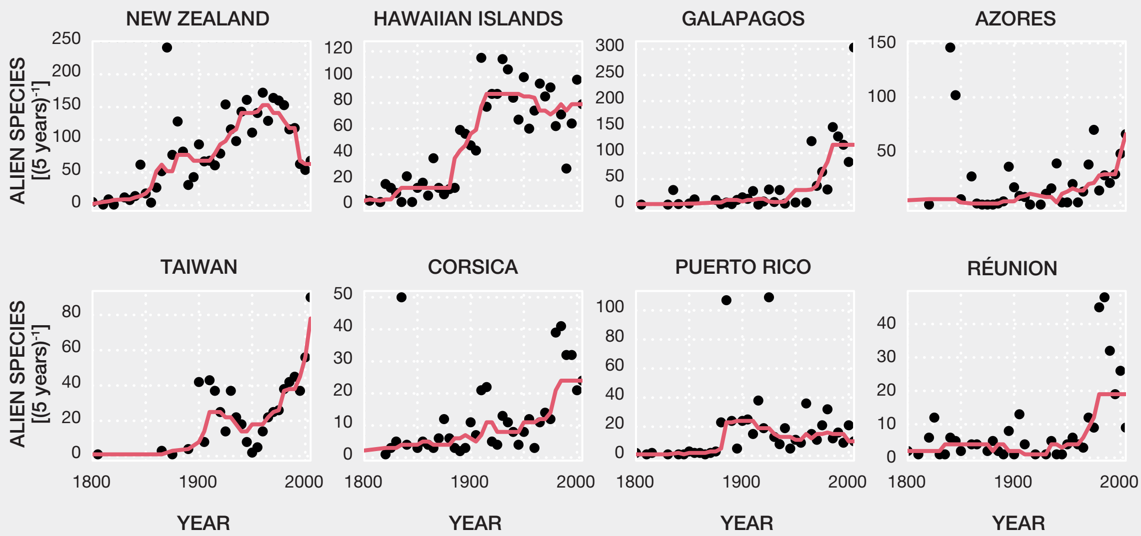

Figure 2 28 **Trends in numbers of established alien species for selected islands.**

The panels show numbers of established alien species per five-year intervals for those islands with the highest numbers of recorded established alien species. Numbers shown underestimate the actual extent of alien species occurrences due to a lack of data. Smoothed trends (lines) are calculated as running medians (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Box 2 6 Land managed, used or owned by Indigenous Peoples and local communities: A global assessment of trends and status of alien and invasive alien species.

Indigenous Peoples and local communities (i.e., typically ethnic groups who are descended from and identify with the original inhabitants of a given region) manage or have tenure rights over a large area of land. For Indigenous Peoples only, it is estimated that they manage or have tenure rights for at least 28 per cent of the total land area worldwide (Garnett *et al.*, 2018). Their land (hereafter called "Indigenous lands") intersects with 40 per cent of the world's protected areas and hosts higher amounts of natural areas compared to other lands (Garnett *et al.*, 2018). Although Indigenous lands are often less inhabited and more remote than other lands, they do not escape anthropogenic pressures. It is unsurprising to find many alien and invasive alien species on lands managed by Indigenous Peoples and local communities and indeed has been frequently reported from such lands all over the world (Gautam *et al.*, 2013; Kannan *et al.*, 2016; Ksenofontov *et al.*, 2019; Miranda-Chumacero *et al.*, 2012; Thorn, 2019). To date, no study has investigated the distribution of alien and invasive alien species on Indigenous lands.

The following analysis was conducted to deepen the understanding about the distribution of alien and invasive alien species on Indigenous land. As described in **section 2.1.4**, occurrences of populations of more than 17,000 established alien species worldwide were obtained using occurrence records provided by GBIF and the Ocean Biodiversity Information System (OBIS). These point-wise occurrences were integrated with a spatial layer of land managed, used or owned by Indigenous Peoples (Garnett *et al.*, 2018) to determine the total number of established alien and invasive alien species recorded on Indigenous lands.

This analysis revealed that, in total, 6,351 established alien species have been recorded on Indigenous lands, which is 34 per cent of all established alien species recorded worldwide in this data set. The number of invasive alien species according to the GRIIS database (Pagad *et al.*, 2022) amounts to 2,355 (56 per cent of the total number globally) on these lands, although it could not be determined whether the invasive alien species pose any impact on these lands (see **Chapter 4**, **section 4.6** for a detailed assessment of impacts by Indigenous Peoples and local communities). The number of established alien species recorded on Indigenous lands is highly correlated with the total number of established alien species of the same

Box 2 6

country (t-test: t=12.8, df=77, $p<0.001$, r=0.82). That is, in countries with high numbers of established alien species, those numbers are also high on Indigenous lands. However, the number of established alien species recorded on Indigenous land is on average consistently lower compared to those numbers recorded on other lands also after taking area into account **(Figure 2.29)**. Hotspots of occurrences with high established alien species numbers on Indigenous lands were found all over the world but particularly in Australia (2,624 alien species), United States (1,719), Mexico (746), Sweden (690) and Russia (650). The same sequence applies to invasive alien species numbers, although at a lower magnitude: Australia (1,172 invasive alien species), United States (691), Mexico (481), Sweden (441), and Russia (436) **(Figure 2.29)**.

An analysis of the trends of alien and invasive alien species on Indigenous lands is currently missing due to a lack of data, but it seems very likely that the number of established alien species on Indigenous lands increased as observed for other regions (**Figures 2.4** and **2.26**) and so are the impacts they cause. A clear knowledge gap exists for information about the trends and status of invasive alien species in coastal waters managed by Indigenous Peoples and local communities.

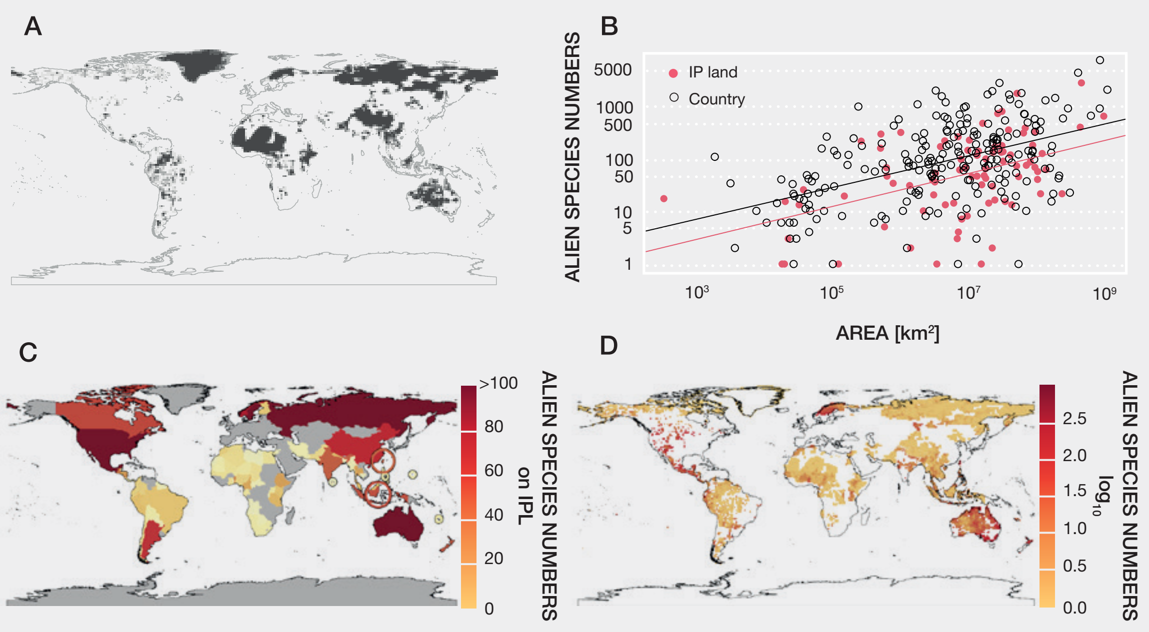

Figure 2 29 **Invasive alien species on Indigenous People's land.**

A data management report for this figure is available at https://doi.org/10.5281/zenodo.7615582

2.4.2 Trends and status of alien and invasive alien species in Africa

This section reports on the trends and status of established alien species of Africa for animals (**section 2.4.2.1**), plants (**section 2.4.2.2**), microorganisms (**section 2.4.2.3**), and islands (**section 2.4.2.4**), and provides an overview of data and knowledge gaps (**section 2.4.2.5**). A description of IPBES regions and sub-regions including a spatial representation is provided online (IPBES Technical Support Unit On Knowledge And Data, 2021) and in **Chapter 1**, **section 1.6.4**.

2.4.2.1 Animals

Trends

The first alien mammal species to arrive in Africa were probably domesticated bovids, pigs, cats, and dogs during the spread of agriculture, followed by commensal rodents, mostly limited at present to anthropized and densely populated areas (Long, 2003). Other introductions took place on the western coast of North Africa where *Mustela nivalis* (weasel) was likely a rodent biocontrol agent, *Apodemus sylvaticus* (long-tailed field mouse), a stowaway, and *Bubalus bubalis* (Asian water buffalo) livestock. More introductions began in the twelfth century such as *Suncus murinus* (Asian house shrew) as a stowaway. A rapid increase of mammal introductions during the nineteenth and twentieth centuries was mainly due to hunting, ecotourism, and the pet trade pathways (Biancolini *et al.*, 2021). Acclimatization societies were very active in South Africa and carried out numerous bird and mammal introductions to "improve" the aesthetic of the South-African landscape from a European point of view after the mid-1800s (B. W. van Wilgen *et al.*, 2020). In the last century, increasing global trade combined with the advent of the game-farming industry and ecotourism resulted in a striking rise in introductions of alien vertebrates and invertebrates (Picker & Griffiths, 2017; B. W. van Wilgen *et al.*, 2020).

As for other taxa, African regions with the earliest records of established alien species tend to have higher numbers of established alien species. For fishes, particularly high numbers of established alien species were recorded in North Africa due to Lessepsian invasion of marine species through the Suez Canal and to its closer socio-economic relationship with Europe **(Figure 2.30)**. Indeed, the number of alien fish in North Africa accelerated markedly after 1869 when the Suez Canal opened (Galil, 2000). In South Africa an increasing trend in established alien species detections is indicated as the number of marine alien species reported has increased from 15 (Griffiths *et al.*, 1992) to 95 established alien species (T. B. Robinson *et al.*, 2020). Although there is no doubt that new species are being introduced, other factors are also contributing to the increase in introductions, such as deeper historical analyses of past introductions (Mead *et al.*, 2011), varying levels of available taxonomic expertise across time (Griffiths *et al.*, 2009), and increased research efforts on underrepresented taxa or in under-studied ecosystems (T. B. Robinson *et al.*, 2020).

With the exception of plants, the introduction of alien species into freshwater systems in Africa has largely been

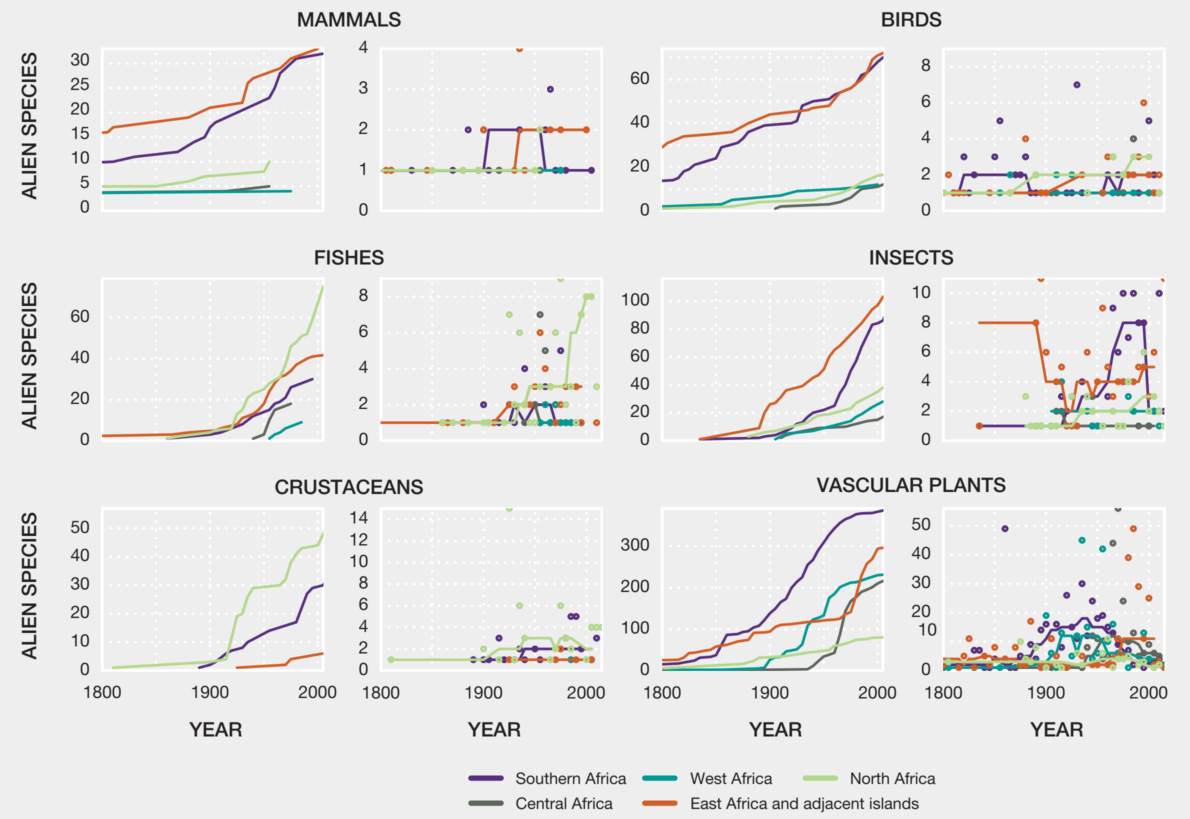

Figure 2 30 **Trends in numbers of established alien species for Africa.**

Panels show cumulative numbers (left panels) and numbers of established alien species per five-year intervals (right panels). Numbers here underestimate the actual extent of established alien species occurrences due to a lack of data. Lines in right panels indicate smoothed trends calculated as running medians (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582 intentional to enhance ecosystem services and promote nutritional, economic, or recreational values (Gherardi, Britton, *et al.*, 2011; Howard & Chege, 2007; Howard & Matindi, 2003; Munyaradzi & Mohamed-Katerere, 2006; Weyl *et al.*, 2020). However, the outcomes of these introductions were often opposite of the intended purpose, with losses of ecosystem function and services (B. W. van Wilgen *et al.*, 2020). For example, in South Africa the overall rate of alien freshwater animal introductions accelerated sharply after 1880 and generally increased over time, with unintentional introductions of invertebrates playing a relevant role (Weyl *et al.*, 2020). Only freshwater fish introductions underwent a significant decrease after the 1950s due to legislation regulating introductions and decreasing demand for new species for angling (Faulkner *et al.*, 2020). In general, the number of invertebrate introductions to South Africa rose over time (Faulkner *et al.*, 2016), this pattern being reported for freshwater (Weyl *et al.*, 2020), terrestrial (Janion-Scheepers & Griffiths, 2020), and marine invertebrate introductions (T. B. Robinson *et al.*, 2020).

Status

In light of Africa's colonial history, there have been surprisingly fewer introductions of alien mammals than to other regions (Long, 2003). Africa currently harbours 44 established alien mammals from seven orders and 18 families (Biancolini *et al.*, 2021). The most represented orders are Cetartiodactyla (17 species), Primates (9), Rodentia (7), and Carnivora (6). These alien species are mainly concentrated along the western Mediterranean coast, South Africa, and Madagascar and originate from within Africa (16), Europe and Central Asia (8), the Americas (8), and Asia and the Pacific (1). The pathways most frequently involved in alien mammal establishment were hunting (15 cases), the pet trade (10), farming (8), and conservation (8) (Biancolini *et al.*, 2021). Escaped game species are a growing problem in South Africa where numerous game-farming estates specialize in alien mammals (D. Spear & Chown, 2009; B. W. van Wilgen *et al.*, 2020). The status of these species is often classified as "within country" instead of alien as they are native to the geopolitical unit of South Africa. Nevertheless, they have been translocated outside of their historical native range (B. W. van Wilgen *et al.*, 2020). For example, *Tragelaphus angasii* (nyala), an antelope native to Africa, is now spreading outside its native range and possibly competing with native herbivores (Biancolini *et al.*, 2021; Downs & Coates, 2005). Of the 44 established alien mammal species, 27 (61.4 per cent) have ecological impacts (Biancolini *et al.*, 2021). For example, *Suncus murinus* (Asian house shrew), one of the "100 of the worst invasive alien species," has a patchy distribution from Madagascar to Egypt, and potentially has overlooked impacts on native plants, invertebrates, and small vertebrates through predation or competition (GISD, 2019). However, some alien mammal introductions were considered benign and carried out for conservation, such as for four primates threatened by habitat loss and translocated from their native mainland range to insular protected areas: *Daubentonia madagascariensis* (aye-aye), *Eulemur albifrons* (white-headed lemur), *Varecia variegata* (black-and-white ruffed lemur), and *Piliocolobus kirkii* (Zanzibar red colobus) (Andriaholinirina, Baden, Blanco, Chikhi, Cooke, *et al.*, 2014; Andriaholinirina, Baden, Blanco, Chikhi, Zaramody, *et al.*, 2014a, 2014b; Biancolini *et al.*, 2021; Davenport *et al.*, 2019).

Most alien bird species in Africa are found in the far south of the continent, although *Corvus splendens* (house crow) is distributed from Sudan to South Africa along the east coast. Most alien species are a legacy of Africa's European colonial past, such as *Fringilla coelebs* (chaffinch) and *Sturnus vulgaris* (common starling) in South Africa. Other notable alien birds in Africa are *Acridotheres tristis* (common myna) and *Passer domesticus* (house sparrow) (E. E. Dyer, Redding, *et al.*, 2017).

The number of alien reptile introductions in Southern Africa has risen in recent decades, but there is limited information about the trends elsewhere in this IPBES region (Capinha *et al.*, 2017; Kraus, 2009; Seebens, Blackburn, *et al.*, 2017; Van Wilgen *et al.*, 2010). For amphibians, many species have been translocated within Southern Africa (Measey *et al.*, 2017).

In contrast to most other taxa, the highest numbers of alien fishes and crustaceans – many marine – are found in North Africa **(Table 2.19)**. East Africa and its adjacent islands have the second highest numbers of alien fishes likely because of introductions in the many lakes of the Rift Valley area, including the three largest, Lakes Victoria, Tanganyika, and Malawi, that have high alien fish population densities and associated fisheries important for subsistence (Pitcher & Hart, 1995). In these lakes and large artificial reservoirs, *Lates niloticus* (Nile perch), *Limnothrissa miodon* (Tanganyika sardine), and tilapias are the main introduced fish species (Craig, 1992; Pitcher & Hart, 1995). Tilapias are tropical fishes in the family Cichlidae (mainly *Oreochromis, Tilapia*, and *Sarotherodon* spp.) that are native to parts of Africa and the Middle East but have been introduced globally mostly for aquaculture and human consumption (Canonico *et al.*, 2005). A total of 21 alien freshwater fishes have established in South Africa, and others have been translocated (Ellender & Weyl, 2014; Weyl *et al.*, 2020). The high number of alien fishes in Southern Africa is likely influenced by greater research efforts compared to other African regions. No alien marine fish have been reported for South Africa yet (T. B. Robinson *et al.*, 2020). Many freshwater fish have been intentionally introduced across Africa in order to maintain or increase fishery yields, enhance sport fisheries, or support the aquaculture industry (Darwall *et al.*, 2011; Ellender & Weyl, 2014; García *et al.*, 2010; Máiz-Tomé *et al.*, 2018).

By 2011, sixteen alien fish species had been introduced to Central Africa (Brooks *et al.*, 2011). In Madagascar, one quarter of the freshwater fish fauna consists of alien species, with 26 alien species present, of which at least 24 were deliberately introduced during the 1950s (Šimková *et al.*, 2019). On Île de la Réunion, six species of fish (and one decapod crustacean, *Macrobrachium rosenbergii* (giant freshwater prawn)) were introduced by 2002, but only four were established by then (Keith, 2002).

Notably, no review on introductions of freshwater alien species in Africa has been produced so far except for crayfish (Madzivanzira *et al.*, 2021). In other cases, current information is available only for specific taxa and has been only comprehensively and recently assessed for South Africa (M. P. Hill *et al.*, 2020; Weyl *et al.*, 2020; Zengeya & Wilson, 2020). Available data show that South Africa hosts 51 alien freshwater invertebrates and 32 alien freshwater fish, while 926 alien plant species are reported, and freshwater and terrestrial species are not distinguished (Zengeya & Wilson, 2020). Seventy-seven alien freshwater animals, largely dominated by fishes, molluscs, and crustaceans, are currently established in South Africa, most of which were intentionally introduced (Picker & Griffiths, 2017; Weyl *et al.*, 2020).

Among alien freshwater jellyfish, the cnidarian *Craspedacusta sowerbii* (peach blossom jellyfish) has been recorded in South Africa and potentially Morocco (Oualid *et al.*, 2019; Weyl *et al.*, 2020). Several species of alien molluscs have been recorded in African freshwaters, with 14 species of gastropods reported by 2011, some of which were released for the biological control of the intermediate hosts of schistosomiasis (Appleton, 2003; Appleton & Brackenbury, 1998). Only one alien freshwater bivalve *Corbicula fluminea* (Asian clam) has been recorded in African waters, an introduction probably related to fish stocking (Clavero *et al.*, 2012; Darwall *et al.*, 2011). Nine species of alien crayfish have been introduced to Africa, mostly for aquaculture. Five have established populations in the wild and three have spread widely in specific parts of Africa: *Procambarus clarkii* (red swamp crayfish) in Eastern Africa, *Cherax quadricarinatus* (redclaw crayfish) in Southern Africa, and *Procambarus virginalis* (Marmorkrebs) in Madagascar (Madzivanzira *et al.*, 2021).

Little is known about marine alien species in Africa. The most studied areas are along the South African coast which includes two large marine ecosystems, the Agulhas current in the east and the Benguela current in the west (Mead *et al.*, 2011; T. B. Robinson *et al.*, 2020). The total number of introduced marine species reported is 95, with 59 per cent considered as invasive alien species. A variety of taxa are represented, from the small protists (e.g., *Mirofolliculina limnoriae*) and dinoflagellates (e.g., *Alexandrium minutum*) to the most conspicuous macroalgae, molluscs, crustaceans, bryozoans, and tunicates. Most biological invasions were reported along the Benguela current large marine ecosystem (70 per cent) and alien species inhabit bays, estuaries, and artificial habitats, while only three are widespread and abundant on open rocky shores (the mussels *Mytilus galloprovincialis* (Mediterranean mussel) and *Semimytilus patagonicus*, and the barnacle *Balanus glandula*) (T. B. Robinson *et al.*, 2020). Angola harbours 29 introduced marine species, mostly concentrated in Luanda, the most studied area of the country (Pestana *et al.*, 2017). The most conspicuous and abundant taxa are bryozoans and tunicates, such as *Schizoporella errata* (branching bryozoan) and *Ascidiella aspersa* (European sea squirt), both global invasive alien species.

2.4.2.2 Plants

Trends

The number of established alien plant species in Africa has continually increased for centuries as reported for multiple African countries (Brundu & Camarda, 2013; L. Henderson, 2006; Maroyi, 2012; Senan *et al.*, 2012; Shaltout *et al.*, 2016). Southern Africa has experienced a steady increase in plant alien species numbers during the entire twentieth century, the most rapid rise of all African regions, and appeared to slow down only towards the end of the century **(Figure 2.30)**. In contrast, alien plant numbers in East Africa showed a marked acceleration starting in the final quarter of the twentieth century and have not yet slowed. In North Africa, alien plant numbers increased slowly but steadily towards the end of the nineteenth century. No readily apparent dynamics were detected for West Africa. However, this detected pattern is, to some extent, likely due to more intensive research and better data collected for the Republic of South Africa relative to the rest of the continent (Pyšek *et al.*, 2008; Pyšek, Pergl, van Kleunen, *et al.*, 2020).

Status

Southern Africa has the highest established alien species richness for all taxa (1,139) among all the subregions of Africa **(Table 2.19)**. Seven other countries harbour over 300 established alien plant species: Congo (522), Ethiopia (421), Morocco (410), Mozambique (396), Benin (333), Algeria (328), and Eswatini (315) (D. M. Richardson *et al.*, 2020). Expressed as the proportional contribution of established alien species to the national flora, countries that rank highest in this respect are Chad (12 per cent), Benin (11 per cent), and Eswatini (10 per cent); in South Africa, because of its extremely rich native flora, the contribution of established alien species to the total floristic richness of the country is only 5 per cent. South Africa also has the highest number of invasive alien species (374, D. M. Richardson *et al.*, 2020). *Bidens pilosa* (blackjack, occurring in 61 per cent of all African regions as defined by GloNAF corresponding mostly to countries), *Ricinus communis* (castor bean, 60 per cent), *Senna occidentalis* (coffee senna, 60 per cent), *Catharanthus roseus* (Madagascar periwinkle, 56 per cent), and *Euphorbia hirta* (garden spurge, 54 per cent) occur in more than half of the regions in Southern Africa. The following are the most widely distributed invasive alien plants in Southern Africa: *Lantana camara* (lantana, invasive in 46 per cent of regions), *Tithonia diversifolia* (Mexican sunflower), *Pontederia crassipes* (water hyacinth), *Chromolaena odorata* (Siam weed), *Leucaena leucocephala* (leucaena), *Prosopis juliflora* (mesquite, all invasive in more than 20 per cent of regions), and *Parthenium hysterophorus* (parthenium weed) (D. M. Richardson *et al.*, 2020). Concerning the donor regions of established alien plant species in Africa, the highest numbers were introduced from temperate Asia (19 per cent of all introductions to individual countries), Europe (13.9 per cent), tropical Asia (13.7 per cent), Southern America (13.4 per cent), and Northern America (10.9 per cent). However, 21 per cent of species that are established in African countries were introduced from another country on that same continent (van Kleunen *et al.*, 2015).

Alien tree species have had the greatest impact throughout Africa on biodiversity, water regimes, fire regimes, and ecosystem functioning (D. M. Richardson *et al.*, 2021). Many tree species used in forestry and agroforestry, especially *Eucalyptus* and *Pinus* (Pine), have been introduced throughout Africa, and some shrubs and trees such as *Acacia colei* (parta), *Acacia melanoxylon* (Australian blackwood), *Broussonetia papyrifera* (paper mulberry), *Calliandra houstoniana* (calliandra), *Calotropis gigantea* (yercum fibre), *Dahlia imperialis* (bell tree dahlia), *Ipomoea carnea* (pink morning glory), *Montanoa hibiscifolia* (tree daisy), and *Tecoma stans* (yellow bells) are well established in many parts of the continent (D. M. Richardson *et al.*, 2021). However, relative to *Pinus* and *Acacia*, *Eucalyptus* appears to have had a lower impact. South Africa's Mediterranean shrublands have been severely invaded by numerous alien trees and shrubs, especially species in the genera *Acacia*, *Hakea*, *Leptospermum* and *Pinus* (B. W. van Wilgen *et al.*, 2016). Australian *Acacia* species are actively promoted for agroforestry in other parts of the continent (D. M. Richardson *et al.*, 2004) and higher-lying areas have been heavily invaded by *Acacia melanoxylon* and *Acacia mearnsii* (black wattle), *Pinus patula* (Mexican weeping pine) and *Pinus radiata* (radiata pine). Pines and acacias are extremely invasive in the mountains of southwestern

Table 2 20 **Numbers of established alien species for subregions of Africa.**

For mammals, birds, and vascular plants ranges of values indicate variation among databases (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this table is available at https://doi.org/10.5281/zenodo.7615582

	Central Africa	East Africa and adjacent islands	North Africa	Southern Africa	West Africa	Total

South Africa and in riparian habitats and other biomes (Holmes *et al.*, 2005). Other tree and shrub invaders with impacts include *Acacia dealbata* (acacia bernier), *Acacia decurrens* (green wattle), several *Rubus* (bramble) species, and *Biancaea decapetala* (Mysore thorn). *Azadirachta indica* (neem tree), *Prosopis juliflora* (mesquite), and *Leucaena leucocephala* (leucaena) are abundant invaders along the coastline of much of Africa, preferring hot and humid conditions. *Chromolaena odorata* (Siam weed) is now common in many countries in Central and Southern Africa, being abundant in open savanna grasslands, woodlands, riparian zones, forest gaps, and edges (D. M. Richardson *et al.*, 2021). **Table 2.20** lists the most widespread invasive alien species in Africa according to GRIIS.

Table 2 21 **Top most widespread invasive alien species for Africa.**

The number of regions where the respective species has been recorded and classified as being invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien species rather than their impacts, which is covered in **Chapter 4**. A maximum of three species is shown for each group (see **section 2.1.4** for further details about data sources and data processing). A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

By 2006, a total of 27 major invasive alien aquatic plants had been recorded in African waters, 16 alien to Africa, and 11 native to other parts of the continent (Howard & Chege, 2007). A recent review records the existence of 19 established alien freshwater plants only in South Africa, mainly introduced through trade and hitchhiking *via* boating and angling (M. P. Hill *et al.*, 2020). In South Africa, the most important invasive alien freshwater macrophyte remains *Pontederia crassipes* (water hyacinth), first recorded as established in KwaZulu-Natal in 1910. Four other species are also highly invasive, collectively referred to along with water hyacinth as the "Big Bad Five": *Pistia stratiotes* (water lettuce), *Salvinia × molesta* (kariba weed), *Myriophyllum aquaticum* (parrot's feather), and *Azolla filiculoides* (water fern) (M. P. Hill *et al.*, 2020; **Chapter 4**, **section 4.3.2.2**).

2.4.2.3 Microorganisms

In general, microbial biological invasions are more readily detected in well-surveyed regions, such as Europe, than in less well-surveyed regions, such as Africa, highlighting the importance of monitoring programmes at continental and inter-continental scale (Waage *et al.*, 2008). Fungi, oomycetes, and other microorganisms are poorly studied in most areas of the African continent. While Africa has been a source for several plant, animal, and human diseases (Bryant *et al.*, 2007; Costard *et al.*, 2009; Pretorius *et al.*, 2010), reports of biological invasions across most of Africa have declined over the years, except for South Africa (Zengeya *et al.*, 2020), most likely due to a lack of resources dedicated to this research. Thus, reliable data are scarce and mostly limited to a few well-researched regions, such as the Cape region (Crous *et al.*, 2006) where the introduction and impact of alien fungal species are best documented (Wood, 2017). In South Africa, nine alien pathogenic species are known to attack native plants, while 23 host-specific pathogens of alien plant species have likely been introduced together with their hosts (Wood, 2017). In addition, one fish pathogen, 11 alien saprotrophic species, and 61 species of alien fungi forming ectomycorrhizae have been reported (Wood, 2017). Furthermore, seven host-specific alien pathogens have been introduced for the biological control of invasive alien species (Wood, 2017).

Compared to other IPBES regions, Africa has the lowest number of known alien macrofungi, with 107 species (Monteiro *et al.*, 2020). Of these, 40 per cent belong to Agaricales, 29 per cent to Boletales and 13 per cent to Russulales. The most widespread macrofungi are *Pyrrhoderma noxium, Amanita muscaria* (fly agaric), *Pisolithus albu*s (white dye-ball fungus), *Rhizopogon luteolus* (yellow false truffle), and *Suillus granulatus* (weeping bolete mushroom), having been recorded for 8 or more countries. The highest numbers of alien macrofungi are reported for South Africa (65), Tanzania (25), Morocco (10), and Kenya (10). A number of countries, mainly from the Central African region, have between 1 to 5 known alien species.

2.4.2.4 Islands

Invasive alien species on islands are a major concern in the western Indian Ocean islands, including Comoros, Mauritius, Seychelles, Île de la Réunion, and smaller nearby islands where mammal predators such as cats and rats and plants negatively affect the increasingly disturbed ecosystems (Bonnaud *et al.*, 2011; Kueffer *et al.*, 2004; Russell *et al.*, 2016; Russell & Le Corre, 2009; Tassin & Laizé, 2015). Île de la Réunion is estimated to have over 2,000 alien plant species, with more than 100 of these classified as invasive (e.g., *Leucaena leucocephala* (leucaena), *Hiptage benghalensis* (hiptage), *Ulex europaeus* (gorse, Baret *et al.*, 2006; Soubeyran *et al.*, 2015). Of the 28 island groups, including 68 archipelagos present in the Western Indian Ocean, alien mammals can be found on each group with an average richness of five species per island group (Russell *et al.*, 2016). There are 12 invasive alien mammal species on Île de la Réunion and various combinations of six of them on the nearby Îles Éparses (Russell & Le Corre, 2009). The islands of East Africa are major hubs of alien reptiles and amphibians globally: Mauritius and Île de la Réunion are inhabited by 17 and 15 alien species, respectively (Capinha *et al.*, 2017; Kraus, 2009; Telford *et al.*, 2019). On Socotra, 88 alien plants have been recorded (Senan *et al.*, 2012). The recent invasion of Madagascar by *Duttaphrynus melanostictus* (Asian common toad) and some alien marine biota poses a severe threat to the native biodiversity of this island (Licata *et al.*, 2019; B. M. Marshall *et al.*, 2018). Similarly, the islands off the Western coast of Africa have repeatedly experienced animal invasions. In São Tomé and Principe, invasions began in the 1470s and by the end of the twentieth century, 14 alien mammal species were established on São Tomé and 12 on Principe (Dutton, 1994). Currently, 25 alien and invasive alien animal species are reported for both islands, of that 5 are birds, 2 ray-finned fish, 13 mammals, 4 insects, and 1 gastropod (De Menezes & Pagad, 2020). In Cabo Verde harbour there are 448 introduced plant taxa, equivalent to 60 per cent of the native flora, according to the Cabo Verde Biodiversity Database (Medina *et al.*, 2015). In addition, there are 38 alien and invasive alien animal species, including 4 ray-finned fishes, 2 gastropods and 2 marine invertebrates, 4 reptile species, 6 bird species, 10 mammal species, and 9 insect species (Martinez *et al.*, 2021).

2.4.2.5 Data and knowledge gaps

Although impacts of invasive alien species on Africa's biodiversity and ecosystem services are well known, there are still large gaps in scientific information (Egoh *et* *al.*, 2020; Faulkner *et al.*, 2015). With the exception of South Africa (B. W. van Wilgen *et al.*, 2020), these gaps are apparent in many subregions, particularly in East Africa and adjacent islands, both for units of analysis and many taxonomic groups. The number of documented alien species in many countries may be significantly underestimated as this is a function of information availability, research intensity, and country development status (McGeoch *et al.*, 2010).

For alien mammals, gaps exist for most of the African continent except for areas such as the western Mediterranean coast, South Africa, Madagascar, and adjacent islands. Knowledge of alien amphibians and reptiles is incomplete due to a lack of data (Capinha *et al.*, 2017; García-Díaz *et al.*, 2015; Kraus, 2009; Seebens, Blackburn, *et al.*, 2017; N. J. van Wilgen *et al.*, 2018). These gaps broadly match the distribution of data-deficient native reptile and amphibian species, which suggests a general scarcity of information about the status of reptiles and amphibians in the region (Böhm *et al.*, 2013; Stuart *et al.*, 2008). Further survey efforts in these data-poor areas can be expected to uncover established populations of alien amphibians and reptiles.

One of the main data gaps regarding freshwater invasions in Africa relates to the understanding of their geographical scope, given that most comprehensive reviews have been produced for South Africa only. A large taxonomic bias was also found, with reviews on faunal invasions, particularly fish invasions, or on specific species such as the highly invasive *Pontederia crassipes* (water hyacinth), dominating the literature, and many fewer studies on other taxonomic groups (Coetzee *et al.*, 2019). Thus, the status of alien and invasive alien species presented here certainly underestimates the true number of freshwater invasive alien species present in the region. Increased research could help to better inform the trends and status of freshwater invasive alien species in Africa.

For vascular plants, Africa is geographically covered completely by the GloNAF database (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2015, 2019), providing data on alien plant species in individual countries, but of varying quality (Pyšek, Pergl, *et al.*, 2017) so that information remains scarce in some regions.

Information on the occurrence of alien fungi is missing for many African countries, mainly in North Africa, East Africa, and adjacent islands. The most complete information is available for South Africa, but even here knowledge is considered incomplete (Wood, 2017). The low number of alien macrofungi reported in most countries is likely a consequence of low research intensity and numbers are certainly underestimated.

2.4.3 Trends and status of alien and invasive alien species in the Americas

This section reports on the trends and status of alien species of the Americas **(Figure 2.31, Table 2.21)** for animals (**section 2.4.3.1**), plants (**section 2.4.3.2**), microorganisms (**section 2.4.3.3**), and islands (**section 2.4.3.4**), and provides an overview of data and knowledge gaps (**section 2.4.3.5**). A description of IPBES regions and sub-regions including a spatial representation is provided online (IPBES Technical Support Unit On Knowledge And Data, 2021) and in **Chapter 1**, **section 1.6.4**.

2.4.3.1 Animals

Trends

The number of alien animals in the Americas has increased across all taxonomic groups, especially post-1850, and across all subregions **(Figure 2.31)**. Particularly steep increases are observed for North America, followed by South America, with the exception of alien birds which also showed steep increases in the Caribbean. Since 1900 the rates of increase have remained stable (e.g., mammals), declining (fishes in North America), or distinctly increasing (arthropods). Increases in numbers of alien arthropods in North America have been shown in several studies (Aukema *et al.*, 2010; Mattson *et al.*, 1994; Nealis *et al.*, 2016) as well as in South America (Fuentes *et al.*, 2020), for freshwater (Ricciardi, 2001, 2006) and for marine animals (Carlton & Eldredge, 2009; Cohen & Carlton, 1998; Ruiz, Fofonoff, *et al.*, 2000). Transfers of species within a continent contribute to the spread and new incidences of alien species occurrences. Within the United States, for example, over 580 freshwater species have been introduced from one watershed to another outside their historical ranges; these introductions are nearly as numerous as those originating from outside the country, and they have increased over time, more than doubling in number since 1950 (USGS, 2021).

Alien mammal introductions in the Americas date to pre-Columbian times in the Caribbean islands for hunting (e.g., *Didelphis marsupialis* (common opossum), *Dasyprocta leporina* (agouti), *Dasypus novemcinctus* (nine-banded armadillo)) (Biancolini *et al.*, 2021; Giovas *et al.*, 2012; Long, 2003). European colonialism caused a surge in introductions of alien species beginning in the fifteenth century and peaking during the twentieth century, with a strong focus on game species and, more recently, on pets (Biancolini *et al.*, 2021; Long, 2003).Considered collectively, the number of alien amphibians and reptiles in the Americas has been increasing since the 1950s and the introduction of new alien species through the pet trade is predicted to either accelerate or remain steady (Kraus, 2009; Lockwood *et al.*, 2019; Perella & Behm, 2020; Powell *et*

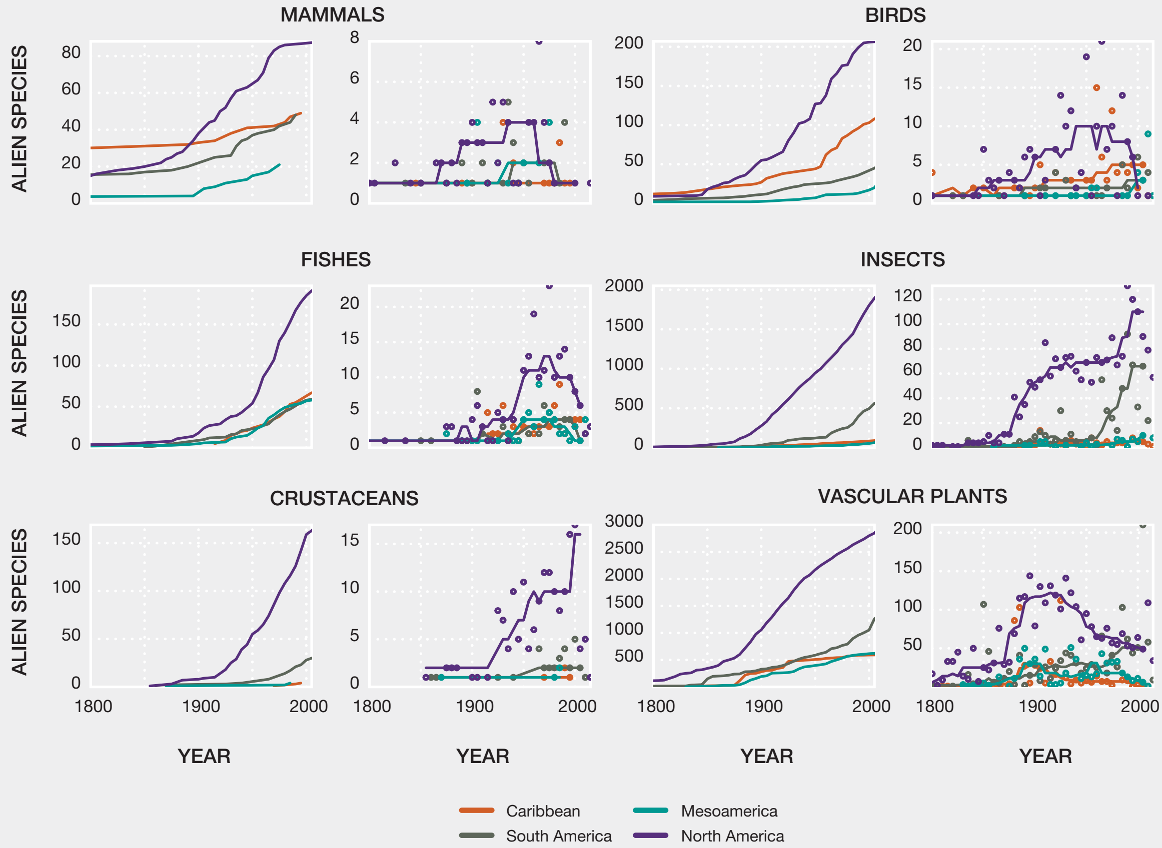

Figure 2 31 **Trends in numbers of established alien species for the Americas.**

The cumulative numbers (left panels) and number of established alien species per five-year intervals (right panels). Numbers shown here underestimate the real extent of alien species occurrences due to a lack of data. Lines in right panels indicate smoothed trends calculated as running medians (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

al., 2011; Seebens, Blackburn, *et al.*, 2017; Stringham & Lockwood, 2018).

The first introductions of alien aquatic species in South America occurred in the 1500s in conjunction with European colonization, but remained relatively low until the1800s and 1900s, when they moderately increased. Alien aquatic introductions began increasing distinctly in the mid 1900s, both in South and North America, as shown in **Figure 3.6** in the IPBES Regional Assessment Report on Biodiversity and Ecosystem Services for the Americas (IPBES, 2018b). Through the 2000s there has been a large increase in the number of records and studies of alien organisms (e.g., Frehse *et al.*, 2016; Vitule *et al.*, 2021). Current data trends show no signs of slowing, either in terms of the number of alien species or in new spatiotemporal records (e.g., Vitule *et al.*, 2021). Aquaculture and the aquarium trade (including e-commerce) are the most important pathways for the introduction of new alien species (e.g., Bezerra *et al.*, 2019; Magalhães *et al.*, 2020; Vitule *et al.*, 2019). Habitat alteration, the elimination of biogeographic barriers (e.g., D. A. dos Santos *et al.*, 2019; Vitule *et al.*, 2012), ballast water, hull fouling (Frehse *et al.*, 2016), and introducing fish for angling are other important mechanisms for introduction that have direct effects on both biodiversity and socio-economic aspects (e.g., Doria *et al.*, 2020; Vitule *et al.*, 2014).

For marine alien species in American waters, seminal studies have highlighted the rising numbers of marine alien species (Cohen & Carlton, 1998; Coles *et al.*, 1999). Recent updates for regions such as for the coastal waters of the American temperate zones found an increase in the total number of detected alien species, while the rate of newly recorded alien species has remained stable in recent decades (Bailey *et al.*, 2020). Teixeira & Creed (2020) reported that the number of introduced species increased by 160 per cent for Brazil between 2009 and 2019. A rise in the number of detected alien species was also found for

Argentina and Uruguay (Schwindt *et al.*, 2020), where the number of detections increased by a factor of 4.5 between 2001 and 2019, with an estimated arrival of one new species every 178 days.

Status

The Americas host a significant number of established alien mammals (96 species) from nine orders and 29 families. Most are from the orders Cetartiodactyla (30 species), Rodentia (28 species), Primates (14 species) and Carnivora (11 species) (Biancolini *et al.*, 2021). Within the Americas, alien mammal richness is high on the east coast of North America, Alaskan islands, Newfoundland Island, central-southern United States, the Caribbean Archipelago, and Patagonia (Malvinas) (Biancolini *et al.*, 2021). Many mammals native to the Americas have been translocated inside the region and are thus classified as being alien (53 species), while the major outside donors were Europe and Central Asia (8 species), followed by Asia and the Pacific (7 species) and Africa (2 species). Alien mammal introductions mainly occurred for sport hunting, the pet trade, so called "faunal improvement" (e.g., releases carried out to aesthetically modify the landscape), farming, and zoos (Biancolini *et al.*, 2021). A well-established hunting industry in North America fuels the introduction of ungulates, frequently contained in large enclosures in the southern United States and Mexico or directly released into the wild (Long, 2003). For example, *Ammotragus lervia* (aoudad), a bovid native to the Northern African savanna and desert areas, is now established in a large range north of Mexico (establishment not reported for Mexico) (Texas Invasive Species Institute, 2021). One of the most invasive alien mammals in the Americas is *Herpestes javanicus auropunctatus* (small Indian mongoose) established on many islands in the Caribbean (Biancolini *et al.*, 2021; Hays & Conant, 2007; Louppe *et al.*, 2020). This species was widely introduced during the nineteenth century as a biological control agent for rodents, and it is considered one of the "100 worst invasive alien species in the world" because of its generalist diet and high predatory efficiency. Another high-profile example of mammal invasion is the ongoing spread of *Hippopotamus amphibius* (so-called "Escobar's hippos"; hippopotamus) in the Magdalena River of Colombia (Biancolini *et al.*, 2021; Jarić *et al.*, 2020). Four individuals of this large African mammal were introduced by Pablo Escobar in the 1980s for his amusement and they escaped captivity in 1993 after his death (Dembitzer, 2017); in 2020, about 80–120 alien hippos were found to occur over 2000 km^2.

Alien bird species are particularly rich in North America, notably Florida and California, where several alien parrot species have established populations (E. E. Dyer, Cassey, *et al.*, 2017). Alien parrots are also widespread in South America. Attempts to establish all the bird species mentioned in Shakespeare's works into North America have a legacy in the distribution of *Sturnus vulgaris* (common starling) across the continents.

In South America, the number of reported alien aquatic organisms (ranging from microscopic fungi, invertebrates, and plants to large mammals (Schwindt *et al.*, 2018) is increasing rapidly (e.g., Fuentes *et al.*, 2020; Vitule *et al.*, 2021), with fish and molluscs (26.8 per cent and 25.2 per cent of studied invasive alien marine species respectively; see Schwindt & Bortolus, 2017, **Figure 2.31**) having the largest number of studies, species, and spatiotemporal occurrence records (e.g., (Bezerra *et al.*, 2019; Frehse *et al.*, 2016; Vitule *et al.*, 2021). The most recent records of fishes in South America indicate that over 75 alien species have been translocated between different basins within South America (Bezerra *et al.*, 2019; Vitule *et al.*, 2019) and more than 80 alien fish species have been introduced from other regions of the world (Doria *et al.*, 2021; Vitule *et al.*, 2019, 2021). Most of the alien aquatic species studied in South America belong to the salmonid and cichlid families, but *Limnoperna fortunei* (golden mussel) is the alien species included in the most publications within the region (Schwindt & Bortolus, 2017).

North America has a long and very well-studied history of aquatic species introductions, particularly for fish (e.g., Courtenay & Meffe, 1989; Fuller *et al.*, 1999; Moyle, 1986). Introductions of European and Asian species that have also been introduced worldwide are noteworthy, such as *Salmo trutta* (brown trout) or *Cyprinus carpio* (common carp), species of tropical or subtropical origin introduced to Florida, and species from elsewhere in the United States introduced to California, and more recently *Cyprinus carpio* in the Mississippi Basin. The Laurentian Great Lakes have many invasive alien animals of Ponto-Caspian origin **(Box 2.9)**, mostly introduced through ballast water (Ricciardi & MacIsaac, 2000; Vanderploeg *et al.*, 2002). *Pterois* species (lionfishes) have spread through the western Atlantic, including parts of North America and the Caribbean. The introduction of *Oreochromis niloticus* (Nile tilapia), *Salmo trutta, Cyprinus carpio*, and many other fish species is widespread throughout the Americas (e.g., Agostinho *et al.*, 2005; Contreras-Balderas *et al.*, 2008; Habit *et al.*, 2010, 2015). Similarly, many species native to small parts of the American continent (e.g., *Gambusia* spp. (Gambusias), *Oncorhynchus mykiss* (rainbow trout), *Poecilia reticulata* (guppy)) have been widely introduced throughout the Americas and elsewhere (Marr *et al.*, 2013).

The Americas is the IPBES region with the highest number of alien reptiles and amphibians **(Table 2.22)**. Within this region, the United States is home to several hotspots of alien amphibians and reptiles (Capinha *et al.*, 2017; Kraus, 2009; Krysko *et al.*, 2011, 2016). Florida (58 species established), California (25 species), and Puerto

Table 2 22 **Numbers of established alien species for subregions of the Americas.**

Numbers of alien species can vary depending on data sources. For mammals, birds and vascular plants, ranges of values indicate variation among databases (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this table is available at https://doi.org/10.5281/zenodo.7615582

	Caribbean	Mesoamerica	North America	South America	Total
Mammals	35-62	8-34	49-95	25-77	83-164
Birds	110-113	29-41	210-211	53-114	249-287

Crustaceans	10	64	173	79	248
Vascular plants	1,402-1,761	1,600-2,242	6,571-7,424	2,492-3,099	8,005-9,325
Algae	4	105	65	50	193
Bryophytes	0	0	34	21	48
Fungi	17	15	174	219	363
Oomycetes	2	2	7	5	12
Bacteria and protozoans	1	4	6	5	14
Total	2,036-2,425	2,612-3,292	11,587-12,487	4,353-5,073	13,370-14,809

Rico (11 species) stand out as global hotspots of alien amphibians and reptiles (Capinha *et al.*, 2017; Kraus, 2009; Krysko *et al.*, 2011, 2016; Meshaka, 2011; Perella & Behm, 2020; Powell *et al.*, 2011). Besides Puerto Rico, other Caribbean islands such as Cuba and the Bahamas are also important global hotspots (Borroto-Páez *et al.*, 2015; Capinha *et al.*, 2017; C. R. Knapp *et al.*, 2011; Kraus, 2009; Powell *et al.*, 2011). In South America, Brazil is the country with the highest number of alien amphibians and reptiles, with a total of 136 species recorded, of which at least seven have established wild populations (Capinha *et al.*, 2017; É. Fonseca *et al.*, 2019; Kraus, 2009).

Marine alien species across the Americas are unequally studied geographically and taxonomically, and compilations are scarce over time and space. Comprehensive assessments are lacking even in well-studied regions, such as the United States, making it difficult to draw general conclusions (Bailey *et al.*, 2020). The first comprehensive assessment was made for the United States for continental coasts finding 298 marine alien species (Ruiz, Fofonoff, *et al.*, 2000). However, this assessment needs updating, that is, as of 2006 there are 257 introduced species in California alone (Ruiz *et al.*, 2011). The reports in the rest of North America and mesoamerica are spatially or taxonomically focused and no comprehensive compilations have been published. The Southwestern Atlantic is the best-known region in South America for marine invasive alien species, yet, unequally studied among countries and sub-regions (Schwindt & Bortolus, 2017). Brazil has the highest number of marine alien species with 138 species (Teixeira & Creed, 2020), followed by Argentina and Uruguay with 129 species (Schwindt *et al.*, 2020). On the Pacific coast, Chile reported 51 alien species (Castilla & Neill, 2009; Villaseñor-Parada *et al.*, 2017), and Colombia 4 (Gracia *et al.*, 2011), but this may be due to lack of research (Schwindt & Bortolus, 2017).

2.4.3.2 Plants

Trends

Over the last two centuries the cumulative rate of increase in established alien plant species was most rapid in North America, quickly accelerating at the end of the nineteenth century (**Figure 2.31**; Lavoie *et al.*, 2012; Pyšek *et al.*, 2019). South America exhibited a slower cumulative increase, likely due to fewer experts and lower research intensity when compared to North America (Frehse *et al.*, 2016; Schwindt *et al.*, 2020; Schwindt & Bortolus, 2017).(Fuentes *et al.*, 2008; Rojas-Sandoval & Acevedo-Rodríguez, 2015; Ugarte *et al.*, 2010). Numbers of alien plant species are expected to increase over the next

Table 2 23 **Top most widespread invasive alien species for the Americas.**

The number of regions where the species has been recorded and classified as being invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distributions of invasive alien species rather than their impacts which are covered in **Chapter 4**. A maximum of three species is shown for each group (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species name	No. of regions	Species name	No. of regions
Mammals		**Molluscs**	
Rattus rattus (black rat)	21	*Lissachatina fulica* (giant African land snail)	12

20 years in emerging South American economies such as Brazil, Mexico, and Argentina based on global trade dynamics and climate change (Seebens *et al.*, 2015) which could reverse the current status of North America as more invaded by plants than South America (Pyšek *et al.*, 2019).

Status

With 5,958 established alien vascular plant species, North America has the highest recorded alien plant richness in the world (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2015). South America harbours 2,667 established alien plants (Pyšek *et al.*, 2019); note that the numbers differ from those presented in **Table 2.21**, because of different data sources and deviating data integration steps (**section 2.1.4** for further details). In the United States, California is the world's richest region in terms of established alien vascular plants with 1,753 established alien plant species, and Florida is a world regional hotspot with 1,473 established alien plants (Kartesz, 2014). *Sonchus oleraceus* (common sowthistle), *Plantago major* (broad-leaved plantain), *Taraxacum officinale* (dandelion), and *Poa annua* (annual meadowgrass) are among the most widely distributed established species in North America (each in more than 85 regions), while for South America the analogous list includes *Eleusine indica* (goose grass), *Sonchus oleraceus, Plantago major, Polygonum aviculare* (prostrate knotweed), and *Brassica rapa* (field mustard) (Pyšek, Pergl, *et al.*, 2017; **Table 2.23**). According to Pyšek, Pergl, *et al.* (2017), countries in Mesoamerica also harbour many established alien plants (Nicaragua 671, Mexico 519, Costa Rica 280, Panama 263), but due to their high native diversity, alien plants make up only 2.0–2.8 per cent of the total floras, the exception being Nicaragua with 10.4 per cent (e.g., Correa A. *et al.*, 2004; Pyšek, Pergl, *et al.*, 2017; Chacón & Saborío, 2012). Some regions in the Caribbean are heavily invaded by established alien plants, both in terms of actual species numbers (Cuba 542, Bahamas 356) or the proportion of established alien plants in the national floras (Bahamas 24 per cent, Barbados 14 per cent). Other countries in the Caribbean harbour 20 to 110 established alien plant species and their contributions to national floras do not exceed 8 per cent (Acevedo-Rodríguez & Strong, 2008; Kartesz, 2014; Pyšek, Pergl, *et al.*, 2017).

2.4.3.3 Microorganisms

Trends

The introduction of microorganisms has a long history in the Americas but is poorly documented as is the case worldwide. Where available, studies on the trends in alien microorganisms usually cover only fungi. For example, first records of alien fungi in Chile have been documented from the early twentieth century and show a continuous increase in numbers until the present (Fuentes *et al.*, 2020).

Status

The Americas harbour at least 199 alien macrofungi species, with approximately 36 per cent belonging to the group Agaricales, 32 per cent to Boletales and 11 per cent to Russulales (Monteiro *et al.*, 2020). Species most widely distributed within the region are *Suillus luteus* (ectomycorrhizal fungus of pine), *Amanita muscaria* (fly agaric), *Rhizopogon roseolus* (ectomycorrhizal fungus), and *Suillus granulatus* (weeping bolete mushroom). Countries with high numbers of known established species occur mainly in South America, and include Brazil (75), Argentina (60), and Chile (40) (Monteiro *et al.*, 2020). In the remaining IPBES sub-regions, higher numbers of known alien macrofungi were found in the United States (including Hawaii) (50), Canada, and Mexico (7 each).

2.4.3.4 Islands

Alien and invasive alien species are widespread on islands of both sides of the Americas: in the Pacific Ocean (notably the Galapagos islands) and the Atlantic Ocean (notably the Caribbean islands; e.g., (Kairo *et al.*, 2003; Rojas-Sandoval & Acevedo-Rodríguez, 2015; Van der Burg *et al.*, 2012). As an example, Caribbean Island forests are extensively dominated by alien tree species (Brandeis *et al.*, 2009; Chinea & Helmer, 2003; Helmer *et al.*, 2012), some of which are shade-tolerant and could permanently change forest species composition (C. J. Brown *et al.*, 2006). In addition, several alien species grow in forest plantations, livestock pastures, and abandoned agricultural fields creating both economic and environmental impacts. Such is the case for *Dichrostachys cinerea* (sickle bush), an alien species that occurs across almost 800,000 hectares in Cuba (Hernández *et al.*, 2002). The Hawaiian Islands are a global hotspot of plant invasions with 1,488 total alien plant species, and numbers for individual islands within the archipelago ranging from 386 to 913 alien species (Imada, 2012).

On the other side of the Americas, the Galapagos Archipelago harbours an estimated 1700 alien species with *Capra* sp. (goat) and *Rubus niveus* (Mysore raspberry) being among the most common until recently (Toral-Granda *et al.*, 2017). Between the 1980s and 1990s, the number of introduced plants has nearly doubled on the Galapagos Islands, reaching nearly 900 species (De Lourdes Torres & Mena, 2018). In addition, a study of the residence time and human-mediated propagule pressure of plants suggested that this archipelago is still in an early stage of plant invasions, due to the booming tourism industry and increasing human population size (Trueman *et al.*, 2010).

2.4.3.5 Data and knowledge gaps

Data availability for the Americas is dominated by studies from North America. Across taxonomic groups, the

Caribbean, Mesoamerica, and South America have considerably less data available relative to North America (Pyšek *et al.*, 2008). Studies on the temporal accumulation of alien species are almost exclusively available for this region except for a few studies for islands in the Caribbean and South America (Fuentes *et al.*, 2008; Rojas-Sandoval & Acevedo-Rodríguez, 2015; Toral-Granda *et al.*, 2017). Only a few studies on temporal trends exist for mainland South America or Mesoamerica (e.g., Fuentes *et al.*, 2020). Temporal information is scarce for most taxonomic groups in North America, including well-investigated groups such as vascular plants, birds, and mammals. For some groups, that are generally less studied globally, such as many invertebrates, fungi, and microorganisms, information is lacking for vast areas of this region.

In South America, regions often considered pristine and less impacted, such as the Amazon basin, lack studies on alien species and could be more thoroughly explored, particularly given recent levels of deforestation which could facilitate biological invasions (e.g., Frehse *et al.*, 2016; Vitule *et al.*, 2021; **Chapter 3**, **section 3.3.1**). In addition, there is a high degree of uncertainty on the status of alien species or populations and due to uncertainties about the native range of many species, the challenge of cryptic invasive alien species may be even greater for South America than the rest of the world (Bortolus *et al.*, 2015; Essl *et al.*, 2018; Jarić *et al.*, 2019).

A notable exception represents alien amphibians and reptiles which are relatively well-known in most of the Americas as a consequence of ongoing surveys and research (Capinha *et al.*, 2017; É. Fonseca *et al.*, 2019; García-Díaz *et al.*, 2015; González-Sánchez *et al.*, 2021; Kraus, 2009; Krysko *et al.*, 2016; Perella & Behm, 2020; N. J. van Wilgen *et al.*, 2018). Nevertheless, clarification of the status (i.e., being alien or native to a certain region) of some species in Mesoamerica and South America is needed (García-Díaz *et al.*, 2015; González-Sánchez *et al.*, 2021), and further work will improve the understanding of the ecology and impacts of the alien amphibians and reptiles present in this region (É. Fonseca *et al.*, 2019; N. J. van Wilgen *et al.*, 2018).

An important data gap exists for countries along the North Atlantic coast of South America (from French Guiana to Guiana; Schwindt & Bortolus, 2017). For example, in Venezuela the number of marine alien species originally reported by Pérez *et al.* (2007) was 22 but was later lowered to 11 alien species by Figueroa López and Brante (2020) due to uncertainty in the provided records. However, the number of marine alien species is likely higher even than the number reported by Pérez *et al.* (2007). No extensive compilations of alien species in general are available for continental Ecuador and for Peru (but see Calder *et al.*, 2021; Cárdenas-Calle *et al.*, 2019).

The availability of records on alien macrofungi for the Americas is dominated by a few countries, notably those for which higher numbers of alien species are reported here, including Argentina, Brazil, Chile and the United States. Important data gaps on established alien species exist for many other countries of the Americas, particularly in the Caribbean and Mesoamerica (Monteiro *et al.*, 2020). In general, information about alien microorganisms is lacking for all of the Americas as is the case for other IPBES regions.

2.4.4 Trends and status of alien and invasive alien species in Asia and the Pacific

This section reports on the trends and status of alien species of Asia and the Pacific for animals (**section 2.4.4.1**), plants (**section 2.4.4.2**), microorganisms (**section 2.4.4.3**), and islands (**section 2.4.4.4**), and provides an overview of data and knowledge gaps (**section 2.4.4.5**). A description of IPBES regions and sub-regions including a spatial representation is provided online (IPBES Technical Support Unit On Knowledge And Data, 2021) and in **Chapter 1**, **section 1.6.4**.

2.4.4.1 Animals

Trends

The numbers of alien animal species increased continuously for all taxonomic groups and all subregions of the Asia-Pacific regions **(Figure 2.32)**. The steepest increases were observed in Oceania for all animal groups considered in **Figure 2.32**, except for fishes. In Oceania, the number of alien animals rose distinctly already in the nineteenth century, much earlier relative to other subregions where steep increases were mostly observed after 1950. Northeast Asia experienced strong increases during that time for birds, fishes, and crustaceans. Likewise, increasing alien species numbers have been reported in various countries for insects (Huang *et al.*, 2011; Yamanaka *et al.*, 2015), gastropods (Barker, 1999; Roll *et al.*, 2009), amphibians and reptiles (Lee *et al.*, 2019), and marine alien species of different groups (Bailey *et al.*, 2020; Hewitt *et al.*, 2004).

Before colonization by Europeans, alien mammals in South-East Asia were introduced *via* ancient exchanges between the Indonesian Archipelago, Papua New Guinea, and Australia with numerous prehistoric introductions of game, fur, pet, and stowaway species (e.g., *Phalanger orientalis* (northern common cuscus), *Sus celebensis* (Sulawesi pig), *Dendrolagus matschiei* (Matschie's tree-kangaroo)) (Biancolini *et al.*, 2021; Heinsohn, 2003; Long, 2003). Introductions surged during the nineteenth century following

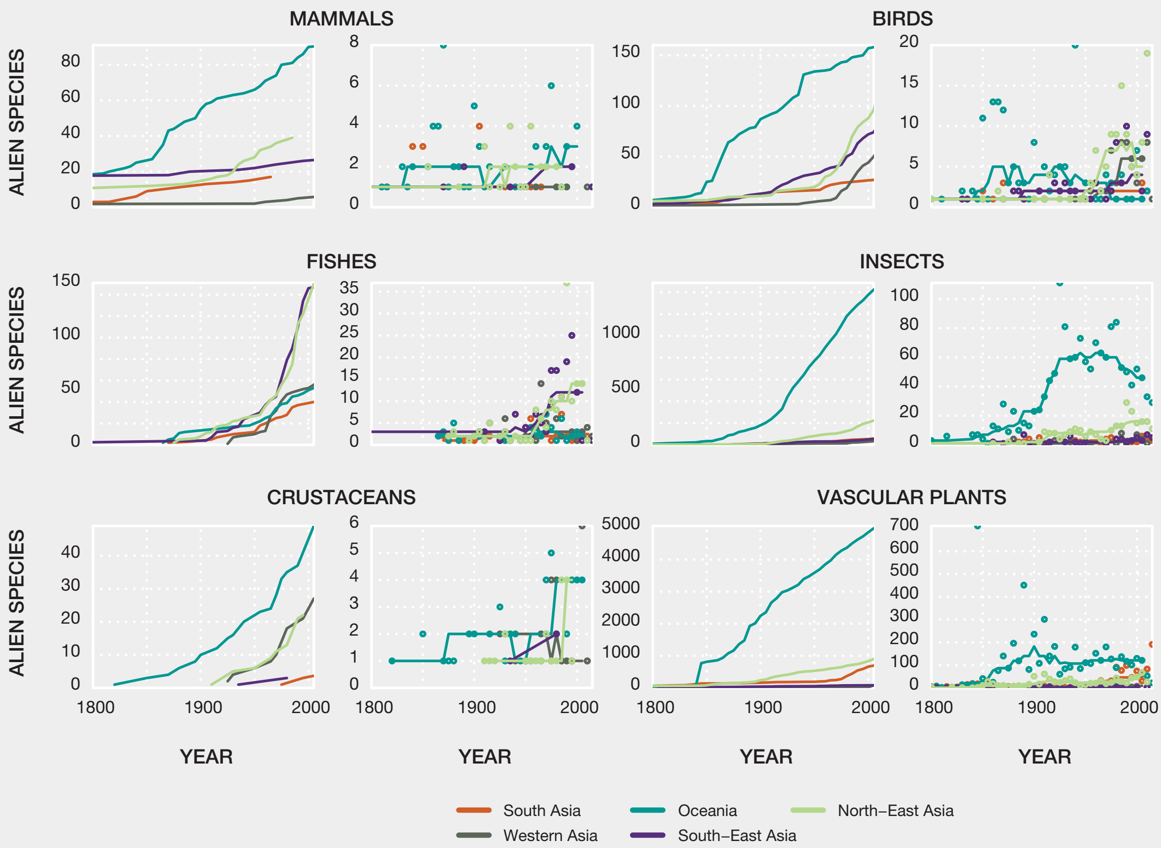

Figure 2 32 **Trends in numbers of established alien species for Asia and the Pacific.**

Cumulative numbers (left panels) and number of established alien species per five-year intervals (right panels). Numbers shown here underestimate the actual extent of alien species occurrences due to a lack of data. Lines in right panels indicate smoothed trends calculated as running medians (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

European colonization when Australia, New Zealand, and other Pacific islands became hotspots for alien mammals that negatively impacted native animal communities (Biancolini *et al.*, 2021; Woinarski *et al.*, 2015). The aim was to supply game species (e.g., *Cervus elaphus* (red deer), *Lepus europaeus* (European hare), *Dama dama* (fallow deer)) or create a familiar environment for colonists. In Central Asia and North-East Asia, alien mammal introductions were largely carried out at the beginning of the nineteenth century to create hunting and furbearing populations (Biancolini *et al.*, 2021; Clout & Russell, 2008; Long, 2003). Native Australian species became the subject of conservation introductions, also called assisted colonization, to offshore islands free of invasive alien mammals (Seddon *et al.*, 2015; Woinarski *et al.*, 2015).

The Asia-Pacific region has experienced a growing number of alien bird, reptile and amphibian introductions, a trend likely to continue in the future (Chapple *et al.*, 2016; Kraus, 2009; Lee *et al.*, 2019; Pili *et al.*, 2020; Seebens, Bacher, *et al.*, 2021; Seebens, Blackburn, *et al.*, 2017; Toomes *et al.*, 2020).

The number of alien freshwater species grew slowly in Asia and the Pacific until the nineteenth century **(Figure 2.32)** when the number of recorded alien freshwater species distinctly increased (H. H. Tan *et al.*, 2020; Yuma *et al.*, 1998). During the twentieth century, aquaculture was the main pathway for freshwater fish species introductions (Saba *et al.*, 2020; Xiong *et al.*, 2015) and in the beginning of the late twentieth century, many freshwater fish species were introduced for ornamental purposes (H. H. Tan *et al.*, 2020; Yuma *et al.*, 1998). The number of ornamental freshwater fish rapidly increased towards the end of the twentieth century and ornamental trade is now the main pathway of introduction (Goren & Ortal, 1999; Saba *et al.*, 2020; Yuma *et al.*, 1998).

As in many other regions, detected numbers of introduced alien marine species in the South Pacific region increased over time. The first assessment for New Zealand documented 129 alien species (Cranfield *et al.*, 1998), while the most recent assessment nearly doubled that number to 214 (Therriault *et al.*, 2021), with 15 alien species considered as new arrivals establishing between 2010 and 2018. Despite these numbers, recent work shows an apparent decline in primary detections since 2005 in several regions across Asia and the Pacific. It is unknown if this decline is a result of effective preventive strategies (**Chapter 5**, **section 5.5.1**) or a reduction in search effort (Bailey *et al.*, 2020). In Asia, alien species introductions occur mainly by unintentional translocations such as ballast water discharged in ports located across China's coast (Y. Chen *et al.*, 2017).

Status

Asia and the Pacific is the region with the highest number of established alien mammals in the world (130 species), from 12 orders and 34 families (Biancolini *et al.*, 2021). The majority are from the orders Cetartiodactyla (30), Diprotodontia (28), Rodentia (26) and Carnivora (21). Areas with high numbers of alien mammals are Japan, the Indonesian archipelago, Australia, New Zealand, and the Pacific islands. These alien species originate mainly from within the region itself (96), while 14 alien species originate from Europe and Central Asia, 13 from the Americas, and 10 from Africa. Major pathways of alien mammal introductions in Asia and the Pacific are hunting (48 alien species), conservation (28), pet trade (27), faunal improvement (27), farming (22), stowaway transportation (16), and biocontrol (12) (Biancolini *et al.*, 2021). During the nineteenth century acclimatization societies sought to "improve" local fauna by introducing many aesthetically pleasing and/or game species to Australia and New Zealand (Biancolini *et al.*, 2021; Simberloff & Rejmanek, 2011). Of the 130 established alien mammal species, 68 (52 per cent) have invasive alien populations (Biancolini *et al.*, 2021). Examples include the prolific generalist *Oryctolagus cuniculus* (rabbits), a well known invasive alien species in Australia (Kirkpatric *et al.*, 2008), and the generalist *Trichosurus vulpecula* (brushtail possum), which was introduced to New Zealand in 1858 for domestic fur and meat trade (Forsyth *et al.*, 2018; Gormley *et al.*, 2012).

Despite Asia and the Pacific having a larger area and more suitable habitats than Europe and Central Asia, the Asia-Pacific region harbours similar numbers of alien amphibians and reptiles as Europe and Central Asia **(Table 2.18)**. This pattern may possibly be a result of stringent biosecurity measures (**Chapter 5**, **section 5.6.3.3**) in some areas such as Australia, New Zealand, and Japan, (Brenton-Rule *et al.*, 2016; Chapple *et al.*, 2016; García-Díaz *et al.*, 2017; Toomes *et al.*, 2020), but also lower relative research intensity in other regions **(Figure 2.6)**. Despite the comparatively low alien species richness, the Asia-Pacific region harbours two of the best-known examples of alien reptiles and amphibians, namely *Boiga irregularis* (brown tree snake) in Guam and *Rhinella marina* (cane toad) in Australia and other Pacific islands (Engeman *et al.*, 2018; Lever, 2003; Rogers *et al.*, 2017; Shine, 2018; Zug, 2013). The notable invasive alien species *Lithobates catesbeianus* (American bullfrog), *Trachemys scripta* (pond slider), and *Eleutherodactylus planirostris* (greenhouse frog) have been reported in China (S. Lin *et al.*, 2017; X. Liu *et al.*, 2015; Shi *et al.*, 2009). Additionally, Japan (17 alien species), the Cook Islands (14 alien species), and island territories such as Taiwan, Province of China, (at least 12 alien species) and Guam, United States (11 alien species) are global hotspots of alien amphibians and reptiles (Capinha *et al.*, 2017; Kraus, 2009; Lee *et al.*, 2019; Zug, 2013).

In Asia, the number of introduced alien freshwater species is highest for China (439) (Xiong *et al.*, 2015), followed by Malaysia (203 freshwater fishes) (Saba *et al.*, 2020) and the Philippines (159 freshwater fishes) (Casal *et al.*, 2007). The number of established alien freshwater fishes is highest in China (61) (Luo *et al.*, 2019), followed by Singapore (42) (H. H. Tan *et al.*, 2020), the Philippines (39) (Casal *et al.*, 2007), and Japan (23) (Yuma *et al.*, 1998). Most of the established alien fishes were introduced for aquaculture (Casal *et al.*, 2007; Luo *et al.*, 2019), while the proportion of introduced ornamental fishes is much lower (Casal *et al.*, 2007; Luo *et al.*, 2019).

A regional assessment of marine alien species across Asia and the Pacific is lacking, and, as in many other marine regions, records are likely underestimated. Lutaenko *et al.* (2013) compiled an atlas of marine invasive alien species in the Northwest Pacific Region, which includes territories from Japan, the Republic of Korea, the Russian Federation and China (Yellow Sea). For Japan, 42 marine alien species were reported (Iwasaki, 2006), mostly concentrated in eutrophicated enclosed bays near large urban cities such as Tokyo Bay and Osaka Bay. Although ballast water and hull fouling are important vectors, 21 species were reported as intentionally introduced for commercial sales, live bait, or fishery studies (Lutaenko *et al.*, 2013). Partial updates were done by Doi *et al.* (2011) adding crustaceans (mainly crabs, amphipods, barnacles, and isopods) to the list of alien species reported by Iwasaki (2006), increasing the 42 by 10 reported alien species. There are few reports about marine species introductions to Korean and Chinese waters. Seo and Lee (2009) reported 136 species suspected to be alien across this vast region of Asia, while 41 alien species are recognized only for the Republic of Korea (Lutaenko *et al.*, 2013). As for the Russian waters of the Northwest Pacific region, 37 marine invasive alien species were reported by 2010 and this number increased to 66 in a later assessment (Zvyagintsev *et al.*, 2011), mostly concentrated around Peter the Great Bay in Russia. Two recent reports for the north Pacific document 73 alien species for the northern central

Table 2 24 **Numbers of established alien species for subregions of Asia and the Pacific.**

Numbers of established alien species can vary depending on data sources. For mammals, birds, and vascular plants ranges of values indicate variation among databases (see **section 2.1.4** for further details on data sources and data processing). Note numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this table is available at https://doi.org/10.5281/zenodo.7615582

Indo-Pacific, 208 species for the northwest Pacific (includes northeast Asia), and 368 for the northeast Pacific (from the United States, Canada up to Alaska; Kestrup *et al.*, 2015; Lee II & Reusser, 2012). In conclusion, the vast region of the north Pacific has a similar number of introduced marine species as the Mediterranean Sea. In addition, the northwest Pacific contains the largest number of alien fishes (34 species), most intentionally released into the wild or maintained in aquaculture facilities.

There are few exhaustive assessments for the south Pacific Ocean with the greatest research efforts in Australia and New Zealand. Surveysof Port Phillip Bay (Australia) detected 100 marine alien species (Hewitt *et al.*, 2004). A subsequent thorough literature reviewthat included data from port surveys yielded 132 alien species (Sliwa *et al.*, 2008). As of March 2018 in New Zealand, 214 established alien species were reported (Therriault *et al.*, 2018). The knowledge of marine bioinvasions of the Pacific Island Countries and Territories is scattered and dispersed in diverse publications. Surveys in Pago Pago Harbor (American Samoa) recognized 17 marine alien species (Coles *et al.*, 2003), 40 alien species were detected from Guam (Paulay *et al.*, 2002), and 11 alien species in Malakal harbour, Palau (M. L. Campbell *et al.*, 2016). Most alien species were associated with transport in ballast water or biofouling (Hewitt & Campbell, 2010), and the number of intentional introductions for aquaculture purposes are low in Australia and New Zealand but high across the Pacific Islands countries (Eldredge, 1994). Many introduction attempts have been conducted in the past 50 years in the south Pacific Ocean, with at least 38 alien species originating from small scale fisheries or aquaculture activities.

2.4.4.2 Plants

Trends

First records of alien plant species in Asia and the Pacific date back more than 1000 years (Wijesundara, 2010), and continual increases in the number of established alien species have been consistently recorded for several Asian and Pacific countries (Banerjee, 2020; C. Chen *et al.*, 2017; Jaryan *et al.*, 2013; Lazkov & Sultanova, 2011; Shrestha, 2016; Vinogradov & Kupriyanov, 2016; Wijesundara, 2010; Wu *et al.*, 2010). The most dramatic increase in the cumulative number of alien plant species is recorded for Oceania, including Australia, New Zealand, and the Pacific Islands **(Figure 2.32)**. Introduction rates peaked in around 1900, followed by a decline and a re-acceleration in the mid-twentieth century **(Figure 2.32)**. The trends for other Asia-Pacific sub-regions are similar to that for Oceania but they have markedly lower absolute numbers of established alien species per time period.

Table 2 25 **Top most widespread invasive alien species for Asia and the Pacific.**

The number of regions where the species has been recorded and classified as being invasive based on GRIIS (Pagad *et al.*, 2022). Note this table only refers to the distribution of invasive alien species rather than their impacts which are covered in **Chapter 4**. A maximum of three species is shown for each group (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species name	No. of regions	Species name	No. of regions
Mammals		**Molluscs**	
Rattus rattus (black rat)	23	*Lissachatina fulica* (giant African land snail)	15
Mus musculus (house mouse)	18	*Pomacea canaliculata* (golden apple snail)	11
Rattus norvegicus (brown rat)	14	*Euglandina rosea* (rosy predator snail)	6
Birds		**Crustaceans**	
Acridotheres tristis (common myna)	16	*Amphibalanus improvisus* (bay barnacle)	3
Columba livia (pigeons)	7	*Cherax quadricarinatus* (redclaw crayfish)	3
Corvus splendens (house crow)	7	*Procambarus clarkii* (red swamp crayfish)	3
Fishes		**Vascular plants**	
Gambusia holbrooki (eastern mosquitofish)	16	*Lantana camara* (lantana)	29
Cyprinus carpio (common carp)	15	*Pontederia crassipes* (water hyacinth)	28
Gambusia affinis (western mosquitofish)	12	*Leucaena leucocephala* (leucaena)	23
Reptiles		**Algae**	
Hemidactylus frenatus (common house gecko)	4	*Alexandrium minutum* (dinoflagellate)	2
Iguana iguana (iguana)	4	*Caulerpa taxifolia* (killer algae)	1
Trachemys scripta elegans (red-eared slider)	4	*Chattonella marina* (raphidophyte)	1
Amphibians		**Bryophytes**	
Lithobates catesbeianus (American bullfrog)	6

Latrodectus geometricus (brown widow spider)	1	*Yersinia pestis* (black death)	1
Latrodectus hasselti (Redback spider)	1		

Status

The Asia-Pacific region includes several global hotspots of established alien plant species (Dawson *et al.*, 2017) as for islands in Oceania (Essl *et al.*, 2019; Moser *et al.*, 2018). Such hotspots include New Zealand with 1,726 established alien plant species (comprising 44.5 per cent of the flora; Howell & Sawyer, 2006), Tahiti with 1,346 (73.8 per cent), and Guam with 833 (66.5 per cent, Raulerson, 2006). Australian states harbour from 1,186 established alien species in Western Australia to 1,584 in New South Wales, corresponding to 12–25 per cent of the total plant diversity in these states (Pyšek, Pergl, *et al.*, 2017; Randall, 2002; Walsh & Stajsic, 2007). Australasia experienced a rapid accumulation of established alien plants during colonization, while the Pacific islands show the steepest increase in established plant species among all global regions (van Kleunen *et al.*, 2015). The most widespread established alien species on the Pacific Islands include *Euphorbia hirta* (garden spurge), *Cenchrus echinatus* (southern sandbur), *Phyllanthus amarus* (jamaicaweed), *Sida rhombifolia* (arrowleaf sida), *Carica papaya* (papaya), *Eleusine indica* (goose grass), and *Euphorbia prostrata* (prostrate sandmat). In Australia and New Zealand,the most widespread established alien species are *Sonchus oleraceus* (common sowthistle), *Solanum americanum* (American black nightshade), *Chenopodiastum murale* (nettle-leaf goosefoot), *Medicago polymorpha* (bur clover), and *Malva parviflora* (pink cheeseweed) (Pyšek, Pergl, *et al.*, 2017; **Table 2.25**). Global hotspots of established alien species also occur in other Asian sub-regions; in South Asia and South-East Asia, India (471 alien plants comprise 2.6 per cent of the flora; Inderjit *et al.*, 2018), the Philippines (628 species, 6.4 per cent; Pelser *et al.*, 2011), and Indonesia (503 species, 1.7 per cent; Biotrop, 2003) are invasion hotspots. In Nepal, 21 established alien plant species have been classified as being invasive (Shrestha, 2016), while 101 invasive alien plant species have been recorded for Bhutan (Dorjee *et al.*, 2020). In North-East Asia, Japan is richest in alien plants (1311 species, 22.6 per cent) and numbers from China range from 100 to 400 (Pyšek, Pergl, *et al.*, 2017). Western Asia is comparatively poor in numbers of alien plants (**Table 2.25**; Pyšek, Pergl, *et al.*, 2017).

2.4.4.3 Microorganisms

Trends

In general, information on the trends of alien microorganisms in Asia is very scarce as for other IPBES regions. Data from China indicate that of the 27 invasive alien fungi recorded so far, only two new additions were reported after the year 2000 (H. G. Xu & Qiang, 2018). In India, only one new invasive alien fungal pathogen (*Puccinia horiana* (white rust of chrysanthemum)) has been recorded in the last five years (Akhtar *et al.*, 2019; Dubey *et al.*, 2021). However, 15 invasive fungal pathogens were intercepted by plant quarantine (Akhtar *et al.*, 2019, 2021; Dubey *et al.*, 2021) between 2015 and 2020. Only scattered information on trends of invasive alien fungi is available from other countries in Asia.

Status

Twenty-seven invasive alien fungal pathogens were recorded from China (H. G. Xu & Qiang, 2018), 21 from India (Akhtar *et al.*, 2019, 2021; Dubey *et al.*, 2021; Government of India, 2005), 30 from the Maldives (Shafia & Saleem, 2003), and 15 from the Lao People's Democratic Republic (Nhoybouakong & Khamphouke, 2003). Further information on invasive alien fungi is not traceable or available from countries in Asia though it is clear from studies by Fisher *et al.* (2020) that several new invasive alien fungi may have been introduced from across the globe.

A comparatively high number of known alien macrofungi has been reported for Asia and the Pacific which harbours at least 235 established alien species (Monteiro *et al.*, 2020). Most of these alien species belong to the order Agaricales (54 per cent), followed by Boletales (21 per cent), and Russulales (10 per cent). The most widespread alien macrofungi is *Pyrrhoderma noxium*. The countries with the highest numbers of known alien macrofungi are New Zealand (170 species) and Australia (40 species). This highlights the paucity of knowledge on invasive alien microparasites in this region. In general, it is assumed that goods, species including humans constantly carry a multitude of microorganisms around the globe and that many of them are introduced every year without detection.

2.4.4.4 Islands

Many islands in the Asia-Pacific region are significantly impacted by invasive alien species (IPBES, 2018b). For example, French Polynesia has undergone severe invasions by species ranging from avian malaria, plants, mammals, ants, birds, and predatory land snails (Brodie *et al.*, 2014; Howarth, 1985; J.-Y. Meyer, 2014; J.-Y. Meyer & Butaud, 2009). Mammals are widely introduced on islands in Asia and the Pacific (Courchamp *et al.*, 2003), with examples including commensal rodents (mice, black rats, brown rats, and Pacific rats), rabbits, pigs, goats, cats, and foxes, in particular on many islands (D. J. Campbell & Atkinson, 2002; Priddel *et al.*, 2000; Reaser *et al.*, 2007; St Clair, 2011; Towns *et al.*, 2006).

Conversely, while some islands are invaded by only a few alien species, they are archetypal examples of island invasions. Invasive *Herpestes* sp. (mongooses) have been introduced on the Japanese islands of Amami-Oshima and Okinawa (Goldson, 2011; Reaser *et al.*, 2007; The Ministry of the Environment of Japan, 2014). On Guam, *Boiga irregularis* (brown tree snake) has spread widely reaching densities in excess of 31,000 individuals per km^2 (CGAPS, 1997; Fritts & Rodda, 1998; Rogers *et al.*, 2017). On Guam and on Christmas Island, *Anoplolepis gracilipes* (yellow crazy ant) invasions were boosted by the invasive *Tachardiaephagus tachardiae* (yellow lac scale insect), which supplies yellow ants with honeydew (O'Dowd *et al.*, 2003; Reaser *et al.*, 2007). Other typical examples are gastropod invasions on many Polynesian islands, such as *Lissachatina fulica* (giant African land snail; Tsatsia & Jackson, 2022). Invasive plants are also a serious issue on many Asia-Pacific islands, such as Tahiti (J.-Y. Meyer & Florence, 1996), Lord Howe Island (T. D. Auld & Hutton, 2004), and Carnac Island (Abbott *et al.*, 2000), while invasive soilborne plant pathogens, such as the fungus *Phytophthora cinnamomi* (Phytophthora dieback), are problematic in over 70 countries including several Australian islands (T. D. Auld & Hutton, 2004; Pickering *et al.*, 2007), Fiji, Samoa, Tuvalu, and New Zealand (e.g., F. Campbell, 2010; Thaman, 2011; Thaman & O'Brien, 2011). Hawaii is another classic example of an archipelago heavily invaded by many species groups, being among the three regions with the most established alien species in the world (Dawson *et al.*, 2017): over 1,000 plants (W. L. Wagner *et al.*, 1999), 3,000 arthropods (Nishida, 2002), and 110 vertebrates (Moulton & Pimm, 1983; Vitousek *et al.*, 1987).

Pacific Islands are widely invaded by alien birds with New Zealand being a global hotspot of alien bird richness. More than 130 species were introduced to New Zealand, mostly deliberately by acclimatization societies set up by British colonists. More than 30 species are now established, including dense populations of several passerine species imported from Britain, such as *Turdus philomelos* (song thrush), *Turdus merula* (Eurasian blackbird), *Prunella modularis* (dunnock), *Chloris* sp. (greenfinch), *Acanthis* sp. (redpoll) and *Emberiza citrinella* (yellowhammer).

2.4.4.5 Knowledge and data gaps

For alien plants, Asia and the Pacific have lower data coverage than other continents; data are available on established alien species for 68.5 per cent of the area of tropical Asia as a whole (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2015). Notable exceptions represent some well-studied invasion hotspots such as Australia, New Zealand and Hawaii (van Kleunen *et al.*, 2015, 2019; **Figure 2.6**). Mainland Asia is a region especially affected by knowledge gaps for alien mammals, likely due to a low sampling effort (Pyšek *et al.*, 2008) and/or linguistic barriers (Angulo *et al.*, 2021). Notably, while reports of alien mammals in Hong Kong, Special Administrative Region of China, are numerous and exhaustive, very little information is available in English for mainland China (Biancolini *et al.*, 2021). However, the situation has improved recently with several specialized accounts published or underway (Dorjee *et al.*, 2020; Inderjit *et al.*, 2018; Patzelt *et al.*, 2022), and this trend is expected to continue. Temporal information such as first records is generally scarce for most regions in Asia and the Pacific.

The completeness of the information about alien amphibians and reptiles and freshwater species in Asia and the Pacific varies substantially by country. While some countries in North-East Asia and Oceania are relatively well-studied, others, particularly in southeast Asia and western Asia, have substantial knowledge gaps (Capinha *et al.*, 2017; Chapple *et al.*, 2016; C. Chen *et al.*, 2017; Cogălniceanu *et al.*, 2014; Das, 2015; Kraus, 2009; Lee *et al.*, 2019; Rights and Resources Initiative, 2015; Seebens, Blackburn, *et al.*, 2017; Soorae *et al.*, 2010; Van Wilgen *et al.*, 2010; Zug, 2013). In addition, further genetic work is needed to resolve the status of various species and populations of alien reptiles throughout the Pacific and western Asia (Cogălniceanu *et al.*, 2014; Zug, 2013).

The total number of marine alien species varies among studies, in part due to a lack of standardized terminology, sampling methods, environments studied, and taxonomic expertise available to assess species lists and record dates (Marchini *et al.*, 2015). For example, many species counted as marine alien species in the northwest Pacific are present in aquaculture facilities, while it remains unknown whether they have established in some cases. Some assessment lists only include species detected on vectors, some others consider different delineations of marine regions, while yet others are country specific.

Asia and the Pacific is grossly under-explored for alien fungi and other microorganisms. The high number of alien macrofungal records in New Zealand and Australia are likely influenced by high research and sampling intensities in these regions. Much less data and fewer studies on alien macrofungi are available for most other countries in Asia and the Pacific.

2.4.5 Trends and status of alien and invasive alien species in Europe and Central Asia

This section reports on the trends and status of alien species of Europe and Central Asia for animals (**section 2.4.5.1**), plants (**section 2.4.5.2**), microorganisms (**section 2.4.5.3**) and islands (**section 2.4.5.4**), and provides an overview of data and knowledge gaps (**section 2.4.5.5**). A description of IPBES regions and sub-regions including a spatial representation is provided online (IPBES Technical Support Unit On Knowledge And Data, 2021) and in **Chapter 1**, **section 1.6.4**.

2.4.5.1 Animals

Trends

The number of alien animal species in Europe and Central Asia has increased across various taxonomic groups including vertebrates (Rabitsch & Nehring, 2017), insects (Roques *et al.*, 2016), molluscs (Peltanová *et al.*, 2012) and freshwater species (Muñoz-Mas & García-Berthou, 2020; Nunes *et al.*, 2015). Comparisons of long-term trends among sub-regions show much larger numbers of alien species recorded for Central and Western Europe, which has the highest numbers of alien species for all animal groups and at all times, compared to other sub-regions **(Figure 2.33)**. While rates of increase remained relatively constant over the last 200 years for alien mammals, they rose sharply in recent decades for birds and invertebrates. Rates of increase of alien species remained relatively constant for all groups in Eastern Europe, but available numbers in Central Asia are often too low to assess trends **(Figure 2.33)**.

Alien mammal introductions first occurred in Europe and Central Asia during prehistoric times, with major introductions from Asia to Europe and from the mainland to islands (Biancolini *et al.*, 2021; Long, 2003). The spread of agriculture brought domestic species (e.g., *Capra hircus* (goats), *Ovis aries* (sheep), *Felis catus* (cat)), while island colonization by humans brought game species (e.g., *Lepus europaeus* (European hare), *Glis glis* (European edible dormouse), *Oryctolagus cuniculus* (rabbits)) as well as stowaways (*Apodemus sylvaticus* (long-tailed field mouse), *Crocidura suaveolens* (lesser white-toothed shrew), *Microtus arvalis* (common vole)) (Biancolini *et al.*, 2021; Long, 2003). Biological invasions of islands intensified with the growth of the sea trade in the following centuries causing the disappearance of many natural island ecosystems, especially in the Mediterranean basin (Masseti, 2009). Hunting has always been and continues to be a major pathway for alien mammals and birds on both the mainland and the islands of Europe and Central Asia (Genovesi *et al.*, 2012; Monaco *et al.*, 2016).

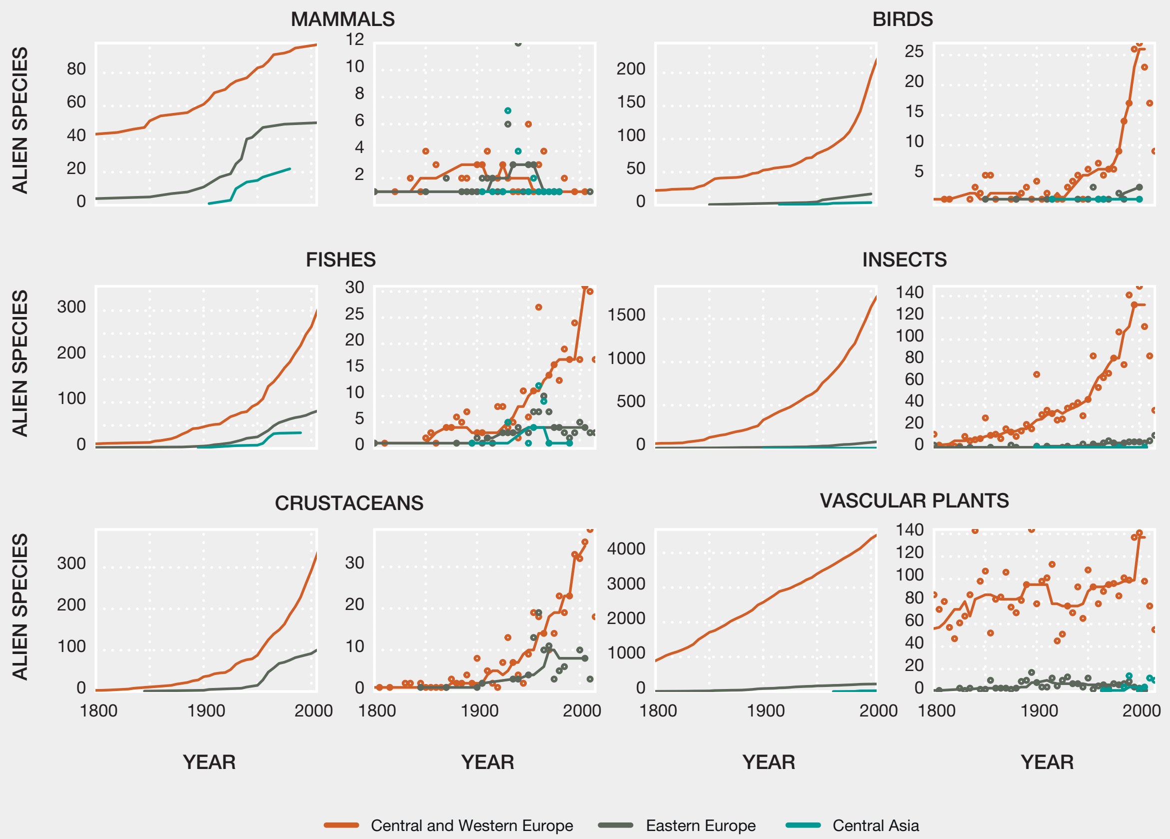

Figure 2.33 **Trends in numbers of established alien species in Europe and Central Asia.**

Cumulative numbers (left panels) and number of established alien species per five-year intervals (right panels). Numbers underestimate the actual extent of alien species occurrences due to a lack of data. Lines in right panels indicate smoothed trends calculated as running medians (**section 2.1.4** for further details about data sources and data processing). Note that presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

The number of alien animal species in Europe and Central Asia has increased across various taxonomic groups including vertebrates (Rabitsch & Nehring, 2017), insects (Roques *et al.*, 2016), molluscs (Peltanová *et al.*, 2012) and freshwater species (Muñoz-Mas & García-Berthou, 2020; Nunes *et al.*, 2015). Comparisons of long-term trends among sub-regions show much larger numbers of established alien species recorded for Central and Western Europe, the highest species numbers for all animal groups and at all times, compared to other sub-regions **(Figure 2.33)**. While rates of increase remained relatively constant over the last 200 years for alien mammals, they rose sharply in recent decades for birds and invertebrates. Rates of increase of established alien species remained relatively constant for all groups in Eastern Europe, but available numbers in Central Asia are often too low to assess trends **(Figure 2.33)**.

Alien mammal introductions first occurred in Europe and Central Asia during prehistoric times, with major introductions from Asia to Europe and from the mainland to islands (Biancolini *et al.*, 2021; Long, 2003). The spread of agriculture brought domestic species (e.g., *Capra hircus* (goats), *Ovis aries* (sheep), *Felis catus* (cat)), while island colonization by humans brought game species (e.g., *Lepus europaeus* (European hare), *Glis glis* (European edible dormouse), *Oryctolagus cuniculus* (rabbits)) as well as stowaways (*Apodemus sylvaticus* (long-tailed field mouse), *Crocidura suaveolens* (lesser white-toothed shrew), *Microtus arvalis* (common vole)) (Biancolini *et al.*, 2021; Long, 2003). Biological invasions of islands intensified with the growth of the sea trade in the following centuries causing the disappearance of many natural island ecosystems, especially in the Mediterranean basin (Masseti, 2009). Hunting has always been and continues to be a major pathway for alien mammals and birds on both the mainland and the islands of Europe and Central Asia (Genovesi *et al.*, 2012; Monaco *et al.*, 2016).

Europe and Central Asia has experienced a growing number of alien reptile and amphibian introductions, a trend that will likely continue (Seebens, Bacher, *et al.*, 2021; Seebens, Blackburn, *et al.*, 2017). Trends in alien reptiles and amphibians follow a similar pattern: historical events and trade routes around the Mediterranean Basin have resulted in some of the oldest known introductions of alien amphibians and reptiles in the world occurring in this region (Mateo *et al.*, 2011; Pleguezuelos, 2002). In line with global trends, the number of alien amphibians and reptiles has increased in this region and the pet trade is expected to contribute more species in the near and medium futures (Capinha *et al.*, 2017; Filz *et al.*, 2018; Kraus, 2009; Mateo *et al.*, 2011).

Introductions of alien freshwater animals increased after the mid-nineteenth century due to the activities of acclimatization societies, mainly for angling (Gherardi *et al.*, 2009). Established alien species numbers also increased notably after World War II due to more intensive trade, openings of major inland canals and waterways in Central and Western Europe, and the intensification of aquaculture (Gherardi *et al.*, 2009; Nunes *et al.*, 2015). The main pathways of introduction were releases and escapes through aquaculture, deliberate stocking, and pet and aquarium trades. The latter acquired more importance as a driver facilitating introductions since the 1990s (Nunes *et al.*, 2015). In central and north-eastern Europe, interconnected canals and waterways were the main pathways of introduction, while in Central and Western Europe releases and escapes are linked to aquaculture and pet and aquarium trades. A slight decrease in introduction rates in recent decades has been reported on the Iberian Peninsula (Muñoz-Mas & García-Berthou, 2020). Alien species introductions are further assisted by unintentional translocations, such as the opening of waterways in Israel (Goren & Ortal, 1999).

Across the coastal areas of Europe, the number of detections and introductions of alien species has increased over time, although numbers differ among assessments (Bailey *et al.*, 2020; Gollasch, 2006; Katsanevakis *et al.*, 2020; Tsiamis *et al.*, 2019), especially for the eastern Mediterranean Sea since the earliest inventories taken during the 1960s (Galil *et al.*, 2021b). For example, the number of marine alien species along the coast of Israel has increased three-fold from 1970 (147 alien species) to 2020 (452 alien species), and this trend is consistent as new alien species detections still appear in the scientific literature. For the Baltic Sea, the annual introduction rate has more than doubled since 1950: 1.4 species per year between 1950 and 1999 and 3.2 between 2000 and 2018 (ICES, 2019).

Status

Currently 85 alien mammals are known to be established in Europe and Central Asia, from 7 orders and 24 families (Biancolini *et al.*, 2021). The most numerous orders are Rodentia (26 species), Cetartiodactyla (24), Carnivora (18) and Eulipotyphla (8). Alien mammal hotspots are present in Central and Western Europe, numerous Mediterranean islands, the British Isles, Italy, Scandinavia, Eastern Europe and European Russia (Biancolini *et al.*, 2021). Most alien mammals are native to other parts of Europe and Central Asia (42) and the major outside donor is Asia and the Pacific (14), followed by the Americas (10), and Africa (4). This great reshuffling of mammal fauna was mainly driven by hunting (36 cases), pet trade (22), stowaway transportation (16), intentional introductions (12), conservation purposes (11) and fur exploitation (11) (Biancolini *et al.*, 2021). For example, squirrels were released or escaped from captivity in the last several decades, creating numerous alien populations scattered across Europe (Biancolini *et al.*,

Table 2 26 **Numbers of established alien species for subregions of Europe and Central Asia.**

For mammals, birds, and vascular plants ranges of values indicate variation among databases (**section 2.1.4** for further details about data sources and data processing). Note presented numbers may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this table is available at https://doi.org/10.5281/zenodo.7615582

	Central and Western Europe	Central Asia	Eastern Europe	Total

Total	12,711-16,587	265-511	2,903-3,413	11,472-15,346

2021). A well-known example is *Sciurus carolinensis* (grey squirrel), which was introduced to the United Kingdom and Italy (Bertolino *et al.*, 2008, 2014; Gaertner *et al.*, 2016). *Ondatra zibethicus* (muskrat), *Nyctereutes procyonoides* (raccoon dog), and *Mustela vison* (American mink) are among the most widespread species in Europe and Central Asia (Biancolini *et al.*, 2021; Genovesi *et al.*, 2012; Tedeschi *et al.*, 2022).

Many alien bird species were introduced during European colonial expansion including a large number introduced to Europe. Game and ornamental species were particularly popular, such that Europe now has populations of a number of alien galliforms and wildfowl. Other such introductions pre-date colonialism, such as *Phasianus colchicus* (common pheasant), which is widespread in Europe and still released in various countries every year by the tens of millions. Prior to the bird flu epidemic of 2005, Europe was a major hub for the caged bird trade, but European Union-wide bans on imports have greatly restricted the influx of species from outside the continent (Reino *et al.*, 2017). There is still extensive trade in captive-bred birds within Europe, and escapes continue to threaten further alien species introductions. The caged bird trade is the major source of alien species in Asia, notably in trade hubs in the Far East. Millions of birds continue to be trapped from wild populations in Asia, and pose a substantial extinction threat to popular species, as well as a risk of new alien populations.

Europe and Central Asia have several global hotspots of alien amphibians and reptiles. These include the Balearic Islands (20 species), mainland Spain (13 species), mainland Italy (11 species), mainland France (10 species), and the United Kingdom (10 species) (Capinha *et al.*, 2017; Ficetola *et al.*, 2010; Kark *et al.*, 2009; Kraus, 2009; Mateo *et al.*, 2011). Fewer alien reptiles and amphibians have been reported from Central Asian countries than in Europe (Capinha *et al.*, 2017; Kraus, 2009).

According to Nunes *et al.* (2015), there are 534 alien freshwater animals (46 per cent native to some European areas) in Europe and Central Asia. The Iberian Peninsula, France, Italy, the United Kingdom, and Germany host the highest numbers of species (Gollasch & Nehring, 2006; R. P. Keller *et al.*, 2009; Muñoz-Mas & García-Berthou, 2020; Nunes *et al.*, 2015; Teletchea & Beisel, 2018). For Uzbekistan, 31 alien freshwater fishes have been recorded (Yuldashov, 2018). Most introduced fish arrived mainly through stocking, aquaculture, or pet and aquarium trades, followed by crustaceans and molluscs, both mainly *via* ornamental trade and through corridors (e.g., canals and waterways; Muñoz-Mas & García-Berthou, 2020; Nunes *et al.*, 2015). Some species, such as *Cyprinus carpio* (common carp), *Sander lucioperca* (pike-perch), *Silurus glanis* (wels catfish) or Ponto-Caspian gobies, are only native to parts of western Europe but have now established in much of European fresh waters (e.g., Leprieur *et al.*, 2008). Similarly, many widespread species such as *Perca fluviatilis* (perch), *Rutilus rutilus* (roach) or *Alburnus alburnus* (bleak) are not native to the peninsulas in southern Europe, which have distinct, threatened fish faunas with high endemism (Yuldashov, 2018).

2.4.5.2 Plants

Trends

Since the start of the nineteenth century, Central and Western Europe has had a steady increase in alien plant introductions and data indicate no deceleration of this trend **(Figure 2.33)**. First records for Eastern Europe and Central Asia show very slow increases, partly due to lower research effort in these regions relative to Central and Western Europe (**section 2.4.5.5**). A recent Europe-wide inventory of established alien plants, including Central and Western, and a portion of Eastern Europe was conducted through the project Delivering Alien Invasive Species In Europe (Lambdon *et al.*, 2008) and recorded 4,139 established alien plant taxa (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2015), an increase of 390 taxa (or 9.6 per cent). The introduction of alien aquatic plants increased after 1950, the main pathway being the ornamental trade, followed by cultivation and contaminants of commodities (Nunes *et al.*, 2015). Ornamental trade and cultivation had similar rates in different European areas while contaminants of commodities were mostly recorded in southern Europe (Nunes *et al.*, 2015). The number of alien aquatic plant species is still relatively low in European freshwaters but is sharply increasing, having doubled in nearly 30 years (Hussner *et al.*, 2010).

Status

In Central and Western Europe, a total of 8,565 alien vascular plants, 497 established alien algae, and 25 established alien bryophytes have been recorded **(Table 2.27)**. The GloNAF database reports 4139 established alien vascular plants (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2015). The highest numbers of established alien plants are recorded in England (1,379), Sweden (874), Scotland (861), Wales (835), France (716), Norway (595), Belgium (508), Italy (478), Spain (454), and Germany (451) indicating that the northern part of the continent, particularly United Kingdom, Ireland, and Scandinavia are heavily invaded by established alien species. Only a few regions in Eastern Europe (perhaps due to lack of data) harbour comparably high numbers of established alien species, such as the European part of Russia (649), Ukraine (626) and Bulgaria (593) (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2015, 2019). Some of these countries also have the highest per centage of established alien species as a proportion of the total flora. In England, established alien species make up 47 per cent of the total flora, in Wales 44 per cent, Scotland 42 per cent, Sweden 35 per cent, in Norway 32 per cent, and in the European part of Russia 37 per cent (Pyšek, Pergl, Dawson, *et al.*, 2020). There are 35 alien species that have become established in more than 30 regions of Europe, that is, at least half of the European regions considered in the GloNAF database, the most widespread being *Erigeron canadensis* (Canadian fleabane; recorded in 76 per cent of regions), *Elodea canadensis* (Canadian pondweed), *Matricaria discoidea* (rounded chamomile), *Oenothera biennis* (common evening primrose), *Solidago canadensis* (Canadian goldenrod) and *Galinsoga parviflora* (gallant soldier) **(Table 2.27)**. Central Asia is generally less invaded by alien plants with country floras in this region harbouring 50–70 established alien species which corresponds to 1.9–4.5 per cent contribution to total plant diversity (Pyšek, Pergl, *et al.*, 2017).

According to Nunes *et al.* (2015), there are 210 alien freshwater plants (38 per cent native to some European areas). Hussner (2012) found that the highest number of alien plant species in all of Europe is reported for Italy and France, followed by Germany, Belgium, Hungary, and the Kingdom of the Netherlands. The most frequently introduced plants are the angiosperms: 200 out of 210 (Nunes *et al.*, 2015).

Over last decade, negative impacts associated with the spread of particular alien aquatic plant species (e.g., *Elodea* spp. (waterweeds), *Pontederia crassipes* (water hyacinth), *Ludwigia* spp. (primrose-willow), *Hydrocotyle ranunculoides* (floating pennywort), *Myriophyllum aquaticum* (parrot's feather)) increased in Europe (Hussner, 2012). Even though the number of alien aquatic plants appears relatively small compared to alien terrestrial plant species, the European and Mediterranean Plant Protection Organization (EPPO, 2021) has listed 18 of these species as invasive or potentially invasive within the European and Mediterranean Plant Protection Organization's region covering most of Europe and parts of Central Asia and North Africa. In total, 96 aquatic alien species from 30 families have been

Table 2 27 **Top most widespread invasive alien species for Europe and Central Asia.**

The number of regions where the species has been recorded and classified as invasive based on GRIIS (Pagad *et al.*, 2022). Note this table refers only to the distribution of invasive alien species rather than their impacts which are covered in **Chapter 4**. A maximum of three species is shown for each group (see **section 2.1.4** for further details about data sources and data processing). "No. of regions" denotes the number of regions with confirmed occurrences of that species according to the chapter database. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

Species name	No. of regions	Species name	No. of regions
Mammals		**Molluscs**	
Mustela vison (American mink)	15	*Dreissena polymorpha* (zebra mussel)	15
Rattus norvegicus (brown rat)	11	*Corbicula fluminea* (Asian clam)	13
Myocastor coypus (coypu)	10	*Potamopyrgus antipodarum* (New Zealand mudsnail)	13
Birds		**Crustaceans**	
Alopochen aegyptiaca (Egyptian goose)	8	*Pacifastacus leniusculus* (American signal crayfish)	18
Branta canadensis (Canada goose)	7	*Amphibalanus improvisus* (bay barnacle)	14
Psittacula krameri (rose-ringed parakeet)	6	*Faxonius limosus* (Spiny-cheek crayfish)	14
Fishes		**Vascular plants**	
Pseudorasbora parva (topmouth gudgeon)	19	*Ailanthus altissima* (tree-of-heaven)	32
Lepomis gibbosus (pumpkinseed)	18	*Robinia pseudoacacia* (black locust)	31
Gambusia holbrooki (eastern mosquitofish)	15	*Solidago canadensis* (Canadian goldenrod)	26
Reptiles		**Algae**	
Trachemys scripta (pond slider)	6	*Sargassum muticum* (wire weed)	7
Trachemys scripta elegans (red-eared slider)	4	*Coscinodiscus wailesii* (diatom)	5
Chelydra serpentina (common snapping turtle)	2	*Bonnemaisonia hamifera* (red algae)	4
Amphibians		**Bryophytes**	
Lithobates catesbeianus (American bullfrog)	7	*Campylopus introflexus* (heath star moss)	10
Pelophylax ridibundus (Eurasian marsh frog)	3	*Orthodontium lineare* (cape thread-moss)	2
Triturus carnifex (Italian crested newt)	3	**Fungi**	
Insects		*Ophiostoma novo-ulmi* (Dutch elm disease)	9
Cameraria ohridella (horsechestnut leafminer)	13	*Hymenoscyphus fraxineus* (ash dieback)	5
Harmonia axyridis (harlequin ladybird)	12	*Ophiostoma ulmi* (Dutch elm disease)	4
Leptinotarsa decemlineata (Colorado potato beetle)	8	**Oomycetes**	
Arachnids		*Aphanomyces astaci* (crayfish plague)	13
Opilio canestrinii (harvestman)	3	*Phytophthora cambivora* (root rot of forest trees)	3
Varroa destructor (Varroa mite)	3	*Phytophthora ramorum* (sudden oak death)	3
Mermessus trilobatus (trilobate dwarf weaver)	2	**Bacteria and protozoans**	
		Anabaenopsis raciborskii (cyanobacteria)	1
		Erwinia amylovora (fireblight)	1

reported as established alien species from at least one European country. Sixteen alien species belong to the family of Hydrocharitaceae, followed by the Nymphaeaceae and Lemnaceae (both with nine plant species). Most aquatic alien plant species introduced into Europe are native to North America (26 per cent) and Asia (29 per cent) (Hussner, 2012). The highest number of aquatic alien plant species was found in Italy (34 species), France (34 species), Germany (27), Belgium, and Hungary (both 26), and was lowest in the Balkan region and the northern and eastern parts of Europe (Hussner, 2012). *Elodea canadensis* (Canadian pondweed) is the most widely distributed alien aquatic plant in Europe, occurring in 41 European countries (but not in Cyprus, Malta, Iceland, Greece, and Montenegro). *Azolla filiculoides* (water fern) is the second most widely distributed species (25 countries), followed by *Vallisneria spiralis* (eelweed) (22) and *Elodea nuttallii* (Nuttall's waterweed) (20) (Hussner, 2012).

2.4.5.3 Microorganisms

Trends

Due to global trade of live plants and animals, the rate of introduction of alien fungi, oomycetes, and other microorganisms to Europe and Central Asia is likely to further accelerate (Hulme, 2021). Several fungi, oomycetes, and other microorganisms causing diseases have been introduced in recent decades (Nunes *et al.*, 2015). For example, within the past 20 years, 5 downy mildew pathogens with the potential to cause significant losses have been introduced to Europe (Gilardi *et al.*, 2013; Görg *et al.*, 2017; Thines, 2011; Thines *et al.*, 2020; Voglmayr *et al.*, 2014). These organisms were most likely introduced with seeds or latently infected plants, making clear the necessity for better quarantine procedures for alien plants and for local production of plants and seeds whenever possible.

Status

Europe and Central Asia has a well-documented history of biological invasions by alien plant and animal parasitic fungi and oomycetes. Well-known examples are *Batrachochytrium dendrobatidis* (chytrid fungus; Longcore *et al.*, 1999), *Aphanomyces astaci* (crayfish plague; Mrugała *et al.*, 2015), *Phytophthora infestans* (Phytophthora blight; Yoshida *et al.*, 2013), and *Plasmopara viticola* (grapevine downy mildew; Gessler *et al.*, 2011). In addition, alien species have also invaded Europe as saprotrophsor symbionts, but the few documented examples such as *Clathrus archeri* (devil's fingers) are likely only the tip of the iceberg (Desprez-Loustau *et al.*, 2007; Litchman, 2010).

In Europe and Central Asia, the highest numbers of invasive alien forest pathogenic fungi are reported from the central-southern region (e.g., France, Italy, and Switzerland; Santini *et al.*, 2013). For example, *Phytophthora ramorum* (sudden oak death), which has had significant impacts on native forests, is thought to have been introduced to the United Kingdom *via* the ornamental plant trade (Jung *et al.*, 2021). Most forest pathogenic fungi are native to the northern hemisphere, but about one third are of unknown origin (Desprez-Loustau, 2009). The incidence in Europe of alien powdery mildews (Erysiphales) is higher in terms of expected species numbers and this may reflect responses to climate change in a group adapted for long-distance aerial spore dispersal (Heluta *et al.*, 2009). Using dried reference collection samples, Gross *et al.* (2021) demonstrated that three species of *Erysiphe* could be linked to the incidence of powdery mildew in oaks, a disease that emerged in Europe at the beginning of the twentieth century. By comparison, the incidence of specialized alien insect parasites of the order Laboulbeniales is comparatively low given their high species numbers (Desprez-Loustau, 2009). More aggressive genotypes of known plant pathogenic fungi may also arrive and become invasive (Arenz *et al.*, 2011). Alien and invasive microfungi pathogenic to animals include *Batrachochytrium dendrobatidis* (chytrid fungus), which is the agent of chytridiomycosis, a disease spread by trade and causing massive amphibian declines worldwide (Weldon *et al.*, 2004), and *Pseudogymnoascus destructans* (white-nose syndrome fungus) in bats (Thakur *et al.*, 2019).

Among all IPBES regions, Europe and Central Asia represents the region with the best available knowledge on the distribution of alien macrofungi with several national lists of alien fungi available (e.g., Desprez-Loustau *et al.*, 2010; Motiejūnaitė *et al.*, 2016). However, information for the Central Asian and Eastern European sub-regions, is much scarcer, and the absence or low number of alien macrofungi as known for these regions is likely a clear underestimation of actual numbers.

2.4.5.4 Islands

Mediterranean islands are biodiversity hotspots and have been invaded by large numbers of alien plant and animal species for centuries, many of which are now established (e.g., Capizzi, 2020; Chainho *et al.*, 2015; Ruffino *et al.*, 2009). Many North Sea and Baltic Sea islands have also been invaded, for example by *Mustela vison* (American mink) (e.g., Bonesi & Palazon, 2007). Islands belonging to Europe include overseas territories in most oceans. In particular, the United Kingdom and France have many islands in the southern Atlantic and in the Pacific. Biological invasions on islands related to European countries may be due to proximity of continents (islands off the Atlantic and Channel Sea coasts) or the colonization of more remote islands (e.g., French Polynesia and New Caledonia). Among the most studied taxa, the mammals of these islands, such as Gough Island, Crozet Island, or the Kerguelen Islands include rats, mice, cats, cattle, and mouflons (Davies *et al.*, 2015; C. W. Jones *et al.*, 2019; Pascal, 1980).

2.4.5.5 Data and knowledge gaps

While sampling and reporting intensity is high for alien mammals in Western Europe, data coverage and quality decrease eastward towards Eastern Europe, including Russia (Biancolini *et al.*, 2021). Significantly fewer sources of information are available for these areas in comparison to Western Europe and reports frequently lack extensive details on alien species trends, ecology, distribution, and impacts. This could reflect linguistic barriers that hinder data sharing (Angulo *et al.*, 2021) as the available literature published in English with respect to Eastern Europe cites numerous works written in other languages (e.g., Russian) (Khlyap *et al.*, 2011). A similar situation is reported for freshwater species, which are well reported for Europe, especially Western Europe (Nunes *et al.*, 2015), while less data are available for Central Asia.

While information available on alien amphibians and reptiles in this IPBES region has been thoroughly collected (Capinha *et al.*, 2017; Kark *et al.*, 2009; Kraus, 2009), some countries in Western Europe and Central Asia have been understudied and those lists of alien amphibians and reptiles are likely incomplete (Capinha *et al.*, 2017; Seebens, Blackburn, *et al.*, 2017; N. J. van Wilgen *et al.*, 2018).

Europe is amongst the best-researched continents for plant invasions (Pyšek, Hulme, *et al.*, 2020) and many regions in Central and Western Europe possess high quality data compared to other parts of the world (Lambdon *et al.*, 2008; Pyšek, Blackburn, *et al.*, 2017; Pyšek, Pergl, Dawson, *et al.*, 2020). Many countries have specialized catalogues and inventories with information going beyond the distribution of alien species (e.g., Celesti-Grapow *et al.*, 2009; E. J. Clements & Foster, 1994; Essl & Rabitsch, 2002; Klotz *et al.*, 2003; Preston *et al.*, 2002, 2004; Pyšek *et al.*, 2002; S. C. P. Reynolds, 2002). For Eastern Europe, there are data gaps and incomplete species lists for several countries including a large part of Russia (van Kleunen *et al.*, 2015, 2019). Work is currently underway to close this data gap (e.g., Leostrin & Pergl, 2021; Vinogradova *et al.*, 2018), and more species are likely to be identified as established alien species in Europe. Some countries in Central Asia also lack inventories (appendix 1 in Pyšek, Blackburn, *et al.*, 2017).

2.5 TRENDS AND STATUS OF ALIEN AND INVASIVE ALIEN SPECIES BY IPBES UNITS OF ANALYSIS

This section reports on the temporal trends and status of the distribution of alien and invasive alien species for each IPBES unit of analysis. IPBES units of analysis represent a broad-based global classification system considering both the state of nature in classes, equivalent to biomes, and in anthropogenically-altered biomes or "anthromes". The units correspond broadly to global classifications of nature and human interactions, serving the need for analysis and communication in a global policy context. More details about the units of analysis are provided in **Chapter 1**, **section 1.6.5** and online (IPBES, 2019b). The following section is sub-divided into an overview (**section 2.5.1**), terrestrial (**section 2.5.2**), freshwater (**section 2.5.3**), and marine (**section 2.5.4**) units of analysis as well as anthroponized areas (**section 2.5.5**).

2.5.1 Overview of trends and status by IPBES units of analysis

While no studies on biological invasion dynamics among comparative units of analysis exist, some studies have investigated patterns using similar delineations of study regions such as freshwater, marine, and terrestrial habitats. In general, far more studies are available for terrestrial alien species (although availability varies for above- and belowground) than for marine and freshwater systems. For instance, one comprehensive global analysis of first records of established alien species shows that 64 per cent of all studies had an explicit focus on terrestrial habitats, 13 per cent addressed marine and 12 per cent freshwater habitats, and the remaining were cross-taxonomic (Seebens, Blackburn, *et al.*, 2017). As a result, most established alien species have been reported from terrestrial habitats (over 75 per cent), while freshwater or marine alien species numbers are both of similarly low range (less than 10 per cent). Terrestrial alien species invasions were usually recorded earlier in time compared to freshwater species, which in turn were reported earlier than marine species (Zieritz *et al.*, 2017). Likewise, before 1840 most (about 75 per cent) established alien species recorded in north-western Europe represented terrestrial species, and the proportion has dropped continuously to less than 20 per cent more recently (Zieritz *et al.*, 2017). Only a few studies compared the trends and status of alien species across terrestrial, freshwater, and marine habitats at large spatial scales (e.g., Roy, Peyton, *et al.*, 2014; Sandvik, Dolmen, *et al.*, 2019; H. Xu *et al.*, 2012; Zieritz *et al.*, 2017). Other studies reported similar increases in established alien species across terrestrial, marine, and freshwater habitats with a tendency of freshwater alien species numbers accelerating more rapidly in recent years (O'Flynn *et al.*, 2014; Roy, Preston, *et al.*, 2014; H. Xu *et al.*, 2012).

2.5.2 Trends and status of alien and invasive alien species in terrestrial units of analysis

Box 2 7 **Mountain regions: A global assessment of trends and status of alien and invasive alien species.**

Elevational patterns of plant invasions have been described for many mountain regions around the world and with very few exceptions, established alien species richness peaks at lower elevations and declines towards the highest elevations, closely following patterns of human settlements and disturbance (e.g., Alexander *et al.*, 2011; Fuentes-Lillo *et al.*, 2021; Haider *et al.*, 2010; Pauchard *et al.*, 2009; Pérez-Postigo *et al.*, 2021; Tanaka & Sato, 2016). Most introduced alien species are pre-adapted to the environmental conditions at low elevations and need a broad environmental tolerance to spread towards high mountain sites (Alexander *et al.*, 2011). Therefore, alien species at high elevations are typically environmental generalists, and only rarely are mountain specialist species directly introduced at high elevations (Alexander *et al.*, 2016; Steyn *et al.*, 2017). As the regional lowlands are the most important source of alien plants found at high elevations, alien mountain floras are surprisingly dissimilar across mountain ranges and continents. In a study analyzing alien species lists from 13 mountain regions, about 60 per cent of alien species were recorded in a single mountain area, and less than 5 per cent were found in more than half of the regions included in the study (McDougall *et al.*, 2011).

Anthropogenic corridors such as roads, trails, and railways strongly facilitate the spread of alien plants from low to high elevations (Alexander *et al.*, 2011; Lembrechts *et al.*, 2017; Liedtke *et al.*, 2020; Rashid *et al.*, 2021; M. Yang *et al.*, 2018), and alien plants are much more common in disturbed habitats directly adjacent to such corridors compared to more remote natural habitats (Seipel *et al.*, 2012). Thus far, few alien species have been able to penetrate natural communities, especially at higher elevations, but those that have invaded are often shade and moisture tolerant (McDougall *et al.*, 2018).

While there is no evidence that alien species in mountains have caused the local extinction of native species, they have a strong impact on multiple dimensions of biodiversity (B. W. van Wilgen *et al.*, 2020). First, they reduce differences in community composition between low and high elevations, and thus negatively affect beta-diversity, leading to a biotic homogenization in mountains – and in the long-term maybe also across mountain regions. A global study based on a standardized vegetation survey demonstrated that alien species along roadsides either shifted the richness peak of native plants to lower elevations, or even changed the shape of the relationship between native species richness and elevation (Haider *et al.*, 2018).

In the last 15–20 years, research on plant invasion patterns in mountains has increased markedly. However, published studies are unevenly spread across mountains worldwide. While there are many studies from regions with temperate or Mediterranean climates, there are few from the subtropics and tropics (e.g., the Andes, mesoamerica, Africa, and Asia) or high latitude boreal and Arctic regions. A second shortcoming is the lack of long-term monitoring of alien species in mountains. Few studies have used permanent monitoring sites to document changes in alien species occurrence in mountains (but see Kalwij *et al.*, 2015; Turner *et al.*, 2021). The Mountain Invasion Research Network (MIREN, www.mountaininvasions.org) has developed a standardized survey protocol to study and monitor patterns of plant invasions into mountains (but not in Africa), which has been applied in 19 regions worldwide since 2007 (Haider *et al.*, 2022; **Figure 2.34**). While assessing future trends of alien plant species distributions in mountains remains a challenge, efforts are being conducted to model invasions using data collected at multiple scales especially under climate change (Lembrechts *et al.*, 2017; Petitpierre *et al.*, 2016) and shifts in biotic interactions using evidence collected through both observational and experimental approaches. Such studies show that future plant invasions in mountains will increase in the future under climate change and increased anthropogenic pressure (Alexander *et al.*, 2016; Petitpierre *et al.*, 2016).

2.5.2.1 Tropical and subtropical dry and humid forests

Tropical and subtropical forests cover about 52 per cent of global forested land and hold 200 billion tons of carbon in aboveground biomass (IPBES, 2019a). These ecosystems harbour the highest biological diversity globally, but also the highest number of threatened species (IPBES, 2019a). Since 1990, over 250 million hectares were cleared for agriculture and urban expansion, infrastructure and mining (IPBES, 2019a; Vancutsem *et al.*, 2021). Although some regions have reported net gain in forest cover, this trend is mainly driven by planted-forest expansion with alien tree and palm species (Sloan & Sayer, 2015).

Trends

Historically, tropical and subtropical dry and humid forests have experienced fewer introductions of alien species relative to temperate ecosystems. Compared to other mainland terrestrial regions of the globe, tropical and subtropical dry and humid forests have lower numbers of

Box 2 7

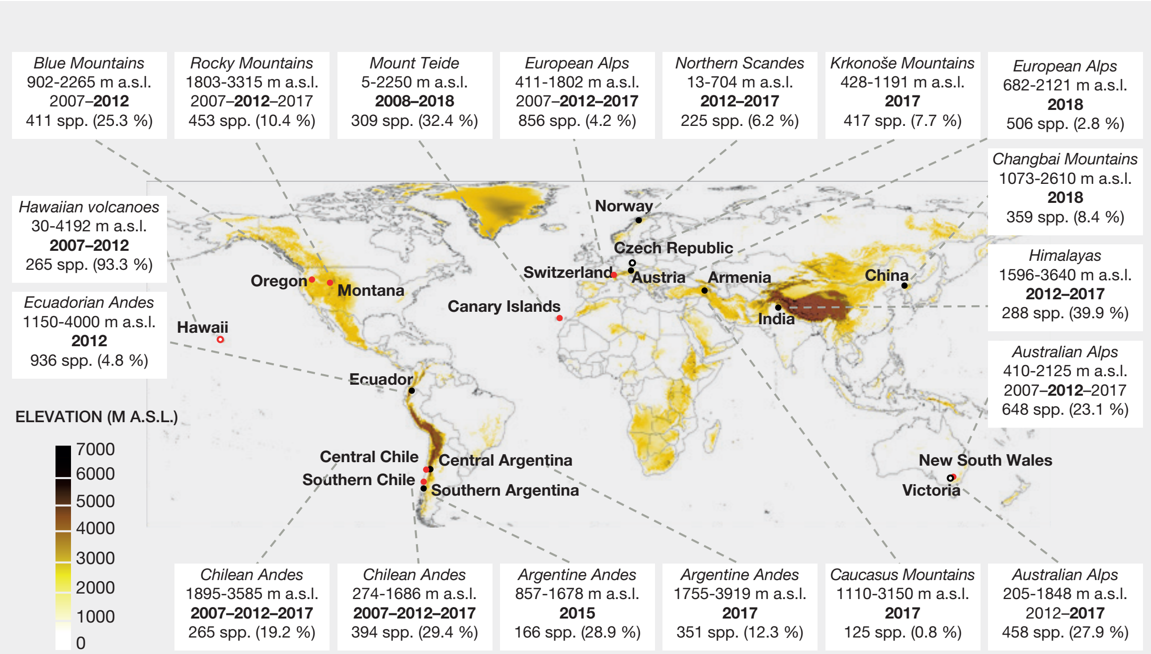

Figure 2 34 **Locations of the MIREN surveys.**

Sites in mountain regions where MIREN surveys have been used to sample and monitor plant invasions across elevational gradients. Source: Haider *et al.* (2022), https://doi.org/10.1002/ece3.8590, under license CC BY 4.0.[3]

invasive alien species for all taxonomic groups (Dawson *et al.*, 2017). For instance, records of invasive alien species in the tropical and dry forests of South America mostly date from the past 50 years and have increased only in the last 20 years (Zenni, 2015; Zenni & Ziller, 2011). Also, tropical South America has two or three times fewer established alien plants than temperate South America despite its greater area (Zenni *et al.*, 2022). However, the recent and ongoing increases in biological invasions in tropical and subtropical dry and humid forests can be attributed in large part to agricultural and urban expansion and increased propagule pressure (Waddell *et al.*, 2020). Forest degradation and clearcutting allow the establishment and spread of numerous invasive alien grass species, some of the most prominent invaders in tropical forest ecosystems (Dar *et al.*, 2019; Zenni, 2015; Zenni & Ziller, 2011).

Lack of reliable baseline information from most countries in Asia prevents a comprehensive analysis of trends of alien plant invasions in tropical and subtropical forests in this region. Available information shows an increase of one to eight major species during a period of 7-18 years in five countries in the region (Banerjee *et al.*, 2021; Government of Myanmar, 2005; Islam *et al.*, 2003; Khuroo *et al.*, 2012; Mukul *et al.*, 2020; Pallewatta *et al.*, 2003; Shrestha & Shrestha, 2021; Tiwari *et al.*, 2005; Wijesundara, 2010).

Status

Some tropical and subtropical dry and humid forests on islands have some of the most noteworthy examples of biological invasions. Hawaii, for instance, has a greater number of established alien species than native species (G. W. Cox, 1999). Species such as *Psidium cattleianum* (strawberry guava), *Morella faya* (firetree), *Hedychium* spp. (ginger), and *Sus scrofa* (feral pig) have caused significant ecological impacts in Hawaiian tropical forests. Another highly invaded tropical island, the Galapagos, considers biological invasions the most relevant threat to native

These maps have been prepared or used for the sole purpose of facilitating the assessment of the broad biogeographical areas represented therein and for purposes of representing scientific data spatially.

biodiversity and the alien taxa outnumber the native species (Zenni *et al.*, 2022). In Guam, invasive alien reptiles (notably *Boiga irregularis* (brown tree snake)) and some invasive alien tree species have been reported to extirpate native species and drastically change ecosystem processes (Fritts & Leasman-Tanner, 2001; Marler, 2020).

In South America, there are 247 known established alien plant species in Bolivia, 503 in Brazil, 265 in Colombia, 348 in Ecuador, 166 in Guyana, 72 in Paraguay, 288 in Peru, and 219 in Venezuela (Zenni *et al.*, 2022). For the Caribbean, there are at least 446 invasive alien species known among plants, invertebrates, vertebrates, fungi, and diseases (Kairo *et al.*, 2003). *Herpestes javanicus auropunctatus* (small Indian mongoose) is one of the most notorious of these species in the Caribbean as it has been associated with the extinction of five native species. In Asia, 179 invasive alien species have been recorded in tropical forests of central India (Dar *et al.*, 2019). For plants, the numbers of invasive alien plants in tropical and subtropical forests (based on data from 10 countries) range from 15 to 58, the highest being in forests of Indonesia (58 species) followed by forests in China (52) (Banerjee *et al.*, 2021; Mukaromah & Imron, 2019; Mukul *et al.*, 2020; Qureshi *et al.*, 2014; Shrestha & Shrestha, 2021; D. T. Tan *et al.*, 2012; Weber *et al.*, 2008; Wijesundara, 2010; H. Xu *et al.*, 2012). The most widespread species in the region are *Lantana camara* (lantana) (recorded in 18 countries of the 19 for which data are available), *Leucaena leucocephala* (leucaena, 18 countries), *Mikania micrantha* (bitter vine, 16 countries), *Ageratum conyzoides* (billy goat weed, 16 countries), *Chromolaena odorata* (Siam weed, 15 countries), *Mimosa diplotricha* (giant sensitive plant, 13 countries), *Prosopis juliflora* (mesquite, 12 countries) and *Parthenium hysterophorus* (parthenium weed, 11 countries).[4] In India, the invasive alien plant *Chromolaena odorata* dominates the understory of forests and has been shown to negatively affect the pollination of native species (Peh, 2010; **Chapter 4**, **section 4.4.3**). Another invasive alien plant *Lantana camara*, a plant species native to South America and invasive in most tropical regions of the world, can greatly reduce the productivity of economically important plants (Peh, 2010).

In Africa in recent decades the establishment of alien tree plantations, mainly pines and eucalyptus, has been a high priority in governmental forestry (Obua *et al.*, 2010; Tumushabe & Mugyenyi, 2017). The replacement of natural forests with alien species, coupled with other human disturbances, has compounded the threat of invasive alien species that include plants such as *Broussonetia papyrifera* (paper mulberry), *Senna spectabilis* (whitebark senna), *Lantana camara* (lantana; Totland *et al.*, 2005), and also insect species like *Gonometa podocarpi* (podocarpus moth; FAO, 2012), *Achaea catocaloides* (African apple tree moth; e.g., Martins *et al.*, 2015) and *Leptocybe invasa* (blue gum chalcid; FAO, 2012). These invasive alien species have the potential to pose a threat to forest ecosystems (Hamilton *et al.*, 2016). However, very little is known about the invasion of alien species into tropical forests and there is no up-to-date detailed assessment of the potential risks that these invasive alien species, especially under rapidly changing climate, are causing to the forests and their associated biodiversity and nature's contributions to people (**Chapter 3**, **section 3.3.4**).

4. Data extracted from the Global Invasive Species Database (GISD; http://www.iucngisd.org/gisd/), GRIIS (https://doi.org/10.5281/zenodo.6348164) and Association of South-east Asian Nations (ASEAN; https://asean.org/)

Data and knowledge gaps

A worldwide review of invasive alien species in tropical and subtropical dry and humid forests has never been done, and most data available to date are at the country-level rather than at the level of biogeographic regions such as units of analysis. Of the countries with major areas covered by tropical and subtropical dry and humid forests, data are available mostly for South America, some parts of Mesoamerica and the Caribbean, and for South Asia, while data is scarce for tropical and subtropical dry and humid forests in Africa.

Biological invasions in tropical and subtropical dry and humid forests have been less studied than most other terrestrial ecosystems. This lack of data is, in part, explained by the lower numbers of invasive alien species recorded for tropical forests compared to other ecosystems. However, given the growing anthropogenic pressure over these regions, it is likely that biological invasions will increase in the next decades in tropical and subtropical forests, especially in regions with high intensity of land use change. Most reports available for tropical and subtropical dry and humid forests are for plant invasions, and there is very limited data on animal invasions except for a few well-studied species, such as *Herpestes javanicus auropunctatus* (small Indian mongoose) and *Boiga irregularis* (brown tree snake). For most regions with these forests, lists of established plant species are available (Pyšek, Pergl, *et al.*, 2017; van Kleunen *et al.*, 2019), but these data provide very little insight into the actual situation of biological invasions in tropical and subtropical dry and humid forests (e.g., spread and impacts).

As a general trend in Asia, the cumulative number of invasive plants is known to increase exponentially over years (e.g., in China: H. Xu *et al.*, 2012). However, information on trends and status of invasive alien plants in tropical and subtropical forests in Asia are largely unavailable. Attempts are currently being made by some countries to prepare national inventories for invasive alien plants (e.g., Dorjee *et al.*, 2020; Mukul *et al.*, 2020), though these lists do not appear to include information on the habitats in which the alien species occur.

2.5.2.2 Temperate and boreal forests and woodlands

Trends

The view that forested ecosystems are resistant to invasions by alien plants has eroded over the past two decades as observations of local dominance by both herbaceous and woody invaders in forests worldwide accumulate (Fridley, 2013; Liebhold *et al.*, 2017; P. H. Martin *et al.*, 2009). Although estimates of trends in alien plant richness specific to forests are difficult to determine for most regions, biological invasions in temperate forests are increasing globally and will likely accelerate as high latitudes continue to warm with climate change (Pauchard *et al.*, 2016; **Chapter 3**, **section 3.3.4**), particularly for boreal forests (Mulder & Spellman, 2019; Sanderson *et al.*, 2012). Habitat fragmentation and road-building activities are also principal drivers that facilitated he increase in forest plant invasions (**Chapter 3**, **section 3.3.1.2**), both as a means to disperse alien propagules and to increase light and nutrient availability, which facilitate the growth of invader source populations that may spread into adjacent closed-canopy forests (R. O. Bustamante & Simonetti, 2005; Flory & Clay, 2009; Kuhman *et al.*, 2010). Afforestation (i.e., plantation of trees in areas without previous tree cover) represents another driver that promotes biological invasions (Ramprasad *et al.*, 2020). Forest invasion research lags behind that of grasslands and wetlands (Nunez-Mir *et al.*, 2017), and temperate and especially boreal forests tend to be remote, making the early stages of biological invasions difficult to monitor (Liebhold *et al.*, 2017). As a result, the colonization of temperate and boreal forests by alien plants is likely much greater than currently reflected in the literature (P. H. Martin *et al.*, 2009).

Status

In the Northern Hemisphere, North American deciduous forests have a larger number of alien plant species than those of Europe and Asia (Fridley, 2013; Heberling *et al.*, 2017), including a substantial number of alien shrubs, lianas, and small trees introduced as ornamentals (Fridley, 2008). In contrast, the most negatively impactful alien plants in European temperate forests are trees (**Chapter 4**, **section 4.3.2.1**; Campagnaro *et al.*, 2018; Essl *et al.*, 2011; Langmaier & Lapin, 2020), many of which were intentionally introduced for timber production or forest reclamation (e.g., *Prunus serotina* (black cherry; Closset-Kopp *et al.*, 2007), *Quercus rubra* (northern red oak; Major *et al.*, 2013), *Robinia pseudoacacia* (black locust; Vítková *et al.*, 2017)), and woody species are the most numerous species in forest understory (V. Wagner *et al.*, 2017). Deciduous forests of East Asia, which tend to have higher levels of native species richness than other temperate forests (Qian & Ricklefs, 2000), remain relatively uninvaded (B. Auld *et al.*, 2003; Fridley, 2013; but see Wavrek *et al.*, 2017); further, woody species in general are strongly under-represented in the alien floras of China (Axmacher & Sang, 2013; Weber *et al.*, 2008), Korea (Heberling *et al.*, 2017), Japan (B. Auld *et al.*, 2003), and the Russian Far East (Kozhevnikov & Kozhevnikova, 2011). Boreal forests across the northern hemisphere are among the least invaded forest types outside the tropics (Leostrin & Pergl, 2021; Sanderson *et al.*, 2012); however, climate change is widely expected to accelerate understory plant invasions (Mulder & Spellman, 2019; **Chapter 3**, **section 3.3.4**), and many fast-growing herbaceous alien species are already disrupting native tree regeneration in forest gaps (e.g., *Cirsium arvense* (creeping thistle); Humber & Hermanutz, 2011). In European (deciduous) forests, 386 alien plant species were recorded in forest understory and the most common, *Impatiens parviflora* (small balsam), was recorded in 21 per cent of sampled plots (V. Wagner *et al.*, 2017). Plant invasions of forests of temperate South America remain understudied but there is some evidence that North American plantation conifers (e.g., *Pinus contorta* (lodgepole pine), *Pseudotsuga menziesii* (Douglas-fir)) are able to establish in native evergreen forests (Pauchard & Alaback, 2004; Peña *et al.*, 2008; Simberloff *et al.*, 2009), along with herbaceous species such as *Prunella vulgaris* (self-heal; Godoy *et al.*, 2011). Plantation conifers (e.g., *Pinus radiata* (radiata pine)) are also an increasing concern in dry eucalypt forests of Australia (M. C. Williams & Wardle, 2005).

Data and knowledge gaps

Although alien plant lists are increasingly available for regions where forest invasions are understudied, including Turkey (Akbulut & Karaköse, 2018; Yazlık *et al.*, 2018), Iran (Sohrabi *et al.*, 2021), and Siberia (Vinogradova *et al.*, 2018), the richness and abundance of invasive alien plants specific to temperate forested habitats remains unknown for many regions outside North America and Europe (Heberling *et al.*, 2017). One of the key knowledge gaps is the role of shade tolerance in alien species establishment: many alien plants establish following disturbance and persist under a closed canopy, but relatively few alien plants can recruit into intact temperate and boreal forests (P. H. Martin *et al.*, 2009; V. Wagner *et al.*, 2021). A priority of future research is to understand the interplay of disturbance, climate change, and biological invasions (**Chapter 3**, **section 3.3.4**) in altering the trajectory of native forest stands to what will likely become novel communities of mixed native and alien species (Chmura, 2020).

2.5.2.3 Mediterranean forests, woodlands and scrub

Trends

Although no comprehensive analysis of the trends of alien species for Mediterranean ecoregions (Mediterranean Basin, South Africa, North America, South America and Australia) exists, it seems likely that the number of alien species increases as observed for other regions. As with other units of analysis, increases in the number of alien species and rates of new records results not only from increased transport of species (e.g., trade, human population, spread, tourism; M. C. Jackson & Grey, 2013), but also from increasing wildfires (e.g., Keeley *et al.*, 2005), increased sampling intensity (both in the field and for bibliographic searches) and greater awareness of invasive alien species (L. Henderson & Wilson, 2017). Some regions and taxa have recently shown a deceleration in new introductions as a result of successful invasive alien species management or national and transnational regulations (European Union, 2014; Murray & Phillips, 2012). This is the case with, for example, birds in the Iberian Peninsula (Abellan *et al.*, 2016), plants and terrestrial vertebrates in Chile (Fuentes *et al.*, 2020), and invasive plants in Australia (Murray & Phillips, 2012).

In South Africa, the South African Plant Invaders Atlas reports a general increase in both the numbers of alien plant species and total area occupied (L. Henderson, 2007). While the rate of spread of alien plants decreased in some cases and even contracted in a few cases as a result of classical biocontrol, overall, 172 new alien plant species emerged between 2006 and 2016 and those already established expanded their ranges (L. Henderson & Wilson, 2017). An increase in alien species numbers in the Mediterranean parts of the country, due to horticulture and floriculture, is reported; the area of fynbos in South Africa is referred to as one the most heavily invaded biomes in the country (L. Henderson, 1998; B. W. van Wilgen, 2018).

Some countries in the Mediterranean Basin (e.g., Portugal) have good records of temporal trends of plant species dating back to 1500. A steady increase in alien species numbers occurred over time with an acceleration in the introduction of new species at late nineteenth century, some deceleration between 1930–1940 and a new acceleration at least up to 2018 (Almeida, 2018; Almeida & Freitas, 2001). Other countries in the Mediterranean Basin, such as Albania (Barina *et al.*, 2014), experienced accelerated introductions later during the mid-twentieth century with few alien species reported before that time.

From 1500 to 1903 more populations of alien birds were introduced to the Mediterranean parts of South Africa, Australia, California, and fewer to Chile and the north-western countries of the Mediterranean Basin. By the end of the twentieth century, this trend exhibited some changes with more bird populations introduced in the north-western countries of the Mediterranean Basin (with a hotspot in Spain), in Western Cape (South Africa) and California (United States) (E. E. Dyer, Cassey, *et al.*, 2017). At least in the Iberian Peninsula, the pronounced increase after 1955 – particularly steep after the 1980s – was followed by a decrease by 2005, possibly explained by the ban of wild-caught birds in Spain after the avian flu and regulations to reduce invasion risk (Abellan *et al.*, 2016).

Amphibians and reptiles were reported as introduced to Mediterranean areas only after 1800, with increasing numbers of records of new established alien species after mid-1900 (Capinha *et al.*, 2017).

In California, United States, alien terrestrial macroinvertebrates have been established since 1700, with many species (ca. 39 per cent) introduced before 1930. A more detailed analysis from 1935 – 2010 demonstrates the regular detection of new species of alien arthropods across the 75 years in three distinct phases: higher mean values early in this period, decreased detections 1970 to late 1980s, followed by an increase (Dowell *et al.*, 2016).

Status

Comprehensive information about terrestrial alien vascular plants is available for most countries with a Mediterranean climate (e.g., Almeida, 2018; Arianoutsou *et al.*, 2010; Barina *et al.*, 2014; Fuentes *et al.*, 2020; Galasso *et al.*, 2018; Meddour *et al.*, 2020; B. W. van Wilgen, 2018), and most of the checklists provide information about the status of the species (Pyšek, Pergl, *et al.*, 2017 for summary data on established alien plants).

All the Mediterranean regions share a higher percentage of alien plant species with southwest Australia than with any other region. Chile and the Mediterranean Basin share comparatively fewer alien plant species with the other regions (Arianoutsou *et al.*, 2013). Common invasive plants in and from Mediterranean areas are *Oxalis pes-caprae* (Bermuda buttercup), *Acacia* spp., *Carpobrotus edulis* (hottentot fig), *Ulex* spp. (Gorse), *Cytisus* spp., and *Hakea* spp. (Pincushion tree). Most Mediterranean areas also share alien species that have originated from different climates, e.g., *Ailanthus altissima* (tree-of-heaven), *Conyza* spp., and *Agave americana* (century plant).

Publications on alien plants are more common than for other taxonomic groups (e.g., Chile; Fuentes *et al.*, 2020; N. J. van Wilgen *et al.*, 2018; IUCN SSC Invasive Species Specialist Group (ISSG)). In Mediterranean areas, alien bird species richness is high in some regions of California, western parts of the Mediterranean basin, South Africa, and Australia (E. E. Dyer, Cassey, *et al.*, 2017). Alien reptiles and amphibians (Capinha *et al.*, 2017) present in the five global Mediterranean areas are more numerous in terms of species numbers in California and Spain, and have few documented species (or are even absent) in northern Africa and Eastern Europe. Terrestrial invertebrates also show high numbers of alien species, for example, in California (over

1,600 species, approximately 85 per cent insects) (Dowell *et al.*, 2016).

Data and knowledge gaps

In countries covering multiple units of analysis, the trends and status for alien species in the Mediterranean zone is mostly not specifically described. Some countries with Mediterranean climates, particularly Syria, Lebanon, Malta, and Macedonia, have not yet published comprehensive inventories of alien species. Detailed distribution maps of specific alien species in Mediterranean areas are not frequently found.

2.5.2.4 Arctic and mountain tundra

Trends

Early introductions of alien plant and vertebrate species in polar regions were largely intentional (e.g., revegetation of industrial sites and fur farming (Forbes & Jefferies, 1999; Usher, 2005), while current introductions are often unintentional (Tolvanen & Kangas, 2016; Wasowicz *et al.*, 2020). Future increases in alien species richness across taxonomic groups for both Arctic and mountain tundra regions is expected due to climate change and increasing anthropogenic activity including deliberate ornamental plant introduction related to tourism development or unintentional introductions along roads, trails, and mineral extraction sites (**Chapter 3**, Carboni *et al.*, 2018; Nielsen & Wall, 2013; Normand *et al.*, 2013; Petitpierre *et al.*, 2016; Solovjova, 2019; C.-J. Wang *et al.*, 2017; Ware *et al.*, 2016; Wasowicz *et al.*, 2013). However, a modelling study on the 100 world's worst invaders projected no increase in suitability of tundra regions to invasive alien species until 2100 as climatic conditions for some of these species might become too extreme in the future, or as ongoing degradation and land use change might render current habitats unsuitable (Bellard, Thuiller, *et al.*, 2013). Invasive alien disease risks are likely to increase in the future under climate change, with potential increases in disease transmission between domestic species and Arctic wildlife, as well as through increased survival probability and range expansion of introduced disease vectors or increased host susceptibility under climate change (Bradley *et al.*, 2005; Dudley *et al.*, 2015; Kutz *et al.*, 2004; Waits *et al.*, 2018).

Similarly, mountain regions have been mostly spared from biological invasions because of low anthropogenic pressure and harsh climates (Kueffer *et al.*, 2013; Pauchard *et al.*, 2009; Petitpierre *et al.*, 2016). However, many high mountain regions globally have increasing alien species richness, especially for plants (Alexander *et al.*, 2016; Becker *et al.*, 2005; Carboni *et al.*, 2018; Pauchard *et al.*, 2009; Pickering *et al.*, 2007; Williamson & Fitter, 1996). Future alien species colonizers are expected to have wide climatic niches (like most current invasive alien species) and will likely increase their range sizes from low elevations *via* an upward expansion of their current range limits, with expansion rates for alien plants being twice as high as for native plant species (Alexander *et al.*, 2011, 2016; Carboni *et al.*, 2018; Dainese *et al.*, 2017). Direct introductions of more specialized (i.e., cold adapted) alien species into high elevation environments will also likely increase because of increased tourism and targeted introduction for ornamental purposes (Alexander *et al.*, 2016; Carboni *et al.*, 2018; Godde *et al.*, 2000; Kueffer *et al.*, 2013; McDougall *et al.*, 2005). Genetic adaptability of alien species at range margins resulting in the colonization of cooler sites will likely further increase the risk of future invasions (Alexander, 2010). Bryophytes are common alien species in cold environments (Rozzi *et al.*, 2008) and the likelihood of alien bryophytes invading high mountain and Arctic tundra ecosystems is assumed to be high (Essl *et al.*, 2013; Pauchard *et al.*, 2016).

Status

Established alien species richness across taxonomic groups decreases towards higher latitudes (Capinha *et al.*, 2017; E. E. Dyer, Cassey, *et al.*, 2017; Essl *et al.*, 2013; Pyšek & Richardson, 2006; Qian, 2008; Sax, 2001) and high elevations (M. Ahmad *et al.*, 2018; Alexander *et al.*, 2011; Q. Guo *et al.*, 2021; Haider *et al.*, 2010; Kalwij *et al.*, 2008; Khuroo *et al.*, 2011; Marini *et al.*, 2013; Western & Juvik, 1983), but exceptions exist (Paiaro *et al.*, 2011; Rosa, 2020). Arctic regions have been identified as coldspots for alien species richness across different taxonomic groups (e.g., plants, birds, mammals, spiders, ants, amphibians, reptiles, fishes), especially Greenland, northern North America and northern Europe (Dawson *et al.*, 2017). Alaska and northern Central Asia have higher alien richness of several taxonomic groups, but these patterns might be influenced by different sampling intensity and data availability across regions (Dawson *et al.*, 2017). In mountain and arctic tundra, alien plants are generally found in anthropogenically disturbed sites and along transportation infrastructure routes (Alexander *et al.*, 2011, 2016; Forbes & Jefferies, 1999; Haider *et al.*, 2010; Kalwij *et al.*, 2008; Khuroo *et al.*, 2011), and their richness decreases with increasing distance from these structures (Arteaga *et al.*, 2009; Haider *et al.*, 2022; Pauchard & Alaback, 2004; Seipel *et al.*, 2012). Successful invaders are mainly graminoid or weedy species (Alexander *et al.*, 2016; Carey *et al.*, 2016; Forbes & Jefferies, 1999; Wasowicz *et al.*, 2020) however, primary invasion along mountain roads tends to promote longer lived species (McDougall *et al.*, 2018). Species richness increases across taxonomic groups are mainly linked to invasions from lower elevations and latitudes under climate change, and increasing anthropogenic pressure associated with intentional introductions (Alexander, 2010; Bertelsmeier *et al.*, 2015; Carboni *et al.*, 2018; Dainese *et al.*, 2017;

Godde *et al.*, 2000; Greve *et al.*, 2017; Kueffer *et al.*, 2013; McDougall *et al.*, 2005; Parkinson & Butler, 2005; Wasowicz *et al.*, 2013, 2020) but some invasive alien species might also lose suitable habitats when the climatic conditions become too extreme in the future (Bellard, Thuiller, *et al.*, 2013).

Data and knowledge gaps

No dedicated gap analysis is currently available for Arctic and mountain tundra regions. However, the same regional gaps emerge across taxonomic groups as for global alien richness datasets. In particular, data is missing for most taxonomic groups in the northern part of Asia (Dawson *et al.*, 2017) and research efforts are generally less intensive for animals and plants at higher latitudes (Lenoir & Svenning, 2015). Given that animals and plants are two of the most studied taxonomic groups, this is likely also true for other taxonomic groups such as mosses, lichens, and microorganisms.

2.5.2.5 Tropical and subtropical grasslands

In the Millennium Ecosystem Assessment (2005) tropical grasslands and savannas were regarded as less affected by plant invasions relative to other biomes, but there is an increasing trend in both distribution and alien species richness in these biomes. Thus, although invasive alien species have only recently been considered as a main threat to biodiversity conservation and functioning of tropical grasslands and savannas, they are likely to become much more widespread in the future. Within the grassland-savanna biome, frequently seasonally flooded river and stream banks are generally substantially more vulnerable to plant invasions than areas away from rivers (Pyšek, Hulme, *et al.*, 2020; D. M. Richardson *et al.*, 2007), but with notable exceptions.

The current low incidence and impact of alien plants in savannas relative to some other terrestrial biomes may be because disturbance, which generally favours invasions, is fundamental to savanna functioning (**Chapter 4**, **section 4.3.2.1**). Savannas are resilient to changes in disturbance regimes (Harrison & Shackleton, 1999; Walker & Noy-Meir, 1982), making them relatively resistant to biological invasions in some areas (Foxcroft, Richardson, *et al.*, 2010). Drivers facilitating plant invasions in savannas include herbivore presence, residence time, intentional introductions for pasture improvements, the introduced species' physiology, and anthropogenic disturbance (Foxcroft, Richardson, *et al.*, 2010). While fire regimes may play a role in preventing alien plant invasions in fire prone systems, the increasing invasion of cacti (less affected by fire in areas denuded of grass cover) in African savannas, and fire adapted African grasses in northern Australian and southern American savanna grasslands are overcoming this barrier.

Trends

Although no study about trends of alien species in tropical and sub-tropical grasslands yet exists, it seems likely that the number of alien species are increasing likewise to other regions worldwide such as temperate grasslands (**section 2.5.2.6**).

Status

Foxcroft, Richardson, *et al.* (2010) suggested that African savannas are less invaded than savannas in the Neotropics and northern Australia, where alien African grasses especially have had significant impacts, due to (i) lower rates of intentional plant introductions to that continent, (ii) the role of large mammalian herbivores in African savannas, (iii) historical and biogeographical issues relating to the regions of origin of alien species, and (iv) the adaptation of African systems to fire. Moreover, many forms of anthropogenic land use over a long period (Bourlière & Hadley, 1983), together with high levels of frequent disturbances, may have resulted in alien plants being not yet very widespread or common in African savannas (Foxcroft, Richardson, *et al.*, 2010). In Southern Africa, L. Henderson and Wells (1986) listed 583 established alien plants for tropical savannas, of which 151 were known to be particularly impactful invasive alien species, and L. Henderson (2007) reported 48 alien species for the savanna biome of South Africa alone. *Lantana camara* (lantana), *Chromolaena odorata* (Siam weed) and *Melia azedarach* (Chinaberry) were the most prominent invasive alien species, followed by *Solanum mauritianum* (tobacco tree), *Acacia mearnsii* (black wattle), *Opuntia ficus-indica* (prickly pear), *Ricinus communis* (castor bean), *Psidium guajava* (guava), and *Jacaranda mimosifolia* (jacaranda). Examples of invasive alien species in protected areas include *Chromolaena odorata* in Hluluwe-Imfolozi (Macdonald, 1983) and *Opuntia stricta* (erect prickly pear) in Kruger National Park (Foxcroft *et al.*, 2004). More recent evidence from East Africa suggests these trends of savannas being less invaded are reversing and biological invasions are rapidly increasing. While the Serengeti-Mara ecosystem in East Africa is relatively free of widespread and abundant invasive alien plants, with a few exceptions, Witt *et al.* (2017) report 51 established alien plant species, with 21 of these recorded as invasive. They consider *Parthenium hysterophorus* (parthenium weed), *Opuntia stricta, Tithonia diversifolia* (Mexican sunflower), *Lantana camara, Chromolaena odorata*, and *Prosopis juliflora* (mesquite) to pose the greatest threats. In central Kenya, Laikipia County, which comprises grasslands, savanna woodland and forest, 145 alien plant species recorded, 67 and 37 were already established or invasive, respectively (Witt *et al.*, 2020). Widespread species in the county included *Opuntia stricta,* *Opuntia ficus-indica, Austrocylindropuntia subulata* (Eve's needle cactus), and other succulents (Witt *et al.*, 2020).

"New World" neotropical savannas are locally highly invaded mostly by African C4 grasses introduced for forage quality improvement (e.g., *Hyparrhenia rufa* (jragua grass), *Urochloa eminii* (signal grass), *Melinis minutiflora* (molasses grass), *Andropogon gayanus* (tambuki grass), *Panicum maximum* (Guinea grass); Rejmánek *et al.*, 2013). In Brazil, this practice was encouraged into the late 1990s (Pivello *et al.*, 1999). In Colombia, Venezuela, and Brazil, about 4 million km^2 were transformed to pasture by using, to a large extent, African C4 grasses (D. G. Williams & Baruch, 2000). Gorgone-Barbosa *et al.* (2015) also reported *Urochloa brizantha* (palisadegrass) to be an aggressive invasive alien grass in the Brazilian Cerrado. Trees are, however, also invasive in grassland savanna in São Paulo State, Brazil, where De Abreu and Durigan (2011) reported that *Pinus elliottii* (slash pine) has completely altered the structure of grassland savannas.

African and European grasses are common alien species in Australia (D'Antonio & Vitousek, 1992). Lonsdale (1994) reported that 466 alien pasture species were intentionally introduced into the savannas of northern Australian and many have become invasive (ca.13 per cent). The most impactful invasive alien species in Australian tropical savannas include *Andropogon gayanus* (Tambuki grass) introduced as a pasture grass in the 1930s, whose invasion has led to several-fold increases in the fuel load and fire intensity, further promoting this species' invasion (Rossiter *et al.*, 2003). In Kakadu, *Mimosa pigra* (giant sensitive plant), *Hymenachne amplexicaulis* (hymenachne), *Urochloa mutica* (para grass) (Setterfield *et al.*, 2013), *Cenchrus ciliaris* (buffel grass), *Cenchrus polystachios* (mission grass), *Themeda quadrivalvis* (grader grass) are other fire-regime altering African grasses, while *Vachellia nilotica* (gum arabic tree) from Africa, *Cryptostegia grandiflora* (rubber vine) from Madagascar, *Jatropha gossypiifolia* (bellyache bush) from Mesoamerica, *Lantana camara* (lantana) from the Neotropics, *Mimosa pigra* from South America, or *Prosopis* species (mesquite) from Americas, and *Ziziphus mauritiana* (jujube) from India are examples of woody species invading Australian savannas. There are also several cactus species introduced from Meso- and South America (Foxcroft, Richardson, *et al.*, 2010). Ratnam *et al.* (2019) also shows that across large stretches of fine- and broad-leaved savannas in Asia, *Lantana camara* and *Prosopis juliflora* are widespread, expanding widely over the past three to four decades.

Data and knowledge gaps

Tropical and subtropical savannas and grasslands are in regions understudied compared to other regions of the world making information about alien species scarce and comprehensive studies lacking. It therefore remains unclear to what degree the often-low numbers of reported established alien species in these ecosystems represent low research effort or true numbers. However, given the low numbers of available studies, it seems likely that numbers of established alien species are likely to be considerably higher than reported.

2.5.2.6 Temperate grasslands

Temperate grasslands once covered 5–10 per cent of the terrestrial surface (Dixon *et al.*, 2014; White *et al.*, 2000), yet now rank among the most threatened biomes globally due to land conversion and degradation (Hoekstra *et al.*, 2004; IPBES, 2019a). In North America, ca. 70 per cent of the Great Plains prairie have been converted to cropland and to a lesser degree to pastures and human settlements. Intensive grazing and agricultural usage have transformed many Pampas areas of South America. Conversion is also pronounced in some parts of Central Asia (including Kazakhstan, Kyrgyzstan, Russia, Tajikistan; V. Wagner *et al.*, 2020), but less so in highly continental Asia (Mongolia and China) where the world's largest temperate grasslands are still found (Wesche *et al.*, 2016).

Trends

The ongoing intensifying anthropogenic pressures on grassland ecosystems including climate change will likely further accelerate the establishment of new alien species in temperate grasslands (**Chapter 3**, **section 3.3.4**; Catford & Jones, 2019).

Although comparative studies are lacking, the North American prairie appears to be the temperate grassland region most impacted by alien biota. The history of alien species introductions is linked to the arrival and spread of European settlers in the nineteenth century, and subsequent land conversion (Seastedt & Pyšek, 2011), associated with plant introductions having far-reaching consequences such as the conversion of prairies to annual grasslands dominated by Eurasian grasses such as *Bromus tectorum* (downy brome) (Mack, 1989). Intentional introductions have played a key role in this trend (Lehan *et al.*, 2013; Mack & Erneberg, 2002). For the entire United States, the cumulative number of introduced insect, mite (Sailer, 1983), and bird (Temple, 1992) species has grown consistently since the 1800s. In Kansas, a state that falls entirely within the temperate grassland biome, the number of introduced vascular plants found outside of cultivation has been steadily increasing since the late 1800s but has slowed in the last century (Woods *et al.*, 2005). A similar increase-and-decline pattern was reported for rangelands of Washington, Oregon, Idaho, Montana, and Wyoming (testimony of Peter Reich cited in (Mitchell, 2000) and is in line with reports for California (Rejmánek & Randall, 2004) and the United States as a whole (Seebens, Blackburn, *et al.*, 2017).

In South American grasslands, the number of records of alien plants (C. R. Fonseca *et al.*, 2013), invertebrates (De Francesco & Lagiglia, 2007), birds (Zufiaurre *et al.*, 2016) and vertebrates are still increasing. However, formal trend analyses are lacking as are comprehensive reviews or summary data.

Review data on trends are missing for the Eurasian steppe biome. Although new plant species continue to colonize even highly continental Asia (Urgamal *et al.*, 2014), they remain mainly confined to ruderal and otherwise disturbed habitats, while frequency and abundance in natural grasslands remains low. For the extensive grassland regions of Mongolia and China, an increase towards a higher share of C4 plants in the otherwise C3-dominated vegetation has been described (Wittmer *et al.*, 2010). This is, however, attributed to a higher share of native species (*Cleistogenes* spp. and Amaranthaceae weeds) and may partly be triggered by warmer climate. In the middle of the last century, almost all introduced plants in Kazakhstan were either cultivated or confined to ruderal plants, with none recorded as colonizing temperate steppe grasslands (Pavlov, 1956). Compared to other continents, the trend in continental Asia might indicate a lower introduction pressure, harsher climate conditions, or time lag compared to temperate grasslands in other continents.

Status

The total number of organisms introduced to temperate grasslands worldwide has never been assessed thoroughly. A comparison of the proportion of alien species among all species across habitats revealed that temperate grasslands exhibit intermediate levels of invasions with lower proportions than urban or agricultural habitats but higher proportions than wetlands or planted forests (Catford & Jones, 2019). In states that lie entirely within the Great Plains of the United States (Kansas, Nebraska, North Dakota, Oklahoma, South Dakota), 790 alien vascular taxa (14.6 per cent of the flora) are found outside of cultivation, with forbs and herbs comprising the largest group (553 taxa, 70 per cent of the alien flora) (data extracted from the PLANTS Database; USDA, NRCS, 2021). Introduced plant species have become so common in the prairies that grasslands lacking any alien species are rare (S. DeKeyser *et al.*, 2010; Larson *et al.*, 2001). Examples of invasive alien species include perennial C3 (e.g., *Bromus inermis* (awnless brome), *Poa angustifolia* (Kentucky bluegrass); E. S. DeKeyser *et al.*, 2015; Otfinowski *et al.*, 2007) and C4 (*Bothriochloa ischaemum* (yellow bluestem), *Dichanthium sericeum* (silky bluegrass); Mittelhauser *et al.*, 2011; Simmons *et al.*, 2007) grasses introduced as forage grasses, as well as annual grasses (e.g., *Bromus tectorum* (downy brome); Ashton *et al.*, 2016) and biennial and perennial forbs (e.g., *Centaurea stoebe* subsp. *australis* (spotted knapweed), *Euphorbia virgata* (leafy spurge); LeJeune & Seastedt, 2001; Dunn, 1985). Although the rate of introduction appears to have slowed in North American temperate grasslands, the regional expansion and range infilling of already introduced alien species is ongoing (e.g., *Ventenata dubia* (North Africa grass); Wallace *et al.*, 2015).

In the central Great Plains, 14 alien earthworm species occur in the wild (J. W. Reynolds, 2016). Furthermore, *Sus scrofa* (feral pig) – descendants from stock introduced from Europe – have become invasive in the southern and northern Great Plains (Brook & van Beest, 2014; Reeves *et al.*, 2021). *Equus caballus* (horse) have escaped and colonized some areas of Australia and the Great Plains, though are highly restricted in their current range for the latter (Nimmo & Miller, 2007; Reeves *et al.*, 2021). Although trees are scarce in the prairie, some invasive alien species, such as *Agrilus planipennis* (emerald ash borer; insect), *Adelges piceae* (balsam woolly adelgid; insect), and *Ophiostoma* species (Dutch elm disease; fungi; Reeves *et al.*, 2021) can damage trees that grow locally.

In South America, around 350 alien plant species have been recorded for the Pampa regions, of which ca. 50 occur in natural and semi-natural grasslands (C. R. Fonseca *et al.*, 2013). In Brazil, the Pampa region had the highest proportion of established alien species relative to total richness and compared to other natural regions (114 alien established alien species out of 1,685 species in total; Zenni, 2015). Invasive alien species are particularly common in the Pampas of Argentina, but also are abundant and problematic in other temperate grasslands of South America. Pampas are subject to invasion by alien shrubs from Eurasia (Mazía *et al.*, 2010; Zalba & Amodeo, 2015) as well as by herbaceous alien species (Dresseno *et al.*, 2018; Hierro *et al.*, 2011). Similar to North America, the latter include alien species that have been introduced as pasture grasses, especially from Africa (*Eragrostis curvula* (weeping lovegrass), *Eragrostis lehmanniana* (Lehmann lovegrass), *Panicum coloratum* (klein grass; D. G. Williams & Baruch, 2000)), and herbs (Tognetti & Chaneton, 2012). Introduced alien pine species have been planted on a large scale in the high-altitudinal temperate grasslands of the Páramo and are showing signs of escape and spread (Hofstede *et al.*, 2002; van Wesenbeeck *et al.*, 2003).

In contrast, numbers of alien species are low in the harsh continental grassland regions of Asia. Several of the most important alien grasses in North American prairies originate from steppes and related grasslands (*Agropyron cristatum* (crested wheatgrass), *Bromus tectorum* (downy brome)), yet the continental climates of central Eurasia are less invaded. Mongolia, with its ca. 1 million km^2 of steppes, has less than 100 alien plant species (out of ca. 3200;

Urgamal *et al.*, 2014). None of these 100 alien plant species achieved high frequency or dominance in steppes, and the few studies on invasive plants from northern China also refer to heavily disturbed areas, fields or sown grasslands rather than natural steppes (Guan *et al.*, 2019; Xun *et al.*, 2017). The same holds true for the extensive steppes of Kazakhstan and surrounding environments, while the steppes of Russia and Europe are heavily converted (Kamp *et al.*, 2016; Smelansky & Tishkov, 2012). The remaining steppes of these regions often have altered plant community compositions, but the species are overwhelmingly native to the regions. Alien plants are typically confined to arable fields, and ruderal and disturbed areas (Sukhorukov, 2011; Vakhlamova *et al.*, 2016).

Equus caballus (horse; Zalba & Loydi, 2014) and *Sus scrofa* (feral pig; Caruso *et al.*, 2018) are known to occur in South American grasslands. Several alien bird species have established in Pampas such as *Myiopsitta monachus* (monk parakeet; Bucher & Aramburú, 2014) and *Sturnus vulgaris* (common starling; Zufiaurre *et al.*, 2016). Data on invertebrates are more anecdotal, yet invasions have been documented for *Rumina decollata* (decollate snail; De Francesco & Lagiglia, 2007).

Data and knowledge gaps

Alien plant invasions in temperate grasslands in the Americas are reasonably well documented in the scientific literature. By comparison, the frequency and impact of other alien taxonomic groups, such as earthworms, remain understudied in these regions. Numbers of documented alien species from the steppes of inner Asia are low and it seems likely that records are missing due to low research intensity and that higher numbers could be expected, particularly in countries of low economic growth.

Records on alien animal species are incomplete with only limited reports available on common invasions in Asia. Widespread alien mammals, such as *Mus musculus* (house mouse), are even thought to have large parts of their native range in continental Asia (Appenborn *et al.*, 2021). Baseline data are available for invertebrates and although far from comprehensive.

2.5.2.7 Deserts and xeric shrublands

Deserts and xeric shrublands correspond, in general, to regions with low population densities and several are located in countries with low per capita gross domestic product. Due to their harsh climate, few alien plants have been able to establish in these habitats (Kalusová *et al.*, 2017). As such, they are expected to harbour fewer alien and invasive alien species than other biomes (Dawson *et al.*, 2017). On the other hand, the harsh abiotic conditions sometimes motivated the introduction of alien species capable of surviving in such habitats to ameliorate human livelihood.

Trends

Comparing rates of alien plant species accumulation, accounting for area, the accumulation of alien plants appears to be slower in deserts and xeric habitats than in colder temperate and Mediterranean regions (Pyšek, Pergl, *et al.*, 2017). Although these habitats used to be considered relatively resistant to alien plant invasion, the recent spread of alien species has been observed (Sandquist, 2014). In Chinese desert areas, the number of new invasive alien species is increasing (Eminniyaz *et al.*, 2017) although this finding could also be explained by changing recording intensities. *Prosopis juliflora* (mesquite) was introduced to many desert regions starting in the 1850s and is now a widespread invader in all regions except Europe and Central Asia (Patnaik *et al.*, 2017). *Cenchrus ciliaris* (buffel grass) was widely introduced in the early 1900s for forage and pasture and now invades large areas in Australia and Americas where it increases wildfire frequency and intensity (V. M. Marshall *et al.*, 2012). *Camelus dromedarius* (dromedary camel) were introduced in the 1800s in Australia to assist transportation across deserts and later escaped and spread (Crowley, 2014).

The number and accumulation of emerging alien species worldwide is expected to continue to increase for most taxonomic groups and continents, though possibly more slowly in deserts and xeric shrubland compared to other biomes. Other studies predict that deserts will be unsuitable for invasive alien species by 2100 (Bellard, Thuiller, *et al.*, 2013). Trade and transport in the subtropics (a zonobiome overlapping much of deserts and xeric shrublands) is expected to be the main driver facilitating biological invasions (Essl *et al.*, 2020), although these areas have comparatively less trade and transport than other more populated regions (subtropics cover approximately 25 per cent of the terrestrial surface of the planet but only have 8 per cent of world population).

Status

Global analyses (Dawson *et al.*, 2017; Turbelin *et al.*, 2017) show some tendency for lower richness of established alien species in deserts and xeric shrublands than in temperate and Mediterranean biomes, but with some variation among regions. The Palearctic deserts in Central Asia and north Africa and the Sahara and Afrotropic deserts south of the Sahara in Africa and the southern fringe of the Arabian Peninsula (with some exceptions, e.g., Southern Africa) show relatively low numbers of alien and invasive alien species. The Australasian deserts, the Nearctic deserts in North America, the Neotropical deserts in South America and the Indo-Malay deserts south of the Himalayas tend to harbour higher numbers of established alien species, although generally much lower compared to Temperate and Mediterranean regions (Dawson *et al.*, 2017; Turbelin *et al.*, 2017).

The different taxonomic groups show some differences both in numbers of established alien species (many more plants than animals) and regionally. The number of established alien plants is generally lower in desert areas than in temperate and Mediterranean climates (e.g., 119 alien plants in the Nama karoo and 75 in the Succulent karoo, both in South Africa (B. W. van Wilgen & Wilson, 2018) and 73–83 alien plants in several parks of the North American Mojave Desert (Abella *et al.*, 2015). In the desert region of Egypt only 17 alien species were reported (Shaltout *et al.*, 2016). Following European settlement of Australia, numerous alien plant species were intentionally introduced for use in crops, pastures, gardens, and horticulture, and others arrived unintentionally. Many subsequently escaped into natural environments and are now considered as "weeds". Of the 54 alien plant species of natural environments of arid and semi-arid Australia that are considered here, 27 were apparently unintentionally introduced, 20 were intentionally introduced, and 7 were probably introduced both unintentionally and intentionally. Livestock, including camels and their harness, and contaminated seed and hay were the most common vectors for unintentional introduction (Crowley, 2014; Friedel, 2020).

Established alien birds are absent or present in only low number in most desert and xeric habitats of the world, with a few exceptions in North American and Southern African deserts (B. W. van Wilgen & Wilson, 2018), possibly because there were few attempts to intentionally introduce alien birds in arid regions (E. E. Dyer, Cassey, *et al.*, 2017). The number of established alien freshwater fishes is similar in both Australian and African deserts but tends to be higher in American and Asian deserts; their occurrences are associated with oases, as is the case of at least four alien freshwater fish species found in the largest oasis in the Mojave Desert (Ash Meadows), in North America (Scoppettone *et al.*, 2005). The number of alien reptiles and amphibians introduced to deserts and xeric habitats is low (mostly below four) compared to other biomes. Regional comparisons indicate lower numbers for Palearctic deserts in Eurasia north of the Himalayas and in north Africa as well as for the Sahara, especially for amphibians (Capinha *et al.*, 2017) than other deserts. In Southern African deserts, none or only one alien species has been reported (B. W. van Wilgen & Wilson, 2018). In a survey of eleven oases in the desert regions of Morocco, five alien ant species have been recorded spreading across seven oases (A. Taheri *et al.*, 2021). Information about alien spiders is missing in many regions; in African deserts there are almost no alien spider species or they are not studied, but in Australian and American deserts, the numbers do not differ much from other biomes (Dawson *et al.*, 2017). For other animal groups, fungi, and microorganisms, little information was available except for the presence of *Batrachochytrium dendrobatidis* (chytrid fungus) associated with declines and extinctions of amphibians worldwide, in oasis of the Baja California Sur Desert, in Mexico (Luja *et al.*, 2012).

Data and knowledge gaps

Deserts and xeric shrublands are less well-studied relative to other biomes (e.g., Crystal-Ornelas & Lockwood, 2020; Florencio *et al.*, 2019). Global studies provide information on the status of alien species in the different desert and xeric shrubland regions, but information on temporal trends is often incomplete or even absent for most deserts. Most available studies focus on plants and animals (but not arthropods) and there were almost no studies on fungi and microorganisms (Pyšek, Hulme, *et al.*, 2020). There is more information for the deserts of North America, but for other less well-surveyed regions, for example Africa (except South Africa) and Asia, information is scarce and limited to few species. The lack of information is particularly concerning because arid areas and desertification may be expected to increase in the future.

2.5.2.8 Cryosphere

Trends

The cryosphere has been less affected by alien species compared to other regions. The low number of reported alien species from the cryosphere have multiple reasons: The cryosphere is difficult to access, anthropogenic pressures have been low (Bennett *et al.*, 2015; Chan *et al.*, 2019; Galera *et al.*, 2018; McGeoch *et al.*, 2015; Ruiz & Hewitt, 2009; Vermeij & Roopnarine, 2008) and inhospitable environments (e.g., low nutrient soils, freezing temperatures, high UV levels) do not favour establishment of alien species. Although the Arctic and Antarctica differ, climate change and increased human activities (tourism and research) are enhancing introductions in both regions (**Chapter 3**, **Box 3.4**; Bartlett *et al.*, 2020; Bender *et al.*, 2016; Cárdenas *et al.*, 2020; Chan *et al.*, 2019; Chown *et al.*, 2012; Chwedorzewska *et al.*, 2015; Duffy *et al.*, 2017; Frenot *et al.*, 2005; K. A. Hughes, Cowan, *et al.*, 2015; K. A. Hughes, Pertierra, *et al.*, 2015; Huiskes *et al.*, 2014; McCarthy *et al.*, 2019; McGeoch *et al.*, 2015; Miller & Ruiz, 2014; Ricciardi *et al.*, 2017; Wasowicz *et al.*, 2020). Plants (seeds, fragments and other propagules) and invertebrates (e.g., springtails) are introduced on clothing and personal equipment of tourists, ships, and aircraft personnel, as well as associated with packing materials (Chown *et al.*, 2012; Huiskes *et al.*, 2014), vehicles (K. A. Hughes *et al.*, 2010), and fresh food imports (K. A. Hughes *et al.*, 2011). In ten years of surveillance (2007-2017; **Glossary**) at the Scott Base in the Ross Sea region of continental Antarctica, 68 invertebrate species (15 alien within the broader Antarctic region) were intercepted on food (60 per cent), clothing and equipment (11 per cent), aircraft and cargo (11 per cent), and packaging material (11 per cent) (Newman *et al.*, 2018). During 2007-2008 in Antarctica, over 20 alien lichens and fungi were intercepted in packaging, foodstuffs, and timber (Osyczka, 2010; Osyczka *et al.*, 2012). Similarly, 1,019 seeds were found under the footwear of 259 travellers to Svalbard during summer 2008 alone (Ware *et al.*, 2012), while the seeds of eight alien plant species were reported in the topsoil of Fildes Peninsula, King George Island (Antarctica), in areas intensively frequented by humans (Fuentes-Lillo *et al.*, 2017).

In the Arctic marine environment, the rate of reported alien species rose sharply from the end of 1990 concomitantly with increased research efforts in the region. Biofouling on commercial ships is not considered an important pathway for marine alien species for the cryosphere due to the low rate of species survival (but see Chan *et al.*, 2019), while biofouling on other vessel types (e.g., leisure crafts, fishing vessels, floating platforms) could become relevant in the future for the recent increase in tourism, fisheries, and oil and gas development in the Arctic (Chan *et al.*, 2019). Species were mainly introduced by ballast water followed by natural spread from neighbouring areas where the species were first introduced, and by aquaculture activities (e.g., *Paralithodes camtschaticus* (red king crab); Chan *et al.*, 2019; Orlov & Ivanov, 1978). Similarly, in the Antarctic marine environment, species were likely introduced by vessels (three by hull fouling, one by ballast water), with the first recorded alien species (a bryozoan) dating back to 1960, followed in 1986 by a crab, and in 1996 by a tunicate and a hydroid; the most recent introduction (a mollusc) was recorded in 2019, although it is likely that this species has subsequently gone extinct (Cárdenas *et al.*, 2020; McCarthy *et al.*, 2019). It is important to note that there is no evidence that any of these species (bryozoan, crab, tunicate, hydroid) are established in the Antarctic (McCarthy *et al.*, 2019). Terrestrial alien plants in the cryosphere consist of predominantly herbaceous species, mostly introduced inadvertently in association with soils or imported fodder for domestic animals (Chwedorzewska *et al.*, 2015; Frenot *et al.*, 2005; Wasowicz *et al.*, 2020). In the Arctic, there are some records of alien neophyte plants reported at the end of the nineteenth century, but their number increased in the 1950s and 1970s with species mostly introduced by seed contamination and transport on vehicles (Wasowicz *et al.*, 2020). In continental Antarctica, few alien plants have been introduced since the 1950s (e.g., *Poa pratensis* (smooth meadow-grass) was introduced unintentionally during tree transplantation experiments in the 1950s and was eradicated in 2015 (Pertierra *et al.*, 2017).

A comprehensive review on alien invertebrates is missing for the Arctic, but detailed data are reported for the Svalbard archipelago (e.g., Wieczorek & Chłond, 2019), with 32 alien invertebrates recorded since 1928 with an increase after 1980s, mostly due to soil importation (Coulson, 2015). In continental Antarctica, alien invertebrates, such as the springtail *Hypogastrura viatica* (springtail), were reported from the 1940s onwards (Hack, 1949; K. A. Hughes, Pertierra, *et al.*, 2015). In terms of alien vertebrates in the Arctic, four fishes (salmonids) were translocated from North America to Scandinavia and Russia for fisheries and aquaculture since the end of 1800 (Lento *et al.*, 2019), some mammals were intentionally farmed (e.g., *Mustela vison* (American mink) from the 1920s), while others unintentionally arrived in the 1960s (e.g., *Microtus levis* (sibling vole) in Svalbard; Sandvik, Dolmen, *et al.*, 2019). In the Antarctic region, alien vertebrates have been reported only for sub-Antarctic islands where they can survive (conditions in the Antarctica itself are probably too extreme unless the species can live synanthropically): some mammals (i.e., rats and mice) were unintentionally introduced since the eighteenth century, others (such as ungulates, cats, rabbits, salmonids) were intentionally introduced beginning in the 1950s (Frenot *et al.*, 2005; Lecomte *et al.*, 2013).

The number of alien species in the cryosphere is expected to increase in the future due to climate change and human pressure (**Chapter 3**, **sections 3.2.2** and **3.3.4**), but reported numbers are also expected to be higher due to the greater research effort, as noted by the growing number of publications on this area (Chan *et al.*, 2019; Chwedorzewska *et al.*, 2020; Duffy *et al.*, 2017; K. A. Hughes & Pertierra, 2016; Ricciardi *et al.*, 2017). A recent exercise of horizon scanning for future potentially invasive alien species in the Antarctic Peninsula underlined the main threat posed by marine invertebrates that can be unintentionally transported in ballast waters and on ship hulls (K. A. Hughes *et al.*, 2020; McCarthy *et al.*, 2019). The threat could be even greater considering the cruise ship volume from the Northern Hemisphere to Antarctica that may increase the probability of introducing species able to survive cold environments (Chwedorzewska *et al.*, 2020).

Status

In the Arctic, 34 marine alien species have been reported, mostly crustaceans, seaweed, fish, and molluscs (Chan *et al.*, 2019). Many more alien species are expected to arrive in the future, with Hudson Bay, Northern Grand Banks, Labrador, Chukchi, Eastern Bering Seas, and Barents and White Seas considered to be the most vulnerable areas (Goldsmit *et al.*, 2020). 341 alien plants (188 established and 11 invasive) are reported, and their numbers are expected to increase due to a warmer climate (Wasowicz *et al.*, 2020). The Svalbard archipelago is one of the most studied Arctic areas for biodiversity and alien species: 98 alien and 5 established alien species are reported (Sandvik, Dolmen, *et al.*, 2019), mostly coming from mainland Norway.

Most alien species cannot survive in Antarctic continental conditions, but several have been able to adapt to new territories by remaining in the vicinity of human settlements (i.e., research stations), where they can reproduce in more favourable conditions (K. A. Hughes *et al.*, 2010; McGeoch *et al.*, 2015). Up to now, only five marine alien invertebrate species have been found (plus one cryptogenic seaweed species) with free-living specimens but not established populations (Cárdenas *et al.*, 2020; McCarthy *et al.*, 2019). This low number of recorded marine alien species in Antarctica could be due to very harsh environmental conditions (harsher than the Arctic), incomplete assessment of local biodiversity, and limited sampling efforts (McCarthy *et al.*, 2019). For terrestrial species in the continental Antarctic (sub-Antarctic islands excluded), there are 15 known alien species – *Poa annua* (smooth meadow-grass) and 14 invertebrates (7 Collembola, 4 Arachnida, 2 Insecta Diptera, 1 Annelida), most of which are found in the Antarctic Peninsula region (Baird *et al.*, 2019; Enríquez *et al.*, 2019; K. A. Hughes *et al.*, 2020; K. A. Hughes, Pertierra, *et al.*, 2015). This could be due to several factors. This Antarctic Peninsula is the area closest to another continent (South America), it is the least climatically extreme region of Antarctica (and has also experienced a rapid rise in temperatures since the 1950s due to climate change), and it has the largest concentration of human activity (due to research teams and tourism) resulting in a relatively high propagule pressure (K. A. Hughes *et al.*, 2020). On the sub-Antarctic islands, which circle the continent, at least 108 alien plants, 72 terrestrial invertebrates, 16 vertebrates are reported (Frenot *et al.*, 2005).

Data and knowledge gaps

Overall, the trends and status of alien species in the cryosphere could be better documented, even if the number of studies on this biome rapidly increased in the last years (Chwedorzewska *et al.*, 2020). However, baseline biodiversity knowledge is poor and suitable taxonomic expertise is often lacking, making it difficult to identify alien species, particularly invertebrates and aquatic species (K. A. Hughes & Convey, 2012). For example, freshwater biodiversity is low in continental Antarctica, generally dominated by cyanobacteria, cyanophytes, bacteria, yeasts, rotifers, nematodes and diatoms; as yet, there are no reports of established alien species, but taxonomic specialists of freshwater and terrestrial Antarctic biota are rare (K. A. Hughes *et al.*, 2020; K. A. Hughes & Convey, 2012).

2.5.3 Trends and status of alien and invasive alien species in freshwater units of analysis

2.5.3.1 Wetlands – peatlands, mires, bogs

Trends

Contrary to other freshwater wetlands, peatlands, mires, and bogs have generally been considered more resistant and resilient to biological invasions due to their extreme environments (such as low nutrients and oxygen, harsh climate in high mountains or salinity) and absence of anthropogenic pressure for many years (Chytrý *et al.*, 2008; Parish *et al.*, 2008; Zefferman *et al.*, 2015). However, landscape transformation, due to peatland drainage for agriculture, peat extraction, deforestation, road construction, and increased international trade since the nineteenth century, is facilitating an increase of alien species in these ecosystems (Miletti *et al.*, 2005; Parish *et al.*, 2008; Rebelo *et al.*, 2018; Catford *et al.*, 2017; Pellerin & Lavoie, 2000; Tousignant *et al.*, 2010). Indeed, many peatlands have been drained for agriculture or mined for peat, which has greatly altered their plant communities. For example, 98 per cent of the fens of the state of Ohio, United States, have been destroyed, and invasion by alien species is an ongoing concern in many remaining fens (Andreas, 1989). In Asia, increased numbers of aquatic invasive alien plants are low (0-5 species) in five countries in the region during a period of 7-18 years (Banerjee *et al.*, 2021; Government of Myanmar,

Box 2 8 **Rapid rise of alien fishes in the Amazon, the world's most biodiverse freshwater region.**

The Amazon region contains the world's richest native diversity of fishes (Toussaint *et al.*, 2016). The extent to which this global centre of endemism has been invaded by alien species has been largely overlooked. A recent study involving 35 regional experts has documented 41 species and 17 families of alien fishes in the region, based on records that extend as far back as 1939 (Doria *et al.*, 2021). Most (75 per cent) of these records were observed since the year 2000, during which time there has been a distinct increase in the accumulated number of alien species with no sign of saturation. This is in contrast to the classical view that biodiverse regions are resistant to invasion. More than half of these alien species are omnivores or carnivores, and are distributed for use in aquaculture or the aquarium trade. Intensive fish farming, in particular, is deemed to be a major burgeoning contributor to species introductions in the region (e.g., Doria *et al.*, 2020).

2005; Islam *et al.*, 2003; Khuroo *et al.*, 2012; Mukul *et al.*, 2020; Pallewatta *et al.*, 2003; Shrestha & Shrestha, 2021; D. T. Tan *et al.*, 2012; Tiwari *et al.*, 2005; Wijesundara, 2010). A lack of baseline data from most countries impedes comprehensive analysis. Increasing anthropogenic threats posed to non-permanent wetlands, including climate change, will likely accelerate the establishment of new alien species (Catford *et al.*, 2013).

Status

Some studies confirm the lower vulnerability of peatlands to biological invasions, with few or even no alien species reported for these areas (Chytrý *et al.*, 2008; Lambdon *et al.*, 2008; Rejmánek *et al.*, 2013; Zedler & Kercher, 2004). For example, in Europe almost 10 per cent of all alien plants occur in peatlands (Lambdon *et al.*, 2008) with frequency of plants introduced after 1500 spanning from 0 in Catalonia and Czech Republic to 0.2 per cent in the United Kingdom (Chytrý *et al.*, 2008). An assessment of Natura 2000 areas in Poland (Perzanowska *et al.*, 2019) showed that the majority of bogs, mires, and fens host a low number of alien species (maximum 10 species), occurring at low frequency. Other studies underline the increasing effect of the anthropogenic pressures on peatlands and the subsequent higher occurrence of alien species (e.g., Jukonienė *et al.*, 2015).

In contrast to peatlands and bogs, riparian habitats are among the most invaded habitats (Catford & Kyle, 2016; Vilà *et al.*, 2007). A study comparing numbers of established species in European habitats (Pyšek, Bacher, *et al.*, 2010) showed that riparian and aquatic habitats are most heavily colonized by alien mammals and herptiles; the latter group is also reaching high species densities in mires. The highest densities of alien bird species are found in aquatic and cultivated habitats. Overall, riparian habitats appear highly invaded by all groups of animal taxa except insects. For plants, alien species numbers from riparian habitats were almost as high as for urban habitats (Pyšek, Bacher, *et al.*, 2010).

Across Asia, the number of invasive alien plants in non-permanent freshwater ecosystems range from 5-13 species in 13 countries (Banerjee *et al.*, 2021; Kurniawan & Paramita, 2020; Mukul *et al.*, 2020; Qureshi *et al.*, 2014; Shrestha & Shrestha, 2021; Sujanapal & Sankaran, 2016; Weber *et al.*, 2008; Wijesundara, 2010; H. Xu *et al.*, 2012). The most dominant species in the region are *Pontederia crassipes* (water hyacinth, recorded in 17 countries of the 19 countries for which data are available), *Pistia stratiotes* (water lettuce, 17), *Salvinia × molesta* (kariba weed, 12), *Mimosa pigra* (giant sensitive plant, 11), and *Alternanthera philoxeroides* (alligator weed, 10).[5] Some of the new additions to the region include *Cabomba caroliniana* (Carolina fanwort) and Typha angustifolia (lesser bulrush). In Kolkheti Lowland (Georgia), 423 alien plants are reported, 308 of which are present in peatland areas: the introduction of these species was favoured by the increased transformation and anthropization of the areas in the nineteenth century (Parish *et al.*, 2008). Wagner *et al.* (2017) found that, among the 83,396 plots of woodland habitats in Europe, broadleaved bog woodlands on acid peat have the second highest mean relative alien species richness per plot (2.2 per cent), probably due to a higher degree of human disturbance (e.g., peat extraction) and the invasiveness (**Chapter 1**, **section 1.4.3**) of some alien species like *Prunus serotina* (black cherry).

Drainage can favour the accessibility of these areas for tourists, facilitating the unintentional introductions of alien species (Parish *et al.*, 2008): in 2018 *Drosera rotundifolia* (common sundew) was found in a peat bog in Nahuel Huapi National Park (Argentina) and its introduction seems related to tourists visiting the area (Vidal-Russell *et al.*, 2019). Other disturbances can promote alien species introduction and spread: in the montane bogs of Haleakala National Park, Hawaii, undisturbed bogs were less invaded, while bogs with feral alien pigs showed an increase in invasive alien plants (Loope *et al.*, 1992). A similar result was found in other areas: in a *Sphagnum*-dominated peatland in the Central Andes of Colombia, increased nutrient additions and physical disturbance due to agricultural activities led to the widespread occurrence of *Cenchrus clandestinus* (Kikuyu grass; Urbina & Benavides, 2015); in a New Zealand bog modified by the surrounding agricultural activities, a higher occurrence of alien invertebrates has been reported compared to undisturbed bogs (Watts *et al.*, 2020). Finally, in some cases, natural and prescribed fires can favour biological invasions in these ecosystems. At Kaituna Wetland, Bay of Plenty (New Zealand), fire disturbance promoted more alien species (Christensen *et al.*, 2019): after four years, the authors found 14 alien vascular species and 10 native species in burnt plots vs 10 alien species and 18 native species in unburnt plots. A similar situation is reported for the United Kingdom where in burnt plots the invasive alien moss *Campylopus introflexus* (heath star moss) was more abundant and present than the native cotton grass *Eriophorum vaginatum* (hare-tail cotton-grass; Noble *et al.*, 2017).

Data and knowledge gaps

There is a lack of comprehensive and in-depth studies on alien species in peatlands across different continents and involving all taxa. The literature mostly presents scattered specific studies, focused on Europe and North America, which are biased towards plants. Information about the temporal trends of alien species in peatlands, bogs and mires, and their status are also mostly missing.

5. Data extracted from the GISDP (http://www.iucngisd.org/gisd/), GRIIS (https://doi.org/10.5281/zenodo.6348164) and ASEAN (https://asean.org/)

2.5.3.2 Inland surface waters and water bodies/freshwater

Trends

The number of alien species in freshwater has been reported to increase all over the world (Cowie, 1998; Hussner *et al.*, 2010; O'Flynn *et al.*, 2014; Ricciardi, 2001; Roll *et al.*, 2009). The trends in rising alien species numbers are very consistent across all taxonomic groups such as aquatic invertebrates (Mangiante *et al.*, 2018; Muñoz-Mas & García-Berthou, 2020; Rabitsch & Nehring, 2017; Roll *et al.*, 2009), vertebrates (A. B. Kumar, 2000; Muñoz-Mas & García-Berthou, 2020) and plants (Hussner *et al.*, 2010; Mangiante *et al.*, 2018; Rabitsch & Nehring, 2017), across habitats such as lakes (Ricciardi, 2001) and rivers (M. C. Jackson & Grey, 2013; Rabitsch & Nehring, 2017) and across continents such as Europe (M. C. Jackson & Grey, 2013; Rabitsch & Nehring, 2017), North America (Mangiante *et al.*, 2018; Ricciardi, 2001), and Asia (Roll *et al.*, 2009). Comprehensive studies for Africa, Australasia, and South America (**Boxes 2.8** and **2.9**) are mostly lacking, but global studies and studies of individual taxonomic groups suggest similar increasing trends (Madzivanzira *et al.*, 2021). In many cases, increases in freshwater alien species numbers accelerated after 1950 (Chambers *et al.*, 1999; Hussner *et al.*, 2010; Mangiante *et al.*, 2018; Mills *et al.*, 1993; Muñoz-Mas & García-Berthou, 2020; Roll *et al.*, 2009), while other studies show consistent increases since 1900 (Rabitsch & Nehring, 2017) or even 1800 (Ricciardi, 2001). The observed acceleration may, however, also result from increased sampling intensity and greater awareness in more recent years (Belmaker *et al.*, 2009; C. J. Costello & Solow, 2003).

Numbers of alien freshwater vertebrates seem to have been increasing for longer compared to invertebrates, although this may also be a consequence of varying sampling intensity and better taxonomic and ecological knowledge (Muñoz-Mas & García-Berthou, 2020). The number of alien insects in freshwaters is comparatively low even though aquatic insects are frequent in native faunas (Fenoglio *et al.*, 2016; Guareschi *et al.*, 2013; Muñoz-Mas & García-Berthou, 2020). This has been attributed to a combination of factors including low economic impact and low probability of transport and survival of alien aquatic insects (Fenoglio *et al.*, 2016). Furthermore, not only has the number of freshwater alien species consistently increased, but the rates of new records over time also rose continuously (M. C. Jackson & Grey, 2013; Leuven *et al.*, 2009; Muñoz-Mas & García-Berthou, 2020; Ricciardi, 2001). Declines in new records of alien species have been observed in a few studies recently (i.e., after 2005), but these declines are likely due to lags in detection and reporting of new alien species (Mangiante *et al.*, 2018; Muñoz-Mas & García-Berthou, 2020; Seebens, Blackburn, *et al.*, 2017). Increases in either species numbers or rates of new records have been associated with increasing import volumes (Cowie, 1998; M. C. Jackson & Grey, 2013; Ricciardi, 2001; Seebens, Essl, *et al.*, 2017), human population size (M. C. Jackson & Grey, 2013), and tourism (Cowie, 1998). Similar increases are reported for alien plants as shown by the Joint Nature Conservation Committee River Macrophytes Database that contains records from standardized vegetation surveys of rivers from across the United Kingdom. Surveys focus on rivers with existing or potential conservation value, and almost 4500 surveys have been undertaken since 1977. River sites were surveyed both pre- and post-1990. Results showed a 31 per cent increase in the presence of invasive alien plant species across two survey periods in the United Kingdom (Pattison *et al.*, 2017).

Status

Although probably due in large part to a knowledge bias, biological invasions in aquatic systems represent only a small fraction of all invasions; for example, of the 2,033 alien species recorded in South Africa, only 191 are aquatic; of these, most are freshwater invasive alien species (Skowno *et al.*, 2019). Global maps of the distribution of alien species exist for fishes (Dawson *et al.*, 2017; Leprieur *et al.*, 2008) and amphibians (Capinha *et al.*, 2017). In both cases, consistently high numbers of alien freshwater species have been reported for Europe and North America, including Hawaii, while hotspots of alien freshwater fishes have also been found in South-East Asia, Central Asia and mesoamerica (e.g., Dawson *et al.*, 2017; Leprieur *et al.*, 2008; **Boxes 2.8** and **2.9**). Leprieur *et al.* (2008) reported occurrences of 9,968 alien fish species in 1,055 river basins worldwide, with up to 95 per cent of present fish species being alien. The global distribution of alien freshwater fishes has been attributed to high per capita gross domestic product and high human population density (**Chapter 3**, **sections 3.2.2** and **3.2.3.6**; Dawson *et al.*, 2017; Leprieur *et al.*, 2008), but also high per centages of urban areas and basin areas (Leprieur *et al.*, 2008). Many alien freshwater species have been intentionally released (A. B. Kumar, 2000; Muñoz-Mas & García-Berthou, 2020; Strayer, 2010) through, for instance, recreational fishing (Davis & Darling, 2017). Introduced fish species often represent large-bodied species (predators and herbivores) (Blanchet *et al.*, 2010), which may alter food web structures with consequences for the whole food web (Cucherousset *et al.*, 2012). Capinha *et al.* (2017) report alien populations for 78 amphibian species, but not all might be classified as freshwater species. Significantly more alien freshwater amphibians have been found in islands compared to mainlands (Capinha *et al.*, 2017). An important pathway for introduction is the construction of inland canals which are responsible for a large number of freshwater alien species such as invertebrates and fish (Faulkner *et al.*, 2020; Galil *et al.*, 2007; Katsanevakis *et al.*, 2013; Schöll, 2007). Among alien freshwater invertebrates, most studies are available

Box 2 9 North American Great Lakes: An assessment of trends of alien species.

The biological invasion history of a region can reveal the changing influence of transport vectors and management actions over time. The North American Great Lakes basin is the world's most invaded freshwater ecosystem (Pagnucco *et al.*, 2015; Ricciardi, 2006). Numbers and taxonomic composition of established alien species discovered in the basin during different time periods are correlated to changes in vector and pathway activities, such as fish stocking, canal development, and transoceanic shipping (Ricciardi, 2006). Thus, the biological invasion history of the basin is punctuated by major phases distinguished by a predominance of particular taxonomic and functional groups as well as taxa from particular donor regions. During periods of fish stocking, for example, fishes and fish pathogens comprised many of the alien species discovered. Similarly, following the transition from solid ballast to ballast water in ships during the early twentieth century, alien species of phytoplankton and zooplankton were discovered more frequently (Mills *et al.*, 1993). The opening of the St. Lawrence Seaway in 1959 marked a period in which ballast water discharge became the dominant vector of invasion. A more recent phase in the history of the basin is distinguished by a mass invasion of Ponto-Caspian species (including *Dreissena polymorpha* (zebra mussel), *Dreissena rostriformis bugensis* (quagga mussel), *Neogobius melanostomus* (round goby), *Cercopagis pengoi* (fishhook waterflea), and several others) and euryhaline invertebrate taxa with resting eggs that can survive transport in ballast tank sediments (Pagnucco *et al.*, 2015; Ricciardi, 2006; Ricciardi & MacIsaac, 2000). Between 1959 and 2006, inclusive, the average rate of discovery of newly established alien species in the basin was 1.69 per year, or one new alien species every 7 months **(Figure 2.35)**. The majority (65 per cent) of these introductions are attributable to ballast water shipping, primarily from European donor regions. However, since 2006, the overall rate of invasion has been reduced, declining by 85 per cent to its lowest level in two centuries (Ricciardi & MacIsaac, 2022) with very few invasions attributable to shipping. This abrupt shift in invasion risk follows the implementation of ballast water regulations by Canada and the United States in 2006 and 2008, respectively.

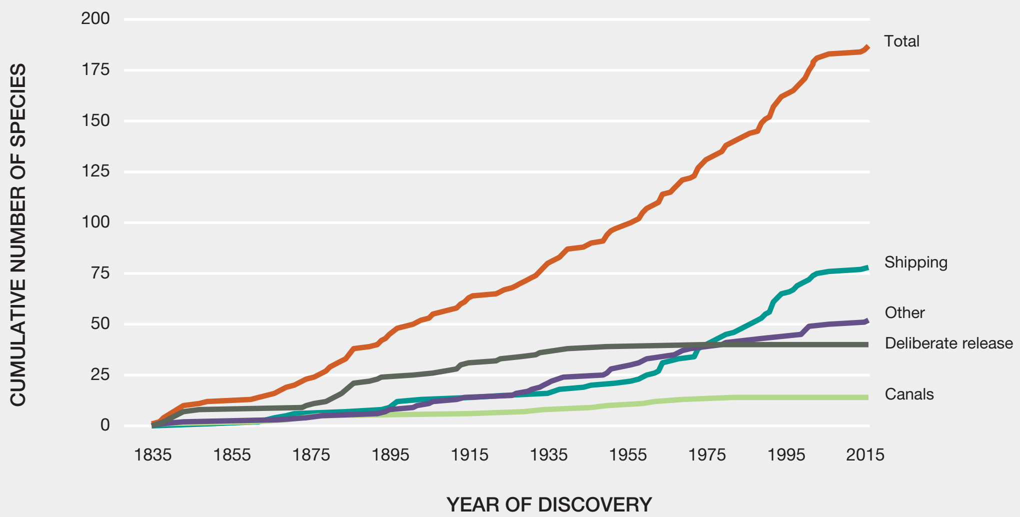

Figure 2 35 Cumulative numbers of alien species in the North American Great Lakes basin.

The total number of alien species is shown in the top most line. Other trend lines show accumulations of species whose introductions are attributable to various vectors, including shipping (ballast water, solid ballast, and hull fouling), canals, deliberate release (e.g., intentional stocking of fishes), and other vectors (e.g., bait, aquarium, and unintentional releases). Data sources: Mills *et al.*, 1993; NOAA, 2021; Ricciardi, 2006.

for freshwater crustaceans and molluscs (Cianfanelli *et al.*, 2016; Cuthbert *et al.*, 2020; Lodge *et al.*, 2012), but no single study exists that shows the global distribution of alien freshwater invertebrates. Compared to aquatic alien animals, aquatic alien plants and algae have been under-investigated. Comprehensive reports on large-scale distributions of aquatic plants are lacking, but global assessments are available for well-investigated individual species such as *Pontederia crassipes* (water hyacinth) (Kriticos & Brunel, 2016), *Azolla filiculoides* (water fern) (Rodríguez-Merino *et al.*, 2019) or *Lemna minuta* (least duckweed) (Ceschin *et al.*, 2018).

Data and knowledge gaps

Inland waters, riparian networks, and channels are very effective corridors for propagules that can easily be dispersed over long distances (Brundu, 2015a; Willby, 2007), but aquatic environments are difficult to monitor and an early detection of a submerged species introduction is seldom possible. No analysis reporting gaps in trends and status of alien species in freshwater systems currently exists, but a comparison of available literature reveals that freshwater systems have been far less investigated than terrestrial and (most likely) marine systems (Seebens, Blackburn, *et al.*, 2017). Among these, the vast majority of studies have been conducted in Europe and North America, while information about the temporal trends in freshwater alien species and their status across continental ranges are largely absent. The only exceptions seem to be fishes and amphibians, for which comprehensive large-scale analyses are available (Capinha *et al.*, 2017; Dawson *et al.*, 2017; Kraus, 2009; Leprieur *et al.*, 2008). However, large information gaps on species occurrences exist among these taxonomic groups, particularly in Asia and Africa (Dawson *et al.*, 2017). Large-scale information is missing for most freshwater invertebrates, including macrophytes and algae. Riparian habitats have been extensively studied for plant invasions (Maskell *et al.*, 2006; D. M. Richardson *et al.*, 2007), but many studies focus on a handful of invasive alien taxa (e.g., Elderd, 2003; Hood & Naiman, 2000; Pyšek & Prach, 1993).

2.5.4 Trends and status of alien and invasive alien species in marine units of analysis

2.5.4.1 Shelf ecosystems (neritic and intertidal/littoral zone)

Trends

The number of marine alien species has been consistently and continuously increasing globally (Bailey *et al.*, 2020) and in individual regions such as in the waters of North America (Cohen & Carlton, 1998; Ruiz, Fofonoff, *et al.*, 2000), Europe (Gollasch, 2006; Katsanevakis *et al.*, 2013; Reise *et al.*, 1998; Zenetos & Galanidi, 2020), Australia (Hewitt *et al.*, 2004), South America (Schwindt *et al.*, 2020; Teixeira & Creed, 2020; Toral-Granda *et al.*, 2017), Africa (Mead *et al.*, 2011; T. B. Robinson *et al.*, 2020) and the Pacific (Carlton & Eldredge, 2009; Coles *et al.*, 1999). Time series of newly reported marine alien species often date back to the early nineteenth century (Carlton *et al.*, 2019; Carlton & Eldredge, 2009; Cohen & Carlton, 1998; Coles *et al.*, 1999; Gollasch, 2006; Hewitt *et al.*, 2004; Mead *et al.*, 2011; Reise *et al.*, 1998; Ruiz, Fofonoff, *et al.*, 2000; Schwindt *et al.*, 2020; Teixeira & Creed, 2020; S. L. Williams & Smith, 2007; Wolff, 2005). Likewise, increases in rates of new alien species records were frequently observed especially in the early twentieth century (Carlton & Eldredge, 2009) or after 1950 (Bailey *et al.*, 2020; Coles *et al.*, 1999; Gollasch, 2006; Hewitt *et al.*, 2004; Mead *et al.*, 2011; Ruiz, Fofonoff, *et al.*, 2000; Schwindt *et al.*, 2020; Teixeira & Creed, 2020; S. L. Williams & Smith, 2007). Wolff (2005) reported an increase in long-distance introduction events after 1950. Increases in marine alien species numbers are not only related to the intensifications of global shipping consistently across studies (i.e., hull fouling and ballast water), aquaculture and cultivation (including stocking and aquarium releases) (Bailey *et al.*, 2020; Coles *et al.*, 1999; Gollasch, 2006; Hewitt *et al.*, 2004; Katsanevakis *et al.*, 2013; Reise *et al.*, 1998), but also increased tourism (Toral-Granda *et al.*, 2017), and natural dispersal from neighbouring alien populations (Gollasch, 2006; Wolff, 2005). Rising shipping activity during both world wars is associated with new marine alien species introductions at naval bases (Coles *et al.*, 1999). Another major pathway was the opening of new shipping canals such as the Panama Canal, the Suez Canal, and the St. Lawrence River (Galil *et al.*, 2007; Mills *et al.*, 1993), which resulted in large numbers of marine alien species introductions, particularly in the Mediterranean Sea (Galil *et al.*, 2014). The extensions of these shipping canals (Galil, Boero, Fraschetti, *et al.*, 2015; Muirhead *et al.*, 2015), as well as the opening of new transport routes such as the Northern Sea routes through the Arctic Ocean due to climate change or the intensification of existing routes, have led to more introductions of marine alien species (Ascensão *et al.*, 2018; Miller & Ruiz, 2014). Sudden declines in newly recorded marine alien species towards the end of the reported time series have been frequently noted (Gollasch, 2006; Wolff, 2005), which are associated with lags in detection and reporting (Wolff, 2005).

Status

One of the few global studies of marine alien species revealed hotspots in coastal areas of the North-East Atlantic, Northern European Seas, the Mediterranean Sea, Hawaiian Islands, and New Zealand (Bailey *et al.*, 2020; **Box 2.10** for more details). Many of the reported established alien species belong to arthropods, fishes, molluscs, and algae (Bailey *et al.*, 2020; Gollasch, 2006). The recently launched database WRiMS (M. J. Costello *et al.*, 2021) revealed similar hotspots, although a direct comparison is difficult due to varying spatial resolutions. That said, many regions that appear to have low numbers of reported alien species (i.e., not "hotspots"), may in fact reflect more on the history and intensity of investigation rather than the intensity of invasion. Until 2019, the Galapagos Islands were reported to be invaded by only five marine species, but a re-investigation revealed a minimum of 53 marine alien species present in that Archipelago (Carlton *et al.*, 2019). Chile is reported to have low numbers of marine alien species, with various hypotheses offered to explain the low alien species richness (Neill *et al.*, 2020), one being low research intensity. Comparing studies of similar sampling areas such as marine bays or port regions revealed alien species numbers of similar ranges with most species found in San Francisco Bay, United States (234 species) (Cohen & Carlton, 1998) followed by the Chesapeake Bay, United States (116 species) (Ruiz *et al.*, 1997), Port Philip Bay, Australia (99 species) (Hewitt *et al.*, 2004), Pearl Harbor, Hawaii (69 species) (Coles *et al.*, 1999) and Coos Bay, Oregon, United States (60) (Ruiz *et al.*, 1997). Most of these numbers are, however, based on data that are more than 20 years old and higher alien species numbers can be expected now. For example, J. T. Carlton & Eldredge (2009) updated the Pearl Harbor number from 69 to more than 175 (many species were older invasions or of other taxonomic groups not noted in Coles *et al.* (1999), and thus not post-1999 invasions).

On the whole Hawaiian Archipelago, 333 marine alien species have been reported (Carlton & Eldredge, 2009, 2015). Among European Seas, by far the largest numbers of marine alien species have been recorded for the Mediterranean Sea (Galil *et al.*, 2021b; Katsanevakis *et al.*, 2020), followed by the North Sea and the Atlantic coast (Gollasch, 2006). Shipping (ballast water and hull fouling) and aquaculture have been consistently reported to represent the most important pathways for the introduction of marine alien species (Bailey *et al.*, 2020; Carlton & Eldredge, 2009; Coles *et al.*, 1999; Floerl & Inglis, 2005; Galil *et al.*, 2014; Gollasch, 2006; Hewitt *et al.*, 2004; Ruiz, Fofonoff, *et al.*, 2000; Schwindt *et al.*, 2020; Ulman *et al.*, 2019; S. L. Williams & Smith, 2007; **Box 2.10**). Often, large numbers of marine alien species are found at sites of intense human activity such as commercial ports (Ruiz *et al.*, 1997), marinas (Ulman *et al.*, 2019), or disturbed habitats (Coles *et al.*, 1999; S. L. Williams & Smith, 2007). Other vectors of introduction are fishing bait or ornamental purposes (Coles *et al.*, 1999; Gollasch, 2006). Patterns of distribution and trends were very similar across a wide range of taxonomic groups such as macroalgae, arthropods, cnidarian, polychaeta, molluscs, and fishes (Gollasch, 2006; Ruiz, Fofonoff, *et al.*, 2000; Seebens *et al.*, 2016; S. L. Williams & Smith, 2007). Microorganisms were frequently introduced (Cohen & Carlton, 1998; Ruiz, Rawlings, *et al.*, 2000); however, studies about the introduction of marine microorganisms and many other small size taxa are largely lacking.

Data and knowledge gaps

Among marine ecosystems, shelf ecosystems are much better investigated compared to the open ocean or the deep sea. Still, information about marine alien species remains one of the major gaps in the field of invasion ecology. Some high research interest regions such as North American

Box 2 10 Marine ecoregions: A global assessment of trends and status of alien and invasive alien species.

An extensive dataset of first detection records of marine alien species from 1965–2015 across 49 marine ecoregions is provided by Bailey *et al.* (2020). This dataset includes three major components of alien species records including the year of first collection, the invasion status, and potential pathways of introduction. Data were analyzed at both regional and global scales to examine the patterns of first record rate, species numbers, and transport pathways.

The assembled dataset included 2,209 records of marine alien species (1,442 unique species belonged to 17 phyla) where ten ecoregions had zero confirmed records during the period of study. On a global scale, about 75 per cent of marine alien species were reported as established and about 20 per cent had unknown invasion status, while the remaining records belonged to species with failed establishments (5.4 per cent) or extinct (0.5 per cent) populations. Most of the marine alien species were likely introduced as stowaways in ships' ballast water or biofouling. Escape of species from aquaculture or mariculture followed a similar pattern, while the corridor pathway and escape of pet or aquarium species increased beginning in the late 1990s. Nearly one-third of marine alien species' records were associated with a single pathway (32.7 per cent), while most were associated with at least two (52.6 per cent), or three (14.1 per cent) pathways. However, the patterns of alien species numbers varied across regions as a result of differences in pathway strength, environmental conditions, habitat size, survey effort, and taxonomic effort. The cumulative number of records from 1965-2015 ranged from zero to more than 500 per ecosystem, with various levels of succession of the population establishment across those regions. Ship fouling, transport stowaway, and ballast water were the dominant pathways in most regions, and were responsible for at least 40 per cent of introduction events. Other pathways became important for individual regions such as the corridor pathway (Suez Canal) in the Mediterranean Sea and escape of aquaculture/mariculture species in the East China Sea, South China Sea, and Yellow Sea (Bailey *et al.*, 2020). Although their dataset represents an extensive global collection of marine alien species records, it only covers about 73 per cent of the world's coastal large marine ecosystems, and data coverage was low in Africa, Meso- and South America, and Asia. As discussed in Bailey *et al.* (2020), marine alien species have undoubtedly occurred and reported in these areas, but due to cost of marine alien species surveys, limited resources, and lack of expertise across many taxa and regions, data of sufficient quality were likely not available for their study.

coastlines and European Seas, including the Mediterranean Sea, are comparatively well investigated, but data is far from complete and regular monitoring does not occur (Tsiamis *et al.*, 2021). Information for most other coastal areas is largely lacking. The most comprehensive available study on the global distribution of marine alien species shows large areas where information or expertise are lacking such as regions in Meso- and South America, Africa, and Asia (Bailey *et al.*, 2020). Even where information is available, lists are highly incomplete for many coastal areas. Based on expert knowledge, true numbers of marine established alien species might be up to ten times higher in some regions than reported in **Figure 2.5**.

2.5.4.2 Surface open ocean

Trends

Established alien species numbers are increasing in the open ocean from the tropics to polar regions due to warming oceans and human activity (M. J. Costello *et al.*, 2021). Many marine alien species tolerate a broader thermal range than native species and are able to show rapid physiological adaptation; both characteristics give alien species more habitat opportunities than natives (Canning-Clode *et al.*, 2011; H. Li *et al.*, 2020). For example, "Caribbean Creep" refers to a number of marine invertebrates (e.g., *Petrolisthes armatus* (green porcelain crab)) from the Caribbean that have expanded their distribution ranges poleward and invaded the southern and mid-Atlantic United States coasts (Canning-Clode *et al.*, 2011). Similarly, "African Creep" refers to the number of marine species moving poleward into the Mediterranean from lower latitudes (Canning-Clode & Carlton, 2017). In 1750, wooden sailing vessels could have carried 120 marine fouling and boring fauna and flora (Carlton, 1999b), while in the twentieth century, over 10,000 different marine species were estimated to be transported daily among different global geographic regions *via* ballast tanks (Carlton, 1999b) prior to the beginnings of detailed formulations for ballast water management. In this century, a vast global effort is underway to implement universal ballast water management strategies to prevent the transport and introduction of invasive alien species (**Chapter 5**, **section 5.5.1**).

The global rate of marine alien species records was relatively stable during 1965–1995 but increased significantly after 1995 and peaked at about 66 primary detections per year during 2005–2010, and then again decreased (Bailey *et al.*, 2020). Arthropods, molluscs, and fishes, by far the most thoroughly studied groups, were also not surprisingly the most frequently reported aquatic alien species during this time period and were most likely introduced as stowaways in ships' ballast water or biofouling. However, direct vector-related evidence was often absent. Arctic ship-based summertime transportation and tourism also increased over the past two decades, co-occurring with sea ice reductions (IPCC, 2019). This increase might bring implications for global trade and traditional shipping corridors economies, alerting the Arctic marine ecosystems and biodiversity, such as from invasive alien species and local pollution (IPCC, 2019). The relatively recent phenomenon of floating plastic debris in the open ocean facilitates the transport of coastal and oceanic species that might normally not survive the open ocean and may result in new and more frequent introductions of alien species across the oceans (**Chapter 3**, **section 3.3.3.3**; Haram *et al.*, 2021).

Environmental and anthropogenic changes have triggered reorganizations of reef ecology, zonation physiology, and dominance (Miranda *et al.*, 2020). One example is the plastic pollution in the ocean such as polystyrene foam which can be a dispersal vehicle for the invasive coral *Tubastraea* spp. (sun corals) (Faria & Kitahara, 2020). For example, in Brazilian reefs *Mussismilia harttii* (scleractinian coral) is threatened by the dominance of invasive sun corals (Faria & Kitahara, 2020; Miranda *et al.*, 2020). Sun corals lack natural predators and can reproduce rapidly with extensive defensive mechanisms which makes them a successful invasive alien species over large areas along the Brazilian coasts (Faria & Kitahara, 2020; Miranda *et al.*, 2020).

Status

There are more than 800 established alien species reported in the European seas only, some of which are invasive and impacting marine ecosystem services and biodiversity (Tsiamis *et al.*, 2018, 2020). Analyses revealed that a large number of alien species were not reported in initial assessments, or were proven to be historical misreporting (Tsiamis *et al.*, 2020). Thus, the Marine Strategy Framework Directive Descriptor 2 was implemented to provide an improved basis for reporting new alien species and to help the establishment of monitoring systems of targeted alien species (Tsiamis *et al.*, 2020). Major intentional introductions for fisheries also occurred with deep-sea species, such as *Paralithodes camtschaticus* (red king crab), native to the north Pacific coast and released in the Barents Sea during the 1960s (ICES, 2005). The species was later captured in the Ionian Sea in the Mediterranean (Faccia *et al.*, 2009), possibly transported by ballast water, though Faccia *et al.* (2009) raised doubts about whether a larva/post-larve presumably arrived in ballast water could withstand summer temperatures for so long – the specimen collected weighed about 4 kg and the estimated age was 10 years. Among tropical marine regions, Hawaii was found to be heavily affected by alien species either due to its location, governance (**Glossary**), or research effort undertaken to understand biological invasions in this region (Alidoost Salimi *et al.*, 2021). An alternative explanation might be also due to lower native biodiversity associated with Hawaiian ecosystems providing more vacant niches being available to the alien species.

The recently launched WRiMS (marinespecies.org/introduced) is an expert-edited world list of introduced marine species and provides information of alien and invasive alien marine organisms (M. J. Costello *et al.*, 2021). An alien marine metazoan species checklist for the Mediterranean Sea lists 573 alien species (Galil *et al.*, 2014). Most of those alien species are thermophilic, originally from the Indo-Pacific or Indian Oceans that invaded the Mediterranean through the Suez Canal (Galil *et al.*, 2014). Additionally, the Information System on Aquatic Non-Indigenous and cryptogenic Species (AquaNIS) database provides information on 859 aquatic alien and cryptogenic species in the North Atlantic region (AquaNIS, 2015).

Data and knowledge gaps

The open sea represents one of the least investigated units of analysis with respect to biological invasions. The size and cost of sampling the open sea presents a particular challenge. Another challenge is how "alien" is defined in the open sea because it is usually defined for much smaller geographic units such as countries – a challenging concept to transfer to the open ocean. Some databases, such as WRiMS (M. J. Costello *et al.*, 2021), also cover the open ocean, but the vast majority of records have likely been sampled along the coasts. However, WRiMS records provide the opportunity to map the actual locations of marine alien species using records from the Ocean Biodiversity Information System (OBIS) or GBIF. Nonetheless, a comprehensive assessment of the trends and status of alien and invasive alien species in open oceans is still missing and difficult to conduct currently due to the lack of records.

There are other global databases of species occurrences such as AlgaeBase (Guiry & Guiry, 2021) or FishBase (Froese & Pauly, 2015), but the information about the status of invasion is incomplete or totally lacking. There are also distributed occurrence records for marine alien species in the GRIIS dataset (Pagad *et al.*, 2022) and other national checklists, but these usually reflect coastal areas rather than occurrences in the open ocean. This lack of information on open ocean alien species occurrences represents one of the largest knowledge gaps across all units of analysis.

2.5.4.3 Deep sea

Trends

As biota occurring at deep ocean depths have been rarely surveyed (Saeedi, Costello, *et al.*, 2019; Saeedi *et al.*, 2020; Saeedi & Brandt, 2020), there are too few records over too short a time period to infer trends. The deep-sea populations of alien species may follow a "boom-and bust" pattern of abundance (Strayer *et al.*, 2017), such as documented between 1995-2002 for *Philine auriformis* (New Zealand sea slug) in southern California, United States (Cadien & Ranasinghe, 2003), settle for long-term low-abundance stability, or, following a time lag or environmental triggering event, result in greatly increased abundance. As depth increases, less measurements are available for biological variables (M. J. Costello *et al.*, 2018; Saeedi, Bernardino, *et al.*, 2019), making estimations of rates of biological invasion challenging in the deep ocean.

Status

Records of biological invasions into depths greater than 200 meters are rare. The intentional introduction of the economically important North Pacific *Paralithodes camtschaticus* (red king crab) in the 1960s into the Barents Sea demonstrated that the deep ocean is not immune to invasions (Dvoretsky & Dvoretsky, 2018; Jørgensen & Nilssen, 2011). Immature individuals remain on the shallow shelf (20–50 m), adult specimens mostly inhabit deep soft-bottom areas (100–400 m), migrating into shallow waters (less than 50 m) for moulting and mating (Sundet & Hjelset, 2011). Specimens of *Pterois* spp. (lionfishes) that invaded the Western North Atlantic/Caribbean region were reported from Bermuda, Curaçao, and Honduras at depths between 250 and 300m (Andradi-Brown, 2019). *Philine auriformis* (New Zealand sea slug) was introduced to the West Coast of North America (southern California, Untied States of America, to British Columbia, Canada) and occurs from the intertidal to more than 300 m (Cadien & Ranasinghe, 2003). In the south-east Mediterranean Sea, four carnivorous Red Sea species, *Champsodon nudivittis* (crocodile toothfish), *Etrumeus golanii* (Golani's round herring), *Trypauchen vagina* (burrowing goby), and *Charybdis longicollis* (lesser swimming crab) were recently recorded at depths over 200 m (Galil *et al.*, 2019; Innocenti *et al.*, 2017). One possible pathway of deep-sea species translocations may be deep submergence vehicles whose use has increased since the 1960s (Voight *et al.*, 2012). It seems realistic to suggest that understanding the scale of deep-sea invasions by alien species remains one of the most important overlooked aspects of marine invasion science.

The deep sea is now also warming, as has been observed in shallow waters, and the temperature of water below 2000 m has increased since 1992, especially in the Southern Ocean (IPCC, 2019). For example, deep Mediterranean waters have warmed by 0.12 °C since the mid-twentieth century and the deep oceans now store 16–89 per cent more heat than before (McClain *et al.*, 2012). Temperature changes and the redistribution of total energy will ultimately impact deep-sea faunal distributions and invasion rates. For example, some deep-sea fish families of Actinopterygii were identified with depths over 1000 m and were proposed as invasive alien species where most of their constituent species live in shallower than 1000 m (Priede & Froese, 2013). Also, the invasion of Erythrean species of the

Levantine basin into the lower continental shelf and upper slope suggests biological invasions in the deep sea warrant more attention (Galil *et al.*, 2019). The west Antarctic Peninsula shelf is rapidly warming and is expected to soon be invaded by lithodid crabs from the Ross Sea waters that have crossed the Antarctic shelf (C. R. Smith *et al.*, 2012).

Data and knowledge gaps

Estimating the gaps in alien species distributions of the deep-sea fauna is challenging because the deep sea is the most unexplored place on Earth and there is much yet to be learned. However, alien species pose a threat to the unique, diverse, and fragile mesophotic "animal forests". Large data and knowledge gaps therefore remain for trends and status of invasive alien species in the deep sea as well as a lack of information the actual data gaps.

2.5.5 Trends and status of alien and invasive alien species in anthropized areas

2.5.5.1 Urban/semi-urban

Urban habitats include constructed, industrial, and other artificial land, human settlements, buildings, industrial developments, transport networks and waste dump sites, but also a diversity of semi-natural and constructed green spaces. Cities contain high densities of people and are hubs of human-mediated movement of commodities. Transport linkages (e.g., airports and harbours) facilitate the introduction and dissemination of alien species through introduction pathways such as trade, tourism, and horticulture (**Chapter 3**, **section 3.2.3**; Dehnen-Schmutz *et al.*, 2007). The intensive study of alien plants in urban areas began in a few cities around the world in the 1980s (Esler, 1987; Kowarik, 1990; Stalter *et al.*, 1992), largely out of natural history interest. Large-scale comparisons of alien plant taxa among cities grew out of a more macroecological approach in Europe in the 1990s (Kowarik, 1995a; Pyšek, 1998), which has since given way to more recent global assessments of patterns of alien species in cities (Aronson *et al.*, 2014; Gaertner *et al.*, 2017).

Trends

Evidence suggests that the rate and extent of biological invasions are increasing globally (Seebens, Blackburn, *et al.*, 2017) and cities often play important roles as hubs for the spread of alien species (Chytrý *et al.*, 2012; McLean *et al.*, 2017). Studies on long-term dynamics of urban floras revealed a steep increase in established alien species numbers along with accelerating urbanization during the last century (Chocholoušková & Pyšek, 2003; S. Knapp *et al.*, 2010; Tretyakova *et al.*, 2018), with alien species occupying a median of 28 per cent (ranging from 25-50 per cent) of their respective urban floras (Aronson *et al.*, 2014; Esler, 1987; Ricotta *et al.*, 2009, 2012; G.-L. Zhu *et al.*, 2019). Several studies from around the world show that more urbanized areas tend to harbour a higher relative abundance and diversity of alien species than rural and peri-urban areas (Aronson *et al.*, 2015; Blair & Johnson, 2008; Cadotte *et al.*, 2017; X. Chen *et al.*, 2014; Lowry *et al.*, 2020), and as urbanization expands, the numbers of alien taxa in urban areas will consequently increase as well.

Projected trends in plant invasions in Europe under different scenarios of future land-use change showed the second highest level for urban areas (Chytrý *et al.*, 2012). Most alien species in cities and urban areas are intentionally introduced ornamental plants that escaped from cultivation (Čeplová *et al.*, 2017; Dehnen-Schmutz *et al.*, 2007; McLean *et al.*, 2017; Padayachee *et al.*, 2017). Studies in the Czech Republic, for example, reveal that 47 per cent of alien species now found in cities and beyond were introduced intentionally, mostly as ornamentals (Pyšek *et al.*, 2002), and work from South Africa showed that twice as many of the most abundant alien species in urban areas were originally introduced for ornamental purposes compared to non-ornamental alien species (McLean *et al.*, 2017). Much like agriculture, plantings of alien plants in urban settings provide suitable habitats for the establishment of alien insects; consequently, urban settings and especially street trees tend to be hotspots for insect invasions (Branco *et al.*, 2019; Dale & Frank, 2017; Paap *et al.*, 2017).

It is likely that a warmer climate together with urban sprawl will increase the invasion risk for cities, especially as species from different climatic regions are transported elsewhere, and especially from warm regions to temperate ones (e.g., Géron *et al.*, 2021; Lososová *et al.*, 2018). For Europe, Lososová et al (2018) suggest that alien species from regions with warm climates, such as those currently limited to southern Europe, are likely to increase their rate of spread and colonize the cities of Central and Western Europe. Alien insects appear to be especially benefiting from increased urban temperatures, for example, alien mosquitos in montane cities in South America (Pedrosa *et al.*, 2020) and alien scale insects in the United States (Meineke *et al.*, 2013).

Status

The most comprehensive global data set on urban floras and bird faunas, based on 110 and 54 cities on all continents, respectively, revealed that the numbers of alien species differ broadly among cities with a median of 3.5 alien bird (range: 0–23) and 213 plant species (range: 38–1058), of the total species richness 112.5 (range: 24–368) for birds and 766 (range: 269–2528) for plants. Among plants, Poa annua (annual meadowgrass), Capsella bursa-pastoris (shepherd's purse), Stellaria media (common chickweed), Plantago lanceolata (ribwort plantain), and Phragmites australis (common reed) have established in the greatest numbers of cities, while among birds such species are Columba livia (pigeons), Passer domesticus (house sparrow), Sturnus vulgaris (common starling), and Hirundo rustica (barn swallow) (Aronson *et al.*, 2014). Further, it appears that intensive land-use change, and biotic interchange have increased the similarity of urban plant assemblages globally. Cities in disparate regions of the globe thus retain regionally distinct native and alien plant assemblages (Palma *et al.*, 2017), while invasive alien species are associated with lower beta diversity among cities (La Sorte *et al.*, 2014).

The numbers of established alien species of plants, insects, herptiles, birds, and mammals, introduced to Europe after 1500 and occurring in habitats defined according to the European Nature Information System were analysed for 115 regional data sets (Pyšek, Bacher, *et al.*, 2010). Cities in Europe on average harbour 70 per cent of established alien plants (ranging from 41–100 per cent in individual regions), 54 per cent (11–76 per cent) of alien insects, 38 per cent (0–100 per cent) of alien herptiles, 14 per cent (0–33 per cent) of alien birds, and 26 per cent (0–100 per cent) of alien mammals. The numbers of established alien plant and insect species found in human-made, urban, or cultivated habitats were the highest of all habitats, if controlled for habitat area in the region (Pyšek, Bacher, *et al.*, 2010). The patterns of urban alien diversity have not been summarized beyond Central and Western Europe, but studies from elsewhere, for example, China, Russia, and Canada, also confirm that urban areas tend to contain very high numbers of alien species (Cadotte, 2021; Tretyakova *et al.*, 2018; Z.-X. Zhu *et al.*, 2019).

Data and knowledge gaps

Although urban ecosystems are hotspots for biological invasions, the field of invasion science has given scant attention to invasion dynamics in towns and cities (Gaertner *et al.*, 2017) with the exception of Europe where this topic has been subject of research for decades (e.g., Kowarik, 1995b; Pyšek, 1998; Sukopp, 2002). Many facets of biological invasions require elaboration in an urban context (Cilliers *et al.*, 2008; Padayachee *et al.*, 2017). The role of cities as launching sites for alien species introduction and spread into natural areas and as recipients of a range of socioecological impacts highlights the need for research to address key limitations that hinder the understanding of invasion dynamics in urban settings. There have been very few urban-rural gradient studies in developing countries (Pauchard *et al.*, 2006), or in tropical environments in general (Cusack & McCleery, 2014). So far, the relationship between levels of urbanization and abundance of alien invasive plants in tropical developing countries appears to resemble that of temperate developed countries (Lowry *et al.*, 2020). Limitations include the dearth of metrics for defining urban–wildland/rural gradients and a shortage of insights on many aspects of urban invasions in less affluent regions (Gaertner *et al.*, 2017). Thus, data on alien taxonomic groups other than plants within cities and ecoregions surrounding each city is needed.

2.5.5.2 Cultivated areas (including cropping, intensive livestock farming, etc.)

Many introductions and secondary spread of alien species occur in cultivated areas. Alien plant species that occur as weeds in agricultural areas can be introduced as contaminants of seeds, or spread by machinery and grazing animals, water channels, etc. In addition, the use of plant protection products may promote the development of herbicide resistant alien weeds, as in the case of Amaranthus, Solanum, etc. In addition, agricultural areas are often first sites of new introduction of novel crops, genetically modified organisms, biofuel crops, and novel genotypes of cultigens. In some parts of the world, ornamental plants are also intensively cultivated in agricultural areas (e.g., Booth *et al.*, 2003). Cultivated plants also suffer from introduced pathogens (e.g., fungal, viral, bacterial).

Various pathways are known to facilitate the accidental introduction of insects, pathogens, and other pests (e.g., nematodes) into cultivated areas around the world. Many groups of insects colonize stored grains and international trade in grain has facilitated the global spread of these insects such that several important species are established in virtually every world region (Morimoto *et al.*, 2019). Other important pathways by which insect pests have globally spread include international trade in fruits and vegetables and global transport of live plants, including soil and planting substrates (Kiritani & Yamamura, 2003; Liebhold *et al.*, 2012). Prior to 1910, there was little recognition of the dangers that such international trade posed for introduction of agricultural pests, but in the early 1900s many countries began to implement regulations aimed at limiting the accidental spread of plant pests with plants and plant parts. A variety of phytosanitary measures have been developed to limit pest movement in international trade, though some pathways remain more difficult to control and many species continue to be unintentionally introduced (E. Allen *et al.*, 2017; Hulme, 2014; **Chapter 5**, **section 5.2.2**).

Trends

Reports on occurrences of alien species on cultivated land are usually restricted to plant pathogens, while more general comprehensive analyses of trends of alien species on cultivated areas are largely lacking. For alien species considered as plant pathogens, which mostly consist of arthropods, fungi and oocmycetes, the number of species has increased continuously since 1800 with a rise also in the rate of annual records until the present (Aukema *et al.*, 2010; Kiritani & Morimoto, 2004; Nealis *et al.*, 2016; R. M. Smith *et al.*, 2018; F.-H. Wan & Yang, 2016). This is very likely a result of increased trade activity, particularly of plant materials, both in terms of increased volumes and increased geographic distances between donor and recipient regions. While the number of studies is geographically restricted to a few well-sampled regions, global analyses are missing; however, it is likely that alien species numbers have been increasing as observed in other world regions.

Status

Agricultural areas in Eastern Europe are the most invaded by alien plants of all European regions (Chytrý *et al.*, 2009). On arable land there were on average 7.3±9.8 per cent of plant species introduced after 1500 in Catalonia (n=506), 5.6±5.2 per cent in the Czech Republic (n=1441) and 14.3±25.6 per cent in the United Kingdom (n=989); these values represent per centages of all plants recorded in vegetation plots 15–200 m^2 in size (Chytrý *et al.*, 2008). For plants introduced from the beginning of Neolithic agriculture until 1500 (Pyšek & Jarošík, 2005), 55.5±13.5 per cent and 16.2±16.0 were reported for the Czech Republic and the United Kingdom, respectively (Chytrý *et al.*, 2008).

Data from cultivated habitats in Europe comparing alien species of plants, insects, herptiles, birds and mammals introduced after 1500 showed that as a per cent of the total alien species in a region, cultivated habitats on average harbour 34 per cent of plants (based on 115 regional datasets: median, with range 5–95 per cent), 46 per cent (26–66 per cent) of insects, 63 per cent (0–100 per cent) of herptiles, 65 per cent (51–85 per cent) of birds, and 30 per cent (0–100 per cent) of mammals (Pyšek, Bacher, *et al.*, 2010). By this measure, cultivated habitats are among those with the highest levels of established alien species (Pyšek, Bacher, *et al.*, 2010).

The domestication of plants and their widespread planting in agriculture has created unique resources that facilitate the establishment of new insect species (Liebhold *et al.*, 2018). Across most continents, the historical expansion of plantings for agriculture and forestry has been followed by the invasion of insects that utilize these crop species as hosts (e.g., Hurley *et al.*, 2016; Margaritopoulos *et al.*, 2009).

Data and knowledge gaps

Information on biological invasions of insects and plants in cultivated areas has been systematically collected in Europe and North America, likely because they act as pests and weeds and negatively impact agricultural production. However, information from other parts of the world is scarce.

2.5.5.3 Aquaculture areas

Inland, coastal, and marine farming is largely based on introduced species and a large share of the industry occurs in South-East Asia and South America. In addition to being an important pathway of introduction for alien species, aquaculture facilities can also contain many pathogens, parasites, and fouling species unintentionally introduced as contaminants with the farmed species and the materials used for their production (e.g., K. E. Costello *et al.*, 2021; Peeler *et al.*, 2011). Molluscs can carry many non-target species with them: for example, several introduced marine algal alien species worldwide were transported in association with mariculture, mainly of molluscs (Mckindsey *et al.*, 2007). In Europe, the production of native oyster *Ostrea edulis* (European oyster) has been greatly impacted by the parasite protozoan *Bonamia ostreae*, one of the diseases notifiable to the World Organisation for Animal Health (WOAH, founded as OIE; Carnegie & Cochennec-Laureau, 2004), and also by the parasitic copepod *Myicola ostreae*, both introduced together with *Magallana gigas* (Pacific oyster) (K. E. Costello *et al.*, 2021). Two bivalves (*Magallana gigas*, and *Ruditapes philippinarum* (Japanese carpet shell)) were responsible for the majority of introductions of contaminants in Europe (60 species), mainly shell foulants or macroalgae used for packaging live oysters and clams (Savini *et al.*, 2010). The aquaculture of *Magallana gigas* is likely responsible of the introduction of *Styela clava* (Asian tunicate) in New Zealand, which poses a threat to the shellfish aquaculture industry (Forrest *et al.*, 2011). Many alien species introduced for aquaculture have escaped from confined systems, established, and become invasive (Ju *et al.*, 2020): for example, the analysis of both marine and estuarine species in California showed that 106 of 126 (84 per cent) introductions were due to aquaculture and led to established populations of alien bivalves (K. E. Costello *et al.*, 2021).

Trends

Worldwide, the introduction of alien species in aquaculture is well-known, but the numbers have significantly increased since the 1950s with technological improvements (i.e., development of artificial propagation, (Shelton & Rothbard, 2006)). Other notable increases were reported in the 1960s and 1970s with the movement of *Tilapia* spp. (tilapia) and *Oreochromis* spp. (tilapia). In the 1990s Asian carp (e.g., *Ctenopharyngodon idella* (grass carp), *Hypophthalmichthys nobilis* (bighead carp), *Hypophthalmichthys molitrix* (silver carp)) was used to meet the growing demand of food to reduce the harvesting of wild species and to diversify the production (De Silva, 2012; De Silva *et al.*, 2006; Naylor *et al.*, 2001; Shelton & Rothbard, 2006). This increasing trend is consistent across the continents (FAO, 2020), particularly in Asia. China, for example, has experienced a notable increase of alien species farmed in aquaculture mostly in the 1990s, even though the introductions started in the 1920s

(Casal, 2006; Cook *et al.*, 2008; Y. Lin *et al.*, 2015; J. Liu & Li, 2010; Q. Wang *et al.*, 2015; Xiong *et al.*, 2015, 2017). A similar increase was reported for Europe beginning in the 1970s (Olenin *et al.*, 2008; Savini *et al.*, 2010; Turchini & De Silva, 2008), and in the Americas (Gozlan, 2008), especially in Latin America and the Caribbean since the 1970s-1980s with the introduction of salmonids, tilapia, Asian carps and shrimps (Shelton & Rothbard, 2006). In the United States, many native species are cultured for food, and tilapia and Asian carp introduction for food production began in the 1950-60s (Shelton & Rothbard, 2006). In Africa, aquaculture production increased since the 1980s (Shelton & Rothbard, 2006), relying mainly on introduced Asian carp and African tilapia moved within the African continent (Bartley & Marttin, 2004). In Africa, three waves of fish introductions (a total of 139 species, 40 per cent for aquaculture) occurred: before 1949, between 1950-1989, and after 1990 (Satia & Bartley, 1998). In Oceania, even though few alien species were introduced for aquaculture since 1900, this region began having an important position in aquaculture production during the 1970s (Gozlan, 2008), with alien species making up 38 per cent of the production on average (Cook *et al.*, 2008). Overall, aquaculture is mainly for food production. However, the market for ornamental and angling species is increasing, especially in Asia, Europe, and North America, thus increasing aquaculture-based introductions for this purpose (reviewed in Gozlan, 2008). Indeed, in the United States, more than half of the 91 fish species introduced through aquaculture are ornamental (J. E. Hill, 2008).

Fish, molluscs, and crustaceans are the most introduced taxonomic groups in aquaculture. Aquaculture is responsible for the majority of fish introductions globally (De Silva *et al.*, 2009; Teletchea, 2019), as confirmed by the positive correlation shown between aquaculture production and the number of fish species introduced to a region (Gozlan, 2008). Overall, the introductions of fish started before the other groups, with a first "wave" before 1900, followed by other waves in the early 1900, after 1950 and after 1960s-70s (Shelton & Rothbard, 2006): Casal (2006), extracting the data of FishBase, reported 3072 fish introductions involving 568 species, with aquaculture being the main reason of introduction (40 per cent), while in 2008, Gozlan (2008) mentioned 624 fish species introduced worldwide, 51 per cent of them for aquaculture. Freshwater fish, particularly *Cyprinus carpio* (common carp), tilapia (specifically *Oreochromis niloticus* (Nile tilapia) is the main farmed tilapia), *Salmo trutta* (brown trout), and *Oncorhynchus mykiss* (rainbow trout) are the most introduced for aquaculture production (De Silva, 2012; Teletchea, 2019). Only 15 marine fish have been introduced for aquaculture (Atalah & Sanchez-Jerez, 2020). In contrast, all molluscs introduced for aquaculture are marine (19 species reported in (De Silva, 2012; X. Guo, 2009), with *Magallana gigas* (Pacific oyster) being one of the most successfully introduced aquatic alien species throughout the world since the end of nineteenth century in United States, Canada, Europe, Australia, New Zealand, Mexico, Peru, Chile, Argentina, and South Africa (De Silva, 2012; X. Guo, 2009). The other alien mollusc species were mostly introduced in the 1960s and from the 1980s (X. Guo, 2009). In the last twenty years, the most widely introduced alien species were reported from the eastern Pacific, such as *Penaeus vannamei* (whiteleg shrimp) reported by Fernández de Alaiza García Madrigal *et al.* (2018); in 2013, its production of 4.3 million tons represented 64 per cent of the global farmed shrimp production. Finally, since the 1970s, many alien seaweeds have been unintentionally introduced through aquaculture, while very few species were intentionally introduced for production (FAO, 2020; Pickering *et al.*, 2007).

Status

Asia is considered the "backbone of global aquaculture production" (De Silva, 2012) with its contribution to over 90 per cent to the sector (De Silva *et al.*, 2009); aquaculture heavily relies on alien species (De Silva *et al.*, 2006, 2009; Ju *et al.*, 2020), particularly, in China, the leading global aquaculture producer (more than 60 per cent of the global production, Cao *et al.*, 2015; Q. Wang *et al.*, 2015). In China, alien species (a total of 179 species, Y. Lin *et al.*, 2015) are involved for over 25 per cent of the total production (Xiong *et al.*, 2017), compared to the 17 per cent of global production of alien species (Shelton & Rothbard, 2006). Asia also stands out for the widely cultured species of *Penaeus vannamei* (whiteleg shrimp), introduced in 1978 in Asia, with contributions from China, Thailand, Indonesia, and Vietnam to most of the world's shrimp production (Liao & Chien, 2011). In Europe, at least 703 alien species introduced to aquatic ecosystems for aquaculture and stocking activities have been reported: fish, crustaceans and molluscs are the most introduced taxonomic groups (Olenin *et al.*, 2008; Savini *et al.*, 2010; Teletchea, 2019; Turchini & De Silva, 2008). In Europe, alien species (mostly *Oncorhynchus mykiss* (rainbow trout), *Hypophthalmichthys molitri* (silver carp) and *Cyprinus carpio* (common carp)) contributed 67 per cent of freshwater aquaculture production, mainly in Western areas with a range of 88-98 per cent (Turchini & De Silva, 2008). The highest production of introduced marine fish is concentrated in the Magellanic province of southern Chile that is considered at risk of environmental impacts caused by escapees from the confined environment (Atalah & Sanchez-Jerez, 2020). Recent planning for diversification in aquaculture reports advised for a shift towards producing more native than alien species (Harvey *et al.*, 2017).

The worst impacts on aquaculture production have been caused by the oomycete *Aphanomyces astaci*, the causative agent of the crayfish plague. Vectored by North American crayfish introduced to Europe for aquaculture, this plague dramatically reduced native populations and the production of native European crayfish (De Silva *et al.*, 2009). Many pathogens can also be carried by alien finfish, especially cyprinids: at least 226 parasite species (34 of which causing important diseases worldwide) have been found in *Cyprinus carpio* (common carp), one of the most introduced alien species (Jeney & Jeney, 1995). In Europe, the seven most farmed cyprinids led to the introduction of 31parasites⁄disease agents (Savini *et al.*, 2010). Similarly, in South Africa many parasites have been introduced with fish and crayfish used for fisheries and aquaculture (Weyl *et al.*, 2020). Despite the high number of pathogens transferred by alien farmed fish, a large-scale mass mortality of farmed fish due to introduction of associated pathogens has not yet been recorded (De Silva *et al.*, 2009). Still, alien farmed shrimps can carry several diseases that lead to important outbreaks in the facilities and relevant economic losses, especially in Asia (Briggs *et al.*, 2004).

Data and knowledge gaps

The Food and Agriculture Organization (FAO) Database on Introductions of Aquatic Species (DIAS) (FAO, 2021) reports the introduction of alien species per country, providing also global maps of species introduced for aquaculture and a focus on some alien species, such as *Cyprinus carpio* (common carp) and *Oreochromis niloticus* (Nile tilapia). In general, there is considerable information available for Asia, the leading continent for aquaculture production, and for Europe and Latin America while for other regions information is often lacking. Recent reviews addressed fish, molluscs and shrimp situations. Studies on temporal trends are limited and mainly available for the three main taxonomic groups fish, molluscs, and crustaceans.

2.5.5.4 Coastal areas intensively used for multiple purposes by humans

Trends

Accumulation rates of established alien species in coastal marine waters frequently show a pattern of exponential accumulation through time, with the number of new reports increasing dramatically during the last 30 years with increased awareness and research effort (Bailey *et al.*, 2020; Leppäkoski *et al.*, 2002; Ruiz *et al.*, 2015). The earliest substantiated reports of established alien marine species date to at least the 1200s (Ojaveer *et al.*, 2018). The type of transported taxa has changed over time as shipping pathways have modernized. For example, historical use of solid ballast, such as rocks, sand, and dirt, was associated with the transportation of seeds and insects while the modern use of seawater ballast correlates with introductions of aquatic taxa ranging from microbes and protists to macroinvertebrates and fishes (Bailey, 2015). There are also now fewer intentional introductions of fishes and macroinvertebrates into the natural environment, likely because the potential negative impacts of such releases are now better understood (Bailey *et al.*, 2020).

While the rate of new alien species records has levelled off and even declined since 2010, possibly due to regulations for ships' ballast water and improved practices by the aquaculture industry (Bailey *et al.*, 2020; **Chapter 5**, **section 5.51**), expectations of continued global shipping growth suggest the risks of biological invasions could increase significantly by 2050 without management of shipping-mediated vectors (Sardain *et al.*, 2019) thus underscoring the importance of existing instruments to prevent introductions *via* ballast water and biofouling. The construction and successive enlargement of canals connecting previously unconnected waterbodies has been responsible for a growing number of established alien species in the Mediterranean (Galil *et al.*, 2017). Similarly, it has been projected that the recent expansion of the Panama Canal could triple the number of established alien species arriving in the Gulf of Mexico and the North American East Coast (Muirhead *et al.*, 2015). In regions such as the Arctic, the changing environmental conditions and the dramatic increase in shipping activity are likely to favour the transport and introduction of new alien species. This increase in alien species is likely to reconfigure the global dynamics of invasive alien species, potentially reshaping marine habitats and ecosystem functions, especially in coastal regions (Goldsmit *et al.*, 2020; Miller & Ruiz, 2014).

Status

There has been extensive research and surveillance of coastal marine alien species in Central and Western Europe, with more than 4,350 detection records for at least 1,370 introduced species of alien or unknown (cryptogenic) origin (AquaNIS, 2015). More than 450 marine alien species have been recorded off the Israeli Mediterranean coast – which serves as a gateway for introductions from the western Indian Ocean and Red Sea, through the Suez Canal, to the Mediterranean Sea (Galil *et al.*, 2021a).

Coastal areas are generally prone to biological invasions. In a global study of established alien species richness of a number of taxonomic groups, Dawson *et al.* (2017) found that hotspots are, other than islands, predominantly coastal mainland regions.

In the Americas, at least 450 alien species are reported from continental North America (Ruiz *et al.*, 2015), and approximately 300 other species from Hawaii (Carlton & Eldredge, 2009). Reported numbers are lower in South America, with 129, 138, and 53 species reported from the south-west Atlantic, Brazil, and the Galápagos Islands, respectively (Carlton *et al.*, 2019; Schwindt *et al.*, 2020; Teixeira & Creed, 2020). Despite the low number of reported alien species, the coastal environments of the south-west Atlantic were affected by one of the largest continental-scale bioinvasion events ever recorded, and which has reshaped vast coastal-marine ecosystems, modifying their coastal geomorphology, biodiversity, primary and secondary productivity in the Americas and Asia (Bortolus *et al.*, 2015, 2019; Qiu, 2013). Researchers have shown that what are now extensive *Sporobolus alterniflorus* (smooth cordgrass) marshes in this region, were probably bare mudflats centuries ago, and that the *Sporobolus alterniflorus* introduction might have led to vast unrecorded shifts in bird, fish, and invertebrate biodiversity, and immense shifts in algal vs. detritus production, with the concomitant trophic cascades that these changes imply (Bortolus *et al.*, 2015, 2019). Reports of mudflat conversion by *Sporobolus alterniflorus* with distinct ecological consequences have also been reported from China (B. Li *et al.*, 2009). Similarly, the coastal systems of North America have been transformed by an introduced genotype of the macrophyte *Phragmites australis* (common reed) causing whole ecosystem and habitat transformations (Bowen *et al.*, 2017; Chambers *et al.*, 1999; Cronin *et al.*, 2015; Dibble & Meyerson, 2014).

In the Asia-Pacific region, at least 650 marine alien and cryptogenic species are reported from New Zealand (Seaward & Inglis, 2018), with another 343 introduced and cryptogenic species reported from Australia (Sliwa *et al.*, 2008), and 213 alien species reported from China (Xiong *et al.*, 2017). At least 95 alien and 39 cryptogenic species are reported from South Africa (T. B. Robinson *et al.*, 2016), with most of the African continent being understudied.

From1965-2015, at least 1,400 unique alien species have been reported as being introduced in coastal ecosystems – approximately one new species detected every 8 days for the last fifty years (Bailey *et al.*, 2020).

Data and knowledge gaps

Records of alien species in coastal environments are more reliable in recent decades as the awareness of alien species introductions and their potential negative impacts began to increase. However, data are still limited for many taxonomic groups and regions of the world (especially Africa, Meso- and South America and Asia) (Bailey *et al.*, 2020). Aquatic alien species are frequently under-reported due to limited research intensity and insufficient taxonomic expertise (especially for smaller-bodied organisms) (Carlton & Fowler, 2018; Ojaveer *et al.*, 2017). Reliable records of alien species introductions exist mainly for plants and animals, with fungi, protists, and microbes generally being understudied.

An accurate number of alien species introduced across global coastal waters is difficult to estimate since organisms were being transported around the world by ships for centuries before inventories of species in the marine environment, resulting in an inability to determine the true origin of a large proportion of species within coastal communities (Bortolus *et al.*, 2015; Carlton, 1996; Hewitt *et al.*, 2004; Schwindt *et al.*, 2020). There can also be long time lags after the initial introduction and establishment of a new population until its discovery (C. J. Costello & Solow, 2003; C. M. Taylor & Hastings, 2005), unless regular and targeted monitoring is taking place (Hayes *et al.*, 2019). In many regions of the world, regular surveillance is hampered by inadequate resources and limited access to taxonomic expertise (Ojaveer *et al.*, 2014). The number of alien introductions is therefore certainly much higher than published literature suggests.

The study of invasive alien vascular plant species introduced in the marine-coastal environments of South America is currently one of the largest gaps to cope with. Besides a few classic examples including genera such as *Tamarix* (tamarisk), *Carpobrotus, Ammophila, Sporobolus*, or *Salsola* (Schwindt *et al.*, 2018), there is little research effort in this area and no updated review or synthesis revising the list of plant invasive alien species for this region. Large regions like South America have invested little effort (e.g., relative to Europe or North America) to recording and monitoring the introduction of alien species. This lack of data has often been misunderstood as an actual lack of invasive alien species. This knowledge gap seriously hampers the ability to recognize pre-existing native ecosystems (i.e., Ecological Mirage Hypothesis; Bortolus *et al.*, 2015; Bortolus & Schwindt, 2007). On the other hand, there is currently an increase in the number of researchers investigating invasive alien species in this region (Schwindt & Bortolus, 2017), which will likely increase the number of reports of introduced species for the region. Nevertheless, this increase is not necessarily, or strictly, due to new introductions, but could also include introductions long overlooked and ignored. For instance, in 2017 scientists found that what was until then considered a native alga, *Melanothamnus harveyi* (Harvey's siphon weed), was in fact the earliest record of an alien coastal marine species for the region, being first reported in 1872 under the name of *Polysiphonia argentinica* (Schwindt *et al.*, 2020). Similarly, *Sporobolus alterniflorus* (smooth cordgrass) was recognized as alien to the southern Atlantic coastal environments by 2015, nearly two centuries after its introduction (Bortolus *et al.*, 2015).

Finally, the lack of research on emerging or understudied transportation pathways, such as the aquarium and bait trades, internet commerce and anthropogenic marine litter (e.g., M. L. Campbell *et al.*, 2017; J. T. Carlton *et al.*, 2017; Fowler *et al.*, 2016; Lenda *et al.*, 2014), likely results in gaps of knowledge. This knowledge gap refers to the relative importance of different introduction mechanisms and the corresponding management priorities for reduction of future introductions of aquatic alien species.

Box 2 11 Good Quality of Life: A global assessment of trends and status of invasive alien species.

Invasive alien species are a significant and growing threat worldwide to the good quality of life (i.e., the achievement of a fulfilled human life, see IPBES glossary[6] for a complete definition) for many communities (Costanza *et al.*, 2006). A literature review conducted by the authors of **Chapter 4** identified about 1050 invasive alien species that impact good quality of life (**Chapter 4**, **Figure 4.2**). In most cases (841 cases), the reported impacts negatively affected good quality of life, while in 212 cases, benefits of invasive alien species were reported. However, it is critical to note that a benefit from an invasive alien species in one sector does not mitigate the harm caused elsewhere, and that the same invasive alien species may both cause harm and produce a benefit. Integrating this invasive alien species list and the distributional data provided in this chapter (**section 2.1.4** for data details) reveals that the United States, Australia, New Zealand, multiple European countries, China, Japan, Canada, Mexico, and South Africa were the countries with highest numbers of invasive alien species with impacts (negative or positive) on the good quality of life **(Figure 2.36)**. This pattern largely reflects the distribution of all identified alien species **(Figure 2.5)** suggesting that in general, more impacts on good quality of life have been reported where more alien species were found.

6. IPBES glossary: https://ipbes.net/glossary

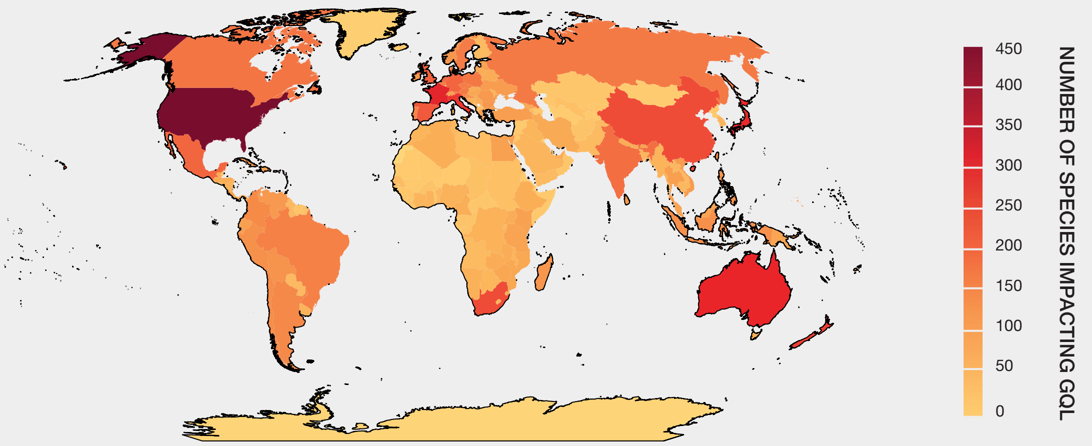

Figure 2 36 Map of invasive alien species numbers with reported impacts on good quality of life.

Species were identified through the literature review conducted by **Chapter 4** of this assessment (data management report available at: https:/doi.org/10.5281/zenodo.5766069) and the distributions of these species were extracted from the database used in **Chapter 2** (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

The total number of invasive alien species with impacts on good quality of life has risen continuously at a nearly linear rate since around 1830 **(Figure 2.37)**. During this time, the rate of increase remained relatively constant at around 15 new invasive alien species with impacts on good quality of life per five years (or three new species annually).

Most invasive alien species with impacts on good quality of life were insects (38 per cent), followed by vascular plants (29 per cent), fishes (7 per cent), molluscs (5 per cent), and mammals (5 per cent). Numerous widespread, well-known invasive alien species often negatively affect various aspects of good quality of life including culture, human health, and the local economy. High profile examples include fish species of the genus Oncorhynchus (trout and salmon) that have been introduced in many parts of the world (Crawford & Muir, 2008) and have changed local economies and livelihoods in areas. Such impacts include hybridization with native species and predation of native fishes (Kitano, 2004; Soto *et al.*, 2001; Woodford & Impson, 2004). The introduction of *Lates niloticus* (Nile perch) has changed the local socio-economic dynamics such as a decline in multi-fisheries subsistence and livelihood (Njiru *et al.*, 2018). In particular, women from marginalized communities have been disadvantaged by the effects of Lates niloticus on subsistence cichlid-based fisheries, and have had to adopt new livelihood practices, with prostitution being a primary one. This has, in turn, spurred inequality, social conflict, health issues (spread of human immunodeficiency virus (HIV) in particular), the loss of cultural practices, and reduced food

Box 2 11

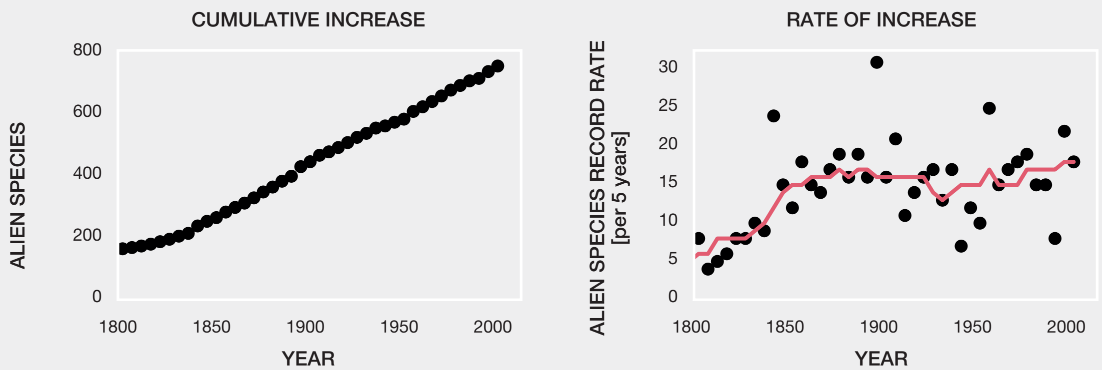

Figure 2 37 **Trends in numbers of invasive alien species with reported impacts on good quality of life.**

Trends are shown as cumulative numbers (left panel) and as rate of increase (i.e., numbers of species per five years) (right panel). The smoothed trend (line) is calculated as running median (**section 2.1.4** for further details about data sources and data processing). Species were identified through the literature review conducted by **Chapter 4** of this assessment (data management report available at: https:/doi.org/10.5281/zenodo.5766069) and the trends for these species were extracted from the database used in **Chapter 2** (**section 2.1.4** for further details about data sources and data processing). Note numbers presented may deviate from those reported in the text due to variation among data sources. A data management report for the data underlying this figure is available at https://doi.org/10.5281/zenodo.7615582

security for local communities, thus affecting human well-being (R. T. Shackleton *et al.*, 2018).

Another prominent example for an invasive alien species with impacts on good quality of life is Spodoptera frugiperda (fall armyworm). This alien insect pest has been spreading for decades and has wide-ranging impacts in many parts of the world including economic losses from reduced maize crop yields (Dassou *et al.*, 2021; De Groote *et al.*, 2020) and reduced local livelihood potential (Kassie *et al.*, 2020). The species is likely to spread further due to suitable climatic conditions (Day *et al.*, 2017; Early *et al.*, 2018). As another example, *Prosopis* spp. (mesquite) is one of the most widely distributed invasive tree species globally. These species have invaded many arid and semi-arid parts of the world, thereby reducing water available for humans and animals (Bekele *et al.*, 2018; Shiferaw *et al.*, 2021), impacting human health *via* allergies, asthma, and physical injuries (Al-Frayh *et al.*, 1999; Mwangi & Swallow, 2008), increasing malaria prevalence due to habitat provision (Muller *et al.*, 2017), reducing grazing capacity (S. Kumar & Mathur, 2014; Mwangi & Swallow, 2008; Ndhlovu *et al.*, 2011), and impacting local economies through increased management costs and loss of grazing (R. T. Shackleton *et al.*, 2014).

Focusing more specifically on Indigenous Peoples and local communities (i.e., typically ethnic groups who are descended from and identify with the original inhabitants of a given region; IPBES glossary[7]) and good quality of life, the assessment identified and assessed 131 regional case studies worldwide of the impacts of invasive alien species on the good quality of life and their effects for Indigenous Peoples and local communities. The most frequently reported species in the case studies were first identified, then species and their impacts on good quality of life concerning taxonomic groups, units of analyses, and IPBES regions. The findings suggested that the biggest impacts were from plant species (85 species, 65 per cent), of which most (79 species) were woody vascular plants.

The three most frequently reported invasive alien plants (38 cases) included either alone or in combination with other species were: *Lantana camara* (lantana), *Prosopis* spp., and *Chromolaena odorata* (Siam weed). Aquatic invasive alien plant species were reported in only six case studies. These included *Pontederia crassipes* (water hyacinth), *Phragmites australis* (common reed), *Hydrilla verticillate* (hydrilla), and *Cryptostegia grandiflora* (rubber vine), amongst others. Overall, fewer case studies (46 case studies) reported invasive alien species' impact on good quality of life for other taxonomic groups. These taxa included fish species (10 species) such as *Cyprinus carpio* (common carp), *Tilapia rendalli* (redbreast tilapia), *Oreochromis mossambicus* (Mozambique tilapia), and *Lates niloticus, Oncorhynchus mykiss* (rainbow trout). Insects (12 studies), were also reported including *Spodoptera frugiperda*, and *Agrilus planipennis* (emerald ash borer). Other taxa were not reported in any case studies.

The majority of case studies (60 per cent; 79 case studies) reported negative impacts of invasive alien species, while others reported both negative and positive impacts. Examples

7. IPBES glossary: https://ipbes.net/glossary

Box 2 11

include *Opuntia ficus-indica* (prickly pear), which is used for fodder and fence lines but has thorns that cause injury to humans and animals (S. E. Shackleton & Shackleton, 2018). Positive impacts of invasive alien species include feral pigs that provide meat (C. J. Robinson & Wallington, 2012), woody plants (e.g., *Acacia, Prosopis, Eucalyptus)* that provide biomass for compost, timber and wood charcoal production (Rogers *et al.*, 2017; Tassin *et al.*, 2012; B. W. van Wilgen, 2012), shade (S. E. Shackleton & Shackleton, 2018), products to sell (Tilahun *et al.*, 2017), and medicinal benefits (Witt *et al.*, 2019). Despite the benefits provided, the positive impacts of invasive alien species on good quality of life do not counteract their negative impacts.

Knowledge and data gaps

There were large differences in the number of studies from the different IPBES regions potentially representing knowledge and data gaps on the effects of invasive alien species on good quality of life. Asia and the Pacific had the most studies (54), followed by Africa (44), the Americas (28), and Europe and Central Asia (3). There appears to be a bias in case studies towards reporting the effects of invasive alien woody vascular plants (65 per cent) on good quality of life since there were many fewer case studies on other widespread alien species groups, particularly invertebrates, microbes, and mammals (5 per cent).

2.6 FUTURE DYNAMICS OF BIOLOGICAL INVASIONS

This section reports on the projected future dynamics of the trends and distribution of alien and invasive alien animal species in general (**section 2.6.1**), for animals (**section 2.6.2**), plants (**section 2.6.3**), and microorganisms (**section 2.6.4**), and addresses limitations for assessing future dynamics of biological invasions (**section 2.6.5**).

2.6.1 Overview of future dynamics of biological invasions

Recent increases in data availability and accessibility provide an improved baseline understanding of historic and current alien species richness and distributions that help to make new and improved projections (E. E. Dyer, Cassey, *et al.*, 2017; Pagad *et al.*, 2022; Seebens, Blackburn, *et al.*, 2017; van Kleunen *et al.*, 2019). However, many gaps still exist at the regional and taxonomic scales (Pyšek *et al.*, 2008). Approaches to forecast dynamics of biological invasions vary, including expert-based systems (e.g., based on individual experts in their field, Indigenous and local knowledge systems (**Glossary**), horizon scanning approaches), various modelling approaches (e.g., expert-based models, correlative models, process-based models, hybrid models; **Chapter 1**, **section 1.6.7.3**) or scenario approaches (exploratory scenarios, target-seeking scenarios, policy-screening scenarios; **Chapter 1**, **section 1.6.7.3**).

Generally, prediction and projection studies have been conducted from regional, continental to global scales (Bellard, Thuiller, *et al.*, 2013; Dullinger *et al.*, 2017) illustrating the potential current and future numbers and distribution of alien species. Studies cover one to multiple species within (e.g., cacti: Masocha & Dube, 2018; termites: Buczkowski & Bertelsmeier, 2017; ants: Bertelsmeier *et al.*, 2015, 2016; Fournier *et al.*, 2019) and across taxonomic groups (e.g., the 100 worst invaders globally as assessed by the IUCN ISSG: Bellard, Thuiller, *et al.*, 2013; Gallardo *et al.*, 2017).

On the global scale, quantitative projections of established alien species numbers under a business-as-usual scenario do exist for the period from 2005–2050 (Seebens, Bacher, *et al.*, 2021). For seven major taxonomic groups established alien species numbers are projected to increase across eight continental regions **(Figure 2.38)**. At the continental scale, the strongest relative increase in established alien species numbers of 64 per cent (2,543 ± 237 species) is expected for Europe, followed by temperate Asia (50 per cent; 1597 ± 197) and South America (49 per cent; 1,391 ± 258). Globally, an average relative increase of 36 per cent, equivalent to 1,195 ± 131 new established alien species is projected (Seebens, Bacher, *et al.*, 2021). A list of relative and absolute projected increases of established alien species numbers until 2050 is given in **Table 2.28**. However, given the projected acceleration of the majority of direct and indirect drivers of change in nature, it is likely that the numbers of established alien species will be higher than those predicted in the business-as-usual scenario **(Table 2.28)**. Comparing past and future trends, the rate of increase of established alien species numbers is expected to increase even further (i.e., acceleration) for arthropods and – to a lower degree – birds worldwide. In contrast, rates are projected to decline for mammals globally and partly for fishes, although rates are still positive, resulting in more alien species, but at a lower rate than observed before (Seebens, Bacher, *et al.*, 2021). However, the number of alien and invasive alien species is expected to rise even without the introduction of any new species by humans, because the majority of already established alien species are still spreading (Seebens, Blackburn, *et al.*, 2021). Thus, already established alien species are likely to spread further also to

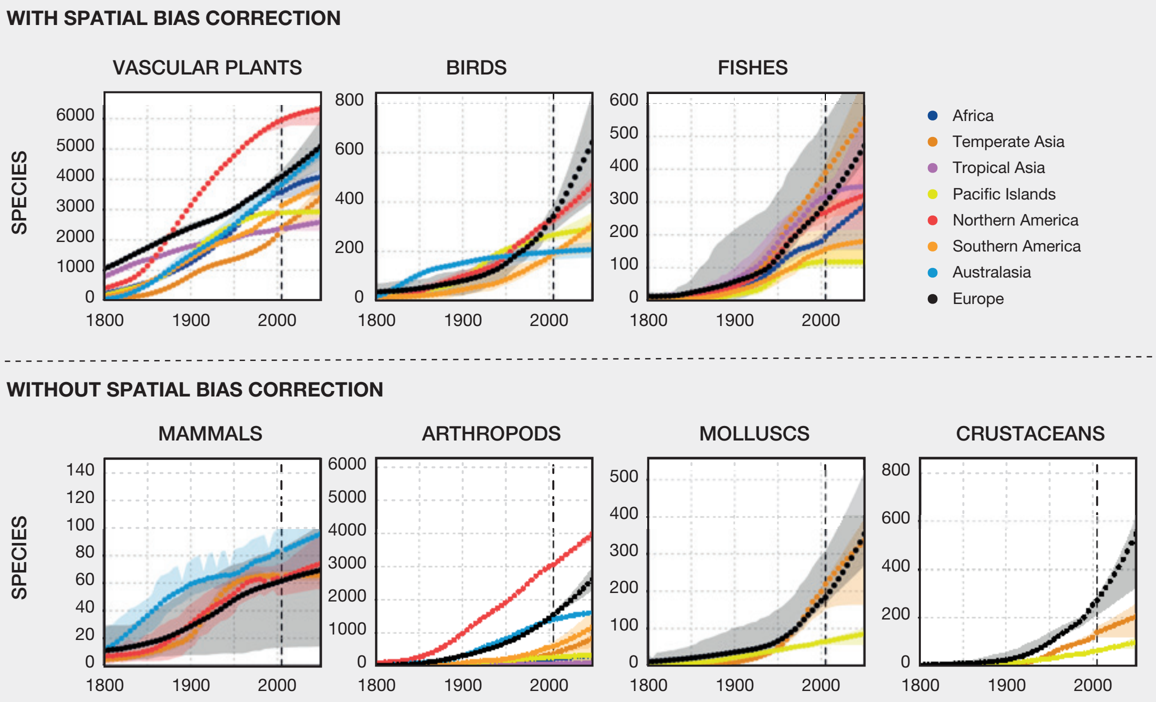

Figure 2 38 **Projected trends of established alien species numbers until 2050.**

Projections are shown for seven major taxonomic groups across eight global regions and based on a business-as-usual scenario that assumes that drivers facilitating biological invasions will develop in the future as has been observed during recent decades. For vascular plants, birds, and fishes a spatial bias correction was applied to account for spatial heterogeneity in data availability. This was not possible for the other taxonomic groups due to data deficiency. Trend lines show averaged trends out of repeated simulations, while variation around the means is indicated by shaded areas. From Seebens *et al.* (2021), https://doi.org/10.1111/gcb.15333, under license CC BY 4.0.

Table 2 28 **Projected relative (per cent) increases of established alien species numbers until 2050.**

Projections are representative for a business-as-usual scenario, assuming similar developments in drivers facilitating biological invasions as observed in the past. Values are mean estimates over 100 model runs with the upper and lower 2.5 per cent confidence interval given in square brackets. The absolute established alien species numbers increase averaged more than 100 model runs are provided in round brackets together with the standard deviation estimates. Data are from Seebens, Bacher, *et al.* (2021).

	Africa	Australasia	Europe	Northern America	Pacific Islands	South America	Temperate Asia	Tropical Asia
Mammals		14 [2, 29] (12±3)	13 [0, 167] (8±9)	16 [1, 46] (10±9)			0 [0, 10] (0±1)	
Birds	42 [0, 75] (59±26)	5 [1, 9] (9±4)	88 [44, 139] (299±53)	42 [32, 46] (138±11)	9 [1, 29] (24±22)	60 [10, 70] (115±20)		67 [36, 91] (78±15)
Fishes	49 [1, 75] (96±39)		59 [37, 104] (175±32)	20 [2, 70] (54±57)	0 [0, 1] (0±0)	16 [1, 96] (25±39)	42 [7, 62] (165±48)	10 [0, 76] (31±34)
Arthropods	51 [0, 73] (109±51)	15 [13, 18] (212±14)	69 [48, 85] (1072±92)	30 [24, 34] (927±31)	26 [1, 35] (70±17)	99 [0, 130] (582±249)	117 [57, 145] (445±87)	35 [0, 58] (24±13)
Molluscs			93 [59, 135] (170±31)		32 [2, 47] (21±7)		53 [3, 73] (116±40)	
Crustaceans			100 [51, 117] (273±34)		56 [10, 90] (36±8)		47 [0, 76] (66±18)	
Vascular plants	14 [4, 19] (503±113)	28 [22, 29] (1065±41)	24 [16, 39] (997±209)	6 [1, 7] (365±33)	1 [0, 2] (38±9)	21 [18, 25] (669±52)	41 [28, 54] (987±170)	10 [0, 17] (227±67)

neighbouring regions, which will result in further increases in alien species numbers regionally.

A literature review[8] on studies including models and scenarios of biological invasions shows that the current literature is dominated by correlative model approaches (57 per cent) and correlative scenarios (87 per cent) and that these studies mainly explore either long-term (2050-2100) or short-term (until 2030) trends (42 per cent and 30 per cent respectively) (**Chapter 1**, **section 1.6.7.3**).

The remainder of this section provides an overview of the general trends of predicted and projected alien species richness and distributions for different taxonomic groups and across scales.

2.6.2 Animals

For some bird species, such as *Corvus splendens* (house crow) and *Acridotheres tristis* (common myna), the current distributions indicate a large potential to spread to new areas (Magory Cohen *et al.*, 2019; Nyári *et al.*, 2006). Similarly, mammals such as *Sus scrofa* (feral pig), *Herpestes javanicus auropunctatus* (small Indian mongoose), and *Procyon lotor* (raccoon) often have a large potential of future invasions worldwide (Lewis *et al.*, 2017; Louppe *et al.*, 2019, 2020). In the marine realm, a study of 19 ascidian species finds a large invasion potential especially at higher latitudes (Lins *et al.*, 2018). For insects, several studies investigated the invasion potential of agricultural pest species (e.g., *Phthorimaea operculella* (potato tuber moth) (Kroschel *et al.*, 2013), *Bactrocera carambolae* (carambola fruit fly) (Marchioro, 2016), *Diabrotica* spp. (e.g., cucumber beetles) (Marchioro & Krechemer, 2018), *Bemisia tabaci* (tocacco whitefly) (Ramos *et al.*, 2018), *Spodoptera frugiperda* (fall armyworm) (Early *et al.*, 2018), *Halyomorpha halys* (brown marmorated stink bug) (Kriticos *et al.*, 2017), *Drosophila suzukii* (spotted wing drosophila) (L. A. dos Santos *et al.*, 2017)), and all studies found a high risk of invasion beyond the current realized distribution. Although less investigated, high invasion potentials have also been identified for other insect species (e.g., Fournier *et al.*, 2019; He *et al.*, 2012; H. Li *et al.*, 2006; Peacock & Worner, 2006). A study on the potential biological invasion risk of protected areas worldwide found that 95 per cent of the protected areas have high habitat suitability for alien mammal species across 11 taxonomic groups (X. Liu *et al.*, 2020).

An analysis of the 100 worst invaders of the world (as assessed by the IUCN ISSG) found a decreased potential for future global distribution of mammals, birds, fishes, reptiles, and amphibians, but an increase in distributions of aquatic and terrestrial invertebrates due to region specific projected changes in climate and land-use, using an ensemble species distribution models approach (Bellard, Leclerc, *et al.*, 2013). Other global and regional studies have focused on the future invasion potential for species from different taxonomic groups such as ants and termites (projected increases for 12 out of 13 species; e.g., Bertelsmeier *et al.*, 2013b, 2015; Buczkowski & Bertelsmeier, 2017; Y. Chen, 2008), beetles (projected increase; e.g., Berzitis *et al.*, 2014; Kistner-Thomas, 2019; C. Wang *et al.*, 2017), flies (northward shift and decrease in global suitability; e.g., Capinha *et al.*, 2014; M. P. Hill *et al.*, 2016; Qin, 2019; S. F. Ryan *et al.*, 2019), other insects (projected increase; e.g., M. P. Hill *et al.*, 2017; Lu *et al.*, 2020), amphibians (projected stable distribution or increase; e.g., Ficetola *et al.*, 2010; Forti *et al.*, 2017; Ihlow *et al.*, 2016), fish (projected increase; e.g., Dong *et al.*, 2020; Kramer *et al.*, 2017) and mammals (projected increase; e.g., Louppe *et al.*, 2019, 2020).

Under different scenarios of change of the global shipping network, which constitutes a major driver responsible for biological invasions (**Chapter 3**, **section 3.2.3.1**), and across taxonomic groups, high invasion risks have been identified for Asia and Europe (especially the Mediterranean) with a projected significant increase in the global invasion risk without management of shipping-mediated vectors (Sardain *et al.*, 2019). A risk assessment in the 19 Arctic ecoregions identified hotspots of future invasion for 23 invasive planktonic and benthic species in Hudson Bay, Northern Grand Banks/Labrador, Chukchi/Eastern Bering Seas and Barents/White Seas (Goldsmit *et al.*, 2020). Contrary to the projected Arctic expansion of the species their global projected range contracted, indicating a northward shift of future invasions (Goldsmit *et al.*, 2020). Mammal species, such as *Procyon lotor* (raccoon) and *Herpestes javanicus auropunctatus* (small Indian mongoose), are expected to shift to higher latitudes (Louppe *et al.*, 2019, 2020). Studies of individual fish species project potential future invasion risk across continents and at the regional scale (Dong *et al.*, 2020; Kramer *et al.*, 2017). For amphibians, two frog species (*Xenopus laevis* (African clawed frog) and *Lithobates catesbeianus* (American bullfrog)) are projected to have stable to decreasing future distributions under climate change (Ficetola *et al.*, 2010; Ihlow *et al.*, 2016). For insects, future potential distributions under climate change scenarios project poleward shifts (Capinha *et al.*, 2014; M. P. Hill *et al.*, 2016; Kistner-Thomas, 2019; Qin *et al.*, 2019) with many species increasing their potential distributions (Bellard, Thuiller, *et al.*, 2013; Bertelsmeier *et al.*, 2015; Buczkowski & Bertelsmeier, 2017; Y. Chen, 2008; Lu *et al.*, 2020; Qin *et al.*, 2019). At the same time, some insect species' distributions (e.g., *Aedes aegypti* (yellow fever mosquito), *Pheidole megacephala* (big-headed ant)) are projected to decrease as well, with the declines mainly located in tropical regions (Bertelsmeier *et al.*, 2013b; Capinha *et al.*, 2014; S. J. Ryan *et al.*, 2019).

8. Data management report available at: https://doi.org/10.5281/zenodo.5706520

In summary, the suite of studies available for projections of future dynamics of alien species suggests that overall ranges of alien species are expected to increase in most cases although with large variation due to a continuous introduction of new individuals and an expansion of ranges to other suitable habitats. In addition, ranges are expected to shift poleward because of global warming (Walther *et al.*, 2009). The total number of alien species is expected to increase until 2050 for most investigated taxonomic groups such as birds, fishes, mammals, arthropods, molluscs, and crustaceans (Seebens, Bacher, *et al.*, 2021). These trends are consistent across all continents except alien birds in Europe, alien mammals in tropical Asia, and alien fish on Pacific Islands, which are projected to reach a plateau. Relative increases between 2005 and 2050 range between 117 per cent (arthropods in temperate Asia) and 5 per cent (birds in Australasia) (Seebens, Bacher, *et al.*, 2021).

2.6.3 Plants

Potential hotspots of alien plants have been identified by modelling the distribution of individual plant species and projecting the distribution under future environmental conditions. For the 100 worst invaders (as defined by the IUCN), Europe, northern North America, and Oceania emerge as potential hotspots for invasion (Bellard *et al.*, 2016), while potential hotspots for cacti emerge in the Mediterranean, tropical savanna regions, and xeric shrubland biomes (Masocha & Dube, 2018). Other global studies on large sets of alien plant species identify high invasion risk in Europe, South America, North America, southwest China and New Zealand as well as the coast of West Africa and the southern coast of Asia (J.-Z. Wan *et al.*, 2016; Y. Wang & Xu, 2016). Regions of high invasion risk change depending on the taxa under investigation. For 10 parasitic Orobanchaceae species tropical and subtropical regions are most suitable for potential future invasions (Mohamed *et al.*, 2006). Higher potential future suitability has also been projected along roadsides (Azan *et al.*, 2015) and at the margins and buffer zones of protected areas (Gallardo *et al.*, 2017; Paclibar & Tadiosa, 2019), while potential future biological invasion risk is lower inside protected areas (Gallardo *et al.*, 2017; Paclibar & Tadiosa, 2019).

On the global scale, future distributions of some alien plant species are projected to expand (e.g., J.-Z. Wan *et al.*, 2016), while others will contract in parts of their current range (e.g., range contractions mainly at lower latitudes; Bellard, Leclerc, *et al.*, 2013) under different climate change scenarios. A recent study predicted the global distribution of 336 terrestrial invasive alien plants under future climate change scenarios (J.-Z. Wan *et al.*, 2016). It identifies the main future invasion hotspots for plant invasions to be in South America, Europe, New Zealand, and northern and Southern Africa (J.-Z. Wan *et al.*, 2016). Other studies focus either on single alien plant species (R. Ahmad *et al.*, 2019; Bourdôt *et al.*, 2012; Heshmati *et al.*, 2019) or sets of species within specific regions (e.g., Adams *et al.*, 2015; R. Ahmad *et al.*, 2019; J. M. Allen & Bradley, 2016; Dullinger *et al.*, 2017; Paclibar & Tadiosa, 2019). Most studies for Northern America and Europe report strong increases in overall potential future range sizes (e.g., Adhikari *et al.*, 2015; J. M. Allen & Bradley, 2016; Dullinger *et al.*, 2017) under global change, with the magnitude of change within these regions varying according to the species investigated and increases in suitable ranges are mainly directed towards higher latitudes (J. M. Allen & Bradley, 2016). Studies for the United States and Europe project that most current invasion hotspots will remain stable spatially, but potential invasion alien species richness will increase between 64 to 102 per cent (J. M. Allen & Bradley, 2016; Dullinger *et al.*, 2017).

For Europe, a prediction of future development of plant invasions until 2080 under three socioeconomic scenarios differing in focus on economic growth vs. sustainability has been made based on data from vegetation plots (Chytrý *et al.*, 2012). Under all scenarios an increase in the level of invasion was projected for north-western and northern Europe, and under two of the scenarios a decrease for some agricultural areas of Eastern Europe where abandonment of agricultural land is expected. However, the implementation of sustainability policies would not automatically restrict the spread of alien plants (Chytrý *et al.*, 2012).

Following a business-as-usual scenario, thereby assuming that drivers will develop in the future as observed in the past, alien vascular plants species numbers are expected to increase steadily across all continents with only North America showing a weak sign of saturation by 2050 (Seebens, Bacher, *et al.*, 2021; **Figure 2.38**). The range of the projected increase of alien vascular plants lies between 1 per cent (Pacific Islands) and 41 per cent (Temperate Asia) from 2005-2050 **(Table 2.28)**. Likewise, relative increases in species numbers are projected to increase more strongly in aquatic than non-aquatic environments (Seebens, Bacher, *et al.*, 2021). In the marine realm, future increases in alien algae species introductions are projected for Asia and Europe (Seebens, Bacher, *et al.*, 2021) and mainly along the major shipping routes (Sardain *et al.*, 2019).

2.6.4 Microorganisms

A recent review of species distribution models used for fungi has identified 75 studies predicting the potential distribution of fungi under current climates (Hao *et al.*, 2020). The majority of studies deal with one species only or with multiple species from the same genus (e.g., *Phytophthora*; Scott *et al.*, 2019) and generally invasion risk is predicted to be higher as currently observed, both in terms of numbers of alien fungi present (Barwell *et al.*, 2021; Bebber *et al.*, 2019; Scott *et al.*, 2019) and of occupied range (e.g., Feldmeier *et al.*, 2016; Kriticos *et al.*, 2013; Yonow *et al.*, 2013). For crop pests including herbivorous arthropods, pathogenic microbes, and virus species numbers within regions are predicted to be higher than observed levels (Bebber *et al.*, 2019) and hotspots of pest invasion are located in Mesoamerica, Europe, North-East Asia and Australia (Bebber, 2015).

Global plant pathogen studies project an increase in potentially suitable areas, especially towards higher latitudes (Avila *et al.*, 2019; Burgess *et al.*, 2017). While for some pathogens (e.g., *Phytophthora cinnamomi* (Phytophthora dieback); Burgess *et al.*, 2017) the entire potential future environmental range is modelled, other approaches couple both the pathogens and hosts when modelling future ranges (e.g., *Diuraphis noxia* (Russian wheat aphid), Avila *et al.*, 2019). Additionally, there are approaches that extend distributional invasion risk measures by impact assessments that assess the overlap of the potential future distribution and cropland area (e.g., *Raoiella indica* (red palm mite); Amaro & de Morais, 2013). Pathogen distribution in many cases is linked to introduced invasive alien species that act as host species and projected invasions thus are inferred from host species presence and distribution change (e.g., chytridiomycosis; O'Hanlon *et al.*, 2018). Crop pests are projected to shift poleward under climate change and increased human activities (Bebber *et al.*, 2013; Fisher *et al.*, 2012, 2020) and under current observed trends the main crop producing countries will be saturated with crop pathogens by 2050 (Bebber *et al.*, 2014). In the marine realm, projections of planktonic and benthic species, as well as algae, identify a future potential poleward shift of alien species under climate change scenarios (Goldsmit *et al.*, 2020; Seebens *et al.*, 2016).

2.6.5 Limitations for assessing future dynamics

Projections of future dynamics of alien and invasive alien species are severely limited by 1) data availability of past and current distributions of species, 2) knowledge gaps of the past and current distribution of species, 3) knowledge gaps of the understanding of causal relationships between species occurrences, environmental changes, drivers of change in nature, biological invasions, and impacts caused by invasive alien species, 4) lack of models to robustly predict future dynamics of biological invasions, and 5) the lack of scenarios covering a range of plausible future dynamics of drivers of change, which would allow exploring future trends under different scenarios. While models and scenarios can still be further developed, closing data gaps, particularly of historic distributions, is very difficult and even impossible in many cases.

Most global studies focus on either individual species or different subsets of species based on specific characteristics (e.g., the 100 of the worst global invaders as assessed by the IUCN ISSG; Bellard, Thuiller, *et al.*, 2013; Gallardo *et al.*, 2017) or on technical criteria such as data availability. Consequently, it is difficult to discern a comprehensive pattern of potential future alien species richness and distribution for individual taxonomic groups (but see Seebens, Bacher, *et al.*, 2021). Additionally, information on alien species distributions is not spatially and taxonomically homogeneous and is biased towards specific regions of the world, like Europe and Northern America (A. C. Hughes *et al.*, 2021; C. Meyer *et al.*, 2016). Although online portals for storing biodiversity data such as GBIF provide billions of occurrence records, the data still covers just a fraction of known species. This limitation in accessibility to species occurrence data severely hampers modelling approaches for predicting and projecting future alien species richness and distribution patterns (**Chapter 1, section 1.6.7.3**).

A major challenge for most groups of microorganisms and fungi is the delineation of their native range resulting from a lack of data for these groups in general, as well as from high taxonomic uncertainty due to frequent historic changes and adaptations of the taxonomic concepts (e.g., due to new technological advancements; De Clerck *et al.*, 2013; Essl *et al.*, 2018; Hao *et al.*, 2020; Sharma *et al.*, 2015). In the absence of the ability to distinguish between the native and alien range of a species, robust risk assessments and predictions on the potential future spread and distribution are not possible.

In addition, alien pathogen research largely focusses on human pathogens, livestock, and cultivated plants, neglecting other facets of biodiversity and ecosystem services (Fischer *et al.*, 2012; Peeler *et al.*, 2011; Roy *et al.*, 2017; Usher, 1986). Further, most invasive alien pathogens are only described once their impacts are recognized in the invaded range (Roy *et al.*, 2017) hampering the identification of potential future alien species risk assessments. Finally, many pathogens undergo host shifts in the invaded range (McTaggart *et al.*, 2016; Peeler *et al.*, 2011; Roy *et al.*, 2017), which can strongly affect disease-induced host mortality in the invaded range, which increases with the evolutionary distance between the native and alien host species (Farrell & Davies, 2019). Such information of host-pathogen associations and interaction however are skewed to few well-studied alien pathogens (Farrell & Davies, 2019).

The systematic literature review of the models and scenarios[9] revealed distinct trends and research gaps. Research is mainly focused on the Americas, followed by Europe and Central Asia, and Asia and the Pacific,

9. Data management report available at: https://doi.org/10.5281/zenodo.5706520

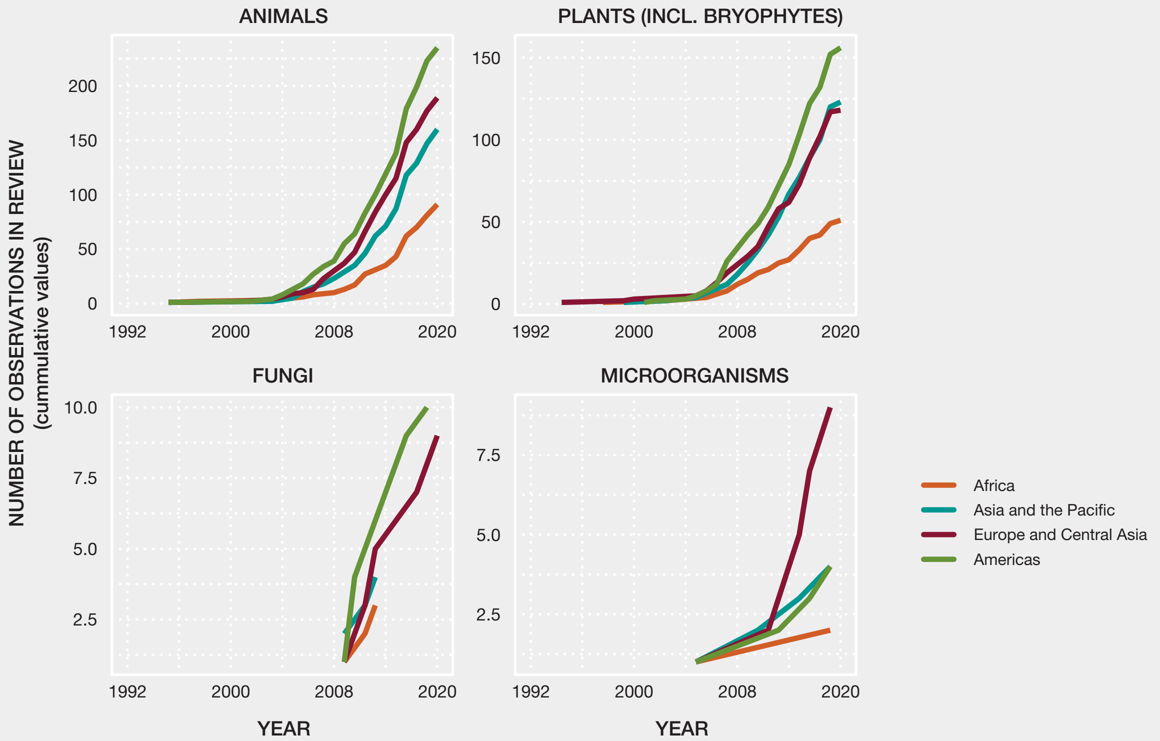

Figure 2 39 **Trends in the number of analyses of future projections across IPBES regions.**

Number of observations is not equal to the number of studies as studies can report on more than one IPBES region and/or taxonomic group. The time reported on the y-axis refers to the date of publication of the respective study. Values are based on a comprehensive literature review about scenarios and models of biological invasions, a data management report is available at https://doi.org/10.5281/zenodo.5706520

indicating a large knowledge gap in models and scenario studies for Africa. The number of studies is accelerating at an equal pace across IPBES regions **(Figure 2.39)**. Plants and animal studies are the most studied taxonomic groups; however, when further separating animals into finer classes, it is clear that animal studies are dominated by research on invertebrates and overall plants are the predominantly studied group, which is consistent over time. Studies for fungi and microorganisms are lacking (**Chapter 1**, **section 1.6.7.3**). Studies projecting alien species distributions into the future are largely lacking for the marine realm and also not very numerous for freshwater regions compared to the terrestrial realm. While the number of studies has accelerated over time, it is more prominent in the terrestrial realm and especially in the Americas **(Figure 2.40)**. Finally, most scenario projections explore long-term (2050-2100) and short-term (until 2030) trends. Very few studies follow a backcasting approach that involves setting a desirable future end-point and determining possible pathways including policy measures to reach that end-point (Dreborg, 1996).

To summarize, there is a distinct lack of model and scenario studies for Africa and Asia and the Pacific, the marine and freshwater realms. Finally, the scientific literature is dominated by correlative models whose application has increased more rapidly than for other modelling approaches. Also, process-based models have accelerated in their application; however, the application of hybrid models that combine both correlative and process-based approaches is not very common. Expert-based systems are not utilized for model and scenario studies implying a major gap in the utilization of these knowledge systems. A comprehensive overview of the review can be found in **Chapter 1**, **section 1.6.7.3** and on identified gaps in **Chapter 6**, **Table 6.10** and **section 6.6.1.1** and all information and data are available in the data management report.[10]

Finally, in addition to data and knowledge gaps, the prediction of future dynamics of biological invasions is severely impeded by a lack of models to predict those dynamics and by scenarios to explore variations among plausible futures. Although several modelling approaches exist for individual species, regions, or drivers as presented

10. Data management report available at: https://doi.org/10.5281/zenodo.5706520

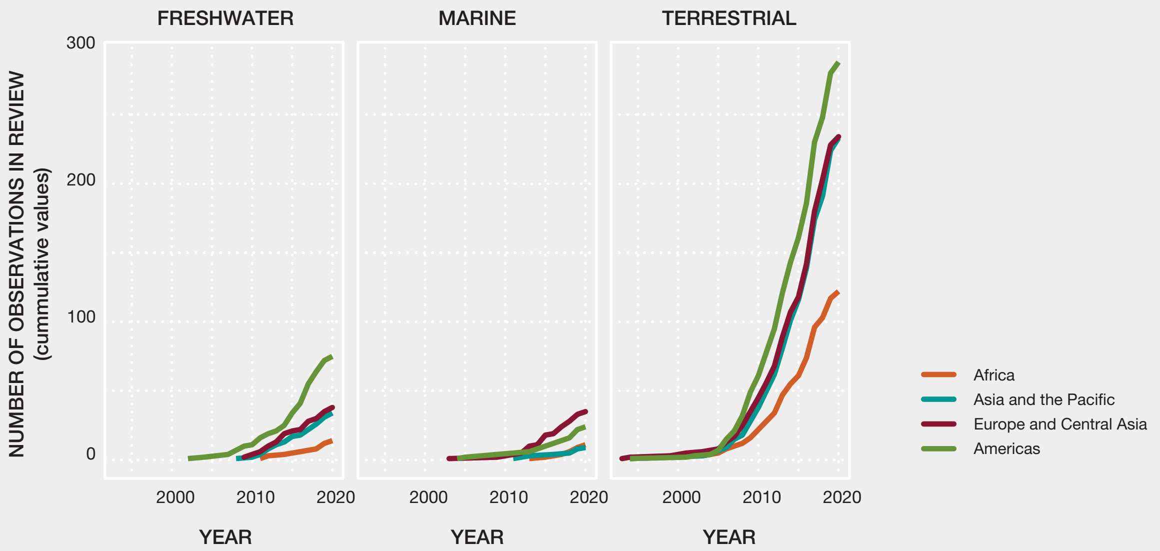

Figure 2 40 **Trends in the number of analyses of future projections for realms.**

Realms are defined as freshwater, marine and terrestrial. Number of observations is not equal to the number of studies as studies can report on more than one IPBES region and realm. The time reported on the y-axis refers to the date of publication of the respective study. Values are based on a comprehensive literature review about scenarios and models of biological invasions, a data management report is available at https://doi.org/10.5281/zenodo.5706520

above, no models are available to simulate biological invasions at large spatial and temporal scales, including a range of different species, drivers and impacts. In addition, quantitative scenarios of biological invasions are missing, which hampers the prediction of biological invasions under different plausible futures of driver developments. Qualitative scenario description recently became available (Roura-Pascual *et al.*, 2021), but the quantification and applications in modelling exercises remain to be tested. The field of biological invasions is distinctly lagging behind the progress of other drivers of change in nature, such as climate change and land-use changes, where much more attention has been paid over recent decades to develop models and scenarios.

2.7 CONCLUSIONS

The main objective of this chapter was to provide a global overview of the current understanding of the temporal trends and the spatial distribution (i.e., status) of alien and invasive alien species. By conducting extensive literature reviews and consulting experts from all over the world, assessment experts have gathered information on the trends and status of alien and invasive alien species across a wide range of taxonomic groups, geographic regions, and ecosystems. This assessment strove to provide an overview, which is as balanced as possible in terms of geographic and taxonomic coverage of species. However, complete coverage across all taxa, habitats, and regions is not possible due to many data and knowledge gaps. In some cases, the widespread gaps make a truly global and extensive assessment of the trends and status difficult. In addition, even well-sampled taxa and regions likely have incomplete information. Although this assessment considered a huge number of publications, including scientific publications, reports, and books in various languages, and consulted many experts, many sources of information could not be considered in this chapter, particularly non-English publications and grey literature, which are difficult to access if experts from that field or region are not directly involved.

Although this chapter provides the most comprehensive assessment of the trends and status of the distribution of known alien and invasive alien species, it is nonetheless based on incomplete data, the extent of which varies by taxa, region, and habitat. However, the existence of such gaps does not imply that any robust conclusions cannot be drawn. In fact, there is a good understanding of the trends and status of alien species for many taxonomic groups and regions, which are presented in this chapter, and the most robust and general conclusions are shown in the executive summary at the beginning of this chapter. However, with incomplete data it is necessary to verify available information by assessing trends and status based on scientific expertise and taking underlying biases into account.

Biological invasions are complex and intertwined with human transportation and goods, as well as other components of global change such as land use change, climate change, and human disturbances. This ecological complexity, the diversity and abundance of alien species, and the difficulty of identifying invaders in new environments, make their prevention and management challenging. The data presented in this chapter demonstrate that there is almost no place on Earth that has not experienced alien species introductions. It also shows that alien species introductions to new ranges are increasing across all taxa, all IPBES regions, and all units of analysis and that there are large data and knowledge gaps across these three sectors. The immediate result is that biological invasions are underestimated, with many species not yet identified as invasive and many ecosystems not yet recorded as invaded, or invaded by all the alien species that are present.

Decision makers often interpret research and develop policies to address biological invasions based on incomplete and biased data. Identifying and closing these data and knowledge gaps is essential to assess and address biological invasions more accurately and comprehensively. While gathering the information underlying this chapter, experts have identified the following major limitations which hindered the assessment:

1. **Lack of regional alien species lists:** For many taxonomic groups, particularly among invertebrates and microorganisms, lists of reported alien species are lacking for many countries. Even for ecologically and economically important groups such as insects, such lists are often lacking.

2. **Incomplete data:** Available lists of alien species occurrences are often incomplete or outdated. While difficult to identify, a comparison of alien species numbers across countries often revealed strong differences among neighbouring countries, differences that are likely influenced by degree of survey intensity rather than actual occurrences. In addition, the spread of alien species is highly dynamic and thus maintaining an up-to-date list of alien species occurrences requires regular monitoring which is rare. Even more rare are data on the abundances of individual populations. They are so scarce that experts were unable to consider alien species population abundances in this chapter.

3. **Lack of standardization:** Available lists of alien species were often generated using different terms that vary in their definitions, concepts (including taxonomies), and data collection and sampling practices, making comparisons of available information across regions and taxa difficult. This is particularly problematic for distinguishing a species' invasion status such as introduced, established, and invasive; these distinctions are often not specified, and if they are, the applied definitions are often not provided. Ideally, data is reported using standard concepts and terminologies, which are also explicitly detailed in the description of the data.

4. **Coarse spatial resolution:** The information on alien species occurrences is usually provided only at a coarse spatial resolution, such as the country level. However, the distribution of alien species within a country is often aggregated towards certain geographic areas within national borders. For a thorough assessment of biological invasions across spatial scales, it is essential to obtain information at finer resolutions that are ideally associated with coordinates of alien species occurrences.

Closing these gaps poses huge challenges to the scientific community. Below is a list of a few key challenges to improving assessments of the trends and status of alien and invasive alien species.

Improving collaboration

To fill data gaps and make invasion science truly global, greater, and more equitable, international collaboration is needed to build more global networks for monitoring, data sharing, and technology transfer (Kuebbing *et al.*, 2022; Meyerson *et al.*, 2022; Nuñez *et al.*, 2021; Packer *et al.*, 2017). The trend towards open-source software, such as QGIS and statistical environments such as R, is helping to reduce disparities between rich and poorer regions, but costs associated with training scientists and executing research as well as prohibitive journal publication costs present serious obstacles (**Chapter 6**, **section 6.6.2.4**). Many invasive alien species-focused research networks, database repositories, intergovernmental and international organizations, and international agreements are already in place (reviewed in Meyerson *et al.*, 2022). Despite these efforts, additional coordination and collaboration are needed, particularly because individual countries often do not have the capacities to respond to the issues of biological invasions sufficiently (**Chapter 6**, **section 6.3.1.1**; Early *et al.*, 2016; Pyšek, Hulme, *et al.*, 2020). In addition, it would be beneficial to engage in a two- or multi-way discussion with public and stakeholders through a new "dialogue communication model" or "public engagement model" (**Chapter 5**, **section 5.2.1**; **Chapter 6**, **section 6.4**), based on a genuine interchange with the public that recognizes and incorporates differences in knowledge, values, perspectives, and interests (Courchamp *et al.*, 2017). This will allow better understanding of biological invasions and supporting data acquisition, research and management.

Closing knowledge gaps

Thoroughly assessing the trends and status of biodiversity requires deep knowledge about nature and the ecosystems supporting biodiversity. Without knowing the species and their life histories, their interactions, and the mechanisms shaping environments worldwide, the state of biodiversity cannot be fully assessed. While information about nature is accumulating at an unprecedented pace, there are still major knowledge gaps, particularly for relatively inconspicuous organisms such as invertebrates, fungi, and microorganisms, and less accessible systems such as in marine habitats, but also inland waters, and in geographic areas such as Central Africa, Central Asia, and remote islands. In addition, there is a lack of an adequate understanding of biotic and abiotic species interactions, without which experts cannot fully grasp how species respond to environmental changes nor build models predicting future biodiversity change under different scenarios of human development. Closing these knowledge gaps is therefore essential to fully inform policies that can safeguard nature and move societies towards sustainability.

Efficient and standardized sampling and data processing

Comprehensive and thorough assessments of biological invasions and biodiversity in general need global and comprehensive monitoring and databases (Latombe *et al.*, 2017; Meyerson *et al.*, 2022; Packer *et al.*, 2017), which can only be obtained by implementing the following:

- Collection of records of alien species occurrences, and regular and repeated deposition into publicly accessible databases, particularly in regions and for taxonomic groups with the most severe gaps.
- Mobilization of existing data by making it accessible to the wider community in electronic formats and by providing these data under the Findable, Accessible, Interoperable, Reusable (FAIR) principles of open science (Wilkinson *et al.*, 2016).
- Standardization of available and accessible data to allow comparison, which could be accomplished by adopting a standard terminology for biodiversity information as Darwin Core has done, and by using open and widely used data formats such as csv or txt (Groom *et al.*, 2019).
- Documentation of data transformation steps, ensuring that they are repeatable and associated with the data (Seebens *et al.*, 2020).
- Finally, integration of standardized data into open databases or data portals such as GBIF or the Ocean Biodiversity Information System (OBIS) to enable researchers and stakeholders to conduct tailored biodiversity assessments.

Ideally, all steps from recording to storing data would follow standard and published protocols to make science, decision-making, and the assessment of biodiversity comprehensive, transparent, interoperable and reproducible, which ultimately increases trust in results and decisions (e.g., De Pooter *et al.*, 2017; Groom *et al.*, 2017; Haider *et al.*, 2022; Roy *et al.*, 2018).

Technological advances

Similar to the increase in information, technologies are developing rapidly including those designed to monitor biodiversity. Advances range from new satellite products to environmental DNA to fully automated biodiversity measurement stations. For example, satellites now provide opportunities to measure not only vegetation patterns at high resolution but also to track the movement of species or to distinguish individual plant species and measure plant traits which can provide early detection of new alien species introductions. Likewise, environmental DNA can help to populate lists of species occurring in certain areas, including rare species and emerging new alien species. Cameras and pattern recognition through artificial intelligence can identify species at comparatively low cost but on large geographic scales. Drones can now monitor biodiversity and fully automated biodiversity stations similar to weather stations are currently developed to obtain high resolution recordings of biodiversity. However, although these developments are promising, the technologies often still require major advancements to get ready for measuring biodiversity at the species level. In addition, many technological solutions are still used in isolation and large-scale solutions to obtain comprehensive coverage of biodiversity monitoring have not yet been achieved.

Engagement with policy makers

Progress towards addressing data gaps for biological invasions can benefit from engagement by policy makers, funding, trained (citizen) scientists, and technicians, adequate infrastructure to achieve standardized tools for long-term monitoring, modular regulatory frameworks that integrate incentives and compliance mechanisms with respect for diverse transcultural needs, biosecurity awareness and measures and synergies with other conservation strategies (Meyerson *et al.*, 2022; **Chapter 5**, **section 5.4.3.2(a)**; **Chapter 6**, **section 6.6.2.1**).

Inclusive biodiversity monitoring (citizen science, Indigenous Peoples and local communities)

Global comprehensive taxonomic monitoring of alien and native biota could be improved through engagement with people outside of academia, agencies, and institutions. People interested in nature and willing to contribute to recording of species occurrences could be encouraged to provide their knowledge and findings to other people and databases through, for example, community science projects, participatory research programmes and online platforms such as iNaturalist, CoralWatch, Project Noah, or e-Bird (Aristeidou *et al.*, 2021; Ballard, Dixon, *et al.*, 2017; Ballard, Robinson, *et al.*, 2017; McKinley *et al.*, 2017; **Chapter 1**, **Box 1.15**; **Chapter 6**, **section 6.6.2.1**). Such a large scale, ideally global, data reporting and sharing programme requires, however, concerted efforts of the international community and thus would benefit from greater efforts and incentives by governments and institutions to encourage people to contribute. Obtaining data through community science of sufficient quality for use in biodiversity assessments can be achieved through concerted coordination and organization, training, guidance, and funding. Standards for sampling and reporting have to be defined and adhered to, and needs and goals must consider the requirements of individual communities. In this way, inclusive biodiversity monitoring would include Indigenous Peoples and local communities who have a deep understanding about those areas that are least represented in global biodiversity assessments. Such an approach to fill data gaps for alien and invasive alien species is inclusive, adaptive, and flexible. As integrated and collaborative networks develop, effective global strategies to address invasive alien species will finally be met.

Accounting for incomplete knowledge

Several data gaps could be filled by increasing efforts and investments into biodiversity research and monitoring. However, it seems unlikely that obtaining complete and regular data at large geographic scales is achievable. Thus, it is also necessary to not only acknowledge the lack of information, but to also quantify uncertainty and incompleteness of data and to explicitly account for those biases in biodiversity assessments and analyses. This requires the development and adoption of standardized methods to quantify uncertainty. Having a standardized approach to measure and account for incomplete data would increase robustness of the results, and increase confidence in individual reports of biological invasions and biodiversity research more generally (Franz & Sterner, 2018).

DRIVERS AFFECTING BIOLOGICAL INVASIONS[1]

COORDINATING LEAD AUTHORS:
Philip E. Hulme (New Zealand), Tohru Ikeda (Japan), Vigdis Vandvik (Norway)

LEAD AUTHORS:
Ryan Blanchard (South Africa), Morelia Camacho-Cervantes (Mexico), Ileana Herrera (Ecuador, Venezuela/Ecuador), Asuka Koyama (Japan), Carolina L. Morales (Argentina), Linus K. Munishi (Tanzania), P. K. T. Nirmalie S. Pallewatta (Sri Lanka), Jan Pergl (Czech Republic), Anthony Ricciardi (Canada)

FELLOWS:
Esra Per (Turkey), Rafael O. Xavier (Brazil)

1. Authors are listed in alphabetical order with, in parentheses, their country or countries of citizenship, separated by a comma when they have more than one; and, following a slash, their country of affiliation, if different from that or those of their citizenship, or their organization if they belong to an international organization. The countries and organizations having nominated the experts are listed on the IPBES website (except for contributing authors who were not nominated).

CONTRIBUTING AUTHORS:
Amy E. Eycott (United Kingdom of Great Britain and Northern Ireland/Norway), Bella S. Galil (Israel), Sonya R. Geange (New Zealand/Norway), Piero Genovesi (Italy/Switzerland, Italy), Estefany Goncalves (Venezuela, Spain/Chile), Sylvia Haider (Germany), Aud H. Halbritter (Norway, Switzerland/Norway), Agnese Marchini (Italy), Niall Moore (United Kingdom of Great Britain and Northern Ireland), Aníbal Pauchard (Chile, Switzerland/Chile), Nahuel Policelli (Argentina), Helen E. Roy (United Kingdom of Great Britain and Northern Ireland), Takaaki Suzuki (Japan), Elena Tricarico (Italy), Caiyun Zhao (China)

REVIEW EDITORS:
Franz Essl (Austria), Aveliina Helm (Estonia)

TECHNICAL SUPPORT UNIT:
Naoki Amako, Ryoko Kawakami, Tanara Renard Truong

Chapter **3**

DRIVERS AFFECTING BIOLOGICAL INVASIONS

EXECUTIVE SUMMARY

1 The IPBES conceptual framework, which classes drivers as either indirect or direct with respect to their impact on nature, can be adapted to address biological invasions *(well established)* {3.1.3}. The IPBES conceptual framework distinguishes between direct drivers of change in natureand indirect drivers, which are societal factors that act on biodiversity and ecosystems through influencing one or more direct drivers {3.1.3}. Biological invasions are facilitated by a broad range of direct drivers {3.3}. As invasive alien species are both intentionally and unintentionally moved by people, some indirect drivers of change in nature, such as trade or travel, can facilitate the transport and introduction of invasive alien species to new regions *(well established)* {3.2.3.1, 3.2.3.2, 3.2.3.3, 3.2.3.4}. Since invasive alien species are part of and interact with nature, changes in the biosphere can also facilitate biological invasions, for example, biodiversity loss can lead to reduced biotic resistance of ecosystems to invasive alien species, and invasive alien species can facilitate the establishment and spread of other alien species *(well established)* {3.3.5, 3.4.2}. Natural drivers, such as tsunamis or hurricanes, are known to facilitate the establishment and further spread of invasive alien species *(well established)* {3.4.1}. By incorporating aspects specific to invasive alien species within the IPBES conceptual framework, this chapter allows a comprehensive assessment of all factors influencing biological invasions **(Figure 3.3)**.

2 Indirect and direct drivers of change in nature play significant but varying roles across all stages of the invasion process *(well established)* {3.1.4, 3.2, 3.3, 3.6.2}. Indirect drivers such as sociocultural norms (particularly human values), demography (human population and migration), economic aspects (especially trade and travel), science and technology (including research) and governance (including unintended consequences of policies that inadvertently facilitate biological invasions) tend to play a stronger role in the transport and introduction stages of the invasion process *(well established)* {3.2, 3.6.2}. In contrast, the five broad classes of direct drivers examined, land- and sea-use changes (resulting from agriculture, forestry and aquaculture), direct exploitation of natural resources (mining and species harvest), pollution (eutrophication and marine plastics), climate change and invasive alien species are all more influential in the establishment and spread of invasive alien species *(established but incomplete)* {3.3, 3.6.2}.

3 The magnitude of most drivers of change in nature have increased significantly since 1950, contributing to the increase of invasive alien species globally *(well established)* {3.1.1}. Recent decades have been characterized by increases in global trade and travel, human population size and urbanization, land- and sea-use change, habitat and biodiversity loss and degradation, direct exploitation of natural resources and pollution, and global temperatures along with shifts in precipitation patterns *(well established)* {3.1.1} **(Figure 3.1)**. This sustained growth in many of the key drivers affecting the transport, introduction, establishment and spread of invasive alien species underlies recent increases in the rates of introduction, establishment and spread of invasive alien species globally *(well established)* {3.2.1, 3.6.2}.

4 International trade is the most significant driver responsible for the transport and introduction of invasive alien species across the globe *(well established)* {3.2.3.1, 3.6.2}. International trade, primarily maritime transport of commodities, has been responsible for the transport and introduction of numerous invasive alien species in both terrestrial and aquatic biomes *(well established)* {3.2.3.1}. Invasive alien species can be the commodity traded, such as ornamental plants, contaminants of commodities, such as weed seeds in grain shipments, or stowaways on shipping containers or vessels, such as biofoulants *(well established)* {3.2.3}. Historically, intentional as well as unintentional introductions through the release or escape of plants, animals and microbial organisms from agriculture, aquaculture, forestry, fisheries and non-commercial uses, have resulted in the establishment and spread of alien species in terrestrial, aquatic and marine ecosystems worldwide *(well established)* {3.3.1.1}. Biofouling and ballast water discharges have had a major influence on biological invasions in coastal marine ecosystems *(well established)* {3.2.3.1}. International trade also influences other drivers of change in nature that facilitate biological invasions, for example by promoting urbanization around major trade ports, driving land- and sea-use changes and direct exploitation of natural resources to meet international market demands, and increasing atmospheric and aquatic pollution *(well established)* {3.2.3.1, 3.2.2.3, 3.3.1, 3.3.2, 3.3.3}.

5 Land-use changes are the most significant drivers accelerating the establishment and spread of invasive alien species *(well established)* {3.3.1, 3.6.2}. Land-use changes are major drivers facilitating invasive alien species by providing opportunities for colonization, establishment and spread of alien species in both terrestrial and coastal environments worldwide *(well established)* {3.3.1}. Land-use changes related to food, fodder and biomass production facilitate the biological invasion process through the replacement of native ecosystems by monocultures of introduced crops and livestock and through intensification and changes in disturbance regimes *(well established)* {3.3.1.1, 3.3.1.2, 3.3.1.5, 3.3.1.6}. Land-use changes related to industry, infrastructure and urban development facilitate biological invasions through creation of corridors and artificial surfaces in terrestrial and coastal environments and more generally through landscape degradation *(well established)* {3.3.1.3, 3.3.1.4, 3.3.1.6}. Fragmented and degraded ecosystems are often vulnerable to colonization and spread by generalist invasive alien species *(well established)* {3.3.1.2, 3.3.1.3}.

6 **Many of the drivers known to negatively impact nature and nature's contributions to people also facilitate the introduction and spread of invasive alien species, potentially causing positive feedback loops *(established but incomplete)* {3.5}.** Increasing and expanding trade and rapid population and economic growth are global phenomena that facilitate the transport and introduction of invasive alien species worldwide, while increasing urbanization, land- and sea-use changes, pollution, ecosystem degradation and biodiversity loss are changes which again facilitate the establishment and spread of invasive alien species *(established but incomplete)* {3.2.2, 3.2.3, 3.3.1, 3.3.3, 3.4.1, 3.4.2, 3.5.3}. Such positive feedback loops between drivers remain poorly understood but are critical to understanding and addressing complex spatial patterns and temporal dynamics in biological invasions *(established but incomplete)* {3.1.5, 3.2.1, 3.2.3.1, 3.2.3.2, 3.3.4, 3.5, 3.6.1}.

7 **Historically important drivers of change in nature such as trade, land-use change and direct exploitation of natural resources remain major causes of invasive alien species introduction and spread but the role of climate change and biodiversity loss will increasingly shape future global trends in invasive alien species, potentially with a significant temporal lag *(established but incomplete)* {3.2.3, 3.3.1, 3.3.2, 3.3.4, 3.4.2}.** While some countries are moving away from intentional introductions of alien species for uses in agriculture, aquaculture, forestry, horticulture, fishing, hunting and ornamental purposes, other countries do not effectively regulate and manage the use of invasive alien species for these purposes, resulting in sustained or increased rates of introduction and spread in affected regions *(established but incomplete)* {3.2.5, 3.2.3.2, 3.3.1.1}. The increasing role of climate change and biodiversity loss in facilitating the establishment and spread of invasive alien species is indicative that past patterns of biological invasions may not be a good guide to future patterns *(well established)* {3.3.4, 3.4.2}. Furthermore, there will be a vast legacy of future invasions (invasion debt) caused by significant time lags in the response of invasive alien species to drivers of change in nature, and the ongoing intensification of many drivers are responsible for increases in this legacy *(established but incomplete)* {3.1.1, 3.1.5}.

8 **Despite major inequalities in wealth worldwide, economic growth facilitates biological invasions in both developed and developing countries *(established but incomplete)* {3.2.3}.** Countries with high levels of consumption tend to expedite the introduction and establishment of alien species, and the cumulative build-up of assets, which support greater consumption, may lead to more immediate increases in numbers of alien species *(established but incomplete)* {3.2.3.6}. Poverty and marginalization created by economic inequality within and among countries may indirectly drive the introduction, establishment and spread of invasive alien species *(well established)* {3.2.3.6}. For those countries with a lower level of wealth, trends suggest that as economies grow and larger asset bases are built, so the risk of invasive alien species introductions might increase *(established but incomplete)* {3.2.3.6}. Risks may also be exacerbated where the route to economic growth and poverty reduction encourages the development of economic sectors based around invasive alien species *(established but incomplete)* {3.2.3.6}. This appears to be a major issue for Indigenous Peoples and local communities who in some cases may have few options but to use invasive alien species for food, fibre and also medicines *(established but incomplete)* {3.2.3.6}.

9 **Many Indigenous Peoples and local communities have a good and holistic understanding of the drivers facilitating invasive alien species on their lands *(well established)* {3.2, 3.3, 3.5} (Box 3.6, Box 3.15).** Indigenous Peoples and local communities point to how policies, governance and institutions aimed at improving livelihoods and the environment may inadvertently cause the introduction of invasive alien species *(established but incomplete)* {3.2.5, 3.2.3.6, 3.3.1.13} **(Box 3.6, Box 3.15)**. For example, they report that promotion of alien species for food, fibre, income generation, or medicinal purposes may act as a driver facilitating biological invasions *(well established)*, and such invasions can be especially facilitated in situations where native biodiversity, including species they traditionally depended on for these benefits, have declined *(established but incomplete)* {3.2.3.6, 3.2.5}. In some cases, Indigenous Peoples and local communities observe that urban areas or anthropogenic corridors act as sources of further spread of invasive species into their lands *(established but incomplete)* {3.2.2, 3.3.1.7}, and they also recognize land-abandonment, sometimes coupled with natural drivers or climate extremes, as responsible for the spread of alien species *(established but incomplete)*

{3.3.1.5.1}. Indigenous Peoples and local communities are well aware that drivers interact in complex ways to drive biological invasions *(well established)* {3.5}. Indigenous Peoples and local communities also identify challenges of land tenure and access rights as significant factors limiting the extent to which they can address invasive alien species on their lands *(established but incomplete)* {3.2.5}. Overall, Indigenous Peoples and local communities broadly align in understanding of the relative importance of drivers and trends in invasive alien species with reports from the scientific literature *(established but incomplete)* **(Box 3.15)**.

10 Few drivers act in isolation, and interactive effects appear to be crucially important, but few studies have examined the interactive effects of several co-occurring drivers in facilitating invasive alien species *(established but incomplete)* {3.1.5, 3.5, 3.6.1, 3.6.3}. There are potentially many multiplicative interactions among drivers that are likely to lead to unprecedented invasion scenarios *(established but incomplete)* {3.1.6, 3.5, 3.6.3}. Yet fewer than 5 per cent of studies examining drivers of biological invasions addressed more than one driver *(well established)* {3.1.6, 3.6.1}. Stakeholders, including decision makers, are currently inadequately prepared to address and react to unexpected consequences arising from additive or multiplicative effects of several drivers on the transport, introduction, establishment and spread of invasive alien species *(established but incomplete)* {3.5, 3.6.3}.

11 Knowledge is biased towards only a subset of drivers, and less is understood regarding how indirect drivers of change in nature influence biological invasions compared to direct drivers *(well established)* {3.6.1}. While this chapter summarizes the available evidence of the role of each direct and indirect driver on biological invasions, the underlying knowledge base is biased *(well established)* {3.6.1}. Most of the recent research addressing the role of drivers in facilitating biological invasions has focused on a subset of drivers, especially economic drivers such as trade and transport, climate change and land-use change *(well established)* {3.6.1}. The importance of sociocultural values and unintended consequences of governance, policy and insitutions in shaping biological invasion remains understudied *(well established)* {3.6.1, 3.6.3}.

12 Biases in the availability of data on how drivers of change in nature influence biological invasions highlight that causal factors are most poorly understood for regions potentially most exposed to increasing risks from invasive alien species *(well established)* {3.6.1}. This chapter examines a variety of sources, including Indigenous and local knowledge, and explicitly includes evidence of biological invasions across multiple geographic regions, taxonomic groups and biomes {3.1.2, 3.6.1}. Nevertheless, the evidence base for how drivers influence biological invasions is largely drawn from developed countries, particularly in Europe, North America and Oceania, terrestrial temperate ecosystems and plants, and there is a lack of information for polar regions and developing countries, especially sub-Saharan Africa, tropical Asia and South America, marine systems and other taxonomic groups *(well established)* {3.6.1, 3.6.3}.

3.1 INTRODUCTION

The concept of direct and indirect drivers of change in nature has been a cornerstone in all the assessments led by the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) to date (Díaz *et al.*, 2015; IPBES, 2016a, 2018f, 2018e, 2018c, 2018d, 2019; Nelson *et al.*, 2006), and the intention in this chapter is not to repeat past material pertaining to the status and trends in the drivers, but to synthesize information on the role of drivers of change in nature in affecting the biological invasion process. Chapter 3 therefore focuses on identifying how different drivers of change in nature affect the transport, introduction and establishment of invasive alien species (**Glossary**; **Box 3.1**). Chapter 3 builds on the status and trends of alien species, and the subset of these termed invasive alien species, documented in **Chapter 2**, with a more in-depth focus on establishing the drivers behind these patterns. The information provided in Chapter 3 contributes to the understanding of the underlying causes of the increase in invasive alien species globally (**Chapter 2**), the impacts of invasive alien species on nature, nature's contributions to people and good quality of life (**Glossary**; **Chapter 4**) and underpins management actions (**Glossary**; **Chapter 5**) and policy options for the prevention and control of invasive alien species and their impacts (**Glossary**; **Chapter 6**).

3.1.1 Setting the scene: increasing global trends in drivers of change in nature

The size and environmental footprint of the world's human population has grown dramatically over the past two centuries, with rates of change accelerating over the past few decades (Steffen *et al.*, 2015). This "great acceleration" (Steffen *et al.*, 2015) can be discerned across a majority of direct and indirect drivers of change in nature, which are of relevance to the increasing trends in the number and abundance of invasive alien species globally (**Chapter 2**). The number of people in the world has grown from 3.7 billion in 1970 to an estimated 7.7 billion in 2019 **(Figure 3.1)**, and while population growth is slowing, a global population of 10 billion may be reached by 2050 (UNEP, 2019; United Nations *et al.*, 2019). An increasing proportion of the global population is living in urban

Box 3 1 **Rationale of the chapter.**

Chapter 3 provides an analysis and synthesis of how direct and indirect anthropogenic drivers of change in nature, along with natural drivers and biodiversity loss itself, are responsible for the transport, introduction, establishment and spread of invasive alien species. The chapter first outlines the conceptual and analytical framework and approaches, then synthesizes the evidence for the role each driver plays across the biological invasion process (**Glossary**), before synthesizing the knowledge and identifying data gaps. Invasive alien species are one of five major classes of direct drivers of change in nature identified by the Global Assessment of Biodiversity and Ecosystem Services (IPBES, 2019), and are the theme of this assessment. Unlike other drivers, invasive alien species are both a direct driver of change in nature and they are integral parts of nature. As a consequence, invasive alien species can be directly affected by drivers that are classified as indirect drivers of change in nature, and invasive alien species along with biodiversity loss can facilitate invasion by other alien species.

Guiding questions:

- What are the main direct and indirect drivers responsible for the introduction, spread, abundance and dynamics of invasive alien species for each invasion stage and taxon?
- How rapidly are potential drivers changing compared to the last 30 years and which drivers are changing most rapidly?

Keywords:
Indirect drivers of change in nature, direct drivers of change in nature, invasive alien species, demographic drivers, economic drivers, science and technological drivers, policies, governance and institutions as drivers, land- and sea-use change, natural resource extraction, pollution, climate change, natural drivers, biodiversity loss, ecosystem resilience, interacting drivers, Indigenous Peoples and local communities.

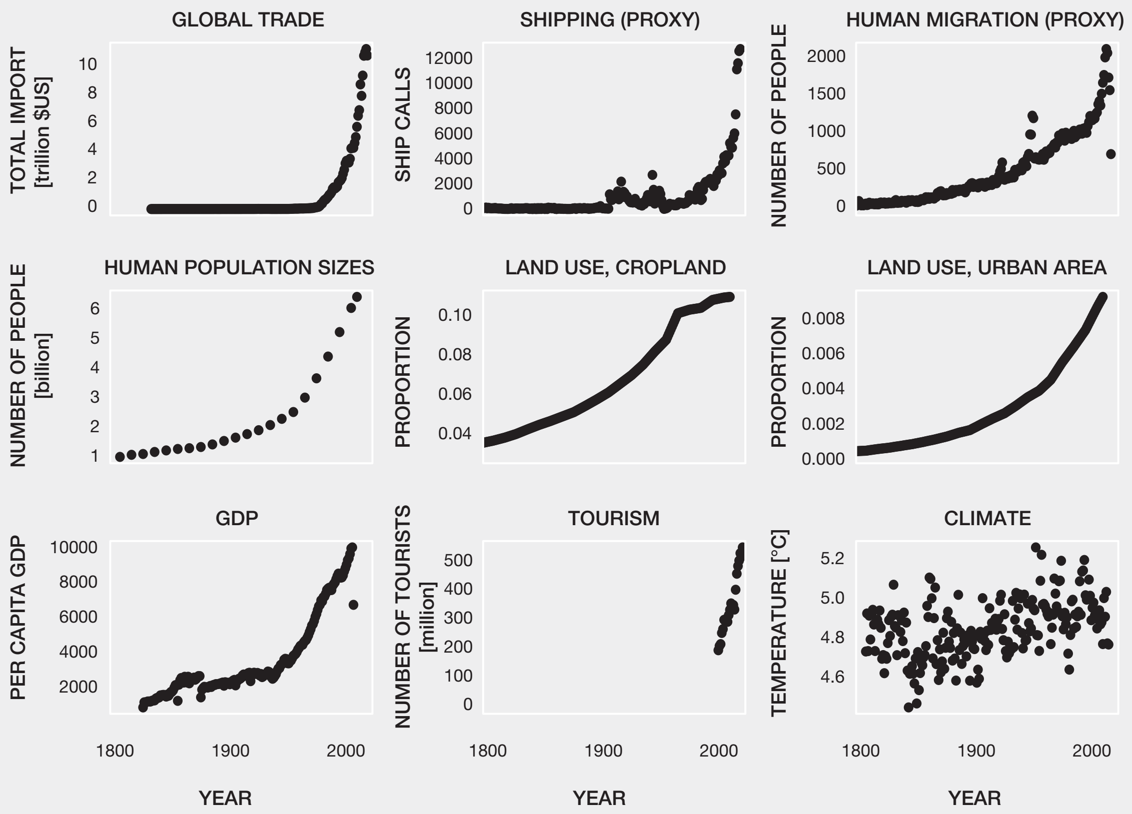

Figure 3 1 **Trends in a selection of drivers and correlates of biological invasions.**

Panels show temporal trends for some of the main drivers and correlates of biological invasions averaged globally. A data management report for this figure is available at https://doi.org/10.5281/zenodo.7615582 areas – the total area of urban settlements has grown by approximately 2.5 times since 1970, accounting for 7.6 per cent of the global land area and housing 3.5 billion people in 2015 (Shukla *et al.*, 2019; UNEP, 2019). Human migration and travel are also increasing **(Figure 3.1)**. Meanwhile, the global economy has grown nearly fivefold over the last 50 years **(Figure 3.1)**, a growth that is projected to continue. This economic growth has been fuelled by an increase in global primary energy production of more than 270 per cent over the same period, of which fossil fuels still contribute more than 80 per cent (IEA, 2020). Consumption has tripled and global trade grown nearly tenfold in the last 50 years **(Figure 3.1)**, with shifting patterns of consumption and production across regions, and increases in transport of goods and people (**Figure 3.1**; IPBES, 2019).

These global population and economic drivers are having dramatic impacts on our lands and seas (IPBES, 2022c). Close to 75 per cent of ice-free land areas and 60 per cent of the oceans are significantly impacted by people, and agricultural crop production has increased by about 300 per cent since 1970, with crops now occupying half of the habitable land on Earth (IPBES, 2019). Of the more than 50,000 wild species harvested for use as food, energy, medicine, materials, income generation, or other uses globally, only 34 per cent are used sustainably (IPBES, 2022c). Water extraction, predominantly for irrigation of agricultural crops, grew by nearly 65 per cent from 1970 to 2010, and over the same period mining of metal ores increased by three and a half times and mining for sand, gravel and clay increased by nearly five times (IRP, 2019). Approximately 60 billion tonnes of renewable and non-renewable resources are now extracted globally every year, having nearly doubled since 1980 (IPBES, 2019). Up to 400 million tonnes of heavy metals, solvents, toxic sludge and other industrial wastes are dumped annually into the

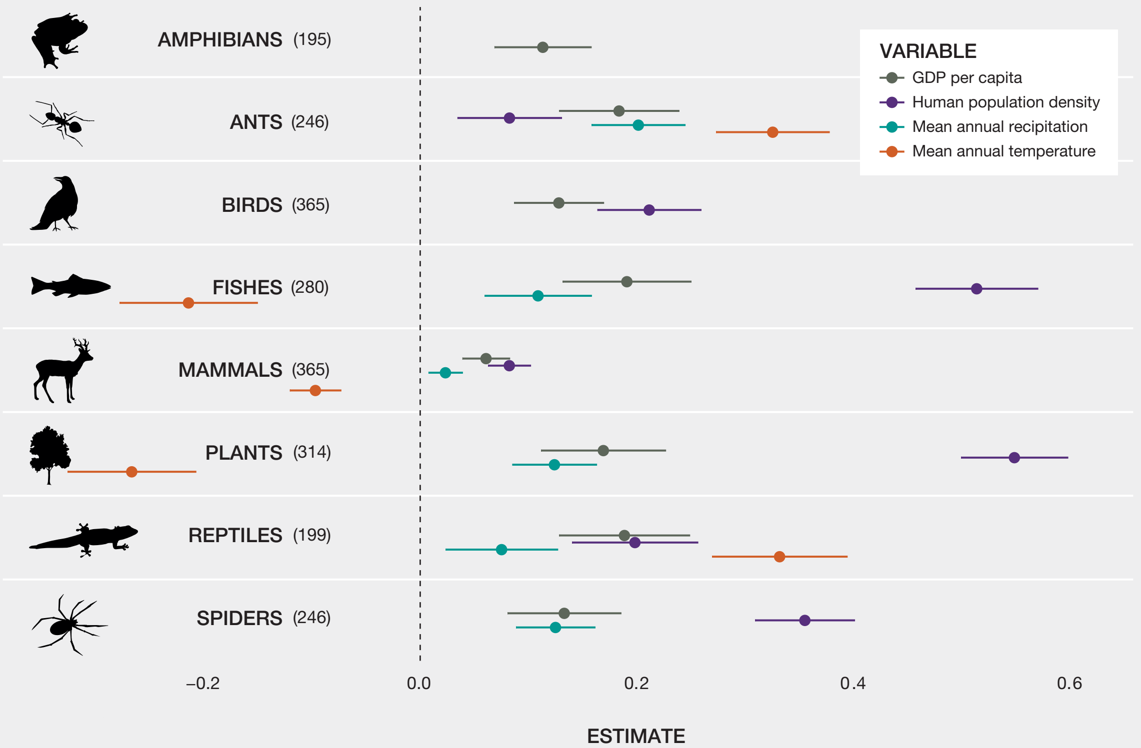

Figure 3 2 **Estimated effects of different factors on established alien species richness across eight taxonomic groups: amphibians, ants, birds, freshwater fishes, mammals, vascular plants, reptiles and spiders (from top to bottom).**

The results of linear mixed models indicate the effects of different factors (GDP per capita; human population density; mean annual precipitation; and mean annual temperature) on alien species (**Glossary**) richness within eight taxonomic groups across 423 mainland regions. Number in parentheses are numbers of regions included per taxonomic group. Overall, taxonomic groups respond differently to the effects of climate and gross domestic product (GDP) per capita, but human population density is consistently among the best predictors with especially high effects for fish, plants and spiders. Estimates (±1 standard error) – represented by dots and lines – of effects were obtained from linear mixed-effects models of ln (species richness + 1), with subcontinental regions nested within continents as random effects. Adapted from Dawson *et al.* (2017) https://doi.org/10.1038/s41559-017-0186, under license CC BY 4.0.

world's waters (UNEP, 2019; IPBES 2019). Nitrogen fluxes to aquatic ecosystems (**Glossary**) have increased up to 20-fold in the last decade (IPBES, 2019). Marine plastic pollution has increased tenfold since 1980, and is found in all oceans at all depths, concentrating in ocean currents (UNEP, 2019).

Accelerating human impacts are changing the Earth's ecosystems and climate at unprecedented rates, to the extent that they are now dominating Earth system processes (IPBES, 2019). Climate has warmed by 1.1°C on average, and is projected to reach at least 1.5°C within the next three decades, and climate change is contributing to changed precipitation patterns, sea level rise, increasing fire risk (**Glossary**) and a higher frequency of extreme events in many regions (IPCC, 2021, 2022). Ecosystems are degrading at unprecedented rates, with climate change exacerbating other threats (Pörtner *et al.*, 2021; **Chapter 4**, **Box 4.5**). This degradation of biodiversity and ecosystems is impacting ecosystem functioning and harming nature's ability to support human well-being (IPBES, 2019, 2022c; IPCC, 2022). A majority of these direct and indirect drivers of change in nature are affecting, and often facilitating, invasive alien species, which are increasing at accelerating rates globally (**Chapter 2**, **Figure 2.2**). The aim of Chapter 3 is to address how these drivers affect the transport, introduction, establishment and spread of invasive alien species.

Drivers do not act in isolation; status and trends in nature are the outcome of the often multiplicative effects of many co-occurring drivers (IPBES, 2019; **Chapter 4**, **Box 4.5**). A recent study systematically and quantitatively ranked direct drivers of change in nature (**section 3.1.2**) in terms of impacts on biodiversity and found that land-use change was generally the most important, but that relative importance of drivers varied across realms, IPBES regions and with the biodiversity components considered (Jaureguiberry *et al.*, 2022) and with scales (Bonebrake *et al.*, 2019). Invasive alien species are recognized as being a driver of change in nature and at the same time a component of biodiversity. A global meta-analysis focussing explicitly on identifying extrinsic factors related to invasive alien species richness found that that human population density of an area, which can be a proxy for multiple and often co-occurring drivers such as trade, travel and land-use, was highly correlated to the number of introduced alien amphibians, fish, plants and spiders within that area (**section 3.1.2** and **Figure 3.2**).

3.1.2 Scope and organization of the chapter with reference to the IPBES conceptual framework

The IPBES conceptual framework and Global Assessment recognize invasive alien species as one of five anthropogenic "direct drivers" of change in nature along with climate change, land- and sea-use change, pollution and direct exploitation of natural resources (Díaz *et al.*, 2015; IPBES, 2019). According to this framework, direct drivers have direct physical (mechanical, chemical, etc.) and biological (physiological, ecological, behavioural) effects on nature (biodiversity and ecosystems) which again impact nature's contributions to people (including ecosystem goods and services) and more generally good quality of life (**Chapter 1**, **Figure 1.11**; Díaz *et al.*, 2018). The IPBES invasive alien species assessment refers to these drivers as "direct drivers of change in nature". The magnitude of the impact of these direct drivers of change on nature, and in some cases on nature's contributions to people and good quality of life, is also shaped by five "indirect drivers" of change: human demography, economic development, technological change, the strength of national and international governance (**Glossary**) as well as sociocultural factors **(Figure 3.3)**. These drivers are described as indirect because they do not directly impact nature (i.e., biodiversity and ecosystems), but act through one or more direct drivers of change in nature (Nelson *et al.*, 2006). Indirect drivers impact nature by affecting the level (e.g., magnitude), direction (e.g., increase or decrease) or rate (e.g., change over time) of the direct drivers. For example, the impacts of economic growth (an indirect driver of change in nature) affects biodiversity or ecosystems through the effects of one or more direct drivers, such as land-use change or pollution.

The classification of drivers outlined through the IPBES conceptual framework has proven useful for synthesis and cross-assessment referencing (e.g., IPBES, 2019; Pörtner *et al.*, 2021) but requires specific consideration for this assessment because invasive alien species are simultaneously the focus of the IPBES invasive alien species assessment and one of the five anthropogenic direct drivers of change in nature (**Figure 3.3**; **Chapter 1**, **section 1.6.1**). This implies that indirect drivers of change in nature may directly affect invasive alien species. For example, international trade is classified as an indirect driver of change in nature, yet an important consequence of trade is that it increases the number of invasive alien species introductions worldwide (Hulme, 2021b), and it does so by directly facilitating the transport and introduction of invasive alien species **(Figure 3.3)**. The process of biological invasions (including all stages: transport, introduction, establishment and spread of invasive alien species; **Glossary**) is also influenced by the five anthropogenic direct drivers of change in nature, including interactions amongst invasive alien species (e.g., by causing "invasional meltdown", **Glossary**; **section 3.3.5.1**; **Chapter 1**, **section 1.3.4**). All five primary direct anthropogenic drivers are therefore also considered in this assessment.

In addition to the main anthropogenic direct and indirect drivers recognized by the IPBES framework, biological invasions can be further facilitated by natural drivers and in particular natural hazards such as tsunamis, floods, fire and hurricanes. While the involvement of human activities within the biological invasion process is inherent to the definition of alien species (**Chapter 1**, **Figure 1.1**), these natural drivers can play a major role in both the introduction of alien species from one region where they are alien to new regions, and also aid their establishment and further spread within regions where they are already present as alien species. A further driver not directly addressed in previous IPBES assessments is biodiversity loss, but in the case of invasive alien species it can be seen as a driver that facilitates their establishment and spread, as a result of reduced resistance of altered natural ecosystems to invasive alien species (**Chapter 1**, **section 1.4.3**). Thus, the transport, introduction, establishment and spread of invasive alien species can be facilitated by both direct and indirect anthropogenic drivers of change in nature, as well as by natural drivers and by biodiversity loss. These drivers do not act in isolation but may interact with each other in different and complex ways (**section 3.1.5**). In part as a result of these complexities, the knowledge base is both limited and fragmented, and attribution of cause-effect relationships can be challenging (**sections 3.1.5**, **3.6.1**). To acknowledge and cover these complexities and limitations, the assessment is organized as follows:

Section 3.2 assesses the role that five indirect drivers of change in nature play in the different stages (transport, introduction, establishment and spread) of the biological invasion process **(Table 3.1)**. The indirect drivers examined are:

- sociocultural drivers and social values (including norms, traditions, cultural beliefs, desires, perceptions);
- demographic (including human population density, migration, international crises and urbanization);
- economic (such as international trade and travel, externalities and wealth, inequality and poverty);
- science and technology (including research and communication and breeding/genomic technology);
- policies, governance and institutions (note that Chapter 3 focuses on the unintended facilitation of biological invasions by policies, governance and institutions targeting other societal objectives (i.e., "perverse incentives", *sensu* IPBES, 2019). Policies, governance and institutions explicitly dealing with biological invasions are dealt with in **Chapter 6**).

Section 3.3 examines the role of the five direct drivers of change in nature in influencing the distribution and abundance of invasive alien species **(Table 3.1)**:

- land- and sea-use changes (including introductions from the direct use of alien species in terrestrial, aquatic and marine bioproduction systems as well as landscape and seascape fragmentation, disturbance and deterioration);
- direct exploitation of natural resources (such as species harvesting, hydrological resource harvesting and mining);
- pollution (including eutrophication and nutrients, other contaminants, marine debris and solid waste);
- climate change (including changes in temperature and precipitation regimes and extremes, carbon dioxide (CO_2) enrichments in air and water, fire regimes, sea level rise and assisted colonization);
- invasive alien species (through biotic facilitation and biological control; **Glossary**).

As explained above, two additional drivers are also considered in section 3.4:

- natural hazards (such as hurricanes, earthquakes, tsunamis).
- biodiversity loss and ecosystem resilience (notably reduced biotic resistance to invasion; Glossary).

Section 3.5 then examines multiple, additive or interacting effects among drivers, especially among anthropogenic direct drivers. Due to knowledge gaps (**section 3.6.1**) this section does not provide an exhaustive assessment but focuses on four illustrative examples of two- or three-way multi-driver impacts and their consequences for biological invasions.

Each subsection within sections 3.2 to 3.5 first briefly describes the trends (**Glossary**) and status of the driver(s) considered, then assesses the overall effects of this driver on the transport, introduction, establishment and spread of invasive alien species and, where there is information, notes specific effects on particular biomes, taxa and units of analysis. Due to the complexities of relationships among drivers and biological invasions coupled with the limited knowledge available (**sections 3.1.3** to **3.1.5**, **Figure 3.3**), a systematic literature search across all topics relevant to the chapter was not feasible, and targeted but coordinated literature searches were conducted instead (**section 3.6.2** for details).[2] In these searches, knowledge was extracted from a broad range of sources, including published scientific literature and reports, and the searches were augmented with literature from the cross-chapter literature review[3] on Indigenous Peoples and local communities and invasive

2. Data management report available at: https://doi.org/10.5281/zenodo.5529309

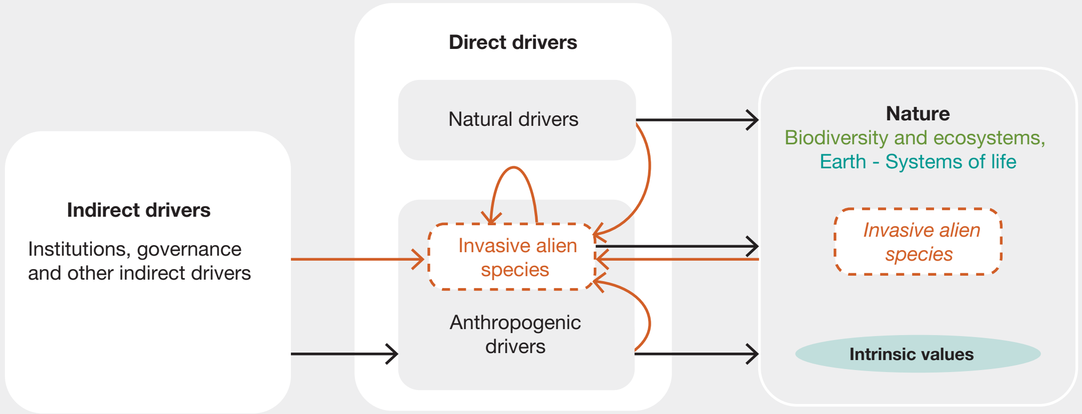

Figure 3 3 **Schematic illustration of how invasive alien species can be influenced by indirect drivers of change in nature, anthropogenic and natural direct drivers of change in nature and by changes to nature (i.e., loss of biodiversity or ecological resilience).**

The assessment builds on the IPBES conceptual framework (Díaz *et al.*, 2015) under license CC BY-NC-SA 3.0, adding focus and detail around how changes to drivers and to nature may influence invasive alien species (lighter arrows). Invasive alien species are classified as one of five direct anthropogenic drivers of change in nature; therefore, they can be influenced both directly and indirectly (*via* other direct drivers) by indirect drivers of change in nature. Biological invasions may also be influenced by all direct drivers of change in nature, including invasive alien species, and by natural drivers (especially natural hazards). Finally, there can also be feedbacks from nature (biodiversity and ecosystems) to invasive alien species, for example, biodiversity loss or invasive alien species can make ecosystems less resistant to further invasive alien species. Invasive alien species are therefore both a driver of change in nature and part of nature (dotted lines). Lighter arrows indicate the focal causal relationships of this chapter, within the context of the IPBES conceptual framework, darker arrows denote additional causal links among drivers and between drivers and nature covered in the IPBES Global Assessment (IPBES, 2019).

alien species. Finally, the authors identify knowledge gaps (**section 3.6.1**) before drawing conclusions and integrating the chapter's findings on the role of drivers of change in nature in facilitating invasive alien species across biomes and realms and across the biological invasion process (**sections 3.6.2**, **3.6.3**).

3.1.3 Identifying drivers of change in nature of relevance for invasive alien species

Chapter 3 adapts the IPBES conceptual framework, recognizing that invasive alien species are, simultaneously, one of the five main direct drivers identified by IPBES (Díaz *et al.*, 2015, 2018; IPBES, 2019), and at the same time the focus of this assessment **(Figure 3.3; Table 3.1)**. Specifically, this chapter acknowledges that some indirect drivers of change in nature, and notably those related to trade, transport and travel, may in fact be directly facilitating the transport, introduction, establishment and spread of invasive alien species. Further, natural drivers, while included in the IPBES conceptual framework as a direct driver, are generally not considered in IPBES assessments (Pereira *et al.*, 2010; Díaz *et al.*, 2015, 2018; IPBES, 2019) but are known to be important factors facilitating biological invasions and are, therefore, included in this chapter (**Figure 3.3**, **section 3.4.1**). Similarly, biodiversity loss can reduce the resilience of ecosystems to invasive alien species and while not considered in the IPBES conceptual framework as a driver, the role of biodiversity loss and changes to ecosystem resilience in facilitating biological invasions is included in Chapter 3 (**section 3.4.2**). Interactions between indirect and direct drivers of change in nature, along with natural drivers and biodiversity loss, create different chains of relationships, attribution, and influences on the biological invasion process. These relationships may vary according to type, intensity, duration and distance. These relationships are captured by cross-referencing between subsections throughout the assessment, and by explicitly considering selected interactive effects (**section 3.5**).

3.1.3.1 Indirect drivers of change in nature affecting invasive alien species

Following previous IPBES assessments (IPBES, 2016a, 2018f, 2018e, 2018c, 2018d, 2019, 2022a), Chapter 3 considers a number of drivers under all five classes of indirect drivers of change in nature: sociocultural, demographic, economic, science and technological and institutional **(Table 3.1)**. It is important to note that indirect drivers of change in nature may both directly and indirectly influence the biological invasion process and the introduction, establishment and spread of invasive alien species **(Box 3.1)**. Sociocultural context, particularly values, beliefs and social norms, can exert significant pressure on decision-making regarding biological invasions (Shackleton *et al.*, 2019; **Chapter 1**, **section 1.5.2**) and is materially manifested in lifestyles and consumption patterns that can act directly in facilitating the introduction and spread of invasive alien species. Demographic drivers, including human population growth and migration, underpin all anthropogenic direct drivers of change in nature that also facilitate biological invasions through increasing urbanization. A significant economic driver that often correlates strongly with the number of alien species found in a country is economic

Table 3 1 **The indirect and direct anthropogenic drivers of change in nature and other factors affecting invasive alien species, as assessed in Chapter 3.**

The IPBES conceptual framework considers indirect and direct drivers of change in nature (Díaz *et al.*, 2015; Nelson *et al.*, 2006). Following the IPBES Global Assessment, this assessment considers five classes of indirect and five classes of direct anthropogenic drivers. In addition, the assessment considers two other classes of drivers: natural drivers and biodiversity loss. For each of these classes of drivers, the assessment considers the influence of a number of specific drivers on the transport, introduction, establishment and spread of invasive alien species. This table shows all the drivers considered in this chapter, with classes of drivers in bold, and drivers under each class in normal font (see **section 3.1.2** for more details).

INDIRECT DRIVERS Anthropogenic factors that affect nature indirectly by altering one or more direct drivers, but which may act both indirectly and directly on invasive alien species.	**ANTHROPOGENIC DIRECT DRIVERS** Factors that describe direct human influence on nature. These may affect invasive alien species directly, or *via* interactions and feedbacks involving other drivers.	**NATURAL DRIVERS AND BIODIVERSITY LOSS** Factors that describe natural drivers and aspects of biodiversity loss which may directly and in interaction with other drivers facilitate invasive alien species.
Sociocultural drivers and social values (3.2.1) **Demographic drivers (3.2.2)** • Regional and national changes in human population density • Human migration • International crises: armed conflict and emergency aid • Urbanization **Economic drivers (3.2.3)** • International trade and global commerce • Human international travel for commerce and tourism • Externalities of negative impacts and cost • Wealth, inequality and poverty **Science and Technology (3.2.4)** • Research • Development of communication technology • Breeding and genomic technologies **Policies, governance and institutions (3.2.5)**	**Land- and sea-use change (3.3.1)** • Introductions from the use of alien species in terrestrial, aquatic and marine bioproduction • Fragmentation of ecosystems • Creation of anthropogenic corridors • Deployment of marine infrastructure • Changes in landscape – seascape disturbance regimes • Landscape – seascape degradation **Direct exploitation of natural resources (3.3.2)** • Species harvesting • Hydrological resources • Fossil fuels and mining **Pollution (3.3.3)** • Eutrophication and nutrient deposition • Other contaminants in water and soil • Marine debris • Dispersal of solid waste **Climate Change (3.3.4)** • Temperature change • Precipitation change • Climate extremes • CO_2 enrichment in air, water • Fire regime changes • Sea level rise • Assisted colonization **Invasive alien species (3.3.5)** • Biotic facilitation • Biological control	**Natural drivers (3.4.1)** Natural hazards such as tsunamis, hurricanes, earthquakes, wildfire, floods and volcanic activity **Biodiversity loss and ecosystem resilience (3.4.2)**

growth, often expressed as per capita gross domestic product (GDP; Dawson *et al.*, 2017; Essl *et al.*, 2011, 2015; Hulme, 2011b), reflecting the intensity of international trade which is a major conduit for the introduction of alien species (Hulme, 2009, 2021b; Seebens *et al.*, 2015; Westphal *et al.*, 2008). While technology is a major factor in economic growth, its effect on biological invasions depends on how it is used. The use of new technologies to limit the transport, introduction, establishment and spread of invasive alien species, along with technological approaches to aid eradication and containment (**Glossary**) of invasive alien species are discussed in **Chapters 5** (**sections 5.5.3**, **5.5.4**) and **6** (**sections 6.3.3.4**, **6.7.2**). **Chapter 3** focuses on the role of technology as a driver, for example, how internet commerce (Walters *et al.*, 2006) is facilitating the introduction and spread of invasive alien species, and on how new technologies such as gene editing can potentially be used to breed species with traits that might make them more likely to be invasive (e.g., cold tolerance, pest resistance). Economic drivers are strongly linked to institutional drivers, which govern production through regulations, taxes and subsidies. The role of policies and institutions in managing biological invasions is addressed in **Chapter 6** whereas the synthesis in **Chapter 3** is restricted to how regulations, taxes and subsidies result in unintended consequences that facilitate the transport, introduction, establishment and spread of invasive alien species (**section 3.2.5**).

3.1.3.2 Anthropogenic direct drivers of change in nature affecting invasive alien species

In line with previous IPBES assessments (IPBES, 2016a, 2018f, 2018e, 2018c, 2018d, 2019, 2022a), this assessment considers the five main anthropogenic direct drivers of change in nature: land-use (including sea-use) change, direct exploitation of natural resources, pollution, invasive alien species and climate change. Land- or sea-use changes can lead to the increased introduction of alien species, either intentionally through the specific use of alien crops and livestock or unintentionally as contaminants of agricultural or aquacultural commodities. Land-use change that leads to habitat (**Glossary**) fragmentation, establishes infrastructure corridors (e.g., roads, canals) through which alien species can spread, alters the baseline rates of disturbance, or more generally degraded habitats can increase the vulnerability of native ecosystems to invasive alien species (Vilà & Ibáñez, 2011). Direct exploitation of natural resources includes both the direct exploitation of biotic resources through species harvesting as well as of abiotic resources such as water and minerals. Harvesting of top predators can lead to trophic cascades that facilitate the establishment of alien species, such as the case of overfishing in the Black Sea resulting in an outbreak of *Mnemiopsis leidyi* (sea walnut; Daskalov *et al.*, 2007). Exploitation of abiotic (e.g., mining) and biotic (e.g., deforestation) resources can drive biological invasions by altering the baseline disturbance regime, which can facilitate the invasion of alien species that are better adapted to the altered conditions (Catford *et al.*, 2012). Pollution, particularly eutrophication, can favour alien species in both aquatic (Vermonden *et al.*, 2010) and terrestrial ecosystems (Brooks, 2003). Climate change, particularly through the effects of higher temperatures and frequency of extreme events, has long been widely expected to increase the rate at which alien species are introduced, establish and spread (Walther *et al.*, 2009). Less well understood is the risk that deliberate translocation of species by humans from one region to another in order to ensure survival in the face of climate change might result in the introduction of invasive alien species (Ricciardi & Simberloff, 2009). Although including invasive alien species as a direct driver affecting biological invasions might sound like circular reasoning, there is increasing evidence of the role that invasive alien species play in facilitating other alien species at different stages of the biological invasion process, aiding dispersal and transportation or as mutualists (e.g., alien mycorrhiza, pollinators and seed dispersers), allowing their reproduction and spread. This process, by which a group of alien species facilitate one another, increasing the likelihood of survival and/or of ecological impact (Braga, Gómez Aparicio, *et al.*, 2018) and potentially causing "an accelerating accumulation of introduced species", has garnered its own term "invasional meltdown" (Simberloff, 2006, **Chapter 1**, **section 1.3.4**; **Chapter 4**, **section 4.7.2**).

3.1.3.3 Natural drivers and biodiversity loss as direct drivers affecting biological invasions

Changes in biodiversity and ecosystems due to natural drivers (including natural hazards) are viewed as innate and integral processes and components of nature itself, and have thus not been extensively considered in prior IPBES assessments (e.g., IPBES, 2019). However, natural drivers can play a significant direct role in the transport, introduction, establishment and spread of invasive alien species both within and beyond their prior invaded range (**Glossary**). Natural large-scale disturbances, such as hurricanes, earthquakes and tsunamis can facilitate the further introduction of alien species from an existing invaded range to new regions, consequently expanding the invaded range (Carlton *et al.*, 2017) as well as facilitating their wider spread in regions where they are already present as alien species (Bellingham *et al.*, 2005). For example, hurricanes appear responsible for the spread of *Cactoblastis cactorum* (cactus moth) between Caribbean islands (Andraca-Gómez *et al.*, 2015), the expansion of *Phragmites australis* (common reed) in the Gulf of Mexico (Bhattarai & Cronin, 2014), and increased rates of recruitment and persistence of invasive alien trees in the subtropical forests of Puerto Rico (Thompson *et al.*, 2007). While native biodiversity is a major component of nature and nature's contributions to people, and thus has been considered as a key response variable in previous IPBES assessments (IPBES, 2019), for invasive alien species biodiversity loss can also be seen as a driver that facilitates biological invasions since loss of biodiversity, and especially reduced functional complexity and/or integrity of ecosystems, can reduce biotic resistance to invasive alien species (Levine *et al.*, 2004). Chapter 3 thus considers the consequences of native biodiversity loss and changes to ecosystem resilience for biological invasions, since this is known as an important feedback mechanism directly influencing the introduction, spread and establishment of invasive alien species (**Figure 3.3**; **Table 3.1**; **section 3.4.2**). This additional complexity is explicitly captured by assessing focal relationships (lighter arrows) from natural drivers and from nature to invasive alien species, in the context of the IPBES conceptual framework **(Figure 3.3)**.

3.1.4 Differential role of drivers along the stages of the biological invasion process

Biological invasions are widely viewed as processes comprising a series of sequential stages (Blackburn *et al.*, 2011; Colautti & MacIsaac, 2004; Theoharides & Dukes, 2007; **Chapter 1**, **section 1.4**). These stages capture the transport of a species to a region beyond its native range, the introduction of the species (intentionally or/ and unintentionally) into habitats in that region, and its subsequent establishment as a self-sustaining population, followed by its wider geographic spread in the invaded range (**Figure 3.4**; **Chapter 1**, **section 1.4**). Pathways of introduction are referred to by the Convention on Biological Diversity as the means by which species are moved to new regions beyond their native range (CBD, 2014; Hulme *et al.*, 2008). Pathway assessment usually focuses on movements until a species reaches the border of an administrative unit, such as a country, although is not restricted to this definition. Pathways are categorized into six major classes (release, escape, contaminant, stowaway, corridor, and unaided) with several sub-classes (CBD, 2014; **Chapter 2, Table 2.1**; **Chapter 1**, **Box 1.6**). In the transport stage, drivers can act by facilitating pathways, such as when economic growth increases trade and transport volumes, thereby facilitating transport of alien species as stowaways (**section 3.2.3**). In later stages of the biological invasion process, drivers can act both intentionally and unintentionally to facilitate the establishment and spread of invasive alien species, such as when alien species are used for or spread as pests or contaminants of goods used for bioeconomic purposes (agriculture, aquaculture, forestry, or as pets or ornamentals)

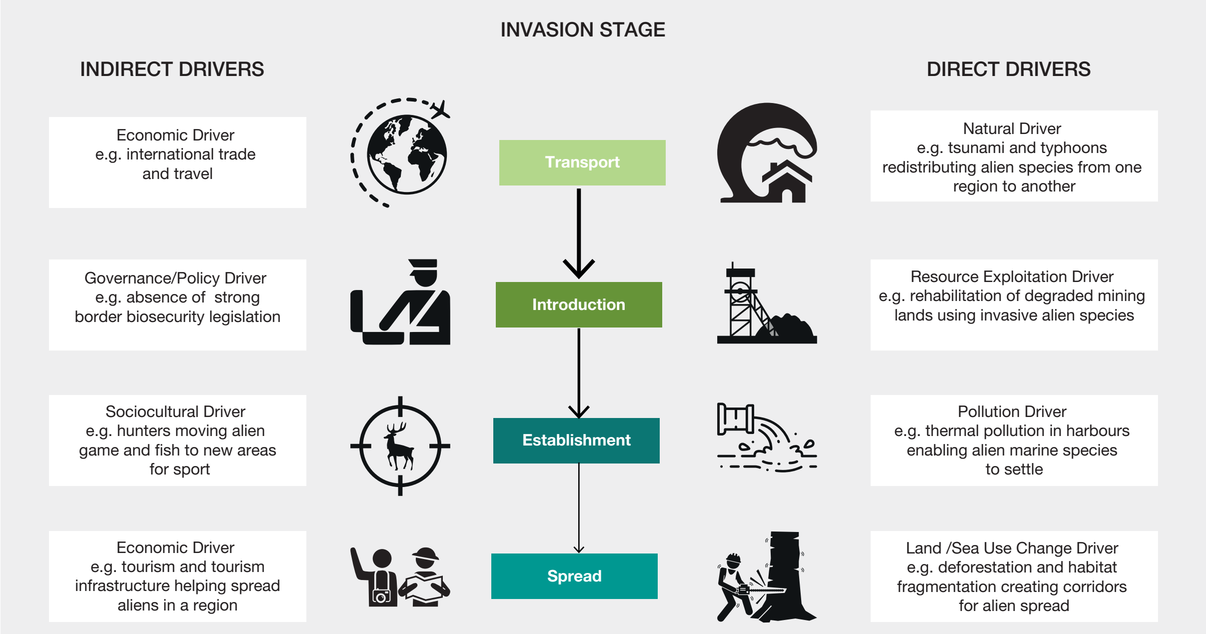

Figure 3 4 **Schematic using selected examples of how both indirect and direct drivers of change in nature may facilitate invasive alien species along four stages in the biological invasion process: transport, introduction, establishment and spread.**

The examples are meant to be illustrative and not an exhaustive set of scenarios with several drivers mentioned also influencing other stages. See **section 3.6.2** for a synthesis of the influence of different drivers on invasive alien species across stages of the biological invasion process, biomes and realms.

or when land-use change or biodiversity loss causes natural ecosystems to be less resistant to biological invasions (**sections 3.3.1**, **3.4.2**).

The biological invasion process is central to the quantitative risk assessment of invasive alien species (Leung *et al.*, 2012; **Chapter 5**, **Figure 5.1**). Nevertheless, while considerable amounts of data are being captured on the dynamics of invasive alien species across some of these biological invasion stages (Abellan *et al.*, 2016; Essl *et al.*, 2015; Gravuer *et al.*, 2008; Moodley *et al.*, 2013; Renault *et al.*, 2018; F. Ribeiro *et al.*, 2008), a full understanding of the causal factors responsible for successful introductions of invasive species remains more limited (Puth & Post, 2005). Species' traits that facilitate the introduction, establishment and spread of particular taxa (McGregor *et al.*, 2012; Moodley *et al.*, 2013; Ribeiro *et al.*, 2008) or direct drivers, such as climate change (Hulme, 2017), have been the focus of the current understanding of the transitions among different biological invasion stages.

Therefore, Chapter 3 aims to systematically[4] examine how different direct and indirect drivers of change in nature, as well as natural drivers and biodiversity loss, may influence each of the four biological invasion stages: transport, introduction, establishment and spread **(Figure 3.4)**. Specifically, each section examines the evidence for each driver within the context of the different biological invasion stages across terrestrial and aquatic biomes and for the major realms or taxonomic groups (plants, invertebrates, vertebrates and microbes; see **sections 3.1.3** and **3.6.1** for details on the search strategy and the knowledge base extracted, respectively).

4. Data management report available at https://doi.org/10.5281/zenodo.5529309

3.1.5 Attributing causality and understanding interactions among drivers

A number of studies suggest recent increases in numbers of alien species (**Chapter 2**; Seebens *et al.*, 2017) are likely augmented by increases in the rates of movement of goods and people (Essl *et al.*, 2019; Murphy & Cheesman, 2006). Due to lagged responses (time lags; or lag phase in the **Glossary**), especially towards the later stages of the biological invasion process, consequences of recent increases in transport and travel are unlikely to be fully realized at present, resulting in potentially quite substantial

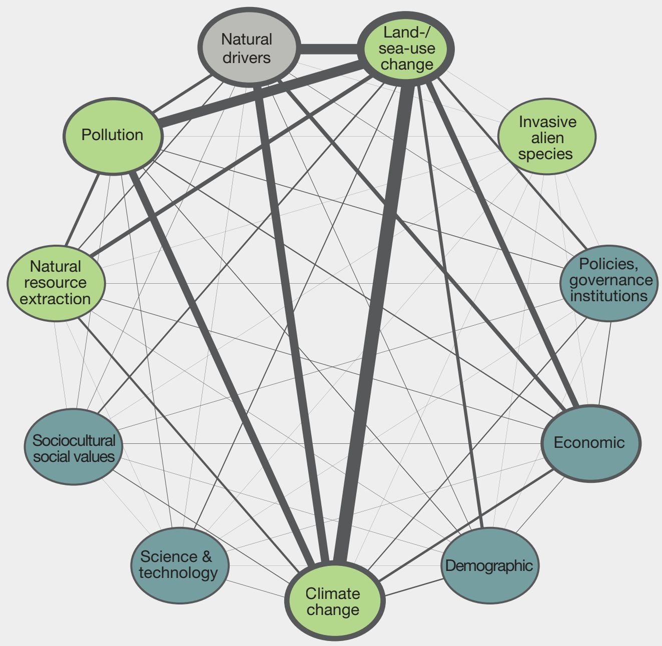

Figure 3 5 **Network diagram illustrating the extent of knowledge on indirect (blue circles), direct (green circles) anthropogenic drivers of change in nature and natural drivers (grey circle), and their interactions (lines).**

The thickness of the lines between drivers is indicative of the number of papers that jointly addressed the two linked drivers. The size of the line surrounding each circle reflects the number of papers listed by Web of Science between 2000 and 2019 generated by a topic search on a particular driver in relation to invasive alien species. Note the greater emphasis on direct drivers both individually and jointly. Note that effects of biodiversity loss on biological invasions are not included in this figure. A data management report for this figure is available at https://doi.org/10.5281/zenodo.7861123 "invasion debts" (**Glossary**; Essl *et al.*, 2011; Rouget *et al.*, 2016; **Chapter 1**, **section 1.4.4**; **Chapter 2**, **section 2.2.1**). As a consequence of increasing rates of introduction, possibly aggravated by climate change, many historical and contemporary invasive alien species are now increasingly emerging as threats to modern agriculture and food security (Subbarao *et al.*, 2015; **Chapter 4**, **sections 4.4**, **4.5**, **4.6.2** and **4.6.3**). However, attributing such global patterns of increasing rates and impacts of invasive alien species to specific drivers, such as travel, trade, or migration, is difficult.

The drivers that directly or indirectly facilitate biological invasions are correlated and causally linked through a series of co-occurring global change trends (**section 3.1.1**). The different stages of the biological invasion process can be affected by different sets of drivers (**section 3.1.4**), and drivers can interact in complex ways to facilitate the biological invasion process (**section 3.5**). While indirect drivers of change in nature may act directly on biological invasions, both natural direct drivers and anthropogenic direct drivers of change in nature can also have indirect effects on biological invasions through their influence on other drivers or *via* feedbacks from biodiversity loss **(Figure 3.3)**. For example, climate change (direct driver of change in nature) can have a direct driving effect on land-use change e.g., through a shift to more intensive agriculture which could lead to a direct effect on biodiversity loss and thus facilitate the introduction of invasive alien species. Similarly, expanding urbanization (an indirect driver ofchange in nature) can lead to increased exploitation of hydrological resources, increased pollution, as well as habitat fragmentation (direct drivers of change in nature). All these factors may increase the extent of invasive alien species, either alone or in concert, and when in concert they may act additively or multiplicatively. Unfortunately, this complexity is rarely captured in studies of invasive alien species and research often attempts to address a single proximate cause of biological invasions rather than teasing apart multiple factors or disentangling the chain of causation from indirect to direct drivers (Hulme, 2022). The multi-driver studies that exist tend to focus on interactive effects of a few key direct drivers of change in nature, notably land-use change, pollution and climate change **(Figure 3.5)**. As a result of these complexities, the knowledge base is both limited and fragmented, and attribution of cause-effect relationships can be challenging. See **section 3.1.2** for an outline of how this challenge was tackled across the chapter, **section 3.6.2** for an overview of the resulting evidence-base, and individual driver subsections (**sections 3.2**, **3.3**, **3.4**, **3.5**) for how this was tackled or each driver.

3.2 THE ROLE OF INDIRECT DRIVERS OF CHANGE IN NATURE ON INVASIVE ALIEN SPECIES

Following previous IPBES assessments (IPBES, 2018a, 2019), the five classes of indirect drivers examined in this chapter are sociocultural drivers and social values (**section 3.2.1**), demographic drivers (**section 3.2.2**), economic drivers (**section 3.2.3**), science and technology drivers (**section 3.2.4**), and finally policies, governance and institutions drivers (**section 3.2.5**). Invasive alien species are classified as a direct driver of change in nature in the IPBES scheme (Díaz *et al.*, 2015) which implies that indirect drivers of change in nature can directly influence invasive alien species (**Figure 3.3**; **sections 3.1.3** and **3.1.4**). The specific mechanism of how these influences occur is discussed under each driver below.

3.2.1 Sociocultural drivers and social values

Sociocultural contexts, particularly social values which are created by social norms, traditions, cultural beliefs, and accepted morally by society, can exert significant pressure on decision-making regarding invasive alien species (Shackleton *et al.*, 2019; **Chapter 1**, **sections 1.5.2** and **1.5.3**). Additionally, sociocultural drivers and social values are manifested in lifestyles and consumption patterns, which act as indirect and direct drivers of change in nature and affect the transport, introduction, establishment and spread of invasive alien species **(Figure 3.6)**. Sociocultural drivers thus interact with other indirect drivers, especially demographic drivers such as changes in population density (**section 3.2.2.1**), migration (**section 3.2.2.2**) and urbanization (**section 3.2.2.4**), as people have a long history of exchanging new species and bringing them with them for ornamental, cultural and practical use. Sociocultural drivers further interact with economic drivers, such as trade (**sections 3.2.3.1**, **3.2.3.2** and **3.2.3.3**) and travel (**section 3.2.3.4**) as well as science and technology drivers, such as communication technology (**section 3.2.4.2**). Sociocultural drivers can influence the rate and magnitude of change in a number of direct drivers of change in nature, particularly related to land- and sea-use changes (**section 3.3.1**), but also species harvesting (**section 3.3.2.1**), pollution (**section 3.3.3**) and drivers related to biodiversity and ecosystem health such as unintended consequences of the intentional introduction of invasive alien species (**section 3.3.5.2**) and biodiversity loss (**section 3.4.2**).

Some alien species are associated with cultural, aesthetic or practical value (**Chapter 1**, **section 1.5.2** and **Chapter 4**,

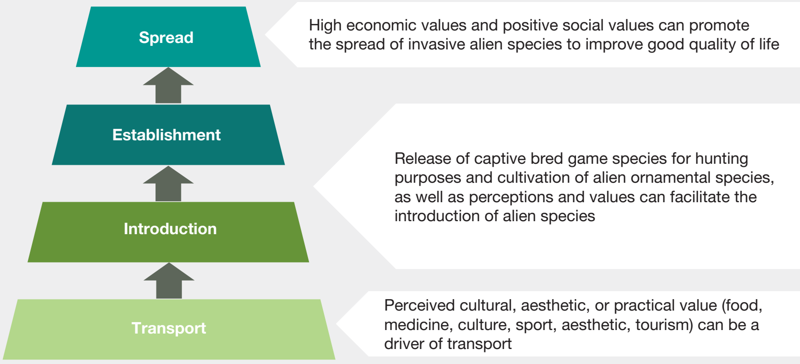

Figure 3 6 **Examples of the role of sociocultural drivers and social values in facilitating invasive alien species across stages of the biological invasion process.**

Illustration of how sociocultural drivers and social values may interact with or operate through a variety of other direct and indirect drivers of change in nature, including economic drivers, harvesting of natural resources and land- and sea-use change, to facilitate invasive alien species across the stages of the biological invasion process.

sections 4.5 and **4.6.3**), and such values can indirectly act to facilitate the introduction of these alien species. Indeed, plants that are economically valuable were shown to be 18 times more likely to become naturalized than those that are not (van Kleunen *et al.*, 2020). In Aboriginal societies in Australia, not only plants important as food and materials but also species of ritual and cultural importance have been intentionally translocated and grown for their societal and cultural benefits (Silcock, 2018). The replacement of native crayfish in Spain with two alien species intentionally introduced from North America to satisfy local tastes is a good example of the economic and social value of promoting the substitution of native species (**Glossary**) with invasive alien species (Clavero, 2016). In contrast, awareness of the adverse impacts of invasive alien species on nature, nature's contributions to people and good quality of life can lead to an increase in action by people and consequently be a driving force behind preventing the introduction of invasive alien species (McNeely, 2001; Shackleton *et al.*, 2019).

The decision to intentionally introduce an alien species or not is largely dependent on the balance between the perceived benefits of specific alien species and the perceived costs of adverse impacts. Therefore, social values have considerable influence on the judgment of whether or not to introduce an alien species (**Chapter 4**, **Box 4.2**). Estévez *et al.* (2015) reported that conflicts over invasive alien species arose primarily from differences in value systems (utilitarian, moralistic, humanistic, negativistic), rather than differences in benefit or risk perceptions between different stakeholder groups and decision-makers (**Chapter 1**, **section 1.5.2**; **Chapter 5**, **section 5.6.1.2**). According to this study, salmonids in South America, alien species of *Acacia* spp. in Africa and *Dreissena polymorpha* (zebra mussel) in Europe are examples of utilitarian vs. naturalistic value-system conflicts whereas alien mammals (example in **Box 3.2**) and trees have caused moralistic or humanistic vs. naturalistic or negativistic value conflicts in all IPBES regions (Estévez *et al.*, 2015). In another global study, Kapitza *et al.* (2019) found that the local public was more likely to focus on sociocultural benefits whereas academics focused on nativeness, and stakeholders from Africa were more likely to identify ecological benefits whereas Europeans were less likely to identify ecological and sociocultural benefits. Contextual factors, such as stakeholder role, socioeconomic status, time since the introduction occurred, and region therefore also affect the overall valuation, which again can impact behavioural choices or actions influencing biological invasions (Kapitza *et al.*, 2019; Shackleton *et al.*, 2007).

There have been many intentional introductions of invasive alien species, motivated by desires to improve specific aspects of good quality of life (**Box 3.2** and **Chapter 2**, **section 2.1.2**). Though the perception that an invasive alien species confers a benefit is not necessarily knowledge-based, it nonetheless serves as a powerful motivation for the introduction of invasive alien species usually as a result of expectations relating to increased employment, wealth, food sources, or other material gains (**Chapter 4**, **section 4.1.2**; **Chapter 5**, **section 5.6.1.2**). Meanwhile, negative impacts related to invasive alien species (whether they are intentionally or unintentionally introduced) such as threats to good quality of life, often motivates the management of biological invasions and specifically the control of invasive alien species (McNeely, 2001; Shackleton *et al.*, 2019). However, different perceptions can and often do co-exist. Specific invasive alien species considered as problematic by one social sector may provide valuable

Box 3 2 The role of hunters intentionally spreading game animals.

Introduction for hunting accounts for a large proportion of intentional introductions of invasive alien birds and mammals, both in absolute numbers and compared to introductions for biological control, pet trade and use of fur (Carpio *et al.*, 2020, 2017; Genovesi *et al.*, 2009; Hulme *et al.*, 2008). Carpio *et al.* (2017) found stocking for hunting to be a dominant source of introductions of invasive alien species. High rates of introduction and establishment can result from intensive human efforts to maintain sufficiently large and stable populations of alien species for hunting (Champagnon *et al.*, 2012, 2016). Introductions may also occur in cases where population sizes of traditionally-used native species have significantly reduced, and alien species are then introduced to supplement hunting or fishing (Carpio *et al.*, 2017; Clavero, 2016), or when alien species are introduced for the diversification of species available for hunting (Carpio *et al.*, 2017). Such efforts and considerations have resulted in large-scale introductions of a number of alien birds and mammals as game species throughout Europe, generating significant revenues through licensing fees and through creating a demand for hunting gear and services. As societal and cultural views on game species vary from being a valuable food resource *via* recreational activity to being an ecological nuisance, policy can follow suit (Duffy & Lepczyk, 2021). Alien species are still released for hunting purposes in Europe, but the rate of new species introduced has been declining over the past 10 years as the knowledge that alien species have negative effects on native ecosystems has increased (Carpio *et al.*, 2017). This increase in knowledge may have contributed to reducing the number of alien species introductions in recent decades (Fèvre *et al.*, 2006). In addition, game managers have criticized the use of alien species for hunting from an ecological perspective (Delibes-Mateos, 2015), and hunters indicate that they favour hunting wild game in biodiversity-rich landscapes rather than released individuals, and are willing to pay at least 20 times more per wild partridge *(Alectoris rufa)* hunted relative to a farm-reared bird (Delibes-Mateos *et al.*, 2014). However, hunters do not always recognize that a game species is alien (Cerri *et al.*, 2016). Furthermore, fines for the illegal importation and/or release of alien species are relatively low and the detection rate of illegal importation is low (Caudell *et al.*, 2016) compared to the economic benefit for hunters and landowners indicating that the introduction of alien species for hunting is still difficult to manage (**Chapter 5**, **Box 5.6**).

Figure 3 7 ***Phasianus colchicus* (common pheasant) killed by a recreational shoot.**

Phasianus colchicus are native to Asia and parts of Europe (Balkans and northern Caucasus) and have been introduced as game birds throughout the world, including Europe, North America, Hawaii, Japan, Australia and New Zealand. In the United Kingdom, pheasants were introduced in the eleventh century and became a popular game bird in the nineteenth century, being widely bred and released for recreational use. The current breeding population in the United Kingdom has 2.3 million female birds (RSPB, 2021). Photo credit: MykolaMoriev, Shutterstock – Copyright.

contributions to people, cultural benefits, or other intrinsic values to another (**Chapter 1**, **section 1.5.2**; McNeely, 2001; Schlaepfer *et al.*, 2011). For example, in poor rural communities in Madagascar, the introduced *Procambarus virginalis* (Marmorkrebs), while acknowledged to be detrimental to rice farming and fishing, is also valued as a cheap and widely accessible protein source for food and feed, and the perception of overall benefit relative to costs is considered high by people not directly involved in fishing or farming and by communities with a long history of crayfish invasion (Andriantsoa *et al.*, 2020). *Opuntia ficus-indica* (prickly pear), an invasive alien cactus, has high economic value to rural communities in South Africa, where it is used for stock fences or as fresh fruit, and as such is considered positively by farmers, which has consequently affected its establishment and spread (Kapitza *et al.*, 2019; Shackleton *et al.*, 2007). Other examples include invasive alien species introduced as game animals **(Box 3.2)** or for recreational fishing.

3.2.2 Demographic drivers

Demographic drivers, including human population growth and movement, are fundamental factors behind many drivers that directly facilitate biological invasions. This section summarizes the evidence for the influence of four main demographic drivers of change in nature: 1) changes in human population density; 2) human migration; 3) international crises, such as armed conflict and emergency relief; and 4) urbanization **(Figure 3.8)**.

Demographic drivers of change in nature interact with other indirect drivers, especially economic drivers, such as trade (**sections 3.2.3.1** to **3.2.3.3**) and travel (**section 3.2.3.4**) and science and technology drivers, such as breeding and genomic technologies (**section 3.2.4.3**). Demographic drivers operate by influencing the rate and magnitude of change in a number of direct drivers, most obviously those related to land- and sea-use change (**section 3.3.1**), but also other direct drivers such as species harvesting (**section 3.3.2.1**), water extraction (**section 3.3.2.2**), pollution (**section 3.3.3**), climate change (**section 3.3.4**) and drivers related to biodiversity and ecosystem health such as unintended consequences of the intentional introduction of invasive alien species (**section 3.3.5.2**) and biodiversity loss (**section 3.4.2**).

3.2.2.1 Regional and national changes in human population density

The world's population has doubled over the last 50 years (IPBES, 2019) and is expected to reach 8.5 billion people in 2030, of which approximately 60 per cent (about 5 billion) will reside in urban areas (**section 3.2.2.4**; United Nations *et al.*, 2019). Coastal areas are experiencing faster growth rates and 51 per cent of the world's population will live within 100km of the coast by 2030 (Kummu *et al.*, 2016). Approximately 75 per cent of the two billion people to be added to the global population by 2050 will live in sub-Saharan Africa (about 50 per cent) and Central and Southern Asia (about 25 per cent) (United Nations *et al.*, 2019). Regions with high human population densities are often associated with high rates of species introductions and establishment of alien species (Pyšek *et al.*, 2020), and have been associated with both intentional and unintentional transport of species to locations outside of their native ranges (Hulme, 2009; Levine & D'Antonio, 2003). Human population density growth enhances regional trade (**section 3.2.3.1**; United Nations *et al.*, 2019), intensifies

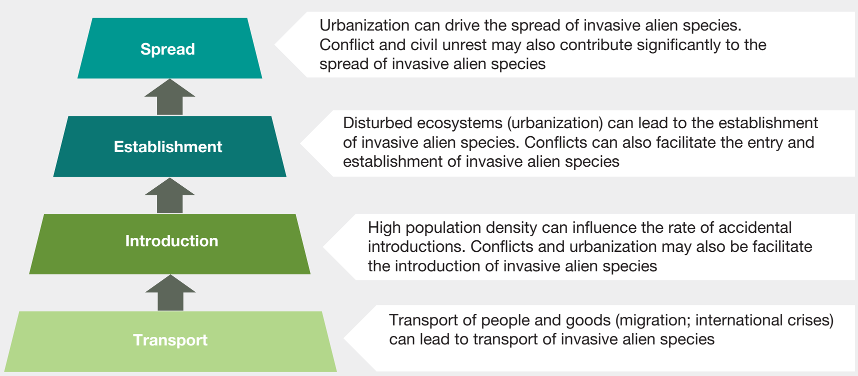

Figure 3 8 **Examples of roles of demographic drivers in facilitating invasive alien species across stages of the biological invasion process.**

Illustration of how demographic factors such as urbanization, international crises and movement of people, directly or *via* other drivers such as land-use change, can facilitate invasive alien species across the stages of the biological invasion process.

urbanization (**section 3.2.2.4**), and increases pressures from a suite of land-use related factors, including nature-based industries (**section 3.3.1.1**), and is associated with the loss, fragmentation and degradation of natural ecosystems (**sections 3.3.1.2** to **3.3.1.5**; IPBES, 2019). These are all factors known to promote alien species in terrestrial (Pyšek *et al.*, 2020) and marine environments (C. C. Murray *et al.*, 2014) across multiple taxonomic groups (Bellard *et al.*, 2016). Evidence from several regional and global studies (Dawson *et al.*, 2017; Essl *et al.*, 2019) shows that alien species richness is positively associated with human population density with human population density-related processes acting on different stages of the biological invasion process (Pyšek *et al.*, 2010). In a global study of a wide taxonomic range of established alien species (**Glossary**), human population density was shown to have the strongest influence on fish, plants and spiders whereas weaker but positive relationships were found for ants, birds, mammals and reptiles (Dawson *et al.*, 2017). In Europe, human population density is positively associated with increased alien species richness for a wide range of plant and animal groups, with highest alien species richness values occurring in regions with more than 91.1 inhabitants/km^2 and the lowest values in regions with fewer than 8.5 inhabitants/km^2 (Pyšek *et al.*, 2010). At the national scale, a comprehensive national alien species assessment in Norway, covering all multicellular organisms, found that for all taxonomic groups considered (terrestrial and aquatic plants, invertebrates, fungi and vertebrates) alien species richness was positively correlated with human population density (Sandvik *et al.*, 2019). Similarly in the United Kingdom, human population density was a good predictor of freshwater fish introductions (Copp *et al.*, 2010). In Brazil, Fonseca *et al.* (2019) showed that human population density influenced the rate of unintentional introductions, resulting in high records of alien amphibians and reptiles in densely-populated areas. At more local scales, evidence shows that increased human population density in surrounding areas is a significant predictor of alien species richness for plants within national parks in the United Stated of America (McKinney, 2002) and for multiple alien taxa (including birds, mammals, vertebrates and plants) in South Africa's Kruger National Park (Spear *et al.*, 2013). The number of visitors (McKinney, 2002) or occupants (Foxcroft *et al.*, 2008) within a national park is positively correlated with alien species richness. A case study on urban wetlands further highlights that alien species richness is correlated with human population density, however found that alien herbs, shrubs and trees all respond differently to human pressures (Ehrenfeld, 2008).

Human population density can be used as a proxy to better understand the role of various human activities across stages of the biological invasion process, and has been shown to facilitate both introduction (Gallardo & Aldridge, 2013; Pyšek *et al.*, 2010) and establishment (Dawson *et al.*, 2017). This may be related to human population density acting as a proxy for propagule pressure (**Glossary**) and the intensity of anthropogenic disturbance (**section 3.3.1**), two mechanisms known to facilitate the introduction and establishment of alien species, respectively (Gallardo & Aldridge, 2013; Roura-Pascual *et al.*, 2011). For example, in Europe, the introduction of alien mammals was significantly correlated with human population density whereas establishment success was not (Jeschke & Genovesi, 2011). At the global scale, other socio-economic factors, such as per capita GDP and proportion of agricultural land, appear to be more important predictors of relative invasive alien species richness than population density across both islands and mainland regions (Essl *et al.*, 2019; Westphal *et al.*, 2008). Essl *et al.* (2019) show that human population density had a greater influence on absolute alien species richness in mainland regions compared to islands, and this pattern was more pertinent for established alien species than for the subset of alien species that were invasive. This illustrates that while population density is correlated with invasive alien species dynamics, the relationship is complex so that countries that have high rates of population growth are not necessarily those with high rates of introduction of invasive alien species.

The review of the literature for this chapter (**section 3.6.1**)[5] highlighted that the majority of the evidence for human population density as a driver that facilitates biological invasions can be found in the terrestrial realm, followed by the freshwater realm, with few marine examples to draw from despite the large concentration of human populations living near to the coast. The IPBES regions of Oceania and Asia-Pacific were the least well studied, with Europe and the Americas having the greatest focus. Despite the other regions (e.g., Africa) being included in global studies, they have relatively few examples to draw from and examples are often from a small selection of countries (e.g., South Africa). Dawson *et al.* (2017) provide a global synthesis of the taxa, however microbes and invertebrates remain poorly studied.

3.2.2.2 Human migration

While the term migrant has specific definitions, Chapter 3 specifically focuses on people moving away from their place of usual residence to take up residence in another country. The rate of migration is increasing: in 2019, 3.5 per cent of the global population (272 million people) were living in a country other than their country of birth, compared with 2.8 per cent in 2000 and 2.4 per cent 1980 (International Organization for Migration, 2019; Vidal *et al.*, 2018). Migrating humans act as direct dispersal vectors (**Glossary**) in the transport and spread of plants, animals and microbes, either unintentionally in the case of pests and diseases or

5. Data management report available at https://doi.org/10.5281/zenodo.5529309

intentionally in the case of pets, livestock, ornamentals, or crops. Sociocultural drivers and social values (**section 3.2.1**) are important factors behind many of these intentional introductions. Human migration thus operates through and in synergy with other indirect drivers of change in nature such as changes in travel, trade and transport (**sections 3.2.3.1** to **3.2.3.4**), urbanization and/or abandonment of land (**section 2.3.3.4** and **3.3.1.5.1**) and population changes, armed conflict and emergency relief (**sections 3.2.2.1** and **3.2.2.3**).

Generally, broad-scale analyses of the spread and distribution of alien species find links between the rate and origins of introductions of new species and human migration history. For example, early introductions of invasive alien plants in Brazil and Australia can be linked to waves of European migration (Phillips *et al.*, 2010; Zenni, 2014), patterns of early bird introductions worldwide spatially and temporally tracked the expansion of European (and especially British) colonialism (Dyer *et al.*, 2017). Patterns of ant invasion dynamics globally bear clear imprints of human demographic patterns including an early wave of biological invasions (1850-1910) coinciding with a period of high human migration (Bertelsmeier *et al.*, 2017). As a more recent example, the number of insect invasions in Europe increased steeply in response to political changes that allowed increased movement of people and goods in Europe after the fall of the Iron Curtain in 1989, and also increased following the expansion and integration of the European Union (Roques *et al.*, 2016). Similarly in line with geopolitical and economic trends, vertebrate introductions from Europe to the United States of America peaked in the nineteenth century paralleling high rates of human migration in the same direction, while alien vertebrate introductions in the opposite direction (United States to Europe) are at their highest now (Jeschke & Strayer, 2005).

Migration can also drive introductions and spread of alien species within regions, for example, immigrants to South Africa from other countries in the region have brought with them their own medicinal plants and have created a market for them (Faulkner *et al.*, 2020). A parallel line of evidence for the role of historic human migration on alien species' distributions comes from intraspecific genetic patterns in alien species. Several studies reveal close congruence with historical large-scale human migration, including for human diseases carried directly by humans or by vectors associated with humans (e.g., Conn *et al.*, 2002), pests (e.g., Puckett & Munshi-South, 2019) and even parasites of pests (e.g., Aketarawong *et al.*, 2015; United Nations Department of Economic and Social Affairs, 2019). Accordingly, political or other barriers to human migration can impede rates of spread of alien species, as is seen in the spread of alien insects across Europe, which appears to have been hampered by the political East-West barrier during the Cold War, as rates of spread were four times higher after 1989 compared to the 1950-1989 period (Roques *et al.*, 2016).

While human migration is increasing globally (United Nations Department of Economic and Social Affairs, Population Division, 2020), other movements of people and goods around the globe resulting from trade and direct use of alien species in nature-based industries (**sections 3.2.3.1**, **3.3.1.1**) and travel and tourism (**section 3.2.3.4**) are increasing even more rapidly (UNWTO, 2021). The relative importance of human migration *per se* in the introduction of invasive alien species is therefore likely to be decreasing. In line with this, recent global analyses reveal only weak influence of human migration on recent patterns in the rate of alien species' introductions, and also weak influences of human migration rates on variation in biological invasions among taxonomic groups and between geographic regions (Seebens *et al.*, 2015). However, human migration is predicted to rise as climate change displaces people from drought-, flood- or storm-hit regions (Rigaud *et al.*, 2018), indicating that human migrations, possibly in interaction with climate change, land-use change or natural drivers, could contribute to increased rates of introduction of invasive alien species in the future. Pressure from invasive alien species could be expected to be highest in countries with the highest inward migration: currently United States, Germany, Saudi Arabia, Russian Federation and the United Kingdom (United Nations Department of Economic and Social Affairs, Population Division, 2020).

While the review of the literature on human migration as a driver facilitating biological invasions undertaken in Chapter 3 is limited in extent, authors considered evidence from plants, vertebrates, invertebrates and microorganisms, and from all IPBES regions, with evidence dating back to colonial times (**Chapter 2**, **section 2.2.1**). As such this section broadly covers relevant variability in terms of geography, taxonomy and realms and time. The literature on migration as a driver facilitating biological invasions is focused on the transport and especially introduction of alien species, with less evidence from the latter stages of the biological invasion process.

3.2.2.3 International crises: armed conflict and emergency relief

International crises, specifically armed conflicts and humanitarian emergency relief and development assistance operations can be powerful indirect drivers of change in nature that may directly facilitate the transport, introduction, establishment and spread of invasive alien species (**Chapter 6**). By 2020, the global number of refugees and asylum seekers was approximately 25 million people (UNHCR, 2020). Both crises and aid can affect biological invasions through abrupt and substantial changes in travel, trade and transport (**sections 3.2.3.1** to **3.2.3.4**), and through substantial and rapid human population movements and changes (**sections 3.2.2.1** and **3.2.2.2**). These trade, transport and population changes affect biological invasions through influencing, broadly, the movement of goods and deployment of infrastructure, and the transport and movement of humans and their luggage, all of which can act as direct dispersal vectors (assisting the uptake and introduction of alien species both intentionally or unintentionally; **section 3.3.1.1**). Crises and aid can also lead to changes in nature through increasing or decreasing the intensity of land- and sea-use (**section 3.3.1.1**), which may again affect biological invasions (e.g., fragmenting landscapes, creating corridors, deploying infrastructure, leading to land-use abandonment, degrading habitats, or changing disturbance regimes; **sections 3.3.1.2** to **3.3.1.6**).

Conflict and civil unrest may contribute significantly to the introduction and spread of invasive alien species through several mechanisms: (i) civil unrest or war can lead to the breakdown of phytosanitary and animal health control and management, and the loss of supply lines for materials as well as to the displacement of large numbers of people; (ii) areas where there is civil unrest or war may be more vulnerable to the introduction of invasive alien species because of the lack of inspections and border controls, facilitating unregulated movement as well as deliberate smuggling of people and their belongings, and also because of the increased movement of military personnel and refugees; (iii) inflows of food aid may also be contaminated with alien species; and (iv) difficulties in obtaining access to border areas because of landmines and other hazards impedes border control (FAO, 2001; Moore, 2005; Murphy & Cheesman, 2006).

War entails transportation of people and goods, deployment of heavy machinery, disturbance of habitats, creation of bare ground, and in some instances intentional introductions of alien species (food supply etc.; Fosberg, 1957). Military transport, equipment and supplies, often covered with dirt or mud from the field, are effective means of dispersal for many alien species (Cofrancesco Jr *et al.*, 2007; Dalsimer, 2002). A number of introductions have been linked to movement of troops and military equipment during the Second World War: *Rattus rattus* (black rat) were introduced to the Midway Islands by navy ships; a desert shrub, *Peganum harmala* (African rue) was introduced inadvertently into New Mexico and Texas *via* airfields; *Tribulus terrestris* (puncture vine) and the agricultural pests *Striga asiatica* (witch weed) and *Globodera rostochiensis* (yellow potato cyst nematode) are believed to have entered North America on returning military equipment; and *Boiga irregularis* (brown tree snake), native to New Guinea, was unintentionally introduced to the island of Guam most likely in military shipments of fruit (Cox, 1999). A root rot of pine trees, *Heterobasidion annosum* (root rot), was inadvertently introduced into Italy by American troops during World War II where it has resulted in an unprecedented mortality rate of *Pinus pinea* (Italian stone pine; Pilcher, 2004). More generally, an increase in marine invasive alien species was observed at Pearl Harbor following World War I and II (Coles *et al.*, 1999). More localized military operations have also led to biological invasions. The introduction of *Diabrotica virgifera* (western corn rootworm) in Serbia in the 1990s was associated with incoming military transport from the United States (EPPO, 1996), and has rapidly become a widespread (**Glossary**) threat to European corn production (Bažok *et al.*, 2021). Habitat disturbance caused by military activity may also facilitate invasive alien species. In Poland, bomb craters were found to have higher numbers of invasive alien plants compared to the surrounding landscape (Krawczyk *et al.*, 2019). Military training activities resulting in soil disturbance facilitated the spread of *Imperata cylindrica* (cogon grass) in military camps in the United States (Yager *et al.*, 2009). Again in the United States, tank traffic activity facilitated invasive alien species in prairie grasslands (Wilson, 1988).

War also facilitates the movement of humans, who may themselves become vectors of alien species including pathogens. For example, the global spread of the Spanish Flu post-World War I was attributed to movement of troops (Neill & Arim, 2011) and a 2010 cholera outbreak in Haiti was attributed to incoming United Nations peacekeeping troops from Nepal (Frerichs *et al.*, 2012). Not all war and crisis-related introductions are unintentional. *Mikania micrantha* (bitter vine) is reported to have been introduced to northeast India to camouflage air strips built by the Allied Forces during World War II to impede the advancing Japanese forces (Kohli *et al.*, 2011; Randerson, 2003). More unique links between armed conflicts and biological invasions also exist, for example, attempts to rectify war damages through replanting activities and making use of invasive alien species in these efforts, i.e., the planting of *Cynodon dactylon* (Bermuda grass) or revegetation of denuded Pacific islands during World War II (Fosberg, 1957). War can also hamper biological invasions, as exemplified by reductions in the rates of global spread of alien ant species due to decreased global trade in both World Wars I and II (Bertelsmeier *et al.*, 2017).

Emergency relief, reconstruction efforts and humanitarian aid after armed conflicts and disasters may also contribute to the introduction and spread of invasive alien species. For example, *Iguana iguana* (iguana), *Osteopilus septentrionalis* (Cuban treefrog) and *Scinax x-signatus* (Venezuela snouted treefrog) were introduced to Dominica, West Indies, *via* emergency relief shipping containers (van den Burg *et al.*, 2019). *Parthenium hysterophorus* (parthenium weed), originally from Mesoamerica, has become invasive in India, where its seeds arrived in grain shipments. It was then spread to Sri Lanka *via* peacekeeping efforts (Kohli *et al.*, 2006; Pallewatta *et al.*, 2003). Aid shipments also resulted in its introduction to Ethiopia (Wittenberg & Cock, 2003).

Such cases have led to local concern when receiving humanitarian aid shipments. For example, due to the highly invasive nature of *Sorghum halepense* (Johnson grass), American Samoa refused the offer of assistance from the Australian International Assistance Program (Tuinoula, 2003).

As illustrated in this section, the scientific and especially grey literature[6] provide a range of examples of how international crises, specifically armed conflicts and emergency relief, may act as a driver facilitating biological invasions both through intentional introductions for various purposes and unintentional introductions through contaminants and stowaways. Authors found evidence from plants, vertebrates, invertebrates and microorganisms; from terrestrial, aquatic and marine systems; and from all IPBES regions. The literature on international crises and aid as a driver facilitating biological invasions covers all stages of the biological invasion process, especially focusing on the introduction and spread phases, the latter often from assessments of impact (**Chapter 4**).

3.2.2.4 Urbanization

Urbanization, the increase in the proportion of a population living in urban areas, results in a large number of people becoming permanently concentrated in relatively small areas, forming cities (IPBES, 2022c). By 2018 approximately 55 per cent of the world's population resided in urban areas, and it is expected that this will exceed 60 per cent by 2030 (United Nations, Department of Economic and Social Affairs, Population Division, 2019). As the global human population increases, the patchwork of urban sprawl and modified environments is increasingly dominating landscapes. This accelerated urban growth has contributed to the extensive fragmentation, reduction and degradation of natural ecosystems worldwide (IPBES, 2019) facilitating the establishment and spread of invasive alien species in urbanized areas (**sections 3.3.1.2** to **3.3.1.5**). Along with the increase in human population density in cities (**section 3.2.2.1**), the volume, frequency and range of movement of people and goods also increases, as does trade (**sections 3.2.3.1** to **3.2.3.4**). The movement in people and goods operates at many scales, from local, through national and regional scales, to global networks, facilitating transport of invasive alien species at all scales.

In a global review of invasive alien plants, vertebrates and invertebrates on islands (749 alien species in total), urban areas had consistently higher abundances of alien species compared to natural ecosystems (Sánchez-Ortiz *et al.*, 2020). Urban areas are centres of transport and travel, facilitating breakdown of biogeographic barriers and high rates of introduction of invasive alien species into urban habitats (Banks *et al.*, 2015). Accordingly, the richness of alien plants in urbanized areas is related to factors such as length of railroads and roads, and the size of the urbanized area (Kühn *et al.*, 2017). However, pathways vary across taxonomic groups, with escape from containment in homes or gardens being the most likely source of invasive alien plants and vertebrates in urban areas, whereas invertebrates are likely to arrive as stowaways or contaminants in transported goods (Padayachee *et al.*, 2017). Many invasive alien species have generalist or opportunistic traits, and urban areas may provide suitable environments and novel opportunities for their establishment and spread. In the case of birds, for example, urban environments offer opportunities for species with flexible foraging strategies to adopt novel food sources; favouring invasive alien birds that tend to be more flexible in their behavioural traits relative to native species (Griffin *et al.*, 2017). Similarly, for plants, the increased disturbance (**section 3.3.1**), pollution and nutrient availability (**section 3.3.3**), and climate warming (**section 3.3.4**) associated with urbanization generate opportunities for alien species, many of which are habitat generalists and/or disturbance and high-nutrient habitat specialists. The number of invasive alien species in urban areas is predicted to increase further due to an increase in propagule pressure and opportunities for the spread and establishment associated with increased global trade, intentional release of alien species, land-use intensification, urbanization and climate change (Dawson *et al.*, 2017).

In some cases, urban areas are a focus for the spread into the wider environment and may have major implications for Indigenous Peoples and local communities, as in the case of Montréal, where wetlands are invaded by invasive alien species due to clearing and filling activities occurring around Indigenous lands (IPBES, 2022b). Accordingly, many studies have found a positive association between the number of invasive alien species within a location and the percentage of urban land in the surrounding landscape (Vilà & Ibáñez, 2011). Similarly, road density, frequency of road use and road improvement increases diversity of alien species in adjacent ecosystems (Vilà & Ibáñez, 2011).

Urbanization can also be a driver for aquatic invasive alien species. Out of 891 species listed in the Global Invasive Species Database (GISD; GISD, 2021), 277 (31 per cent) are associated with urban areas, 395 (44 per cent) are associated with inland waters (wetlands, lakes, or water courses), and 147 (16 per cent) are associated with both urban areas and inland waters (**Chapter 2**, **section 2.5.5.1**). Urbanization provides two means for enhanced invasions into wetlands. First, large numbers of species are imported (intentionally or unintentionally) into urban areas, creating high propagule pressures, and second, urbanization causes disturbance of existing ecosystems (Hassall, 2014). For example, deployment of infrastructure (**section 3.3.1.4**) such as stormwater ponds may harbour the invasive

6. Data management report available at https://doi.org/10.5281/zenodo.5529309

alien *Anaxyrus fowleri* (Fowler's toad) and construction may facilitate the dispersal of this invasive alien species. Urbanization may facilitate biological invasion in or around aquatic environments through modification of channels and banks (**section 3.3.1.4**), disturbance from traffic, presence of pet animals (**section 3.3.5**), dumping of rubbish (**section 3.3.3**), and reductions in permeability of surrounding land (Hassall, 2014; **section 3.3.1.6**).

Urbanization also plays a role in the relative distribution and abundance of both native and alien species in marine environments. Deployment of marine infrastructure (**section 3.3.1.4**) is an important direct driver, and large coastal and marine areas of Europe, North America, Asia and Australia are nowadays covered by sea walls, dikes, breakwaters, groynes, jetties, pilings, bridges, artificial reefs, offshore platforms and energy installations, which are linked to urban areas. A study carried out by Airoldi *et al.* (2015) found that marine infrastructures along sandy shores disproportionally favour alien over native hard bottom species, affecting alien species' spread at regional scales.

3.2.3 Economic drivers

Alien species are dispersed globally and regionally both intentionally and unintentionally through trade and commerce (**sections 3.2.3.1** to **3.2.3.3**) and by travellers and tourists (**section 3.2.3.4**). While the causal relationships are complex, the resulting pattern can be relatively simple and predictable. The number of alien species found in a country often correlates with per capita GDP (Dawson *et al.*, 2017; Essl *et al.*, 2011) reflecting the intensity of international trade which is a major conduit for the introduction of alien species (Hulme, 2009).

Economic drivers impact and interact with other indirect drivers of change in nature, especially demographic drivers, such as population density (**section 3.2.2.1**) and urbanization (**section 3.2.2.4**). Economic drivers operate by influencing the rate and magnitude of change in the majority of the direct drivers of change in nature, including those related to land- and sea-use change (**section 3.3.1**), direct exploitation of natural resources (**section 3.3.2**), pollution (**section 3.3.3**), climate change (**section 3.3.4**), and drivers related to the intentional introduction of invasive alien species and associated unintended consequences (**section 3.3.5.2**) and biodiversity loss (**section 3.4.2**). Section 3.2.3 describes evidence for links between specific economic drivers and invasive alien species (**Figure 3.9**) and makes reference to other indirect and direct drivers when relevant. Mechanistic links between the ensuing direct drivers and invasive alien species are discussed in **section 3.3**.

3.2.3.1 International trade and global commerce

International trade (whether legal or illegal) in commodities (e.g., minerals, petrochemical products, agricultural products, machinery and electronic goods, plants and wildlife) is an important route through which invasive alien species are introduced into new regions (Hulme, 2021b). International trade has grown dramatically since 1950 (Hulme, 2009, 2021b), and the quarterly world trade volume more than doubled from 2005 (2.5 trillion US dollars (US$)) to 2019 (over US$6 trillion; WTO, 2021), so that few nations in the world are not linked to others through trade. In many ways, trade is a universal driver facilitating biological invasions across contexts, playing a role in the introduction of aquatic and terrestrial taxa

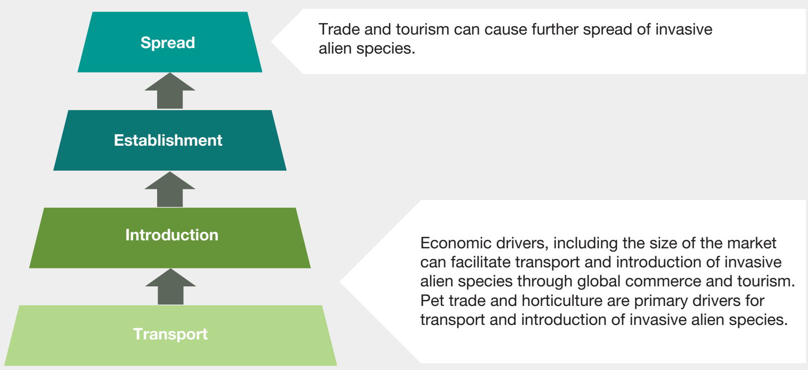

Figure 3 9 **Examples of the role of economic drivers in facilitating invasive alien species across stages of the biological invasion process.**

Economic factors such as size of markets and trade and use of specific invasive alien organisms can facilitate their transport and introduction, whereas trade and tourism can facilitate the further spread of invasive alien species within regions.

across the world. The demand for increased international trade has led to a major shift in the magnitude and reach of international shipping, and to the development of ports and deep-water harbours, inter-regional canals and global air freight (Hulme, 2009a; **section 3.3.1.3**, **Box 3.7**; **section 3.3.1.4**). Government officials at international borders regularly intercept invasive alien species associated with a wide range of imported commodities and transport vectors (Bacon *et al.*, 2012; Caley *et al.*, 2015; McCullough *et al.*, 2006; Work *et al.*, 2005). Clearly, the more locations at which international commodities first arrive in a country (airports, seaports, land-borders), the greater the likelihood that invasive alien species will succeed in finding a suitable environment (**Chapter 1**, **section 1.4.1**; **Chapter 2**, **section 2.1.2**).

The direct effects of trade have largely been quantified using relationships between imports and the number of alien species in a region or patterns in the global spread of species linked to shipping and air traffic networks (Hulme, 2021b). Alien species may themselves be the imported commodity (e.g., aquarium, ornamental, pet, crop, or pollinator species; **Box 3.3**), or a contaminant of a commodity (e.g., plant pathogens on a host plant, seeds trapped in wool fleeces, or insects in grain shipments), or be associated with a transport vector as a stowaway (e.g., hull fouling or ballast water organisms associated with marine transport). For example, invasive alien species of ornamental fish (Padilla & Williams, 2004; Hixon *et al.*, 2016), plants (Hulme *et al.*, 2018) and insects **(Box 3.3)** are traded globally as a commodity. The international pet trade is recognized as a primary driver for the introduction of invasive alien animals (Hulme, 2015a; Maceda-Veiga *et al.*, 2013). The introduction of *Aedes albopictus* (Asian tiger mosquito) is well known as a contaminant of imported used tyres (Benedict *et al.*, 2007), and large numbers of alien vertebrate and invertebrate species have been introduced as stowaways in ballast water (Molnar *et al.*, 2008). There is also evidence that illegal wildlife trade also runs the risk of introducing some invasive alien species into new regions (García-Díaz *et al.*, 2016). Furthermore, international trade has been a driver for the initial construction and, more recently, expansion of shipping canals (e.g., Suez, Panama) that by linking previously separate marine regions have facilitated the spread of invasive alien species between seas and oceans (Golani, 2021; Hulme, 2015b; **section 3.3.1.3**, **Box 3.7**). In addition to the transport and introduction of invasive alien species across international borders, commerce can also facilitate the establishment and spread of alien species within a region. For example, the size of the national market for ornamental plants (Dehnen-Schmutz *et al.*, 2007) and freshwater crayfish (Chucholl, 2013) is a strong driver that increases the likelihood of species becoming established in the wild. Such trends are likely to be exacerbated by the growth in e-commerce (**Glossary**) of alien species (Humair *et al.*, 2015).

Not all alien species introductions are associated with a specific commodity; some alien species may enter a region on vectors rather than commodities, that is they are associated with the mode of transport. Alien species introduced in ballast water are more likely to reflect the volume, frequency, age and origin of marine vessels than the specific commodities carried by shipping (Hulme, 2021b). The network of global ship movements and the estimated volume of ballast water discharges in ports worldwide have been used successfully to identify the major source regions for invasive alien species in several maritime ecoregions (Seebens *et al.*, 2016). However, there has been a five-fold increase over the past 30 years in the number of shipping containers carrying international trade but, despite the risk containers pose, there have been no studies to date attempting to relate contemporary risk of invasive alien species to variation in the number of containers imported or indeed their global itineraries (Hulme, 2021b).

There is often a strong correlation between the number of alien species in a country and the value of commodity imports, supporting the view that international trade is a key driver in the introduction of invasive alien species (Levine & D'Antonio, 2003; Santini *et al.*, 2013; Seebens *et al.*, 2015; Westphal *et al.*, 2008). Such relationships are often nonlinear, suggesting that the effect of imports on alien species numbers becomes less strong once a certain threshold is reached, and can vary in strength quite markedly depending on the taxonomic group examined (Hulme, 2021b). Coarse correlations with the value of all commodity imports often mask important detail regarding the relationship between trade and the multiple pathways of introduction of alien species (Hulme *et al.*, 2008). Even within a single pathway there may be subtle differences in the risk posed by particular commodities, as in the case of invasive alien insects that are more likely to enter the United States as contaminants of commodities transported in refrigerated rather than unrefrigerated cargo (Work *et al.*, 2005).

Knowledge that the likelihood of the introduction of alien species varies by trading partner has led to studies examining wider bilateral trade relationships more thoroughly (Hulme, 2021b). As a result, data on the magnitude of bilateral trade between regions is often used to estimate the scale of future biological invasions and has, to date, pointed to a significant increase in risk over the next decades (Bradley *et al.*, 2012; Seebens *et al.*, 2015). These risks differ by global region, with some evidence suggesting there are greater risks for developing countries (Seebens *et al.*, 2015). Given the strong link between international trade and biological invasions, the global economic slowdown that was initiated by the 2008 financial crisis (Constantinescu *et al.*, 2016) might be expected to have reduced the rate of alien species establishment however, evidence suggests rates of establishment are likely to lag behind economic drivers by as much as two decades (Seebens *et al.*, 2015). Thus, for the foreseeable future, rates of alien species introductions through trade will continue to increase. As a consequence, future trends in international trade, including e-commerce, new trade routes, and major infrastructure developments, will lead to pressure on national borders that may soon outstrip the resources available for intervention (**Chapter 6**, **section 6.3.1.4**).

Box 3 3 **Trade of bumblebee colonies for crop pollination as a driver that facilitates the introduction of invasive alien species.**

Many pollinators and flower visitors from various insect orders and families have been introduced and established out of their native ranges (Bartomeus *et al.*, 2013; Goulson, 2003, **Chapter 1**, **Box 1.11**). Unintentional transportation with their host materials accounted for the establishment of cavity-nesting bees (e.g., *Anthidium manicatum* (wool carder bee)), whereas crop pollination motivated the intentional transportation and introduction of *Apis* (honey bees) and *Bombus* (bumble bees) (Gibbs & Sheffield, 2009; Goulson, 2003; Schweiger *et al.*, 2010). While different subspecies of *Apis mellifera* (European honeybee), native to Europe and Africa, have been managed at least since 2450 B.C., (Crane, 1999) and introduced in all continents (except Antarctica) where they were not native, the introduction of *Bombus* spp. (bumblebee) colonies is relatively recent (Osterman *et al.*, 2021). Bumblebees live in colonial nests and can buzz pollinate (whereby bees use vibrations to extract pollen from flowers, incidentally, fertilizing them), making them suitable pollinators for a wide range of crops, in particular those grown in greenhouses. The rearing of bumblebee colonies of European species *Bombus terrestris* started in the 1980s and in a few years triggered a massive trade of colonies within and beyond its native range (**Figure 3.10**). This species has invaded many countries in which it has been intentionally introduced (e.g., Japan, New Zealand, Chile) expanding its range even to countries were introduction was not allowed, as is the case of Argentina (Aizen *et al.*, 2019). In South America, *Bombus terrestris* has spread across Chile (Montalva *et al.*, 2011) from the Atacama Desert to the southernmost islands south of the Tierra del Fuego Archipelago and to South West Argentina (Morales *et al.*, 2013). In this region *Bombus terrestris* achieves unusually high abundance and dominance of local pollinator communities (Aizen *et al.*, 2014; Morales *et al.*, 2017). Moreover, the indroduction of *Bombus terrestris* has facilitated the co-introduction of novel pathogens (Arbetman *et al.*, 2013; **section 3.3.5.1**).

Figure 3 10 **Growers can purchase bees in a box that will fly from flower to flower, distributing pollen among the plants.**

3.2.3.2 Trade in plants for horticulture, agriculture, ornamental use and nurseries

Globally, 67 per cent of alien terrestrial plants have been introduced intentionally through horticultural (46 per cent) or agricultural (21 per cent) pathways (Turbelin *et al.*, 2017). Ornamental use of plants is a dominant driver facilitating the introduction of invasive alien species that has also been increasing in recent years (Dodd *et al.*, 2015; Faulkner *et al.*, 2016; Hulme *et al.*, 2018; Lambdon *et al.*, 2008; Lehan *et al.*, 2013; Mayer *et al.*, 2017). Accordingly, there is an increasing rate of escapes from ornamental cultivation into the wild (Haeuser *et al.*, 2018; van Kleunen *et al.*, 2018), with at least 75 per cent of the global established alien flora grown in domestic gardens, and 95 per cent grown in botanical gardens (van Kleunen *et al.*, 2018). In some countries (e.g., United Kingdom, New Zealand) the number of species in cultivation exceed the number of native species in the wild (Armitage *et al.*, 2016; Gaddum, 1999; Hulme, 2020), and in some, such as the United States, alien species form the bulk of nursery stock (Brzuszek & Harkess, 2009). Unintentional introduction through seed contaminants associated with the intentional introduction of ornamental plants is regarded as the second most important source of invasive alien plants in the United States and has become increasingly important in recent years (Lehan *et al.*, 2013). Horticulture was also the primary pathway (**Glossary**) of alien introductions in Puerto Rico and the Virgin Islands (Rojas-Sandoval & Acevedo-Rodríguez, 2015). In the West Indies, 75 per cent of all invasive alien plants have escaped from cultivation, and 51 per cent of all introductions are through the ornamental pathway (Rojas-Sandoval *et al.*, 2017).

Ornamental and agricultural use is also a major source of aquatic plant invasions. In the People's Republic of China, more than 50 alien freshwater aquatic plants have been introduced for ornamental, landscaping, water purification, forage and other purposes, around 20 per cent of which are now considered invasive (Wu & Ding, 2019). In Europe and the Mediterranean region, large numbers of ornamental aquatic alien plants are unintentionally released from aquaria, dumped from water gardens, or escaping from managed environments, a number of which have become invasive (Brundu, 2015). Many ornamental aquatic alien species may become widely distributed, for example *Pontederia crassipes* (water hyacinth) which was introduced from South America to botanic gardens and ornamental ponds around the world from the nineteenth century onwards is now found across more than 50 countries on five continents (Sharma *et al.*, 2015; **section 3.5.2**, **Box 3.12**).

3.2.3.3 Trade in terrestrial pet animals

Pet trade is a major pathway of alien animal introductions (Hulme, 2015a). It is estimated that 70 per cent of households in the United States and 38 per cent of households in Europe have pets. In addition to the majority of dogs and cats, fishes, birds, small mammals and reptiles are commonly kept (Mazzamuto *et al.*, 2021). In Europe, a systematic review revealed invasive alien mammal introductions were primarily a result of escapes by pets (69 per cent) and from zoos (50 per cent) and fur farms (38 per cent), while far fewer arose from other agricultural species or biological control and none were reported as contaminants, stowaways or *via* corridors (Tedeschi *et al.*, 2021). Pet escapes and releases are major drivers facilitating vertebrate invasions (e.g., mammals in Brazil (da Rosa *et al.*, 2017) and amphibians and reptiles of the United States (Krysko *et al.*, 2016) and European Union (Hulme *et al.*, 2008; Katsanevakis *et al.*, 2013)).

Pets also have the potential to become important vectors for pathogens and microorganisms that cause disease in animals and humans, in particular pets derived from wild animals (Day, 2011). The spread of monkeypox to humans in the United States is thought to be due to contact with prairie dogs sold as pets (Brown, 2008) and pets are considered to have been important in the transmission of chytridiomycosis and ranaviral disease, which cause severe damage to amphibians (Schloegel *et al.*, 2012).

3.2.3.4 International travel for commerce and tourism

In 2019, there were approximately 1.5 billion international passenger arrivals associated with tourism, a five-fold increase in the number of travellers compared with 1980 (UNWTO, 2021). The continued expansion of the worldwide air transport network has facilitated this global movement of human passengers and, by increasingly linking regions of the world with similar climates, has facilitated the introduction of invasive alien species (Tatem, 2009). While some invasive alien species, particularly mosquitoes (Brown *et al.*, 2012), can be unintentionally transported in commercial passenger aircraft, the highest risk of introducing a wide range of alien species comes from the passengers. Passengers often intentionally transport fresh food items, untreated timber, or animal skin products, either for personal consumption or as gifts, which may carry alien species or alien pathogens as contaminants on the passengers themselves or in their luggage. In the United States, border inspections have found that more than half of all pests encountered were associated with traveller baggage rather than cargo (McCullough *et al.*, 2006). Although some international travellers attempt to intentionally smuggle live animals, plants and food products that could be themselves invasive alien species or harbour them as contaminants (Chown *et al.*, 2012; Soon & Manning, 2018), most international travellers are unaware of the risk they pose in unintentionally introducing stowaways. International travellers can also introduce stowaways on their clothing, footwear and equipment (e.g., tents, fishing tackle and golf clubs). A single gram of soil attached to footwear can harbour 5 million bacteria, 50,000 fungi, 3 seeds and 40 nematodes, and these taxa may often include potential invasive alien species (Hulme, 2015a). When these figures are multiplied up by the more than one billion international travellers worldwide (Glaesser *et al.*, 2017), the global movement of alien stowaways is substantial. Up to half of hikers sampled in mixed evergreen forest in California were found to be carrying *Phytophthora*

Box 3 4 International tourists and scientists visiting Antarctica.

Strong climatic and geographic barriers, attributes associated with low habitat invasibility, naturally isolate Antarctica from the rest of the world (Chwedorzewska *et al.*, 2020). Climate change and an increasing number of visitors (G. A. Duffy *et al.*, 2017; Greve *et al.*, 2017) have weakened these barriers, leading Antarctica to become an area of special concern for the management of biological invasions (**Chapter 6**, **Box 6.10**). An average of 9.5 seeds per visitor are carried to Antarctica every summer (Chown *et al.*, 2012). The highest risk of seed transportation is associated with science programs **(Figure 3.11)** and tourist support personnel rather than with the increasing tourist numbers (Chown *et al.*, 2012; Chwedorzewska *et al.*, 2020; Huiskes *et al.*, 2014). Between the summers of 2019 and 2020, about 74,400 tourists visited Antarctica and 18 nations had established over 50 research stations (Hughes *et al.*, 2020; IAATO, 2020). Alien plants and invertebrate species in Antarctica are found almost exclusively close to visitor sites and research stations (Molina-Montenegro *et al.*, 2012, 2014).

Figure 3 11 **Research stations in Antarctica increase the risk of biological invasions.**

The Australian Antarctic Division has 4 permanent research stations in Antarctica and the subantarctic. Photo credit: David Barringhaus/Australian Antarctic Division – Copyright.

The introduction, establishment and spread of *Poa annua* (annual meadowgrass) in different localities in Antarctica is well documented (Chwedorzewska *et al.*, 2015). *Poa annua*, an annual grass native to Europe and an invasive alien species in the Andes, has been observed in the vicinity of Arctowski Station on King George Island in Antarctica since 1985 (Chwedorzewska, 2008). In this site, *Poa annua* maintains a genetically diverse population, which has been attributed to intense human activity in the station facilitating multiple introductions from different source populations (Chwedorzewska, 2008). Fuentes-Lillo *et al.* (2017) found a connection between human activity and invasive alien plants in the Fildes Peninsula in King George Island. These authors found higher concentration of seeds in soil samples at sites with increased human activity (i.e., next to dormitories of logistics personnel). Six of the eight alien species recorded in soil samples were also found in King George Island; *Taraxacum officinale* (dandelion) and *Poa annua* have been the most successful colonising alien species in these ecosystems (Fuentes-Lillo *et al.*, 2017).

ramorum, the causal agent of sudden oak death, in soil on their shoes (Davidson *et al.*, 2005). It also appears that tourists visiting caves may be responsible for spreading *Pseudogymnoascus destructans* (white-nose syndrome fungus) in bats (Puechmaille *et al.*, 2011). Similarly, tourists are known to spread weed seeds into national parks (Pickering & Mount, 2010).

The motives and Interests of tourists are also changing with increasing interest in recreational activities (e.g., golf, fishing), agritourism (e.g., winery visits), visits (including camping) to national parks and reserves (Hulme, 2015a). This change in behaviour poses an increased risk of introductions into areas that may not yet been exposed to invasive alien species. The number of passengers embarking on world and extended length cruises is doubling every decade (Klein, 2011) and has permitted access to coastal areas previously exposed to low numbers of visitors. Since 1990, international visitor numbers to the Antarctic continent have increased almost 10-fold (Hulme *et al.*, 2012) and up to half of tourists and visiting scientists unintentionally bring with them seeds of alien plant species which could pose a considerable risk of establishing in the region (Huiskes *et al.*, 2014). Much of this risk is not simply from the tourists themselves but the support crews **(Box 3.4)**. Similar risks are found in the Arctic where people and their luggage are responsible for around 5 per cent of all alien plant introductions (Wasowicz *et al.*, 2020). While the number of international passenger arrivals world-wide has more than doubled since 1990, it is in emerging economies in Africa, Asia and South America where the rate of growth of passenger arrivals has been highest and these regions may be less well prepared to face new risks from invasive alien species (Glaesser *et al.*, 2017). With forecasts of global tourist numbers reaching 1.8 billion international travellers in 2030, combined with new destinations previously less exposed to invasive alien species and more activities in less visited areas, the future risk of introducing invasive alien species appears significant (Hulme, 2015a).

3.2.3.5 Externalities of negative impacts and cost

The introduction of invasive alien species is usually an unintended or intended consequence of economic activities that not only brings species into areas where they were not present, but also affects the frequency of repeated introductions and the spread of established alien species (Touza *et al.*, 2007; **section 3.2.3**). However, control is difficult because those whose actions result in the introduction of invasive alien species are rarely those affected, and they are often not held accountable for their actions (Perrings *et al.*, 2005; Tollington *et al.*, 2017; **section 3.2.1**). For example, in trade of plants and animals, the prices paid by the importer to the exporter include production and transport costs, but usually do not include the costs incurred when animals or plants become invasive. Alien species that lead to improved quality of life and economic benefits are considered public goods, especially in cases where awareness of the impacts of invasive alien species is limited. In addition, the characteristics of public goods, such as “non-rival” and “non-excludable”, create incentives to free-ride and further increase market inefficiency (Marbuah *et al.*, 2014; Touza *et al.*, 2008). These activities of economic agents that affect others without going directly through the market are called “externalitie” (**Glossary**), and externalities that negatively affect other agents are called “negative externalitie” (**Chapter 6**, **section 6.2.1(6)**). The damages and management costs incurred by biological invasions are a typical case of negative externalities arising from economic actions, and for many of the examples listed under **sections 3.2.1**, **3.2.2.3** and **3.2.3.2**, negative externalities are an important explanation for why high rates of invasions are being sustained (**Chapter 2**) despite known negative impacts on nature, nature’s contributions to people and good quality of life (**Chapter 4**).

Internalization of externalities can be a powerful driver to prevent the introduction of invasive alien species (**Chapter 6**, **section 6.2.1.(6)**). But the current situation of leaving externalities unattended without recognizing their existence is a driving force for the introduction of invasive alien species that underlies many social, economic and demographic drivers.

3.2.3.6 Wealth, inequality and poverty

Are invasive alien species primarily a problem of wealthy countries? National GDP has been a frequent metric used to explain variation in the number of alien species among different countries, with countries having a higher GDP being more invaded (Essl *et al.*, 2011; Hulme, 2021b; Seebens *et al.*, 2017). This positive relationship between GDP and the number of alien species in a country appears to hold both across global and regional scales as well as for quite different taxa including fish, mammals, birds, plants and agricultural pathogens (**Chapter 2**, **section 2.1**). Such trends may be indicative that countries with higher levels of consumption tend to facilitate the introduction and establishment of alien species. However, the current number of alien species in a country is the result of a cumulative process where alien species have accumulated over several centuries (**Chapter 2**). Hence, research has shown that historical levels of GDP might be a better predictor of the number of alien species found in a country than the current GDP (Essl *et al.*, 2011). This illustrates that GDP is a flow and that the best measure of a process that, in many countries, has deep historical roots, is the stock of wealth in any country. This wealth measure is the cumulative effect of past investments, and accounts for the assets such as natural capital, produced capital, and human capital that underpin growth and consumption possibilities (Perrings, 2010). Few studies have examined the role of wealth on numbers of invasive alien species, but where it has been examined it has been found to explain a small but significant amount of variation in the numbers of alien species in Europe (Pyšek *et al.*, 2010). Since the wealth of a country is a more important determinant of numbers of alien species than the contemporary GDP, the cumulative build-up of assets which support greater consumption may lead to more immediate increases in numbers of alien species than rapid changes in GDP.

The current combined gross national income of all countries in the world is estimated to be over US$94 trillion, with 10 countries accounting for 68 per cent of this amount (IMF, 2021). The distribution of this wealth is also often highly uneven within countries, so that the 10 per cent richest individuals concentrate 52 per cent of the world income, whereas 50 per cent of the global population accounts for only 8.5 per cent (Chancel *et al.*, 2022). Poverty and marginalization created by economic inequality within and among countries may indirectly drive the introduction, establishment and spread of invasive alien species. For those countries with a lower level of wealth, the warning signs suggest that as the economies grow and build a larger asset base, the risk of alien species introductions might also increase. This risk may be further exacerbated where the route to economic growth and poverty reduction encourages the development of economic sectors based around alien species (**sections 3.2.2.3**, **3.2.3.6**, **3.2.5**, **3.3.1.1**). For example, the invasive alien tree *Prosopis juliflora* (mesquite) was intentionally introduced in many eastern Africa countries to improve the livelihood of communities with very low income subjected to malnutrition and food shortages, as it may be a reliable source of firewood and animal fodder in arid regions (Pasiecznik *et al.*, 2007; **section 3.2.5**, **Box 3.6**); however, the species have become highly dominant in many regions, thus decreasing biodiversity and threatening the water supply (Pasiecznik *et al.*, 2007; **Chapter 4**, **boxes 4.8** and **4.9**). Invasive alien species are also important for the subsistence and income of certain low income communities in South Africa, including the invasive cactus *Opuntia ficus-indica* (prickly pear) in the Eastern Cape Province and multiple alien species cultivated in urban gardens in the Limpopo province (e.g., the invasive tree *Schinus terebinthifolius* (Brazilian pepper tree)). In many cases, it is not clear how the cultivation of these invasive alien species has contributed to their spread (Mdweshu & Maroyi, 2020; Mosina *et al.*, 2015). Some Indigenous Peoples and local communities can also be more inclined to use alien plants if they experience a loss of traditional medicine knowledge and a loss of historically used medicinal plants (IPBES, 2020). In rural Mexico, there are economic incentives to farm the invasive alien fish *Oreochromis* spp. (tilapia) which has been viewed as having a positive impact as a route out of poverty (Martinez-Cordero & Sanchez-Zazueta, 2022). However, there are examples showing that using alien species to promote economic growth may lead to more poverty and inequality, such as the use of *Lates niloticus* (Nile perch), which was introduced into many African lakes (Kelly, 2018; see **section 3.2.5, 3.3.2.1**). In the Lake Victoria basin, the invasion of the Nile perch nearly exterminated native fish populations, and local communities were ultimately forced to shift from traditional fishing, which ensured their subsistence, to catching the invasive alien perch. Nile perch fishing supplies external markets and provides minimum income to households, thus leading to more poverty, malnutrition and lower quality of life (Geheb *et al.*, 2008; **Chapter 4**, **Boxes 4.8** and **4.9**).

3.2.4 Science and technology

While science and technology are major factors underpinning demographic and economic changes, science and technology can also act as indirect drivers of change in nature affecting invasive alien species **(Figure 3.12)**. This section focuses on how research activities (**section 3.2.4.1**), the rise and spread of communication technology (**section 3.2.4.2**), and breeding and genome technologies (**section 3.2.4.3**) can facilitate the transport, introduction, establishment and spread of invasive alien species. Science and technology may interact with economic drivers through the role of information technology in supporting international trade in invasive alien species (**section 3.2.3.1**), and with biological invasions *via* unintended consequences of introducing and/or controlling invasive alien species themselves (**section 3.3.5**). Section 3.2.4 describes evidence for links between specific science and technology drivers and invasive alien species, and makes reference to other indirect and direct drivers when relevant, whereas the specific contribution of science and technology to controlling invasive alien species is dealt with in **Chapter 5**, **section 5.4.4**.

3.2.4.1 Research

Scientific research can involve the transport, rearing, storing, manipulation and experimental release (either under controlled conditions or outdoors) of living organisms. While most evidence to date points to scientific research and related activities as important drivers in the stages of transportation and introduction of invasive alien species, there is a paucity of evidence on their role in establishment and spread.

There are a number of documented examples of use of organisms outside of their native ranges for laboratory research which have resulted in biological invasions. For instance, *Xenopus laevis* (African clawed frog) is the most studied amphibian worldwide and one of the best model organisms for studies in cell, molecular and developmental

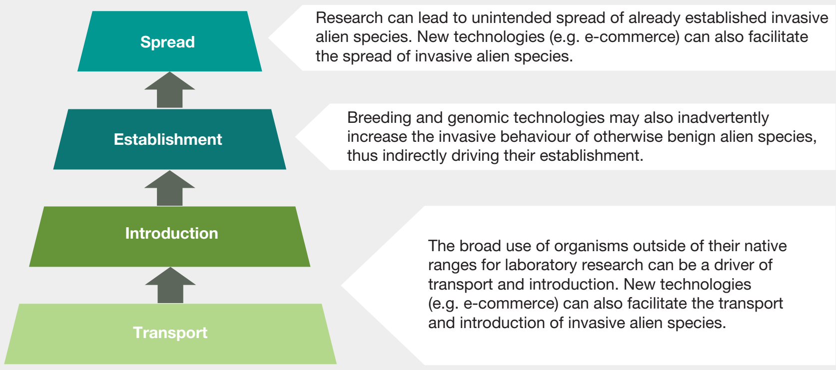

Figure 3 12 **Examples of the role of science and technology in facilitating invasive alien species across stages of the biological invasion process.**

Science and technology can facilitate the transport and spread of invasive alien species *via* their specific use in research and their trade through e-commerce. Breeding and genome technologies may select for traits that increase invasiveness, and research and e-commerce can also facilitate further spread of invasive alien species.

biology. *Xenopus laevis* has been continuously introduced for the past 50 years, and intentionally released in Europe, Asia and North and South America and is likely responsible for the spread of the chytrid fungus of the genus *Batrachochytrium* (Fisher & Garner, 2007, 2020; Weldon *et al.*, 2004). Agronomic research has also led to the introduction of wild relatives of crops outside their ranges. For instance, populations of *Solanum chacoense* (Chaco potato), a wild relative of *Solanum tuberosum* (potato), has established close to research centres where the species was most certainly introduced as part of breeding programs in Australia, China, New Zealand, United States and Argentina (Simon *et al.*, 2010). Unintentional or intentional releases from aquaria have been listed among the major sources of invasive alien invertebrates and fishes in estuaries and rivers (Englund, 2002), and escapes of plant propagules or seeds from botanic gardens is also responsible for some major plant invasions **(Box 3.5)**. In addition, unintentional releases from experimental farms conducting agricultural research (**section 3.3.1.1.4**) are major sources of some of the established populations of highly invasive mammals and birds including *Mustela vison* (American mink), *Myocastor coypus* (coypu), *Ondatra zibethicus* (muskrat), *Nyctereutes procyonoides* (raccoon dog), *Procyon lotor* (raccoon), *Threskiornis aethiopicus* (sacred ibis) and *Oxyura jamaicensis* (ruddy duck) (Barrat *et al.*, 2010).

Devices, sampling gear and equipment used in research activities within natural habitats may act as vectors of invasive alien species. For instance, barnacles frequently attach to the leg-rings used to identify individual wading birds by ornithologists and can be transported long distances along bird migratory routes, "hitch-hiking" with their host birds. Since more than 30 living barnacles can attach to a single ring, this can lead to substantial transportation and introductions to new areas (Tøttrup *et al.*, 2010). More recently, the use of submersible assets, like remote-operated vehicles and human-occupied vehicles, open a novel potential pathway through which scientific research can aid the transport of invasive alien species. In particular, the use of remote-operated vehicles has expanded the reach of human influence to regions where humans themselves cannot access. These high-technology vectors have a tremendous potential to increase transport of invasive alien species in marine ecosystems (Thaler *et al.*, 2015), as illustrated by the transport and potential introduction of living limpets from deep-sea hydrothermal vents to other distant vents (Voight *et al.*, 2012).

3.2.4.2 Development of communication technology

The development of communication technology is an important driving force for the globalization of markets. As of 2021, 63 per cent of the world population (i.e., 4.9 billion people) had internet access, an almost five-times increase compared with 2005, and 95 per cent was covered by broadband mobile network (i.e., 3G and over; International Telecommunication Union, 2021). New distribution channels such as internet trading (e-commerce) have caused significant changes in the movement of organisms. In e-commerce trading surveys, between 30 and 80 per cent of recognized invasive alien plant species were detected on auction sites daily, making it possible to obtain invasive alien plants from almost anywhere in the world (Humair *et al.*, 2015). Due to the difficulty in tracing the contents of express mail, and the increasing volume of trade through this route, the current biosecurity (**Glossary**) system cannot

Box 3 5 **The role of botanic gardens in the introduction of invasive alien plants.**

Botanic gardens **(Figure 3.13)** have made a significant contribution to the collection, cultivation and distribution of plant species for research and scientific uses worldwide (Sharrock, 2011) but have also been implicated in the introduction, early cultivation and/or local spread of invasive alien plant species into global biodiversity hotspots (Hulme, 2011a). Studies exploring the global increase of alien plant species have identified the establishment of botanic gardens as an important driver facilitating biological invasions (Seebens *et al.*, 2017). The global emergence of new alien plant species, defined as the first record of an alien species anywhere in the world, has been found to be related to the number of botanic gardens established in a region (Seebens *et al.*, 2018). A study from China examined the association between the first record of an invasive alien species in a region and multiple possible explanatory factors, including botanic gardens (Ni & Hulme, 2021). The researchers found that botanic gardens, including their history and number of species in living collections, generally play more important roles in influencing the number of first records of invasive alien plants compared to socioeconomic variables (such as Gross Domestic Product) and environmental factors (such as climate). However, invasive alien species primarily introduced for horticultural uses were more influenced by botanic gardens, while those introduced for agricultural uses were more strongly associated with climate variables, and the numbers of species introduced unintentionally were shaped by trade (**sections 3.2.1**, **3.2.3.1** to **3.2.3.4**, **3.3.1.4**). This research is the strongest evidence to date pointing to the role botanic gardens may play in the invasions of ornamental plant species. Despite signing up to the Global Strategy for Plant Conservation, most botanic gardens rarely implement regional codes of conduct to prevent plant invasions, few have a policy for biological invasions, and there is limited monitoring (**Glossary**) of garden escapes (Hulme, 2015b). Given the rapid increase in living collections, especially in Asia, this suggests botanic gardens may become increasingly important for the introduction of alien species in the future.

Figure 3 13 **Botanical gardens facilitate the introduction of invasive alien species.**

The China National Botanical Garden cultivate 6,000 species of plant, including 2,000 kinds of trees and bushes, 1,620 varieties of tropical and subtropical plants, 500 species of flowers and 1,900 kinds of fruit trees several of which are believed to have escaped and become established. Photo credit: Top Photo Corporation, Shutterstock – Copyright.

adequately manage internet trade (Humair *et al.*, 2015). In e-commerce, invasive alien plants are traded over longer distances than traditional commerce in plants, where people visited horticultural nurseries to make their purchases. In particular, seeds of invasive alien plants were transported further than saplings of alien plants (Lenda *et al.*, 2014). In the aquatic alien plant trade, a variety of invasive or import prohibited plants were sold online, and the traders lack knowledge about species identification and regulation. This is also the case for the trade in freshwater aquatic plants for aquaria in Brazil, where unregulated e-commerce has stimulated illegal trade and contributed to the introduction and spread of invasive alien macrophytes (Peres *et al.*, 2018). In the internet trading of ornamental marine life, unregulated e-commerce has contributed to the introduction and spread of invasive alien macroalgae in Europe, North America and Australia (Walters *et al.*, 2006). Many wholesalers and retailers lack awareness of the potential risks of ornamental marine species (Morrisey *et al.*, 2011). Online trading of freshwater invasive alien crayfish as pets is prevalent and has become a major route of biological invasions of crayfish and their contaminants and stowaways in many parts of the world (Chucholl, 2013; Faulkes, 2010, 2015; Papavlasopoulou *et al.*, 2014). E-commerce and social media also have supported an extensive world trade network of alien ornamental freshwater fishes, where customers often also have little knowledge of the risks of releasing these invasive alien species in the wild (Magalhães & Jacobi, 2010; Mazza *et al.*, 2015).

3.2.4.3 Breeding and genomic technologies

The modification of phenotypic traits to increase biomass, growth, and resistance to pests, diseases and stressors, etc., can increase the invasion potential of species that otherwise would not be invasive (e.g., Flory *et al.*, 2012 and references therein). Plant and animal traits that have traditionally been modified through breeding, selection and hybridization can now be more effectively modified *via* genomic technologies. The application of these techniques to crop and stock species has catalysed debates over the invasive potential of these “novel taxa” and how to adapt invasive alien species risks assessments and biosafety measures to deal with them (Hoenicka & Fladung, 2006; Luke Flory *et al.*, 2012; Quinn *et al.*, 2015; **Chapter 5**, **section 5.4.4.2**).

Studies suggest that risks posed by novel taxa are often inevitable and can vary spatially, temporally and according to the type of organism and the purpose of the trait selection process (Ellstrand *et al.*, 2013). There is good evidence that traditional breeding of plant species native to other regions for ornamental purposes has increased their invasive potential in North America (Ross *et al.*, 2008; Wilson & Mecca, 2003). For example, cultivars of the ornamental Asian shrub *Ardisia crenata* (coral berry) artificially selected for dense foliage show higher competitive ability and seedling recruitment success than native populations, which likely favours their dominance in the understory of mesic forests in Florida (Kitajima *et al.*, 2006). The ornamental clonal herb *Kalanchoe × houghtonii* (Houghton’s hybrid), which is an artificial hybrid obtained from the crossing of two species endemic to Madagascar (*Kalanchoe daigremontiana* (devil’s backbone) and *Kalanchoe delagoensis* (chandelier plant)) that exhibits a highly effective clonal growth which possibly has contributed to its wide distribution and local dominance in tropical arid and semi-arid ecosystems (Guerra-García *et al.*, 2015; Herrando-Moraira *et al.*, 2020). There is concern that the invasive potential of some pasture grasses has increased as a result of intensive artificial selection, which has used multiple tools (e.g., ploidy manipulation and introduction of endophytes) to maximize grass productivity under the specific conditions of each region of interest (Driscoll *et al.*, 2014). Transgenes for herbicide resistance present in the genetically modified *Agrostis stolonifera* (creeping bentgrass) used as lawn grass were found in wild *Agrostis* populations, suggesting that the resulting novel genotypes may be persistent and possibly favour these genetically modified organisms outside cultivation (Reichman *et al.*, 2006). Similar or even higher risks may apply to the selection of bioenergy crops (Richardson & Blanchard, 2011); for example, selection for fertility in the highly productive *Miscanthus × longiberbis* (giant miscanthus cultivar) led to a high increase in its potential to escape cultivation (Smith *et al.*, 2015). Among invasive alien trees, selection for high timber and forage production may have indirectly increased the invasion potential of a cultivar of the tropical tree *Leucaena leucocephala* subsp. *glabrata* (white leadtree) in certain areas in Northeast Australia (C. S. Walton, 2003). Similarly, provenance forestry trials and common garden experiments designed to select the seed sources of alien pine species most likely to succeed under distinct conditions in the introduced range possibly contributed to the high invasion success of some of these species in South America (Zenni, 2014; Zenni *et al.*, 2017).

There is evidence that human selection of specific behaviours in the hybrid fish *Xiphophorus hellerii × maculatus* (red swordtail) contributed to the emergence of established invasive alien populations in Hawaii, with a behaviour syndrome characterized by high aggression and exploration (D’Amore *et al.*, 2019). Among invertebrates, the artificial hybrid between European and East African honeybee species shows superior pollen extraction ability and higher swarming rate (i.e., the process of colony splitting to generate new colonies) than the European species (Pesante *et al.*, 1987), which may have contributed to its spread in the Americas to the detriment of native pollinators (Santos *et al.*, 2012).

Cultivating genetically modified crops may also indirectly favour the spread of invasive alien pests and pathogens; for example, the invasive tomato moth, *Tuta absoluta* (tomato leafminer), has been found to establish and spread rapidly in farms planted with genetically modified tomato cultivars, whereas traditionally bred cultivars have been shown to be resistant to this pest (Rakha *et al.*, 2017). As an example of how artificial selection may indirectly favour vertebrate invasions, intensive artificial selection has increased the fecundity of domestic pigs, so that hybridization and admixture between populations of domesticated pigs and wild boar have been associated with feral swine genotypes with higher fitness and hence more likely to establish and spread in natural ecosystems beyond the species' range in Europe (Canu *et al.*, 2018; Fulgione *et al.*, 2016; Goedbloed *et al.*, 2013), North America (Smyser *et al.*, 2020) and South America (de Oliveira *et al.*, 2018).

3.2.5 Policies, governance and institutions

Policies, governance and institutions underlie most direct and other indirect drivers of change in nature in complex ways. For example, economic drivers (**section 3.2.3**) are strongly linked to policy and institutional drivers, which govern production through regulations, taxes and subsidies, and affect terrestrial, aquatic and marine bioproduction systems, which in turn facilitate biological invasions (**section 3.3.1**). A common thread running through many of these systems is that policies, governance and institutions are focussed on the economic and production systems, with consequences for biological invasions receiving little attention. These unintended consequences are the focus of this section, which deals with regulations, taxes and subsidies that may result in unintended facilitation of the introduction, establishment and spread of invasive alien species (**Figure 3.14)**. The role of policies and institutions explicitly tasked with the control of invasive alien species and management of biological invasions are addressed in **Chapter 6**.

In an era of globalization and increasing interconnectedness between people, states and regions, there is an increasing reliance on supranational arrangements for the organization of human societies, referred to as international institutions and organizations. The annual amount of international official assistance for development has increased from less than US$80 billion in 2000 to over US$127 billion in 2010, particularly as a result of increasing bilateral disbursements to low-income countries (World Bank & International Monetary Fund, 2012). By providing the regulatory frameworks for transboundary activities, international institutions and organizations may act as indirect drivers facilitating the uptake, transportation, establishment and spread of invasive alien species, due to promotion of other indirect demographic and economic drivers of change in nature such as migration (**section 3.2.2.2**), trade (**section 3.2.3.1** to **3.2.3.3**) and human travel (**section 3.2.3.4**). In addition, international institutions and organizations may also influence direct drivers of change in nature, including the deployment of infrastructure (**section 3.3.1.4**), introductions from agriculture, forestry, fisheries and aquaculture (**sections 3.2.3.2**; **3.2.3.3** and **3.3.1.1**), and multilateral measures against climate change which may again facilitate invasive alien species. Moreover, international agreements and supranational decisions may scale down to national governance, an indirect driver of change which may facilitate invasive alien species (**section 3.2.5**). Although the role of governance in facilitating invasive alien species has been occasionally evaluated (Evans *et al.*, 2018), with a few exceptions (Mwangi & Swallow, 2008; Pérez *et al.*, 2003), there is a paucity of studies specifically addressing the role of international organizations and institutions in managing biological invasions. While it is hard to draw overall geographical patterns because of the global scale of this driver, its influence is expected to be global. This section illustrates the issue of international institutions and organizations acting as an indirect driver promoting invasive alien species by facilitating different stages of the biological invasion process.

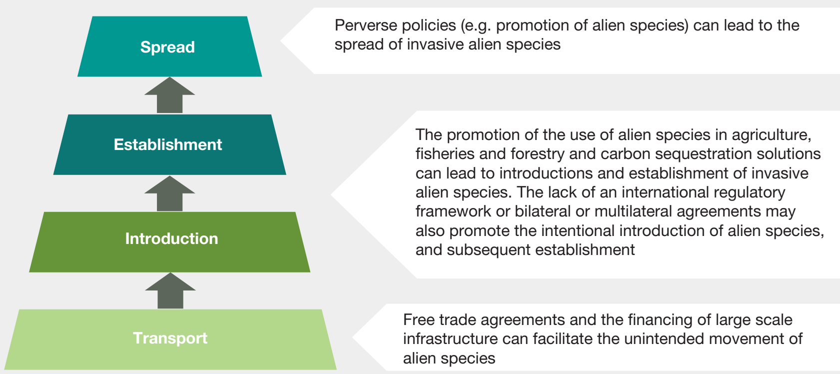

Figure 3 14 **Examples of the role of policies, governance and institutions in facilitating invasive alien species across stages of the invasion process.**

Free trade agreements, finance, promotion of species for use in agriculture, fisheries or forestry outside their native range, lack of regulatory frameworks and unintended consequences (active promotion of invasive alien species for other benefits, without consideration of risks) are some examples of drivers of changes in nature facilitating invasive alien species across invasion stages.

International funding agencies for economic development and regional integration may indirectly influence the uptake, and transport of invasive alien species by financing large scale infrastructure that facilitates the unintended movement of alien species (e.g., navigation channels and tunnels; Hulme, 2015b). In addition, international funding agencies may facilitate the introduction, release, and establishment of invasive alien species by actively promoting the use of alien species in agriculture, fisheries and forestry and carbon sequestration solutions (**sections 3.2.3.2**; **3.3.1.1**). An emblematic example is the promotion of the highly invasive leguminous tree *Prosopis juliflora* (mesquite; **section 3.2.3.6**; **Box 3.6**) from Central and South America into many arid and semi-arid regions of the world. Similarly, *Pontederia crassipes* (water hyacinth) has been promoted by international aid agencies in Africa for biomass production (**section 3.5.2**, **Box 3.12**). Its spread rapidly affected water flow regimes, impeding hydroelectric power production, water quality and fisheries (Batanouny & El-Fiky, 1984). In Vanuatu, the Central American woody species *Cordia alliodora* (Ecuador laurel) introduced to promote timber production, invaded native ecosystems and ultimately turned out to be unsuitable for timber production in that climate (Tolfts, 1997). Alien plants were introduced in many countries for economic development, including Tonga (Space & Flynn, 2001). *Lates niloticus* (Nile perch; **Chapter 4**, **Box 4.10**) is a notable example of an invasive alien species arising from aid-related fish introductions. This species was first introduced into Lake Victoria, East Africa, in the mid-1950s to supplement dwindling fish stocks. The population took 20 years to build up, but the Nile perch has since had a substantial impact on the ecological balance of the lake (Ogutu-Ohwayo, 1998), and is implicated in the extinction of more than 200 endemic fish species (Lowe *et al.*, 2000). Lake Victoria has been described as a major evolutionary and ecological disaster caused by the release of an invasive alien species, although the relative contributions and cause-effect relations between invasive alien species and other concurrent drivers of change in nature have been hotly debated (Marshall, 2018; van Zwieten *et al.*, 2015; **Chapter 4**, **Box 4.10**). More generally, international aid and assistance programmes have actively promoted the use of farmed plants, fish and animals in new regions, many of which are invasive and/or are hosts of other invasive alien species (**sections 3.2.2.3**; **3.3.1.1**).

Free trade agreements, being treaties between two or more countries or states to facilitate trade and eliminate trade barriers, increase the flux of goods between regions and may facilitate the uptake and transportation of invasive alien species, either as subject of commerce (when traded goods are living organisms), or more frequently as by-product of transport (e.g., unintentional introductions in ballast water, as stowaways in packaging and cargo, or as contamination of crop products with agricultural pests). Furthermore, the World Trade Organisation (WTO) in an attempt to prevent quarantine laws becoming trade barriers has discouraged nations from using quarantine laws to stop the spread of invasive alien species (Riley, 2005), illustrating the challenge of addressing national policies that drive biological invasions to account for the transboundary aspect of biological invasions (Hulme, 2015a).

More recently, as economic multilateral instruments have been developed to tackle climate change, taxes based on carbon and carbon-trading markets (e.g., Reducing Emissions from Deforestation and forest Degradation (REDD+)) have been implemented under the international governance framework of the Kyoto Protocol (United Nations, 1997). Such initiatives are a possible driver for the establishment and spread of invasive alien species, such as fast-growing trees from large-scale plantations for carbon

Box 3 6 National and international policies resulting in the introduction and spread of *Prosopis juliflora* (mesquite), as reported by Indigenous Peoples and local communities.

In Botswana, Ethiopia, India, Jordan and Kenya, Indigenous Peoples and local communities have reported the intentional introduction of *Prosopis juliflora* (mesquite) by governments and associated international programs with the aim of halting land degradation, controlling desertification and deforestation and improving the good quality of life of the local communities (Al-Assaf *et al.*, 2020; Becker *et al.*, 2016; Haregeweyn *et al.*, 2013; Linders *et al.*, 2020). In Kenya for instance, the Chamus pastoralists report that *Prosopis juliflora* was introduced twice: first in 1973 through a government initiative; and 10 years later, through the Fuelwood Afforestation Extension Project, a joint initiative from the Food and Agricultural Organization (FAO) and the Government of Kenya (Becker *et al.*, 2016). In Ethiopia, the Afar recall that the species was introduced in the 1980s in state farms and settlements to improve the microclimate, provide shade, halt land degradation, provide fuel wood, as a source of pods for fodder, and to increase sustainability of livelihoods in the Afar region of Ethiopia (Linders *et al.*, 2020). In India, Indigenous Peoples and local communities report that *Prosopis juliflora* was introduced to ameliorate saline soils, and as a source of timber, fuelwood and fibre in the latter half of nineteenth century; and that the species was later promoted by the government from the 1970s onward to combat desertification and soil salinization in North-West India (Duenn *et al.*, 2017).

sequestration (Dickie *et al.*, 2014; Lindenmayer *et al.*, 2012). In fact, a global survey of 226 carbon projects shows that 6 per cent use predominantly alien species and 18 per cent use a mixture of native and alien species (Lindenmayer *et al.*, 2012). Dickie *et al.* (2014) list *Acacia*, *Casuarina* (beefwood), *Eucalyptus, Falcataria* (peacocksplume), *Pinus* (pine) and *Pseudotsuga* (douglas-fir) as major invasive alien genera commonly used for carbon sequestration (**section 3.3.1.1.2**). Similarly, recommendations to introduce alien tree species into British native woodlands as part of adaptive management (**Glossary**) strategies to mitigate rapid climate change, and the potential impacts of associated pests and diseases, will increase the risk of biological invasions as well (Ennos *et al.*, 2019). Overall, although the role of international organizations as indirect drivers facilitating biological invasions has largely been neglected, the evidence to date suggest they may play a role in transport and introduction (*via* trade and infrastructure, see **section 3.2.3.1**) and release and establishment (*via* agriculture, forestry and aquaculture, see **section 3.3.1.1**), which deserves further attention.

Furthermore, international and national programs targeted at biological control of existing pests have resulted in the widespread introduction of invasive alien species. Since 1955, *Euglandina rosea* (rosy predator snail) has been introduced to at least 27 island groups and continental countries, including many Pacific islands, in most cases with the aim of controlling the invasive *Lissachatina fulica* (giant African land snail). The effects in terms of control of the African snail have been limited, but these releases have been catastrophic to many native species; *Euglandina rosea* has caused the extinction of 134 land snail species and the declines of many more species (Gerlach *et al.*, 2021). The introduction of *Gambusia affinis* (western mosquitofish) and *Gambusia holbrooki* (eastern mosquitofish) in most temperate and tropical countries as biological control agents for mosquitoes started in the early 1990s and continues to date. These species are now the most widespread fish in the world, recorded in six continents. Mosquito fish have strong negative effects on freshwater ecosystems and on native fish through predation on juveniles and eggs and/or through competition with species with similar ecological niches (W. E. Walton *et al.*, 2012).

Indigenous Peoples and local communities have also reported that national policies limiting land tenure and access rights can be significant drivers of invasive alien species on their lands (IPBES, 2022b). Indigenous Peoples and local communities will often monitor and manage the numbers of invasive alien species and their impacts on their lands and waters (**Chapter 5**), but their ability to do this is greatly reduced if they do not have access or clear ownership of the lands and waters. Access is indeed crucial for monitoring and management, and land tenure can be essential for communities to actively manage their environments. Moreover, many Indigenous Peoples and local communities actively defend their lands from encroachment by industry and other disruptive influences that can also be drivers for invasive alien species (e.g., deforestation; **section 3.3.1**). Lack of clear land tenure or access rights can also prevent Indigenous Peoples and local communities from effectively defending their lands against this environmental degradation, which can in turn lead to an increase in invasive alien species. Indigenous Peoples and local communities have also noted that lack of access to lands and waters and lack of land tenure can lead to communities leaving.

3.3 THE ROLE OF DIRECT DRIVERS OF CHANGE IN NATURE, NATURAL DRIVERS AND BIODIVERSITY LOSS ON INVASIVE ALIEN SPECIES

This section examines five classes of direct drivers of change in nature that together encompass major human influences on the distribution and abundance of invasive alien species **(Table 3.1)**. The definition and classes of drivers are sourced from the IPBES Global Assessment (IPBES, 2019) but adapted for the purposes of invasive alien species by selecting drivers of relevance for biological invasions. This section thus considers land- and sea-use changes, including farming, fishing, logging (**section 3.3.1**); direct exploitation of natural resources, such as mining and species harvesting (**section 3.3.2**); pollution, including both aerial, soluble and solid waste, with a focus on eutrophication and marine debris (**section 3.3.3**); climate change, including both long-term trends and climatic variability, as well as CO_2 fertilization, changes in climate-related extremes and sea level rise (**section 3.3.4**), and the role of invasive alien species and the management of biological invasions, through biotic facilitation and biological control (**section 3.3.5**). Each subsection first assesses the overall trends in and influence of the driver on invasive alien species, including interlinkages with other drivers, and then, where data allow, notes the specific effects of the drivers on particular biomes, taxonomic groups and units of analysis.

3.3.1 Land- and sea-use change

Land-use change is the major driver of change in nature causing loss of biodiversity and natural habitats globally, affecting close to 75 per cent of ice-free land areas (IPBES, 2019). Agriculture and forestry are major causes of land-use change, for example, global crop production has increased by about 300 per cent since 1970, with crops now occupying half of the habitable land on Earth (IPBES, 2019). Much of the information available for sea-use change is within the context of climate change and specifically changes in physical and biogeochemical properties of the ocean in response to climate warming (IPCC, 2019). However, degradation and loss of natural habitats can occur with many sea-uses, including mining and mineral extraction, coastal developments, land reclamation, wind energy and recreational aquaculture (Vrees, 2021). Some of these sea-uses are anticipated to remain at a constant level but increases are forecast for others. For example in the North Sea, surface mineral extraction, water sport recreation, wind farms and possibly mariculture are all projected to increase (Vrees, 2021). Land- and sea-use change stem from major economic (**section 3.2.3**) and demographic (**section 3.2.2**) indirect drivers.

According to some Indigenous Peoples and local communities, land- and sea-use change is the main driver affecting the establishment and spread of invasive alien species on their lands and seas (**section 3.6.2**, **Box 6.13**). A recent review of native and invasive alien plant, vertebrate and invertebrate biodiversity on islands revealed that number and abundance of alien species are generally higher in areas affected by land-use (plantation forests, agricultural or urban sites) as compared to native habitat (794 alien taxa assessed), whereas the opposite is the case for native biodiversity (5517 native taxa assessed; Sánchez-Ortiz *et al.*, 2020). Habitat fragmentation and agricultural intensification were found to be the most commonly studied drivers facilitating plant invasions in a review by Vilà & Ibáñez (2011), with few studies focusing on the roles of habitat loss, land abandonment and afforestation. Land-use changes, in particular agricultural practices, are an important driver facilitating the spread of fungal and bacterial plant pathogens (Anderson *et al.*, 2004). Studies on alien pathogens tend to highlight their role within agricultural, horticultural or forestry systems, however, with less focus on spread to native systems (Anderson *et al.*, 2004; Panzavolta *et al.*, 2021).

Land- and sea-use change can affect invasive alien species in two main ways, firstly, by directly increasing the rate of introduction of alien species (**section 3.3.1.1**), either intentionally (e.g., through the specific use of alien crops and livestock), or unintentionally (e.g., as contaminants of agricultural or aquacultural commodities). Secondly, a variety of land- and sea-use change related processes increase the vulnerability of native ecosystems to invasive alien species (Vilà & Ibáñez, 2011), including habitat fragmentation (**section 3.3.1.2**), establishment of corridors of disturbed habitat through which alien species can spread (**section 3.3.1.3**), deployment of infrastructure (**section 3.3.1.4**), altering disturbance regimes (**section 3.3.1.5**), or other forms of anthropogenic landscape degradation (**section 3.3.1.6**). **Section 3.3.1** thus describes evidence for links between specific land- and sea-use change drivers and invasive alien species **(Figure 3.15)**, and makes reference made to other indirect and direct drivers when relevant. The demographic and economic indirect drivers behind these land- and sea-use change are described in **section 3.2**.

3.3.1.1 Intentional or unintentional introductions from the use of alien species in terrestrial and marine bioproduction systems

Industries based around the growth and harvest of biological resources, including agriculture, aquaculture, forestry, biofuel and carbon sequestration, forage production and

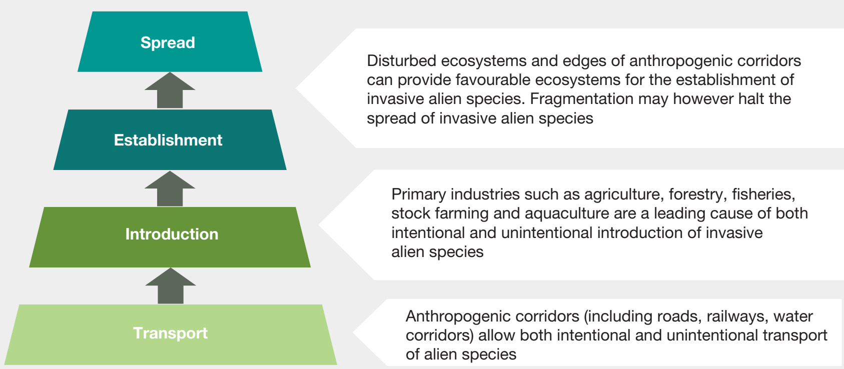

Figure 3 15 **Examples of the role of land- and sea-use change in facilitating invasive alien species across stages of the biological invasion process.**

Anthropogenic corridors can facilitate both the intentional and unintentional transport of invasive alien species, primary industries can facilitate their introduction, and disturbance can facilitate their establishment and spread.

agriculture, are an important cause of the introduction of invasive alien species, both intentionally (e.g., release of plants, animals, or organisms used for pest or weed control into terrestrial or aquatic environments) and unintentionally (e.g., spread of weeds, pathogens, pests and escape from fields/plantations or other containment) (Hulme *et al.*, 2008). Invasive alien species, particularly those from agricultural systems, can facilitate the spread and establishment of pathogens that would otherwise be absent from the introduced range and may pose risks for disease transmission for humans, domestic animals and other native wildlife (Chinchio *et al.*, 2020).

3.3.1.1.1 Aquaculture

Aquaculture (farming of marine organisms) is the largest sector worldwide, after shipping, responsible for introduction of marine alien species (Ojaveer *et al.*, 2018; Bailey *et al.*, 2020). Although the production of marine fish and crustaceans has grown since the millennium, it is now eclipsed by the live-weight volume of marine bivalves and seaweeds which has grown, respectively, from 10 and 11 to 18 and 32 million tonnes per annum between 2000 and 2018 (FAO, 2021). Both the farmed species and/or storage (and other) infrastructures (e.g., cages, nets, floats and ropes) serve as agents of intentional and unintentional introductions and spread of invasive alien species (Campbell *et al.*, 2017). Farmed species are either placed in the sea in enclosures (cages, net pens, rafts), or intentionally released into the environment (Naylor *et al.*, 2001). Intentional introductions comprise both legal and clandestine translocations (Özcan & Galil, 2006; Stentiford & Lightner, 2011; Megahed, 2014). Unintentional introductions consist of “spillover” from crops farmed or stocked in natural habitats (e.g., marine algae farming, marine stock enhancement); escape, unintentional release, or spawning from culture facilities (Arechavala-Lopez *et al.*, 2018, 2017); and alien species associated with the farmed species, or equipment used for culture or transportation of the farmed species (Reise *et al.*, 1998; Mineur *et al.*, 2007). Arguably, due to the high permeability of marine farming facilities, the use of alien species in these settings are essentially intentional introductions to the wild (FAO, 1995; Grosholz *et al.*, 2015). *Tilapia* species are the third most important fish in aquaculture globally, and have established as alien in every country where they have been introduced (Canonico *et al.*, 2005). *Magallana gigas* (Pacific oyster) is one of the most widely used marine invertebrates, introduced primarily for aquaculture in 66 countries, of which alien populations have established in at least 17 (Herbert *et al.*, 2016). The open sea farming of *Undaria pinnatifida* (Asian kelp) and carrageenan-producing seaweeds *Kappaphycus alvarezii* (elkhorn sea moss) and *Eucheuma denticulatum* (eucheuma seaweed), has facilitated their spread to surrounding areas, including marine protected areas, in European, Indian, South America and African coastal waters (Floc’h *et al.*, 1991; Chandrasekaran *et al.*, 2008; Barrios *et al.*, 2007; Tano *et al.*, 2015).

Freshwater aquaculture involves mainly fish (De Silva *et al.*, 2009; Teletchea, 2019) and crayfish (Lodge *et al.*, 2012; Madzivanzira *et al.*, 2021). Globally, the number of alien freshwater fish species is positively correlated with aquaculture production (Gozlan, 2008), and the establishment of alien species from aquaculture has been documented for all continents where introductions have occurred (Britton & Orsi, 2012; De Silva *et al.*, 2006; De Silva, 2012; Gozlan, 2008; Lin *et al.*, 2015; J. Liu & Li, 2010; Luo *et al.*, 2019; Nunes *et al.*, 2015; Ortega *et al.*, 2015; Saba *et al.*, 2020; Shelton & Rothbard, 2006; Q. Wang *et al.*, 2015). Aquaculture is a major source of invasive alien species at national and regional scales. Of the approximately 500 documented introductions of freshwater fishes in the Mediterranean basin, more than 35 per cent are associated with aquaculture (Tricarico, 2012). In the Balkans, 36 species of freshwater fish have been introduced into inland waters *via* aquaculture (Piria *et al.*, 2018). In California, 126 alien species associated with commercial aquaculture have been reported, of which 106 have become established and are negatively affecting native species.

Parasites of a wide range of farmed marine organisms also appear as invasive alien species worldwide. *Haplosporidium nelsoni* (MSX oyster pathogen), a parasite of the Pacific oyster, has spread to estuaries from Maine to Florida, affecting the native *Crassostrea virginica* (eastern oyster; Andrews, 1984; Burreson *et al.*, 2000). Outbreaks of the intrahemocytic parasite *Bonamia ostreae*, protozoan parasite *Marteilia refringens*, two species of parasitic copepods *Mytilicola orientalis* (oyster redworm) and *Myicola ostreae* and the *Ostreid herpesvirus* (OsHV-1), affect farmed Pacific oysters and all originate from imports of stock (Mineur *et al.*, 2014). *Anguillicola crassus*, a blood feeding swimbladder parasitic nematode in eels native to eastern Asia, was widely introduced with its host, *Anguilla japonica* (Japanese eel), to Europe and North America, where it is now widespread in native eel populations sometimes at a prevalence up to 82 per cent of adult and juvenile eels (Barse *et al.*, 2001; Aieta & Oliveira, 2009; T. C. Pratt *et al.*, 2019; Warshafsky *et al.*, 2019). The illegal importation of penaeid prawns from Turkey into Italy was revealed only when the white spot disease was detected (Stentiford & Lightner, 2011). The high concentration of salmon farming in seas off Europe and Canada has been implicated in outbreaks of sea lice (*Lepeophtheirus salmonis* (salmon louse), *Caligus* spp.) in wild salmon (*Oncorhynchus gorbuscha* (pink salmon), *Oncorhynchus keta* (chum salmon)) in these waters (Krkošek *et al.*, 2005). Farmed pacific oysters have served as primary and secondary vectors for the introduction for algae, invertebrates and pathogens affecting both farmed and native oysters (Wolff & Reise, 2002; Mineur *et al.*, 2007, 2014; Verlaque *et al.*, 2015), including invasive alien species such as *Gracilaria vermiculophylla* (black wart weed), *Codium fragile* (dead man's fingers), *Sargassum muticum* (wire weed), *Undaria pinnatifida* (Asian kelp), the sea squirts *Botrylloides violaceus* (violet tunicate), *Didemnum vexillum* (carpet sea squirt) and *Styela clava* (Asian tunicate).

Fish breeds such as farmed *Salmo salar* (Atlantic salmon) have undergone domestication, i.e., intensive selective breeding, and a limited pool of domesticated broodstock, eggs and sperm is shared worldwide (Roberge *et al.*, 2008; Solberg *et al.*, 2020). In the past half century tens of millions of farmed salmon have escaped into the wild (Wringe *et al.*, 2018). Interbreeding between farmed and wild Atlantic salmon in Norwegian waters has altered age and size at maturation in 62 wild salmon populations, caused widespread changes to fitness-related life-history traits, thus threatening already vulnerable wild populations (Karlsson *et al.*, 2016; Bolstad *et al.*, 2017). Interbreeding between farmed and wild conspecific populations is also found in *Sparus aurata* (gilthead sea bream), *Dicentrarchus labrax* (European sea bass), *Argyrosomus regius* (brown meagre) and *Gadus morhua* (Atlantic cod) (Somarakis *et al.*, 2013; Jørstad *et al.*, 2014; Izquierdo-Gómez *et al.*, 2017; Arechavala-Lopez *et al.*, 2017, 2018). *Symphodus melops* (corkwing wrasse), used to control sea lice in salmon farms, also escapes and hybridizes with individuals in local populations (Faust *et al.*, 2018).

3.3.1.1.2 Forestry, agroforestry, biofuel and carbon sequestration

Trees and shrubs have been introduced globally for wood production, fruit and seed crops, erosion control, live fences and building material (Richardson, 1998; Richardson & Rejmánek, 2011; van Kleunen *et al.*, 2020). Of introductions of invasive alien trees and shrubs, 13 per cent were attributed to forestry, 10 per cent to food, and seven per cent to agroforestry (Richardson & Rejmánek, 2011). Many trees extensively used in forestry have high potential to become invasive alien species, including the genera *Pinus* (Richardson, 2006; Fernandes *et al.*, 2016; Brundu *et al.*, 2020), *Acacia* (Donaldson *et al.*, 2014; Richardson *et al.*, 2011, 2015) and *Eucalyptus* (Bennett, 2010; Forsyth *et al.*, 2004; Hirsch *et al.*, 2020; Simberloff & Rejmanek, 2011). Of the roughly 100 *Pinus* species, at least 17 species are now considered as invasive alien species in natural ecosystems, particularly in the southern hemisphere (Richardson & Blanchard, 2011; Richardson & Nsikani, 2021). Of the approximately 200 *Eucalyptus* species cultivated within South Africa (Henderson, 2009), six are listed as invasive alien species by the National Environmental Management Biodiversity Act. Studies in the Iberian Peninsula also show *Eucalyptus globulus* (Tasmanian blue gum) can spread from plantations (Fernandes *et al.*, 2016). *Acacia* species from Australia are widely distributed invasive alien species (Le Maitre *et al.*, 2011). Over 70 *Acacia* species were introduced throughout South Africa for forestry, dune stabilization and ornamental use during the 19th and 20th centuries (Bennett, 2011). Of these 70 introduced species, 14 are now considered to be invasive alien species, four of which arose from commercial forestry plantations (Van Wilgen *et al.*, 2011). The southern hemisphere (e.g., South America, Oceania) has been particularly affected by tree invasions, because of the massive scale of commercial plantations and the absence of competition by native tree species (García *et al.*, 2018; Nuñez *et al.*, 2017; Richardson *et al.*, 2021).

Increased interest in biomass-based energy has increased the use of alien species with rapid growth rates, ease of establishment, wide environmental tolerances, and prolific seed production in plantations, characteristics that also promote them as potential invasive alien species (Barney & DiTomaso, 2008; Leakey, 2009; Richardson & Blanchard, 2011). Across the south-eastern United States, *Eucalyptus* species are commonly utilized for bio-energy (Callaham *et al.*, 2013; Lorentz & Minogue, 2015), and have the potential to invade surroundings woodlands (Callaham *et al.*, 2013). Large stature grasses, such as bamboo, are also used as common biofuel crops, with "running" bamboo species noted to present a significantly higher risk of biological invasion than "clumping" species (Lieurance *et al.*, 2018). The perennial grasses *Miscanthus sinensis* (eulalia) and *Miscanthus sacchariflorus* (Amur silvergrass), planted for ornamental and biofuel uses, also pose high risks across Europe and North America, especially in grassland and tall herb vegetation, ruderal habitats and roadsides (Schnitzler & Essl, 2015). Climate modelling indicates *Miscanthus* (silvergrass) species have already been introduced to most of the suitable regions in the northern hemisphere, whereas there is climatic potential for further expansion in the southern hemisphere, suggesting increased future biological invasion threat there (Hager *et al.*, 2014).

Food forestry, whereby a diversity of food plants is planted in natural or seminatural forested ecosystems, may represent an emerging pathway for the introduction, establishment and spread of alien species into natural or near-natural ecosystems. For example, a recent study identified almost 500 alien species used in the fast-growing food forestry sector in the Netherlands alone, including a number of high -risk invasive aliens including *Akebia quinata* (five-leaf akebia), *Helianthus tuberosus* (Jerusalem artichoke), *Rhus typhina* (staghorn sumac), *Rosa rugosa* (rugosa rose) and *Vaccinium macrocarpon* (cranberry) (Hoppenreijs *et al.*, 2019).

Plantation forests are also hotspots (invasion hotspot in the **Glossary**) for unintentional introductions of invasive alien species In a global review of invasive alien plants, vertebrates and invertebrates on islands (794 alien species), plantation forests had consistently higher numbers and abundances of alien species as compared to native habitat (Sánchez-Ortiz *et al.*, 2020). Invasive forest pathogens have been responsible for many disease outbreaks across commercial, natural and urban forest ecosystems, and generally occur as a result of unintentional introductions *via* containment or stowaway (Burgess *et al.*, 2016; Migliorini *et al.*, 2015; Paap *et al.*, 2020). Notable examples include; *Cryphonectria parasitica* (blight of chestnut), *Ophiostoma novo-ulmi* (Dutch elm disease), *Phytophthora cinnamomi* (Phytophthora dieback), *Phytophthora ramorum* (sudden oak death) and *Hymenoscyphus fraxineus* (ash dieback) (Brasier & Buck, 2001; Pautasso *et al.*, 2013; Rigling & Prospero, 2018; Rizzo & Garbelotto, 2003; Shearer *et al.*, 2007).

3.3.1.1.3 Forage production and livestock grazing

Forage production and pastures for domestic herbivores is a major land-use in almost all biomes of the world (Brondizio *et al.*, 2019). Management of such lands is a major source of biological introductions, because species sown or planted for forage, or weeds associated with these land-uses, may escape and spread into natural ecosystems (Nuñez *et al.*, 2017; O'Connor & van Wilgen, 2020; Pándi *et al.*, 2014). In a survey by Driscoll *et al.* (2014), 91 per cent of grasses developed by agribusiness for pasture were listed as weeds somewhere in the world, and often in the same countries where they were actively been developed and marketed. Policies aiming to facilitate pastoral development can also be responsible for introductions, such as occurred for the pasture grass *Andropogon gayanus* (tambuki grass) in Australia (Cook & Dias, 2006), which is now known to increase wildfire intensity, and transform species-rich savannah systems into alien-dominated grasslands (Driscoll *et al.*, 2014; **section 3.2.5**). In Texas, United States, alien grass species were seen as the future of forage production during the early twentieth century, and several introduced species have since escaped pasture cultivation: *Bothriochloa ischaemum* (yellow bluestem), *Dichanthium annulatum* (Kleberg's bluestem), *Dichanthium aristatum* (angelton bluestem), *Cenchrus ciliaris* (buffel grass), *Megathyrsus maximus* (Guinea grass), *Eragrostis lehmanniana* (Lehmann lovegrass) and *Cynodon dactylon* (Bermuda grass) (Wied *et al.*, 2020). Several of these economically important pasture grasses are invasive alien species throughout several countries. *Megathyrsus maximus*, with its high yield, palatability and tolerance of herbivory is now considered a weed species throughout Africa, America, Australia and Asia (Randall, 2017; Rhodes *et al.*, 2021). *Cenchrus ciliaris* has become a problematic species across Australia, the United States, Mexico and South America (V. M. Marshall *et al.*, 2012) and Bermuda grass now also has a cosmopolitan distribution and is considered one of the world's worst weeds (Randall, 2017; Way, 2014). Some invasive alien species in agricultural systems were introduced through planting of windbreaks and hedgerows, including the globally versatile *Ulex europaeus* (gorse), one of the most invasive alien species in the world, introduced from Europe to Australia, Chile, New Zealand, Sri Lanka and the United States (Roberts & Florentine, 2021). In Southern Africa, invasive alien *Opuntia* (pricklypear) species were initially grown as wind-breaks, fences, and also supplementary fodder sources (S. E. Shackleton & Shackleton, 2018).

Some introduced species also act as hosts of further invasive alien species. For example, in the United States, *Festuca arundinacea* (tall fescue), a cool season-grass introduced from Europe, dominates grasslands and is considered an invasive alien species across multiple states (Barnes *et al.*, 2013; Pfeifer-Meister *et al.*, 2008). The spread of tall fescue is concerning as it also may act as a reservoir host for *Alternaria* (fungal pathogen), which produces crop damaging mycotoxins (H. E. Wilson *et al.*, 2014).

3.3.1.1.4 Agriculture

In a global study of terrestrial plant invasions 407 (46 per cent) of 886 alien plants were introduced intentionally through agricultural pathways (Turbelin *et al.*, 2017). This study reports three of the top five terrestrial invasive alien plant species globally to have their main introduction pathways associated with agricultural practices: *Cyperus rotundus* (purple nutsedge; found in 37 per cent of countries), *Ricinus communis* (castor bean; 31 per cent) and *Leucaena leucocephala* (leucaena; 27 per cent). Agricultural use is also a major source of aquatic plant invasions. In China, several alien freshwater aquatic plants have been introduced for landscaping, water purification and forage purposes, five of which are now considered to be invasive alien species: *Sporobolus alterniflorus* (smooth cordgrass), *Azolla filiculoides* (water fern), *Alternanthera philoxeroides* (alligator weed), *Urochloa brizantha* (palisadegrass) and *Urochloa mutica* (para grass) (Wu & Ding, 2019).

The occurrence of some ungulates as invasive alien species arose from agricultural practices (Spear & Chown, 2009). Farms or hunting of species for fur has resulted in the intentional introduction, or escape from farms or captivity, of: *Mustela vison* (American mink) in Europe (Bonesi & Palazon, 2007; E. J. Fraser *et al.*, 2017); *Procyon lotor* (racoon) in Europe (Beltrán-Beck *et al.*, 2012); *Oryctolagus cuniculus* (rabbits) throughout the world (Lees & Bell, 2008) and particularly in New Zealand (C. M. King & Forsyth, 2021), Australia (Myers *et al.*, 1994) and South America (Howard & Amaya, 1975; Iriarte *et al.*, 2005); *Vulpes vulpes* (red fox) in Australia (Saunders *et al.*, 2010); and *Trichosurus vulpecula* (brushtail possum) in New Zealand (Clout, 2006; C. Jones *et al.*, 2012). **Section 3.3.2.1** on stocking for hunting and **section 3.2.3.3** on pet trade also discuss how these drivers have facilitated invasive alien species.

Agriculture has also facilitated biological invasions by plant and animal pathogens, parasites and diseases. Alien plant pathogens may be introduced *via* seeds and soil used in agriculture (Pimentel *et al.*, 2001). For example, 65 per cent of plant pathogens in the United States were considered alien species (Pimentel *et al.*, 1992), 74 per cent in the United Kingdom (Carlile, 1988), 82 per cent in Australia (Persley & Syme, 1990), 85 per cent in South Africa (Nel, 1983), 74 per cent in India (Singh, 1985), and 75 per cent in Brazil (Echandi *et al.*, 1972). Many microbes and other parasites accompany livestock as they are introduced into new countries (Pimentel *et al.*, 2001). *Mycobacterium bovis* (bovine tuberculosis) was introduced to many places, including New Zealand, as cattle were transported out of Europe during the nineteenth century (N. H. Smith, 2012). In New Zealand, bovine tuberculosis is now also prevalent in other invasive alien species including *Trichosurus vulpecula* (brushtail possum), *Sus scrofa* (feral pig), *Mustela putorius furo* (ferret), *Mustela erminea* (ermine), *Erinaceus europaeus* (European hedgehog) and deer species (Livingstone *et al.*, 2015). In Europe, the introduction of *Procyon lotor* (racoon) also established *Baylisascaris procyonis* (raccoon roundworm), which may potentially induce central nervous system disease in humans (Chinchio *et al.*, 2020).

3.3.1.2 Fragmentation of ecosystems

Increasing exploitation of natural resources and land-use changes have led to widespread fragmentation of terrestrial ecosystems, so that 70 per cent of remaining forest areas globally are now within 1 km distance of a forest edge (IPBES, 2019). Fragmentation is usually associated with loss of total habitat area, changes in habitat quality, and increased biotic and abiotic influence from the surrounding landscape (Eriksson *et al.*, 2002; Sodhi *et al.*, 2010; Vilà & Ibáñez, 2011). Fragmentation of landscapes and habitats is one of the most significant process driving decrease of native biodiversity and species richness globally (IPBES, 2019; Millennium Ecosystem Assessment, 2005b).

Fragmentation increases the proportion of the native habitat exposed to edge effects, where higher propagule pressure and faster growth of pioneer and generalist species, many of which are alien, can drive replacement of native habitat specialists (Laurance & Peres, 2006; Lobo *et al.*, 2011; B. A. Santos *et al.*, 2008; Tabarelli *et al.*, 2008). The increased edge-to-interior ratio of fragmented landscapes increases the prevalence of invasive alien species in fragments, as shown for plant and lepidopteran diversity in South Texas (Stilley & Gabler, 2021), woody plant diversity in New England (J. M. Allen *et al.*, 2013), *Hovenia dulcis* (Japanese raisin tree) in Brazilian Atlantic forest patches (Padilha *et al.*, 2015) and *Sporobolus alterniflorus* (smooth cordgrass) in mangroves along the coast of China (Z. Zhang *et al.*, 2021). Recent studies also document increased spread of invasive alien species in fragmented landscapes over time, such as the study from Achury *et al.* (2021) of *Linepithema humile* (Argentine ant) invading coastal southern California. Similarly, *Ulex europaeus* (gorse) spread widely in fragmented landscapes of south-central Chile while large intact forest areas experienced lower rates of invasion over the same time period (Altamirano *et al.*, 2016).

As fragmentation increases, the remaining fragments are more isolated from each other, which may both promote and hinder biological invasions. Increased patch isolation may promote biological invasions if invasive alien species are more common in the habitats surrounding the patches, as has been shown for alien pasture grasses which frequently occur in Australian forest fragments surrounded by landscapes with high pasture cover (S. Butler *et al.*, 2014). Another example is the prevalence of *Aulacaspis yasumatsui* (cycad aulacaspis scale) on cycads in Guam, where isolated fragments suffered greater damage from these alien scale insects than did fragments with higher connectivity (Marler & Krishnapillai, 2020). Connectivity of native habitats may also be promoting the spread of invasive alien species which are dependent upon native dispersal vector species that depend on this habitat (e.g., Guiden *et al.*, 2015).

Some cases exist in which the fragmented habitat is less favourable to invasive alien species. Insect pests and specialist pathogens of forest trees are less common in counties of the United States which have more fragmented forests (Guo, Riitters, *et al.*, 2018). In the case of animals, patches further apart than the organism is able to cross may hinder the spread of invasive alien species (e.g., Bridgman *et al.*, 2012). The reproductive success of the invasive alien tree *Ligustrum lucidum* (broad-leaf privet) is lower in forest fragments than continuous forests, not due to lower seed production but due to unfavourable soil conditions for seedling establishment in fragments (Aguirre-Acosta *et al.*, 2014). In aquatic environments, artificial fragmentation (e.g., underwater barriers) may slow down the spread of alien species, even though some barriers may be more effective for native species than for alien species (Airoldi *et al.*, 2015).

Fragmentation of native habitat also creates corridors for invasive alien species (**section 3.3.1.3**), increased disturbance (**section 3.3.1.5**) and lower patch habitat quality (**section 3.3.1.6**). A mechanism by which fragmentation promotes biological invasion may be through rendering native populations more vulnerable to local extinction (Hanski, 1999), leaving vacant niches and hence decreasing biotic resistance to invasions and ecosystem resilience (**section 3.4.2**). Most of the evidence for the effects of fragmentation on biological invasions comes from invasive alien plants or plant pest species, and specifically in relation to the spread stage of the biological invasion process (**Chapter 1**, **section 1.4.4**).

3.3.1.3 Creation of anthropogenic corridors

Different types of anthropogenic corridors act as major routes for the transport and spread of invasive alien species (e.g., Galil *et al.*, 2015; Hulme *et al.*, 2008), although these are often not explicitly considered in pathway assessments (CBD, 2014; Leclerc *et al.*, 2018). Anthropogenic corridors, including roads, highways, railways, hiking trails, tunnels, pipelines, power lines, canals and bridges, are rapidly expanding for trade, travel and transport (**sections 3.2.3.1** to **3.2.3.4**). It is projected that length of roads will increase by over 60 per cent (or to between 3 and 4.7 million km) globally from 2010 to 2050 (Dulac, 2013), a large fraction of which is projected to be built in developing countries in some of the world's last remaining wilderness areas, such as the Amazon, the Congo basin and New Guinea (Meijer *et al.*, 2018). The volume of freight transported *via* anthropogenic corridors has consistently grown since the 1960s especially in Europe and North America (**section 3.1.1**; Hulme, 2009a).

Anthropogenic corridors allow both intentional and unintentional transport of invasive alien species, and they create disturbed and transformed habitat such as road and canal verges that allow subsequent establishment and spread of invasive alien species into otherwise impassable regions. The mechanism of the influence of anthropogenic corridors on the stages of the biological invasion process can be summarized as follows; 1) allowing easier transport and spread of invasive alien species by natural (e.g., wind, water, animals) or human mediated (e.g., cars, trains, ships, people) vectors, 2) facilitating establishment of invasive alien species by disturbing, stressing or removing native species and ecosystems along corridor verges, 3) providing new corridor verge habitats for invasive alien species to establish and spread by altering abiotic environmental conditions (e.g., soils, hydrology, wind; Trombulak & Frissell, 2000).

In terrestrial biomes, several global surveys provide evidence that the abundance and diversity of alien plants is higher along roads compared to adjacent native habitat, and decreases with distance away from the roads (Lázaro-Lobo & Ervin, 2019; Suárez-Esteban *et al.*, 2016). The long linear features of roads and railways facilitate the long-distance dispersal of alien seeds (Hulme, 2006). In a selectively logged tropical forest in Bolivia, logging vehicles spread the seeds of the alien *Megathyrsus maximus* (Guinea grass) at least 500 m from the established populations (Veldman & Putz, 2010). Road density and road age also positively correlate with alien species' distributions (Hulme, 2009). For example, alien earthworms have spread farther from older roads in boreal forests of Canada (Cameron & Bayne, 2009), suggesting roads provide fringe sources for colonization of native habitat. Anthropogenic corridors also drastically alter the surrounding biotic, physical and chemical environments. The edges of anthropogenic corridors (e.g., roadsides, highways, railways) provide favourable habitats for the establishment of alien plants (e.g., M. J. Hansen & Clevenger, 2005; Jodoin *et al.*, 2008; Sullivan *et al.*, 2009). Rural roads, mountainside highways and powerlines change the surrounding plant species composition, and enhance the establishment of invasive alien species in mountainous and protected areas (L. G. Anderson *et al.*, 2015; Mortensen *et al.*, 2009; Rentch *et al.*, 2005; Spooner, 2015; Wagner *et al.*, 2014). Some Indigenous Peoples and local communities also observe the role of anthropogenic corridors in facilitating biological invasions, for instance, people in Arunachal Himalayas in India view road construction and road use as the drivers facilitating biological invasion, as well as introduction of cattle which brought alien seeds (Kosaka *et al.*, 2010). In alpine and Arctic ecosystems, the establishment and subsequent spread of alien plants is increased along mountain roads, hiking trails and buried oil pipelines (Alexander *et al.*, 2016; Langor *et al.*, 2014; Liedtke *et al.*, 2020; **section 3.3.5.1**, **Box 3.10**).

In freshwater and marine biomes, canals facilitate the transport, introduction and spread of invasive alien species at global and regional scales (Asth *et al.*, 2021; Bij de Vaate *et al.*, 2002; Boudouresque & Verlaque, 2012). The role of these water corridors in facilitating biological invasions are well studied for fish and aquatic invertebrates (Devin *et al.*, 2005; Karatayev *et al.*, 2008; Rakauskas *et al.*, 2016), especially in Europe (e.g., Katsanevakis *et al.*, 2013). For example, 507 marine alien species have arrived in European Seas through canals, such as the Suez Canal (**Box 3.7**; Katsanevakis *et al.*, 2013). Since the eighteenth century, the connection of the European seas and rivers to the Eurasian waterways *via* canals showed a stepwise increase, and the extensive network of inland waterways has allowed the biological invasion of aquatic alien species from different biogeographical regions (Leuven *et al.*, 2009), such as the establishment of Ponto-Caspian invertebrates throughout the central European corridors (Karatayev *et al.*, 2008). Another example is the shipping canals near Chicago, Illinois that link the Great Lakes with the Mississippi River, which have allowed the exchange of 15 species of fish and invertebrates formerly confined to just one of the basins (Rahel, 2002). Additionally, inter-basin water transfers provide a direct link between previously isolated catchments and thereby modify the water flow, chemistry and temperature of receiving waters. Water inflow *via* canals can result in eutrophication and changes in salinity, thereby allowing the establishment of invasive alien species (e.g., Pienimäki & Leppäkoski, 2004; Sarà *et al.*, 2018).

Thus, creation of anthropogenic corridors is an important driver across all stages of the biological invasion process (transport, introduction, establishment and spread) for various taxa (e.g., plants, vertebrates and invertebrates) in terrestrial, freshwater and marine biomes.

Box 3 7 **The Suez Canal and invasive alien species.**

The Suez Canal, a linchpin of transportation networks between Europe and Asia, carries over 10 per cent of global trade, with19,000 vessels transiting the Canal in 2020 (Veiga, 2021). The Canal is also the main pathway of alien species introduction into the Mediterranean Sea. The Suez Canal was opened over 150 years ago, yet Erythraean species are newly recorded in the Mediterranean to this very day **(Figure 3.16)**. Biological invasions by Erythraean species are driven by the region's environmental characteristics and anthropogenic activities. The latter include: physical changes to the Canal that have impacted its hydrography and hydrology, and increased its potential as a "corridor"; and changes to the Levantine marine environment that have made it more susceptible to biological invasion by modifying its hydrological properties and species diversity, and destabilizing the shelf community structure (Galil, 2006).

The Suez Canal (8 m deep, with cross-section area 304 m^2, when built in 1869) is hydrographically complex, passing through five anthropogenic lakes of widely diverse salinity (Menzalah, Ballah, Timsah, Large and Small Bitter Lakes). The dissolution of the Bitter Lakes' salt bed, complete by the 1960s, removed the early Canal's salinity barrier. A recent study of the Canal's flow intensity and direction (1923–2016) supports unidirectional biological invasions into the Mediterranean, with significant increase in northward flow during the early 1980s following a major expansion (depth from 15.5 to 19.5 m, doubling cross-section area), and a second expansion in 2015 after the opening of the "new" Suez Canal (Biton, 2020). A larger Canal accommodates transit of more and larger vessels, many in ballast and befouled, and discharges a larger volume of Red Sea waters with their entrained biota into the Mediterranean Sea.

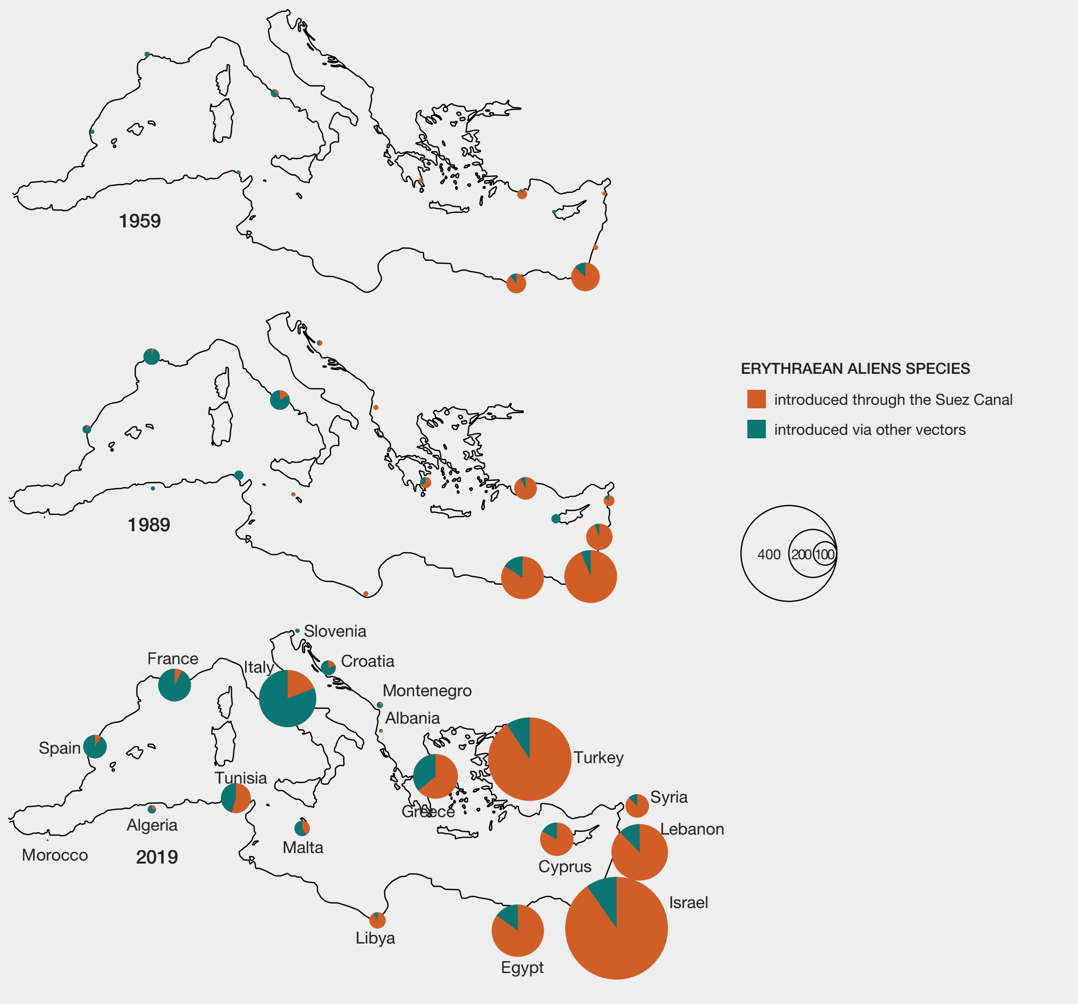

Figure 3 16 **Number of multicellular marine alien species in peri-Mediterranean countries, and their means of introduction, 1959, 1989, 2019.**

Lighter tone: Erythraean aliens (i.e., introduced through the Suez Canal), darker tone: alien species introduced *via* other vectors. A data management report for this figure is available at https://doi.org/10.5281/zenodo.7861139

3.3.1.4 Deployment of marine infrastructure

Coastal landscapes are being transformed through marine urban sprawl with an increase in construction of artificial structures to support commercial, residential and tourist activities (Dafforn *et al.*, 2015; Bulleri & Chapman, 2010). Indeed, more than 50 per cent of the shorelines of some regions of Europe, United States, Australia, and Asia are modified by hard engineering. Offshore aquaculture facilities and offshore energy infrastructures are also increasing in prevalence. Marine urbanization is predicted to escalate in the future as sea-level rises and extreme climate events, including storms, increase in frequency (Dafforn *et al.*, 2015). Artificial structures alter seascapes and the functioning of marine ecosystems through local and regional effects (Bulleri & Chapman, 2010; Todd *et al.*, 2019) including the establishment and spread of invasive alien species.

The potential for invasive alien species to utilize marine infrastructure is widely recognized (Bulleri & Chapman, 2010; Bulleri & Airoldi, 2005; Vaselli *et al.*, 2008). Marine infrastructure can facilitate invasive alien species by providing artificial hard substrates that some invasive alien species can colonize (Farr *et al.*, 2021). Indeed, artificial hard structures such as breakwaters, jetties, seawalls, floating pontoons and pier pilings provide suitable habitats for alien species (Bulleri & Airoldi, 2005; S. L. Williams & Smith, 2007) and can also function as corridors through unsuitable habitats (Bulleri & Airoldi, 2005). Nearshore infrastructure is considered to provide entry points for invasive alien species, with the numbers of invasive alien species on pontoons and pilings being 1.5-2.5 times higher than on natural rocky reefs (Glasby *et al.*, 2007). *Codium fragile* (dead man's fingers), an invasive alien seaweed species native to east Asia, colonized hard structures installed to provide coastal protection in the northern Adriatic Sea and is now found on temperate rocky shores around the world (Bulleri & Airoldi, 2005), and has also replaced native kelp on the leeward shores of the United States (Levin *et al.*, 2002). Similarly, a study on invasive alien ascidians demonstrated that ascidian species spread onto natural habitats from marine infrastructure, and that species differ in the rate and success of this secondary spread (Simkanin *et al.*, 2012). In a global literature survey, the alien ascidians *Botrylloides violaceus* (violet tunicate) and *Botryllus schlosseri* (star ascidian) were reported four times as often in anthropogenic marine habitats relative to natural habitats, while two other alien ascidians, *Didemnum vexillum* (carpet sea squirt) and *Styela clava* (Asian tunicate), were encountered on floating docks, pilings and aquaculture installations eight times as often as they were found in nearby natural habitats (Simkanin *et al.*, 2012). These findings illustrate the differences in biological invasion potential and/or rate between closely related species.

Offshore floating structures, such as wind facilities, can provide substrate for introduced hard-substrate benthic organisms to colonise, and thus can contribute to the further spread of invasive alien species, especially in the intertidal zone (Kerckhof *et al.*, 2016). Deepwater and offshore floating infrastructures generally are considered less likely to be colonized by invasive alien species than nearshore infrastructures (Farr *et al.*, 2021) because the nearshore is often associated with higher human activity and consequently increased pathways of introduction in comparison to offshore locations.

3.3.1.5 Changes in landscape-seascape disturbance regimes (intensification and reduction)

Changes in landscape-seascape disturbance regimes, including both intensification and reduction in disturbance intensity, have been ubiquitous in natural ecosystems as a result of human activities; for example over 50 per cent of the global land area has experienced changed fire regimes, and fires are expected to become more common in coming decades as a result of climate change and increasing human occupation (IPBES, 2018b). Such changes may affect the capacity of invasive alien species to establish and thrive through direct effects of changes in disturbances. Effects may also be more indirect, through interfering with native competitors, grazers, or predators, or through the modification of fire frequencies or nutrient and water regimes (**sections 3.3.4.5**, **3.3.3.1** and **3.3.1.5** respectively). At broader spatial scales, changes in landscape-seascape disturbance regimes may affect invasive alien species through fragmenting landscapes, creating corridors, the deployment of infrastructure, or degrading habitats, but also through protecting areas from disturbance, for example in designated protected areas (**sections 3.3.1.2** to **3.3.1.5**).

In an observational study spanning 200 sites around the world, disturbance *per se* was found to be a weak predictor of plant invasions (Moles *et al.*, 2012). An older literature survey (Lozon & MacIsaac, 1997) found a greater importance of disturbance for successful plant invasions (implicated in 67 per cent of disturbance caused by invasive alien species) than by animals (implicated in 28 per cent of disturbance caused by invasive alien species), particularly during the establishment phase (86 per cent vs. 12 per cent relied on disturbance for plants vs. animals). The role of landscape disturbance in influencing microbial invasive alien species is far less understood than for macro-organisms, but the literature that exists suggests patterns remain similar with sites of high disturbance, anthropogenic impact, fluctuating resource supplies and release from predators resulting in increased establishment of invasive alien microbial species (Litchman, 2010). Overall, increased landscape disturbance *per se* hence seems to have a weak but positive role in facilitating invasions.

A more nuanced analysis focusing on changes in disturbance regimes, however, can provide better predictive power than disturbance regime *per se*. Several reviews have found that changes in land-use regimes, and in particular in human-mediated disturbance regimes related to fire, grazing and agriculture, facilitate plant invasions through both direct and indirect pathways (Jauni *et al.*, 2015; Moore, 2005; Vilà & Ibáñez, 2011). Experimental studies support these observations, frequently indicating that changes to disturbance regimes, both increases and decreases in disturbance frequency and intensity relative to natural or historic levels, and in particular the introduction of novel disturbance types, provide opportunities for alien plant species to establish (Kempel *et al.*, 2013). **Sections 3.3.1.5.1**, **3.3.1.5.2** and **3.3.1.5.3** therefore summarize the ways in which changes, and particularly intensification of human disturbance regimes, increase the establishment and spread of invasive alien species. There is stronger evidence for disturbance effects on terrestrial systems and plants than other systems and taxonomic groups, but some evidence also exists from aquatic and marine systems and for vertebrates, invertebrates and microorganisms. All IPBES regions are represented, with much of the evidence from Australia and the United States. The literature on disturbance regimes as a driver that facilitates invasive alien species covers all stages of the biological invasion process, but with more evidence on the establishment and spread stages, the latter often associated with documentation of the impact on native biodiversity and human livelihoods (**Chapter 4**).

3.3.1.5.1 Agricultural disturbance regimes

In terrestrial biomes, a global meta-analysis (Jauni *et al.*, 2015) found that plant invasions can be facilitated by discrete disturbance events such as fire, agricultural activity, and more generally broad shifts in anthropogenic activity. Specifically, they found that increased domestic grazer activity and general anthropogenic disturbance events increased both the diversity and abundance of alien species, whilst fire- or soil-based disturbance activities led only to increases in diversity of alien species. This trend was stronger in forest ecosystems than in wetlands and grasslands. Importantly, time elapsed since the disturbance occurred was considered critical, with significant responses only observed in cases where communities were monitored more than five years post-disturbance. In line with these findings, in Ghana, conversion to maize production resulted in increasing removal of fallow trees, which has encouraged land degradation and facilitated establishment and spread of *Chromolaena odorata* (Siam weed; Amanor, 1991). In arid and semi-arid rangelands of the United States, livestock overgrazing decreases the plant cover of native palatable grasses and accelerates the dominance of alien annual grasses (e.g., *Bromus tectorum* (downy brome); Chambers *et al.*, 2007; Keeley *et al.*, 2003). In the grasslands of the Austral Andean Mountains in Argentina, establishment of the invasive alien *Pinus halepensis* (Aleppo pine) was considerably higher in areas grazed by feral horses, where perennial grasses were negatively affected by defoliation, giving advantage to the alien plant *Echium plantagineum* (Paterson's curse) (de Villalobos & Schwerdt, 2020; de Villalobos & Zalba, 2010). In Australia, overgrazing by introduced feral camels, buffalo and pigs has facilitated invasive alien species establishment in arid and semi-arid ecosystems throughout the country (Burrows, 2018; Sloane *et al.*, 2021). Invasive alien plants often have higher performance and higher resource use efficiency than coexisting native species, suggesting a higher ability to benefit from increased resource availability resulting from changes in disturbance regimes as a potential mechanism (e.g., Daehler, 2003; Kolar & Lodge, 2001; Leishman & Thomson, 2005). Among animals, *Solenopsis invicta* (red imported fire ant) was characterized as a "disturbance specialist" when subjected to mowing and ploughing regimes, to the extent that the species was found not to invade forest habitats of native ants in the absence of such disturbances (J. R. King & Tschinkel, 2008). Increasing agricultural disturbance also benefited alien predatory *Coccinellidae* (ladybeetles) in Chile, and these alien ladybeetles could be considered "disturbance specialists" (Grez *et al.*, 2013). Modified landscapes may also support higher abundances of invasive alien animals than unmodified landscapes, for example introduced *Vulpes vulpes* (red fox) thrive within Australian agricultural systems (Graham *et al.*, 2012; Towerton *et al.*, 2011).

Biological invasions in terrestrial systems may be affected by land abandonment as well as land-use intensification. After abandonment, the succession from agricultural to forested landscapes is generally associated with an increased spread in plant invasions, particularly after crop abandonment (Vilà & Ibáñez, 2011), which may be linked to higher competitive ability and hence establishment and spread of some invasive alien species under the reduced disturbance intensity and frequency in post-abandonment vegetation (van der Zanden *et al.*, 2017). The role of abandonment in facilitating invasive alien species is well known among Indigenous Peoples and local communities in several parts of the world. In the Panchase area of Nepal, Indigenous communities report that land-abandonment has led to the establishment and spread of invasive alien species (Schwilch *et al.*, 2017). In the Amatole District of the Eastern Cape, South Africa, local communities noticed that the abandonment of arable fields coupled with the dispersal of seeds by local birds have led to invasion by *Lantana camara* (lantana; Jevon & Shackleton, 2015). Indigenous Peoples and local communities in South Africa have also observed that some abandoned agricultural lands can become hotspots of invasive alien species (C. M. Shackleton & Gambiza, 2008).

3.3.1.5.2 Changes to fire regimes

Fire is a key natural disturbance process that plays an important role in regulating community composition and ecosystem functioning in a diversity of ecological systems worldwide (He *et al.*, 2019; Keeley *et al.*, 2011; Pausas & Keeley, 2019). In fire-adapted systems, continuation of the historic natural or anthropogenic fire regimes generally has relatively little influence on either native species performance or the establishment of alien species whereas loss of traditional fire regimes may benefit invasive alien species (Alba *et al.*, 2015; L. T. Kelly *et al.*, 2020; Velle *et al.*, 2014). A meta-analysis of the role of fire on native and invasive alien species found that prescribed low-intensity burns may benefit native species but generally do not affect alien species, whereas wildfires consistently enhanced alien species performance and diversity, and especially so in arid shrublands, temperate forests and heathlands (Alba *et al.*, 2015). The evidence from this global study was largely from the United States and Australia, pointing to regional knowledge gaps. Invasive alien species may benefit from both reduction and enhancement of fire regimes relative to historic levels. For example, in naturally fire-prone prairies in the United States, fire suppression led to the dominance of invasive alien earthworms (Callaham *et al.*, 2003; Callaham & Blair, 1999), and increased frequency or intensity of fire relative to historic fire regimes tended to increase diversity and performance of alien plants, whereas native biodiversity was highest when historic fire regimes were maintained (D'Antonio, 2000). In tussock grasslands in New Zealand, alien spiders were more successful at colonizing after burning, which provided an initial advantage in resource competition for these invasive alien arthropods (Malumbres-Olarte *et al.*, 2014). Intensified fires along with overgrazing led to the loss of fire-intolerant trees and shrub species and facilitated the establishment of the alien grass *Bromus tectorum* (downy brome) in shrublands and increased establishment and spread of invasive alien species in coniferous forests (Chambers *et al.*, 2007, 2014; Keeley *et al.*, 2003; Roundy *et al.*, 2014).

Some invasive alien species not only benefit from modified fire regimes, but once established, may in turn further modify fire behaviour and community composition (Grace *et al.*, 2001). For example, some alien species increase the fuel load or flammability of the ecosystem, resulting in increased fire frequency or intensity (Brooks *et al.*, 2004; Mandle *et al.*, 2011). Alternatively, burned environments may be more susceptible to biological invasion by species with fire specific traits, such as seed release contingent upon fire or smoke (Franzese & Raffaele, 2017; Gaertner *et al.*, 2014). In many cases, fire primarily influences native and alien animal species through effects on vegetation structure and composition. For example, within Australian tropical savannahs, invasive alien predators such as feral cats, dingoes and snakes may be attracted to burnt landscapes, where they may hunt more effectively (Lozon & MacIsaac, 1997; H. W. McGregor *et al.*, 2014, 2016). In Australian forests, prescribed forest fires reduced understory cover by more than 80 per cent and the occurrence of invasive alien predators increased five-fold, whereas medium-sized native mammalian prey were disadvantaged (Hradsky *et al.*, 2017). Climate and land-use change are now driving changes in global fire regimes, pointing to potentially important interactive effects (**section 3.3.4**).

3.3.1.5.3 Aquatic and marine disturbance regime changes

The biological invasion of aquatic alien species may be facilitated through land-use intensification in the watershed. There is an increased likelihood of invasive alien species establishing within impacted watersheds where increased sedimentation, altered flow rates, increased pollution and habitat destruction lower intrinsic biotic resistance (Havel *et al.*, 2015). In New Zealand braided river systems, alien and native aquatic plants respond to different drivers of change in nature, and in particular disturbances to flow regimes. For example, winter flow variability may increase alien species, while flow stabilization may promote coverage of such species (Brummer *et al.*, 2016). Regulated flow regimes, including floods, also mediate invasive alien plants in the Australian Murray-Darling river catchments (Catford *et al.*, 2011, 2014), with impacts mediated by seasonality along with species' life-history strategies (Greet *et al.*, 2013). In China, the rate of onward spread and establishment of *Lithobates catesbeianus* (American bullfrog) from the points of introduction (for aquaculture) throughout the local watershed was facilitated by native habitat loss and land-use change (X. Wang *et al.*, 2022). In the Mediterranean Sea, fish overgrazing and sediment disturbance caused by vessel anchoring decrease the resistance of native seagrass beds, and thereby allow the establishment and spread of invasive alien *Caulerpa racemosa* (green algae; Tamburello *et al.*, 2014). In Italy, however, clearance of seagrass *Posidonia oceanica* (Neptune grass) led to a reduction in the apparent ecological resistance towards the *Caulerpa cylindracea* (green algae) invasion (Casoli *et al.*, 2021; Marín-Guirao *et al.*, 2015).

3.3.1.6 Landscape and seascape degradation

Anthropogenic degradation of terrestrial ecosystems occurs in nearly all types of landscapes around the world, although there are no consistent global figures about the extent of this phenomenon (IPBES, 2018b). Landscape and seascape degradation involves many processes that drive the decline of biodiversity and ecosystem functioning, and in some cases nature's contributions to people in many parts of the world (IPBES, 2018b; Millennium Ecosystem Assessment, 2005a; United Nations Convention to Combat Desertification, 2017). This section summarizes the roles of desertification, soil/water salinization, soil/water erosion and soil/water acidification in affecting biological invasions.

Land degradation related to desertification is a pervasive global phenomenon in arid and semiarid ecosystems subjected to overgrazing (**section 3.3.1.5**), fire (**section 3.3.4.5**) and drought (**section 3.3.4.2**). Separating out the influence of land degradation *per se* from other interlinked drivers responsible for biological invasions is difficult (IPBES, 2018b; Ravi *et al.*, 2009). Acceleration of soil erosion due to agriculture and mismanagement is widely reported, especially from Asia, Latin America and Africa (FAO, 2015; IPBES, 2018b). Soil erosion can increase the establishment of alien species, as exemplified by annual *Bromus* grass in arid and semiarid grasslands of the United States (Germino *et al.*, 2016).

Additionally, invasive alien species may be intentionally introduced to restore degraded land, for example Indigenous Peoples and local communities report the intentional introduction of invasive alien species to manage land degradation (**section 3.2.5**, **Box 3.6**). Stress-tolerant alien plants are often planted in degraded areas for ecosystem restoration (**Glossary**), and can spread from the planted areas (Hobbs *et al.*, 2006), for instance, alien grasses (e.g., *Bromus tectorum* (downy brome)) seeded for preventing soil erosion in degraded grasslands or for livestock forage in overgrazed rangelands (D'Antonio & Meyerson, 2002; D'Antonio & Vitousek, 1992) and alien trees have been planted to stabilize riparian zones. Irrigated land damaged by salinization is estimated globally to be 60 million ha (FAO, 2015; IPBES, 2018b; Squires & Glenn, 2011). Soil salinization associated with waterlogging leads to the replacement of pre-existing native perennial herbaceous plants with salinity-tolerant alien annual plants in southern Australia (Hobbs *et al.*, 2006).

Especially in North America, Europe and Australia, estuarine and coastal areas have been dramatically transformed over the past 150 to 300 years. Degradation linked to industrialization/urbanization (**sections 3.2.2.4** and **3.3.1.4**) has resulted in accelerated establishment and spread of invasive alien species in once diverse and productive areas (Lotze *et al.*, 2006). For example, creation of a metropolitan coastal front in Athens and the Piraeus port led to the occupancy of an alien scleractinian coral, *Oculina patagonica*, in shallow coastal habitats of the Mediterranean Sea (Salomidi *et al.*, 2013). Overexploitation, pollution, disease and climate change are causing global declines of coastal lagoons and coral reefs, especially on the Great Barrier Reef (IPBES, 2018d). There however seems to be clear evidence that coastal disturbance (e.g., harbour constructions) could be a driver facilitating biological invasions (Boudouresque & Verlaque, 2012; J. Klein *et al.*, 2005).

In aquatic systems, invasive alien species may become more prevalent as construction of water storage infrastructure increases (**section 3.3.1.4**), and in many cases, the mechanisms are linked to changes in disturbance regimes. Features such as reservoirs may act as stepping stones for invasive alien species by providing a homogenous, species-poor, early successional habitat providing little biotic resistance for initial occupation (Havel *et al.*, 2005, 2015; **section 3.4.2**). In the Laurentian Great Lakes region of Wisconsin, United States, Johnson *et al.* (2008) found dams and impoundments to be a significant predictor of occurrence for the invasive alien species *Bythotrephes longimanus* (spiny water flea), *Dreissena polymorpha* (zebra mussel), *Osmerus mordax* (rainbow smelt), *Orconectes rusticus* (rusty crayfish) and *Myriophyllum spicatum* (spiked watermilfoil) – ranging between 2.4 to 300 times more likely to occur in impoundments than natural lakes, even after taking into account other environmental and anthropogenic factors. In the same systems, impoundments were also more likely to support multiple invasive alien species (P. T. Johnson *et al.*, 2008).

3.3.2 Direct exploitation of natural resources

Direct exploitation of natural resources includes both the exploitation of biotic resources through species harvesting (**section 3.3.2.1**) as well as of abiotic resources such as water (**section 3.3.2.2**) and mining for minerals and fossil fuels (**section 3.3.2.3**). These changes are closely linked with major economic (**section 3.2.3**) and demographic (**section 3.2.2**) indirect drivers of change in nature and may lead to a range of wider ecosystem impacts, including habitat degradation and loss as well as changes in landscape and seascape disturbance regimes (**section 3.3.1**). Section 3.3.2 thus describes evidence for links between the extraction of specific resources and invasive alien species **(Figure 3.17)**, and makes reference to other indirect and direct drivers when relevant. The demographic and economic background of these changes are described in **section 3.2** and consequences of land degradation more generally is described in **section 3.3.1**.

3.3.2.1 Species harvesting

Globally, the extraction of biological resources for human use for food, fibre and fuel has doubled since 1970, now constituting more than 22 billion tonnes per year (IPBES, 2019). The livelihood of over 350 million people depends on the extraction of non-timber forest resources, and over six million tons of medium to large wild animals are harvested every year in the tropics, where they are often an important food source (IPBES, 2019). Both terrestrial and freshwater ecosystems are affected by species harvesting in different ways. About 50,000 wild species are harvested for food, energy, medicine, materials, income generation, or other uses globally, and an assessment of 10,098 species

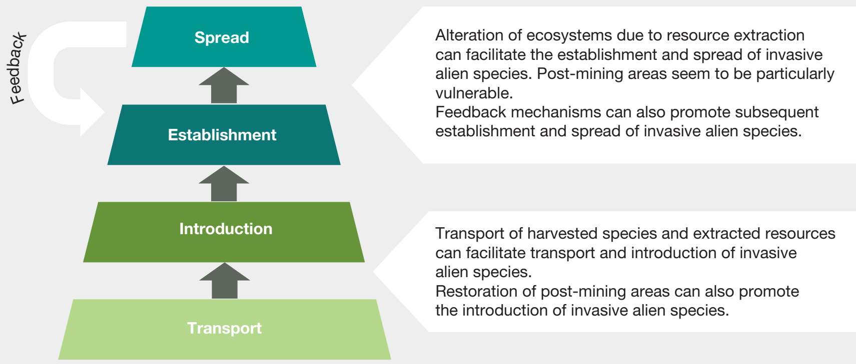

Figure 3 17 **Examples of the role of direct exploitation of natural resources as a driver facilitating invasive alien species across stages of the biological invasion process.**

Transport of harvested species and efforts to restore degraded areas are examples of activities that can lead to the transport and introduction of alien species, the on-site activities related to extraction can facilitate establishment and spread. Introductions of alien species for harvesting often occur at a massive scale, increasing the risk of feedbacks facilitating further introductions.

across 10 taxonomic groups shows that at least 34 per cent are used sustainably, whereas unsustainable harvesting contributes towards elevated extinction risk for 28-29 per cent of near-threatened and threatened species (IPBES, 2022c).

The loss of native biomass and biodiversity in an ecosystem through harvesting has been directly and indirectly linked to increased susceptibility to biological invasions by a wide range of alien species and in a wide range of terrestrial and aquatic environments (IPBES, 2022c; Iverson *et al.*, 2019; Kota *et al.*, 2007; Rebbeck *et al.*, 2017; Schrama & Bardgett, 2016). Many studies of the role of overharvesting on the success of invasive alien species explore indirect effects through trophic changes (Barrios-O'Neill *et al.*, 2016; Kota *et al.*, 2007; Rand & Tscharntke, 2007). For example, an extensive study in the Mediterranean Sea shows that the loss of predators through overfishing resulted in an increase in alien invertebrates in the prey fauna (Rilov *et al.*, 2018). Success of invasive alien species and their impacts may vary, however, depending on whether the harvested native predators are generalists or specialists, and on the intensity and nature of the interaction (Rand & Tscharntke, 2007; W. E. Snyder & Evans, 2006; Tylianakis *et al.*, 2008). Loss of hunted and fished native species may also motivate the release of alien species as alternative species for harvest, as discussed below for terrestrial and aquatic settings.

3.3.2.1.1 Introduction of game for hunting

Stocking of game for hunting purposes is a common practice in many parts of the world, for both recreational and subsistence uses (**section 3.2.1**, **Box 3.2**), and can be an important driver facilitating invasive alien species in many different contexts. A European study (Carpio *et al.*, 2017) found stocking for hunting to be a dominant source of mammal introductions (24 per cent of all known introductions) and birds (30 per cent). Similar patterns were observed in Latin America, where 39 per cent and 22 per cent respectively, of the introduced mammals (69 species in total) and birds (62 species), were introduced intentionally for hunting purposes, compared to an overall 11.2 per cent for food and feed, 5.3 per cent for biological control, and 4.2 per cent for fur industry (Carpio *et al.*, 2020). In the United States, game ranches are also sources of invasive alien species (Geist, 1985). Common alien species introduced for sport or game hunting include: deer species in New Zealand (C. M. King & Barrett, 2005), Australia (N. E. Davis *et al.*, 2016), Latin America (Petrides, 1975) and Europe (Carpio *et al.*, 2017); *Sus scrofa* (feral pig) native to Eurasia and now present on all continents but Antarctica, along with many oceanic islands (Barrios-Garcia & Ballari, 2012; Long, 2003); and various bird species such as pheasants (Blanco-Aguiar *et al.*, 2008) and *Anas platyrhynchos* (mallard) in Australia, New Zealand, South Africa and Hawaii (Rhymer *et al.*, 1994; Fowler *et al.*, 2009; Guay & Tracey, 2009; Government of the Republic of South Africa, 2016). Attempts to control invasive alien species introduced for hunting using biological control have led to further biological invasions, for example the introduction of mustelids to control rabbits and hedgehogs to control garden pests in New Zealand (C. M. King & Forsyth, 2021).

3.3.2.1.2 Introductions of aquatic and marine species for fisheries and angling purposes

Intentional release of fishes and other marine organisms into rivers, lakes and seas to enhance recreational fishing as well as livelihoods is both widespread and common (**section 3.2.1**). These introductions can be distinguished from those linked to aquaculture by being intentionally released into the wild, although the high permeability of aquaculture installations suggests the distinction is somewhat arbitrary (**section 3.3.1.1.1**, FAO, 1995; Grosholz *et al.*, 2015). Globally, hatchery-reared juveniles of more than 180 species of fish and shellfish have been released in the wild for various purposes, including replacing locally extinct stocks (restocking), augmenting a viable fishery (stock enhancement) and creating new fisheries (sea ranching) (Bartley & Bell, 2008; Kitada, 2018; Q. Wang *et al.*, 2006). As many of these releases are occurring at massive scales either outside the native distribution of the species or facilitating spread outside the native range, this constitutes a substantial pathway for aquatic introductions. Introductions, unintentional as well as intentional (e.g., live bait) and legal as well as illegal, have led to the establishment and spread of alien species in freshwater systems in Europe, North America, South America, South Africa and Oceania (Britton & Orsi, 2012; Cambray, 2003; Carpio *et al.*, 2019; Cerri *et al.*, 2018; A. J. S. Davis & Darling, 2017; Ellender & Weyl, 2014; Gherardi *et al.*, 2009; Lintermans, 2004; V. R. Ribeiro *et al.*, 2017; E. R. C. Smith *et al.*, 2020; M. R. Snyder *et al.*, 2020; Weyl *et al.*, 2020). In the Mediterranean basin alone, stocking (for angling, commercial purposes, or biological control) is implicated in over 35 per cent of more than 500 documented freshwater fish introductions (Tricarico, 2012). In the Arctic, *Paralithodes camtschaticus* (red king crab) was intentionally introduced from the Sea of Okhotsk to the Barents Sea in the 1960s to establish a new commercial fishery, and it is currently established and is spreading to the extent that it is commercially harvested by Russian and Norwegian fisheries (Hindar *et al.*, 2020). *Oncorhynchus gorbuscha* (pink salmon) was introduced to several rivers in North-west Russia in the 1950s, and while the first return to rivers in Russia and Northern Norway was recorded in the 1960s, a self-sustaining population did not establish until several decades later. From 2017 onwards, rapid establishment and spread occurred, to the extent that the pink salmon was a dominant fish species in several rivers in Northern Norway in 2021 (with up to 23-fold increase in population size from 2019-2021), and it had spread along the entire Norwegian coast (Berntsen *et al.*, 2022; Hindar *et al.*, 2020).

A compelling example of the cascading effect of species harvesting is the loss of almost 200 species of endemic cichlids following overfishing and introduction of the predatory alien fish *Lates niloticus* (Nile perch) into Lake Nabugabo and Lake Victoria in Africa (Bwanika *et al.*, 2006; Rahel, 2002). Both overharvesting of native species and altered abiotic conditions allowed alien fishes to become established in the lakes, which then eliminated the native species through competition or predation (B. E. Marshall, 2018; Rahel, 2002). The cascade of ecological interactions leading to the demise of native fish in Lake Victoria started with overfishing in the first half of the twentieth century (Aloo *et al.*, 2017), followed by a series of introductions of the invasive alien fish *Lates niloticus*. The *Lates niloticus* population in Lake Victoria peaked at around 2.3 million tonnes in 1999, when it accounted for 92 per cent of the total fish biomass, but fell to less than 300 000 tonnes in 2008, of which the majority were below the required length for export. *Lates niloticus* has subsequently depleted its native prey, hypochromine cichlid fishes (IPBES, 2019), and unsustainable fishing in the lake continued (Luomba, 2016). This top-down cascade led to profound changes in the lake ecosystem, resulting in further reduction in population size and extinction of a number of endemic fishes (**Chapter 4**, **Box 4.10**; B. E. Marshall, 2018).

3.3.2.2 Hydrological resource harvesting

Global water use has increased six-fold over the last 100 years and recent increases in water use have been at a rate of 1 per cent per year (United Nations, 2020). This increasing water use has required large investments in infrastructure, including 50,000 dams and over 16 million reservoirs worldwide (IPBES, 2019), as well as extensive extraction of groundwater resources (International Groundwater Resources Assessment Centre, 2018). There is an increasing recognition that human-mediated hydrological disturbances directly or indirectly facilitate plant and animal invasions (Brummer *et al.*, 2016; Richardson, Holmes, *et al.*, 2007; Truscott *et al.*, 2006). As many alien species thrive in low-competition environments created by hydrological disturbances, biological invasions are often positively associated with the level of hydrological and other disturbances (M. A. Davis *et al.*, 2000; Ricciardi *et al.*, 2017).

Damming and channelization of freshwaters (streams and rivers) and their associated reservoirs can facilitate biological invasions through several mechanisms. First, hydrological alterations through dam constructions may act as reservoirs for invasive alien species and create new habitats which may be colonized by invasive alien species (Richardson, Holmes, *et al.*, 2007). Second, water diversions create new hydrological connections that can facilitate the transfer of a broad suite of aquatic species (including invasive alien species) into new regions. For example, the Chicago Area Waterway was constructed more than 100 years ago to connect Lake Michigan and the Mississippi River, and has permitted invasive alien species to move south from the Great Lakes, and may allow invasive alien *Hypophthalmichthys molitrix* (silver carp) and *Hypophthalmichthys nobilis* (bighead carp) to spread in the opposite direction (e.g., Jerde *et al.*, 2013). Similarly, the water supply to both Los Angeles and San Diego from the lower Colorado River below Lake Mead has been colonized by the biofouling *Dreissena rostriformis* *bugensis* (quagga mussel; e.g., Hickey, 2010). Further, the South-to-North Water Transfer Project, which diverts water from the Yangtze River to northern China, is predicted to promote the further spread of an array of aquatic invasive alien plants, including *Alternanthera philoxeroides* (alligator weed), *Pontederia crassipes* (water hyacinth) and *Pistia stratiotes* (water lettuce) into northern waterbodies (D. Liu *et al.*, 2017).

Hydrological resource use that causes periodic rise and fall of (surface and ground) water levels can make space and resources available for invasive alien species to establish and spread in aquatic and adjacent terrestrial habitats. An example is the invasions of African grasses, including *Melinis minutiflora* (molasses grass), in waterlogged Neotropical savannahs which were driven by changes in the groundwater depth from hydrological disturbance (Xavier *et al.*, 2017). Once an invasive alien species establishes, positive feedback mechanisms, occurring *via* biotic facilitation by the invasive alien species (**section 3.3.5.1**), can promote subsequent biological invasions and promote further spread of invasive alien species, as has been observed for riparian habitats in Czech Republic in which an invasive plant, *Heracleum mantegazzianum* (giant hogweed), resulted in extensive spread in adjacent terrestrial landscapes (Pyšek *et al.*, 2008).

Hydrological alterations or disturbance (e.g., water abstraction) sometimes occur concurrently with other altered habitat conditions (e.g., dryness, salinization, erosion and land and sea degradation) that also favour the introduction and further establishment of invasive alien species. Such alterations in aquatic habitat have favoured establishment of invasive alien species such as *Dreissena polymorpha* (zebra mussel) and *Potamocorbula amurensis* (Amur River clam) in high numbers, with negative consequences for many pelagic and benthic fauna species, especially native mussels in those ecosystems (Grosholz, 2002).

3.3.2.3 Mining (minerals, metal, fossils fuels)

Mining for minerals, metals, oil and other fossil fuels is driven by the energy demands of modern society (Ali *et al.*, 2017) and the transport of these materials accounts for 30 per cent of maritime traffic (IUCN, 2020) contributing to 60 per cent of global GDP (IPBES, 2019). Resource extraction activities also assist in the introduction of invasive alien species to new locations. While mining has a relatively small contribution to overall land-use change (less than about 1 per cent of the area; Maus *et al.*, 2020), its ecological footprint is large (Sonter *et al.*, 2014).

The transport of equipment, the construction of roads or harbours to access mining sites, and the associated increase in vehicles or ships for construction of infrastructure and for transport of mining products can act as pathways and vectors for the introduction of invasive alien species and pathogens, while also facilitating the establishment and spread of invasive alien species due to increased disturbance (F. Bell & Donnelly, 2006; Gelbard & Belnap, 2003; **sections 3.3.1.3**, **3.3.1.4**, **3.3.1.5** and **3.3.1.6**). For example, vehicles and road drainage assisted in the dispersal of spores of *Phytophthora lateralis*, an alien root disease, known to infect the native *Chamaecyparis lawsoniana* (Port Orford cedar) in coal mining areas in the United States (Zobel *et al.*, 1985). Similarly, the introduction of marine invasive alien *Tubastraea* spp. (sun corals) to Brazil was associated with towing and anchoring of oil platforms in coastal waters (Capel *et al.*, 2019). The disturbance and disruption to landscapes caused by mining and resource extraction creates suitable habitats for alien grasses, shrubs and trees to establish and spread (Franklin *et al.*, 2012; Lemke *et al.*, 2013). This can occur across several different types of mining such as coal bed mining (Bergquist *et al.*, 2007; Oliphant *et al.*, 2017), open pit mines (Hou *et al.*, 2019) and fossil fuel extraction activities (Butt *et al.*, 2013). In the context of mining, increased abundance of established invasive alien species are associated with disturbed and fragmented of habitats, the removal of native vegetation cover or through the altered soil nutrients from mine-water discharge (Bergquist *et al.*, 2007).

Mining increasingly tends to occur in remote and previously undisturbed areas (Butt *et al.*, 2013), which may enhance the potential contribution of mining to invasive alien species colonization and establishment in new areas globally. For example, there has been a significant increase in the exploration of oil and gas in marine environments (Jouffray *et al.*, 2020), particularly in Africa (G. Zhang *et al.*, 2019) and the Arctic and Antarctic regions (Petrick *et al.*, 2017), increasing the risk of biological invasions in the marine realm, across multiple taxa, from shipping (Seebens *et al.*, 2013) and discharges of ballast water (Holbech & Pedersen, 2018). Multiple regions and ecosystems across the world are at risk of increased mining activity, including forests (Macdonald *et al.*, 2015), mangroves (Numbere, 2019), the Arctic (Vestergaard *et al.*, 2018) and oceans (Pirotta *et al.*, 2019).

The restoration of post-mining landscapes may also act as a potential pathway for the introduction of alien and invasive alien species. For example, several studies highlight the use of alien species in restoration activities (Mayonde *et al.*, 2015; Oliphant *et al.*, 2017). In South Africa, alien *Tamarix* (tamarisk) species, which have been used in the restoration of post-mining landscapes, have since hybridized with indigenous *Tamarix* species, posing a potential risk for future biological invasions by hybrids (Mayonde *et al.*, 2015; **section 3.3.5.1**). In the United States, the planting of the alien shrub *Elaeagnus umbellata* (autumn olive) has resulted in spread of the species beyond the sites of introduction, which hinders vegetation recovery (Oliphant *et al.*, 2017). Post-mining areas may also be considered as potentially suitable sites for the cultivation of biofuel feedstocks from known invasive alien species, which may spread beyond the area of introduction due to the inherent invasive traits of the species. While the outcomes of introducing known invasive alien species to improve soil conditions where native vegetation is unable to grow due to contamination is beneficial, introducing new species to areas where they were not before (Prabakaran *et al.*, 2019) may increase the risk of alien species spreading to new areas. A meta-analysis of small mammal recovery in passive and actively restored mining areas (Lawer *et al.*, 2019) found that the abundance of invasive alien species was significantly higher in actively restored areas compared to native species. Similarly, studies on the vegetation composition of four coal mines in the Yunnan Province, China, found that invasive alien species occur mainly in degraded areas where active mining or restoration activities are taking place (Hou *et al.*, 2019). However, invasive alien species occurrence can also be influenced by the type of mine and the material extracted (Hou *et al.*, 2019). In a review of the recovery of post-mining landscapes from North America, Europe and Australia, Macdonald *et al.* (2015) found that native species recovery was slowed by the establishment of invasive alien plants.

The evidence for mining as a driver of change in nature that facilitates biological invasions reported in this section stems mainly from terrestrial and marine realms and from Europe and the Americas. Most evidence exists for the introduction, establishment and spread of plants and trees, with little representation of other taxa apart from mammals.

3.3.3 Pollution

Pollution entails releasing new chemical or physical substances or increasing the level or concentration of already-existing substances into ecosystems. Although there are no consistent global assessments on the increase and impacts of pollution, it is believed that pollution has increased at rates similar to the total population growth (IPBES, 2019). Pollution can facilitate invasive alien species through increasing nutrient and resource levels available in ecosystems, such as is the case with eutrophication (**section 3.3.3.1**), through introducing new chemical substances in water or soil (**section 3.3.3.2**) and through dispersal of solids (**section 3.3.3.4**). Marine debris (notably, plastics) are treated separately (**section 3.3.3.3**) because they are a major emerging issue in the context of biological invasions. These pollution sources stem from major economic (**section 3.2.3**) and demographic (**section 3.2.2**) indirect drivers. **Section 3.3.3** thus describes evidence for links between specific pollutants and invasive alien species (**Figure 3.18)**, and makes reference to other indirect and direct drivers when relevant, whereas the demographic and economic background of these changes are described in **section 3.2**.

3.3.3.1 Eutrophication and nutrient deposition

Eutrophication refers to the increase of macronutrients, primarily nitrogen and/or phosphorus in the environment. Major sources are fertilizer use, runoff from animal husbandry and combustion by-products (Stevens, 2019). Common pathways for eutrophication are atmospheric deposition (a major source of oxidized nitrogen) and

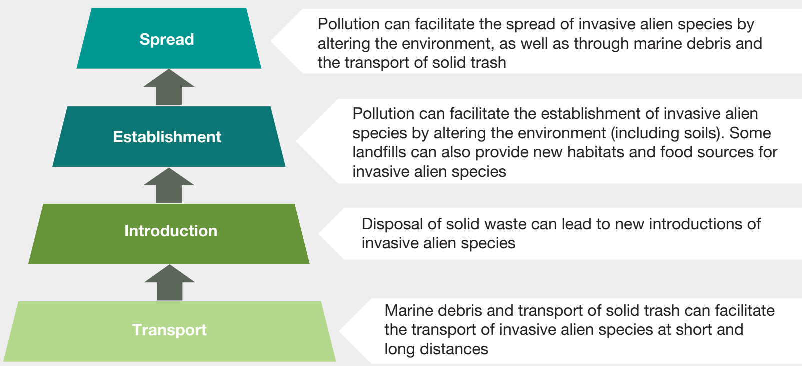

Figure 3 18 **Examples of the role of pollution as a driver of change in nature that facilitates invasive alien species across stages of the biological invasion process.**

Solids (marine debris, solid waste) can facilitate the transport and introduction of invasive alien species and provide habitat and surfaces where alien species can establish and spread. Nutrient and chemical pollution can change habitat quality, making sites more hospitable to invasive alien species.

run-off (nitrogen, phosphorous and other macronutrients, particularly affecting freshwater and coastal systems). The global use of fertilizers increased linearly during the second half of the twentieth century (IPBES, 2019), and for many regions a further increase in the balance of both nitrogen and phosphorus in the soil is expected in the following decades (FAO, 2015). Accordingly, during the last decade alone, there was a four to 20 fold increase in nitrogen flux in aquatic ecosystems (IPBES, 2019). Initial emissions are driven by economic (**section 3.2.3**) and demographic drivers (**section 3.2.2**), as described in the IPBES Global Assessment (IPBES, 2019). Pollution may interact with land- and sea-use change (**section 3.3.1**) and climate change (**section 3.3.4**) in driving the establishment and spread of alien species.

Invasive alien plant species often originate from relatively nitrogen-rich habitats (Dostál *et al.*, 2013), and are hence hypothesized to be more likely to establish and spread under increased nitrogen availability. In line with this, replicated experiments across hundreds of sites in Arctic, boreal, temperate, Mediterranean and tropical grasslands demonstrate that nitrogen addition generally increases the occurrence, abundance, and impact of invasive alien plants, a pattern that is especially pronounced towards warmer and wetter sites (Borer *et al.*, 2017; Seabloom *et al.*, 2013). A review from the United States reported that in temperate and Mediterranean temperate vegetation, increased abundance of invasive alien species is consistently documented as an impact when nitrogen deposition exceeds the critical load for that vegetation type (Pardo *et al.*, 2011). Nitrogen deposition and eutrophication have also been associated with increased abundance of alien tree and understory plant species in a wide range of other habitats, including tropical humid forests (Cusack *et al.*, 2016), temperate forests (Gilliam, 2006) and European lowland heaths (Fagúndez, 2013). Urban and other strongly human-impacted areas may be especially susceptible to invasive alien species facilitated by eutrophication (Ladd, 2016). Eutrophication may also interact with and feedback to other drivers in facilitating invasive alien species, for example, several reviews find that across Mediterranean-type ecosystems, nitrogen deposition favours alien grasses, which accumulate dead biomass in the dry season, increasing wildfire risk (Ochoa-Hueso *et al.*, 2011; Ochoa-Hueso & Manrique, 2010; Vasquez *et al.*, 2008; **section 3.3.1.5.2**).

In aquatic systems, a global study of invasive alien chironomids found that a high proportion of the reported cases were from eutrophic waters, including anthropogenic urban lakes and drainage channels and wastewater treatment plants (Linders *et al.*, 2020). Eutrophication also facilitates alien algae invasions in European lakes and streams (Wilk-Woźniak & Najberek, 2013) and aquatic plant invasions in China (Wu & Ding, 2019). A meta-analysis of drivers of change in freshwater systems revealed surprisingly few studies that explicitly consider alien species (Alahuhta *et al.*, 2019). A review of over 400 marine algal invasions found that most invasive alien species were encountered in eutrophicated waters, but also points out that several vectors and disturbances correlate with eutrophication, and that there is a general lack of experimental studies so it is difficult to establish causality (S. L. Williams & Smith, 2007). A well-studied biological invasion by the potentially toxic dinoflagellate *Prorocentrum minimum* in the Baltic Sea was empirically linked to eutrophication (Hajdu *et al.*, 2005). Eutrophication caused by aquaculture can be particularly conducive to macroalgal invasion in former seagrass beds (Boudouresque *et al.*, 2021; Gennaro & Piazzi, 2011). Extreme eutrophication in aquatic systems can lead to hypoxia. Upon recovery, empty niches may be filled with opportunistic invasive alien species, as shown for an invasive alien nematode which dominates areas of the recovering Ems estuary on the border between the Netherlands and Germany (Essink, 2003).

Studies of eutrophication as a driver affecting invasive alien species are most often focused on plants and algae as they are autotrophic and take macronutrients up directly from the environment. Such studies focus on the establishment and spread phase of the biological invasion process and most focus on alien species of vascular plants in Europe and North America (the geographic bias in these studies largely reflecting overall bias in the location of scientific studies). The available evidence suggests that the role of eutrophication in driving biological invasions is often variable, and both species- and system-specific. On one hand, alien species that respond positively to nitrogen availability in their native range also tend to respond positively to high nutrient availability in their invaded ranges (Borer *et al.*, 2017). On the other hand, in the absence of extrinsic nutrient addition, or in systems where nutrient addition *per se* does not lead to increased productivity or growth, such as for example in tropical forests, alien species can nevertheless benefit from nutrient addition (Cusack *et al.*, 2016). Marine studies are particularly focused on the spread of invasive alien species in Mediterranean seagrass ecosystems.[7] Authors found no studies directly linking eutrophication to terrestrial vertebrate invasions, despite the potential for a link between soil nitrogen and invasive alien herbivores *via* bottom-up processes.

3.3.3.2 Other contaminants in water and soil

Human modification of environments due to high pressure on direct exploitation of natural resources (**section 3.3.2**), land-use change (**section 3.3.1**) and urbanization (**section**

7. Data management report available at https://doi.org/10.5281/zenodo.5529309

3.2.2.4) has led to deposition of diverse contaminants in soil and water. Construction and maintenance of roads introduces metals (especially lead, but also aluminium, iron, cadmium, copper, manganese, titanium, nickel, zinc and boron), salts, ozone and nutrients into roadside environments (Trombulak & Frissell, 2000). This introduction creates an opportunity for alien species that are highly tolerant to contaminants to establish in areas where native species are struggling. For example the roadside *Melinis repens* (natal redtop) is a common naturalized species in Australia and high levels of trace metal were found in its tissues (C. Pratt & Lottermoser, 2007). Zhang *et al.* (2008) found that higher tolerance to lead stress enabled the alien *Sambucus canadensis* (American black elderberry) to outperform the native *Kummerowia striata* (Japanese lespedeza) and may have promoted its rapid establishment in lead contaminated soil. In Brazil, in a rocky neotropical savannah, Barbosa *et al.* (2010) found that paved roads, by reducing aluminium toxicity, favour alien species and helps them during the first stages of the biological invasion process. However, in some cases, soil contamination can also limit the fitness of invasive alien species and influence the dynamics between invasive alien and native species. De la Riva and Trumble (2016) investigated the effect of selenium on reproduction and competitive behaviour of the invasive alien *Linepithema humile* (Argentine ant) and found environmental toxins may not only pose problems for native ant species, but may also serve as a potential obstacle for establishment among alien species; *Linepithema humile* reproduced less when exposed to selenium.

Pollutants in aquatic systems, including metals contained within antifouling paints, can enhance the establishment success of invasive alien species (Piola & Johnston, 2008), particularly those that have a positive association with metal contamination such as the invasive alien hull-fouling bryozoan *Watersipora subtorquata* (McKenzie *et al.*, 2012). Additionally translocations of static maritime structures and movement of semi-submersible rigs continue apace in the Anthropocene and so act as largely overlooked and unregulated vectors of marine invasive alien species (Iacarella *et al.*, 2019; Wanless *et al.*, 2010). Also, water pollution caused by high alkalinity and nitrate concentration (**section 3.3.3.1**) is associated with the occurrence of aquatic invasive alien species that are among Europe's top 10 invasive alien species, such as *Dreissena polymorpha* (zebra mussel), *Procambarus clarkii* (red swamp crayfish) and *Salvelinus fontinalis* (brook trout) (Gallardo, 2014).

3.3.3.3 Marine debris

Marine debris is defined as "any persistent manufactured or processed solid material discarded, disposed of or abandoned in the marine and coastal environment" (Agamuthu *et al.*, 2019), thus dispersal of any alien species through marine debris is considered anthropogenic. The six main categories of marine debris are plastic, paper, metal, textile, glass and rubber (Agamuthu *et al.*, 2019). Plastic comprises 50 to 90 per cent of the total marine debris found globally (Eriksen *et al.*, 2014). A 2014 estimate of the amount of plastic pollution floating on the ocean revealed that there is a minimum of 5.25 trillion particles weighing 268,940 tons (Eriksen *et al.*, 2014). In the absence of further regulations, the amount of plastic entering aquatic ecosystems annually is expected to increase from 14 million tons per year in 2016 to 23-37 million tons per year by 2040 (United Nations Environment Programme, 2021). This burgeoning amount of plastic debris in the ocean has created unprecedented opportunities for the dispersal of marine organisms through rafting, representing a potential mechanism for biological invasions. Floating marine debris can disperse attached organisms significant distances depending on the ocean current speed and direction, and thus facilitates first introductions (*via* long-distance transport) to a new region, and secondary spread (short-distance transport) within an invaded region (Rech *et al.*, 2016). Floating plastic degrades much more slowly than natural rafting material and therefore is a potentially more potent vector for long-distance dispersal of invasive alien species (Agamuthu *et al.*, 2019).

Flotsam and jetsam (floating debris) usually start their floating journey in a "clean" state (i.e., free of fouling biota). Debris provides a new habitat for marine species adding new surfaces for colonization by organisms. Because debris usually spends a long time periods in the marine environment, debris often hosts an extensive and reproductively active fouling biota, before becoming part of marine floating litter (Kiessling *et al.*, 2015). For example, in Colombia, 86 per cent of marine debris is composed by wooden materials and plastic litter, which generate the optimal conditions for species to float away and colonize novel areas. Indeed, this study found that 62 per cent of the surveyed beaches were found to have marine fauna using floating plastic or wood as a substrate for potential rafting and dispersal (Gracia C. *et al.*, 2018). Organisms ranging from algae to reptiles (i.e., iguanas) have been observed to raft on floating objects, but the most common species include barnacles, polychaete worms, bryozoans, hydroids and molluscs. There is evidence for the transport of 270 species belonging to 85 taxa, including at least five invasive alien species on floating objects on the sea; however this phenomenon is likely still underestimated due to the limited number of studies and observations at the species level (Avio *et al.*, 2017). The highest numbers of rafting taxa on floating litter were found in the Pacific and North Atlantic, which might be explained by the overall high research effort undertaken in these regions (Kiessling *et al.*, 2015).

Marine plastic debris is largely attributed to fisheries and leisure or household gear (Gracia C. *et al.*, 2018). Off the

Asturian coast, Spain, rafting biota identified included species of goose barnacles, acorn barnacles, bivalves, gastropods, polychaetes and bryozoan, and hydrozoan colonies attached to stranded litter, many of which were alien species, such as *Magallana gigas* (Pacific oyster) and *Austrominius modestus* (Australian barnacle) (Rech *et al.*, 2018). Plastics, except for foam, sustained a more diverse attached community than non-plastic materials (Rech *et al.*, 2018). Another study carried out in New Zealand identified that the most common biofouling taxa traveling in marine debris were hydroids, bryozoans, algae and polychaetes (Campbell *et al.*, 2017). Off the Cantabrian Coast, alien species expansions could be reinforced by the presence of manufactured objects in the sea. *Austrominius modestus, Magallana gigas*, the potentially invasive alien *Amphibalanus Amphitrite* (striped barnacle) and other 14 species were found attached to plastic bottles and fishing gear, in particular on ropes (Miralles *et al.*, 2018). Off the west coast of Svalbard, a study that assessed the density of macro-plastic litter and the biota established on them found that the largest objects (fishing boxes, containers) were colonized by *Semibalanus* sp. (barnacles), *Lepas* sp. (goose barnacles), *Mytilus* sp. (blue shells), bryozoans and marine macro-algae.

Box 3 8 **The spread of invasive alien species on Japanese tsunami marine debris.**

On the 11 March 2011, an undersea megathrust earthquake struck Japan and created a tsunami on its East coast (specifically in the Tohoku coast of Northeast Honshu, Japan) that reached 38.38 m in height (Carlton *et al.*, 2017; Shimada, 2016). The tsunami produced abundant marine debris and caused the translocations of multiple taxa that were concentrated in the Pacific Northwest of the United States. At least 289 living Japanese coastal marine species have been found since 2012 on the coastlines of North America and Hawaii; the biota included macroinvertebrates, fish, microinvertebrates and protists (Carlton *et al.*, 2017). According to Miller *et al.* (2018), one of the most common species arriving on Japanese tsunami marine debris is *Mytilus galloprovincialis* (Mediterranean mussel). During the following years after the tsunami, various reports associated the appearance of new invasive alien species, not previously reported, with this event. The establishment of rafting species will depend on the number and frequency of reproductively viable individuals being transported on the marine debris coupled with the presence of suitable environments in the recipient range (Carlton *et al.*, 2017). The tsunami occurred early in the breeding season for many coastal species, which may have contributed to a successful settlement on Japanese tsunami marine debris (J. A. Miller *et al.*, 2018).

Figure 3 19 **Marine debris caused by the 2011 tsunami in Japan.**

The derelict was discovered off the coast of Seal Rock, Oregon, USA in April 2015 after having been missing from Japan since the tsunami on 11 March 2011. Photo credit: John W. Chapman – under license CC BY 4.0.

The rafting of groups of adult organisms favours their better biological dispersal compared to larval transport, and is regarded as the main reason for reappearance of the genus Mytilus on Svalbard (Weslawski & Kotwicki, 2018). In the western Mediterranean Sea, plastics were the major type of debris found because of its poor degradability; however, glass, cans, fishing nets and polyurethane containers were also found. Macro-benthos living on raft material comprised mainly molluscs, polychaetes and bryozoans, large fish were found commonly below large plastic bags, while following resources linked with the bags, these fish might move outside of their native range (Aliani & Molcard, 2003). Non-plastic objects, while less abundant and less ephemeral, can still help in spreading invasive alien species, as shown by an example of 10 alien mollusc species found on a single buoy (Ivkić *et al.*, 2019).

Marine debris can interact with other drivers in facilitating biological invasions. Notably, natural disasters can enhance the movement of invasive alien species traveling on marine debris (**section 3.4.1**). For several years following the Japanese tsunami in 2011, debris with living species from Japan has landed on coastlines from Midway Atoll to Hawaii Island and from south central Alaska to central California **(Box 3.8)**. Using the data from this event to model potential establishment, Simkanin *et al.*(2019) found that of 48 invertebrate and algal species on the Japanese tsunami marine debris, 27 per cent (13 species) had landed on Asturian coast locations with suitable environmental conditions for establishment and survival, and a further 43 per cent (21 species) had environmental requirements met in other areas where tsunami debris likely landed (but had not been documented).

3.3.3.4 Dispersal of solid waste

In 2016, humans generated over 2 billion tons of municipal solid waste, and by 2050 this number is predicted to increase to 3.4 billion (Kaza *et al.*, 2018). Solid waste can both transport and sustain a high variety of alien organisms, thus contributing to the spread of invasive alien species. A global review reported the establishment of 215 alien plant species in waste disposal sites (Plaza *et al.*, 2018). In Pakistan, industrial waste increased the recruitment of the invasive alien tropical trees *Prosopis juliflora* (mesquite) and *Leucaena leucocephala* (leucaena) (Uzair *et al.*, 2009). In central Brazil, the dispersal of the invasive alien grass *Arundo donax* (giant reed) seems to be assisted by the disposal of construction waste (Simões *et al.*, 2014). Disposal of garden waste may facilitate the spread of ornamental alien plant species, as examples, in Spain the cactus *Opuntia engelmannii* subsp. *lindheimeri* (Lindheimer pricklypear; Elorza *et al.*, 2004), in Argentina, the fast-growing liana *Podranea ricasoliana* (pink trumpet vine; Hurrell *et al.*, 2012) and the rhizomatous fern *Pteris parkeri* (Cretan brake; Guerrero, 2017). Dumping garden waste in close proximity to watercourses contributed to the spread of *Reynoutria sachalinensis* (giant knotweed) and *Reynoutria japonica* (Japanese knotweed) in riparian habitats in the Czech Republic (Pyšek & Prach, 1996). Irresponsible disposal of fragments of alien aquarium macrophytes and macroalgae may promote their introduction and spread in nature (Cohen *et al.*, 2007; Odom *et al.*, 2014; Vranken *et al.*, 2018). Waste disposal sites are a source of propagules of alien plants that can spread into natural habitats. In central Brazil, savannah adjacent to landfills has ten times more alien species than nearby savannah not adjacent to landfills (Santana & Encinas, 2008). Urban mixed deciduous forest sites in Switzerland close to illegal garden waste dumping areas exhibit over 30 times more alien species than nearby control areas (Rusterholz *et al.*, 2012). In addition, landfill areas used for compost production may contain many alien plants (Vaverková *et al.*, 2020), so that the distribution and use of this compost, for example in agriculture, could promote biological invasions (Pietsch, 2005).

Waste disposal sites are often used as a food source by alien vertebrates found close to urban areas (**section 3.2.2.4**), such as *Rattus norvegicus* (brown rat), *Felis catus* (cat) and *Sus scrofa* (feral pig) (Plaza & Lambertucci, 2017). Food waste has been found to be an important item in the diet of feral cats in Mexico (Ortiz-Alcaraz *et al.*, 2017) and Australia (Hutchings, 2003), and a rubbish tip in Australia supported a high density of feral cats (Denny *et al.*, 2002). Among alien birds, food waste consumption has contributed to the establishment and spread of *Threskiornis aethiopicus* (sacred ibis) in the United States (Calle & Gawlik, 2011) and Western Europe (Clergeau & Yésou, 2006), as well as for *Passer domesticus* (house sparrow) in urban sites in Kenya (Imboma, 2014). In eastern Madagascar, the abundance of the invasive alien *Duttaphrynus melanostictus* (Asian common toad) is positively related to the presence of rubbish dumps (Licata *et al.*, 2019). Disposal of green waste containing small alien vertebrates may also contribute to their spread, as was possibly the case during the rapid expansion of *Leiocephalus carinatus armouri* (northern curly-tailed lizard) in Florida (H. T. Smith & Engeman, 2003). In South Central United States, landfills facilitate the establishment and spread of *Paratrechina fulva* (tawny crazy ant; ISAC, 2016). In South America, waste disposal sites provide food and hiding sites for *Lissachatina fulica* (giant African land snail; Gregoric *et al.*, 2013; Kaique & Nara, 2017; Thiengo *et al.*, 2007). Alien species account for 30 per cent of the richness and abundance of macro-snails in landfills in the United Kingdom (Rahman *et al.*, 2016). The accumulation of water in solid waste disposed in urban areas favours the proliferation of alien mosquitos of the genus *Aedes*, which are vectors of several diseases that affect humans (e.g., *Aedes aegypti* (yellow fever mosquito); Baldacchino *et al.*, 2015).

In summary, the disposal of solid waste has contributed to the introduction, establishment and spread of a wide variety of alien plant and animal species in terrestrial and aquatic habitats across continents. Most of the studies took place in Europe and North America. There is a lack of studies in the East Asia and Pacific regions, where the highest amount of solid wastes are produced (Kaza *et al.*, 2018).

3.3.4 Climate change

Anthropogenic climate change has emerged as a dominant threat to Earth's biodiversity and ecosystems over the last few decades, altering species' ranges and abundances, reshuffling biological communities, restructuring food webs, and altering ecosystem functions (IPBES, 2019; IPCC, 2022). Alterations in global temperature and precipitation regimes are predicted to facilitate biological invasions by increasing the likelihood of introduction and establishment of invasive alien species in many areas, thus increasing the potential invaded range of invasive alien species (Hellmann *et al.*, 2008; IPBES, 2019; IPCC, 2022; Walther *et al.*, 2009). Climate change may further facilitate biological invasions by increasing rates of reproduction and survival in sites where invasive alien species are already present, hence facilitating their establishment and further spread (Chown *et al.*, 2012; Fløjgaard *et al.*, 2009; Loomans *et al.*, 2013). The range or population growth rates of some alien species may currently be limited by climatic variables which may become more favourable in the future (e.g., low temperature, low precipitation in regions where these climate factors show increasing trends; Bradley *et al.*, 2010; Ibáñez *et al.*, 2009; O'Donnell *et al.*, 2012). Some studies based on bioclimatic models predict that more frequent extreme events may have potential to trigger or alter the trajectory of biological invasions (Hulme, 2017; Pyšek *et al.*, 2020). While models and projections point to potentially strong impacts of climate change on biological invasions (**section 3.6.3**, **Box 3.14**), empirical data that unambiguously attribute shifts in alien species' distributions and abundances to climate change are rare.

Climate change entails shifts in both mean conditions and the frequency and magnitude of climatic extremes, all of which can have consequences for biological invasions. This section synthesizes knowledge about how invasive alien species are affected by changes in temperatures (**section 3.3.4.1**), precipitation regimes (**section 3.3.4.2**), extreme events (**section 3.3.4.3**), CO_2 concentrations (**section 3.3.4.4**), fire frequencies and magnitudes (**section 3.3.4.5**), sea level rise (**section 3.3.4.6**), and, assisted colonization is an example of a climate mitigation strategy with high relevance for invasive alien species **(Box 3.9)**. Climate change results from major economic (**section 3.2.3**) and demographic (**section 3.2.2**) indirect drivers over long timescales. **Section 3.3.4** describes evidence for links between specific climatic changes and invasive alien species **(Figure 3.20)**, and makes reference to other indirect and direct drivers when relevant. The demographic and economic background or these changes are described in **section 3.2**.

3.3.4.1 Temperature change

Global mean surface temperature is projected to rise between 1.4°C and 4.4°C by the end of the twenty-first

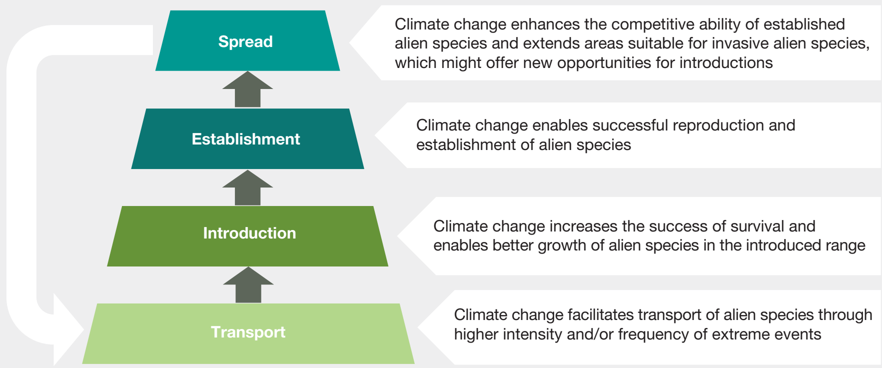

Figure 3 20 **Examples of the role of climate change as a driver of change facilitating invasive alien species across stages of the biological invasion process.**

Extreme events may facilitate transport, changes in climatic conditions may enhance survival, reproduction, and competitive ability, which in turn increases introduction establishment and spread, of alien species. Climate change may extend the geographic ranges potentially suitable for invasive species, providing potential feedback from spread (within the invaded range) to transport (to new areas beyond the current invaded range). Adapted from Walther *et al.* (2009).

Box 3 9 **Assisted colonization.**

Species translocations for conservation purposes have been conducted for decades, but the vast majority are reintroductions or population enhancements of species within their historical range, whereas assisted colonization (variously termed “assisted colonization”, “assisted migration” and “managed relocation”; Hoegh-Guldberg *et al.*, 2008; J. M. Mueller & Hellmann, 2008; Richardson *et al.*, 2009) is concerned with moving species into areas beyond the range in which they have a recent evolutionary history. Assisted colonization could become a significant driver facilitating biological invasions in the future as climate change adaptation and ecosystem restoration strategies increasingly argue for species translocation (D. M. Hansen, 2015; Lunt *et al.*, 2013). Thus far, assisted colonizations of animals have typically involved relatively short-distance translocations, most often to islands (e.g., Freifeld *et al.*, 2016; Griffiths *et al.*, 2010; Scoleri *et al.*, 2020). Since the mid-2000s there have been an increasing number of proposals to intentionally introduce plants and animals to favourable habitats beyond their historical ranges, with the goal of protecting such species against climate change and other environmental stressors (Seddon, 2010).

It has been proposed that decisions regarding assisted colonization schemes can be guided safely by an assessment of the costs and benefits of translocation (Hoegh-Guldberg *et al.*, 2008), including the potential ecological or economic impacts of biological invasions. Others have argued that the ability of ecologists to forecast ecological costs is weak (Ricciardi & Simberloff, 2009). Some researchers suggest that the risks of ecological disruption can be reduced by moving species within the same continent (J. M. Mueller & Hellmann, 2008), especially where closely related species exist. In such situations the translocated species is less likely to encounter communities that lack eco-evolutionary experience with functionally similar taxa and thus the species’ abundance and impact are more likely to be constrained through species interactions; however, this rationale ignores risks of hybridization, competitive displacement and disease transmission (Arcella *et al.*, 2014; Morales *et al.*, 2013; Simler *et al.*, 2019). Given the global influence of climate change as a stressor, the issue of assisted colonization is relevant to biotas in all regions and terrestrial, freshwater and coastal marine realms.

century (2081–2100) relative to 1986–2005, depending on how greenhouse gas emissions develop (Arias *et al.*, 2021; IPCC, 2014, 2021). Warming seems to be strongest at high northern latitudes and with variable rates in mountainous biomes in comparison to lowlands (Loarie *et al.*, 2009; Mountain Research Initiative EDW Working Group, 2015; C. Nolan *et al.*, 2018; Q. Wang *et al.*, 2016). The warming is associated with other changes in ecosystems such as contraction of snow cover and permafrost areas (Luláková *et al.*, 2019) and increased risk of heat and precipitation extremes (IPCC, 2007, 2021) affecting the productivity and water-use efficiency and spatial shifts of habitats (Svenning & Sandel, 2013).

The general expectation is that with increasing temperatures, some established alien species will be able to expand their ranges polewards and to high elevations and thus expand their introduced ranges without additional human assistance. Warming is a major component in forecasts of the responses of 100 of the world’s worst invasive alien species to climate change, according to the International Union for Conservation of Nature (IUCN), who project significant range shifts, and hence further spread of invasive alien species within and beyond their current invaded ranges (Bellard *et al.*, 2013). For example, outbreaks of bluetongue virus, a disease of ruminants transmitted by *Culicoides* species (biting midges), occurred for the first time in northern Europe in 2006 as a result of warmer temperatures. In the future, these northern regions will become increasingly suitable for this midge vector, which could spread unaided on prevailing winds (A. E. Jones *et al.*, 2019). Increased temperatures may benefit the establishment of some alien species regularly intercepted at the border by quarantine officers as contaminants of goods (particularly agricultural and horticultural produce) or stowaways on transport vectors (such as in or on boats). Since the 1970s, the establishment in the United Kingdom of alien invertebrate plant pests intercepted at ports of entry or for which outbreaks have been reported is positively correlated with average winter temperatures, but no such relationship was found for plant pathogens (Hulme, 2017). However, increases in winter temperature was found to facilitate the spread of plant pathogens in North America (Kliejunas, 2011).

Climate change may increase the probability of establishment and spread of alien species that are currently present in a particular region in anthropogenic environments such as buildings, glasshouses, and gardens but are limited by climate from surviving in nature. For example, in the United Kingdom warmer winter temperatures are expected to increase the probability that *Liriomyza huidobrensis* (serpentine leafminer) and the soil-borne *Athelia rolfsii* (sclerotium rot), currently found in glasshouses, will be able to overwinter outside and consequently establish (Baker *et al.*, 1996; Hardwick *et al.*, 1996). Similarly, casual annual C4 weeds (e.g., *Setaria viridis* (green foxtail), *Digitaria sanguinalis* (large crabgrass)) that do not tolerate frost and thus do not currently survive the winter in the United Kingdom may become problematic in arable agriculture in a warmer future when this constraint is lifted, especially as they are well-adapted to high temperatures that some British native plants may not tolerate as well (Froud-Williams, 1996). For insects in temperate regions, a major effect of climate warming is enhanced individual growth and development and consequent increased winter survival, allowing range expansion to more northerly latitudes (Bale *et al.*, 2002). Thus several invasive alien insect species, many of which are crop pests and diseases, may expand their ranges northward and upward under climate change (Lehmann *et al.*, 2020). In aquatic systems, substantial non-breeding populations of the *Trachemys scripta* (pond slider) have persisted for some time in regions where climate change could soon facilitate reproduction and subsequent establishment and spread (Rödder *et al.*, 2009). Similarly, warming of North American lakes is likely to increase thermal suitability for species of fishes currently with a more southerly distribution, including many alien species, that could potentially expand their distribution poleward into alien regions, potentially as far as the Arctic (Ricciardi *et al.*, 2020).

Several empirical studies support and confirm some of these projections. Higher temperatures, extended summer seasons, and increasing available thermal budget for growth are recognized as potential explanations for ongoing polewards shifts in species' distributions (S. C. Mason *et al.*, 2015; Parmesan & Yohe, 2003). There is evidence that alien species may be especially well-suited to exploit opportunities for range expansions offered by warming. For example, over the past two decades, alien plant species in the European Alps have colonized higher altitudes approximately twice as rapidly as native species (Dainese *et al.*, 2017). As another example, the majority of alien species in the Mediterranean originate from the Red Sea (i.e., Lessepsian migrants; about 67 per cent of all alien species; **section 3.3.1.3**, **Box 3.7**), with a small proportion (about 7 per cent) from other tropical areas. These alien species have long been confined to the easternmost Levantine shores, and the warming of the Mediterranean is now facilitating their further spread (Lejeusne *et al.*, 2010). Temperature has been found to limit key performance parameters in alien species across taxonomic groups and regions, including fecundity in mammals (D. J. Bell & Webb, 1991), fish (Fobert *et al.*, 2011) and birds (Shwartz *et al.*, 2009); growth in marine algae (Hales & Fletcher, 1989) and fish (Kornis *et al.*, 2012); survival in amphipods (Ashton *et al.*, 2007; Cowling *et al.*, 2003) and mosquitoes (Roiz *et al.*, 2011) and growth, survival and fecundity in plants (Willis & Hulme, 2002). However, temperature sensitivity in such performance parameters does not automatically translate into increased performance in a warming climate. For example, in the United Kingdom, alien plants have a faster phenological response to warming than co-occurring native species, yet this has not translated into a faster spread (Hulme, 2011b).

As climate change progresses, some regions, biomes and taxonomic groups will be subjected to climates not previously encountered, and invasive alien species are projected to either decrease or increase (Bellard *et al.*, 2013b; **Chapter 2**, **section 2.6**). Bellard *et al.* (2013) project future hotspots of invasive alien species to be in biomes at higher latitudes where future climate change is projected to be less extreme (e.g., temperate mixed forests and woodlands) whereas biomes expected to shift into extreme climatic zones (e.g., tropical forest) may experience a decrease in number of invasive alien species. The ranges of invasive alien terrestrial and aquatic invertebrates, aquatic plants and microorganisms are projected to increase, whereas the ranges of invasive alien amphibians, birds and fungi could experience range contractions under future climate projections (Bellard *et al.*, 2013b; **Chapter 2**, **section 2.6**).

3.3.4.2 Precipitation change

Climate change has caused an increase in global average precipitation since the mid-twentieth century, which has been accelerating since the 1980s, but with great regional and temporal variability, so that precipitation is increasing in some regions, decreasing in others, with interannual variability and seasonality also changing (IPCC, 2021). Few studies explicitly link biological invasions to precipitation change, and effects of precipitation change may relate both to water *per se* and to consequences for disturbance regimes or dispersal. Precipitation extremes cause disturbances which can create open sites suitable for colonization, especially in and along streams where precipitation extremes may also be associated with increased propagule pressure, leading to increased risk of biological invasions (Pyšek, Bacher, *et al.*, 2010). For example, drought and changes in flow regimes of rivers and streams (which are of relevance for precipitation change) can facilitate the spread of invasive alien plant species along streams in Europe, both directly and through negatively affecting the native plant community (Catford *et al.*, 2011, 2014). As another example, invasive alien European *Bromus* spp. grasses in North America can exploit available soil moisture more efficiently and thus recover more rapidly than native vegetation after drought enabling them to invade areas formerly dominated by native woody species following periods of drought (Ricciardi *et al.*, 2020). Precipitation changes may interact with temperature changes in affecting future ranges of invasive alien species. For example, the potential invaded range of *Bactrocera dorsalis* (Oriental fruit fly), a major pest throughout South East Asia that has invaded (and been eradicated from) a number of Pacific Islands and mainland areas in North America and elsewhere is projected to extend further polewards as cold stress boundaries recede, but also contract in areas where precipitation decreases substantially (Stephens *et al.*, 2007). In North America, concurrent changes in precipitation and temperature are projected to extend the potential invaded range for many invasive alien species of forest ecosystems (Dukes *et al.*, 2009). In particular, forest fungal pathogens in

Europe (123 taxa, of which 42 per cent are considered to be alien species) and North America (18 taxa) are sensitive to both low temperatures and drought, and are generally expected to extend their invaded ranges with increasing temperature and precipitation (Dukes *et al.*, 2009; Santini *et al.*, 2013). Precipitation change may also affect the distribution of invasive alien insects. *Solenopsis invicta* (red imported fire ant) was introduced to the United States from sub-Amazonian South America (native range) in the 1930s or 1940s, and has since expanded throughout North America and to Australia and New Zealand along with a number of tropical islands. The potential invaded range of the red imported fire ant is limited by both low temperature and low precipitation, and future projections entail both expansions and contractions, the latter largely in areas where precipitation is projected to decrease (Morrison *et al.*, 2004).

3.3.4.3 Climate extremes

Anthropogenic climate change is causing increasing frequency and/or intensity of climate extremes, including temperature extremes, heavy precipitation and pluvial floods, river floods, droughts, storms (including tropical cyclones), as well as compound events (IPCC, 2021). High-temperature extremes (including heatwaves) have become more frequent and more intense across most land regions since the 1950s, and marine heatwaves have approximately doubled in frequency since the 1980s (IPCC, 2021). The frequency and intensity of heavy precipitation events have increased since the 1950s over most land area, and agricultural and ecological droughts have increased in some regions due to increased land evapotranspiration (IPCC, 2021). Climate extremes can cause dramatic ecosystem destabilization and an abrupt shift towards an alternative ecosystem state (Jentsch *et al.*, 2007), which may affect all stages of the biological invasion process (i.e., transport, introduction, establishment and spread; **Chapter 1**, **section 1.4**) (Hulme, 2017). However, global and quantitative assessments on the response of invasive alien species to extreme climatic events seem to be limited even for generally better-studied taxonomic groups such as plants (Orsenigo *et al.*, 2014) and insects (Bale *et al.*, 2002).

There is evidence that climate extremes (e.g., heavy winds, hurricanes, storms and floods) enhance long-distance transport and spread of invasive alien plants, vertebrates, invertebrates and invasive alien species that are agricultural pests and pathogens (Aylor, 2003; J. K. M. Brown & Hovmøller, 2002; Diez *et al.*, 2012; Hellmann *et al.*, 2008; Nagarajan & Singh, 1990). In terrestrial ecosystems, extreme hurricanes in Northern and Central America resulted in the long-distance spread of invasive alien weeds (Masters & Norgrove, 2010), alien vertebrates (e.g., *Iguana iguana* (iguana) and *Osteopilus septentrionalis* (Cuban treefrog); van den Burg *et al.*, 2019) and diseases (*Xanthomonas axonopodis* (gummosis: grasses); Masters & Norgrove, 2010). The frequency of hurricanes positively relates with the large-scale pattern of spread of alien *Phragmites australis* (common reed) in the United States (Bhattarai & Cronin, 2014).

In freshwater and marine biomes, extreme hydrological events (sometimes caused by strong winds) such as storms and floods may facilitate the transport, spread and establishment of invasive alien aquatic organisms (Anufriieva & Shadrin, 2018). Severe floods may allow fishes to escape from farm ponds and culture cages into natural water bodies (Canonico *et al.*, 2005). The Foe Indigenous People around Lake Kutubu in the Southern Highlands Province of Papua New Guinea have also observed the role of climate extremes in facilitating biological invasions. The shift from artisanal small-scale fishing to fish farming introduced alien fish (e.g., *Cyprinus carpio* (common carp)) and plants (*Pontederia crassipes* (water hyacinth)) to fish farms, which then escaped into Lake Kutubu during heavy rains of 2010-2012 (P. T. Smith *et al.*, 2016).

In polar ecosystems, genomic analyses revealed that *Durvillaea antarctica* (cochayuyo) has recently travelled more than 20,000 km by storm-forced surface waves (or oceanic storm waves) and reached Antarctica from mid-latitude source populations (C. I. Fraser *et al.*, 2018). In subarctic regions, extreme heatwaves cause hypoxia and high water temperatures, which seem to lead to widespread mortality of native freshwater fishes and facilitate the invasion of cool and warm water alien species (Rolls *et al.*, 2017).

Increased incidence and severity of heavy winds may also facilitate increased seasonal northward spread of plant pests and pathogens (Aylor, 2003; J. K. M. Brown & Hovmøller, 2002; Hopkinson, 1999; Olfert *et al.*, 2016, 2017), resulting in biological invasions beyond the current northern range limit of these species. For example, cereal rusts (Pucciniales) typically overwinter on cereals and grasses in the southern United States and northern Mexico, and the spores are blown northward in the spring or early summer by wind currents, affecting winter and spring cereal crops (Eversmeyer & Kramer, 2000; Xi *et al.*, 2015). Increased incidence and severity of heavy winds under climate change may enhance transport of rust species into the United States and Canada, thus facilitating biological invasions (Eversmeyer & Kramer, 2000; Xi *et al.*, 2015).

Extreme climatic events that cause catastrophic and widespread damage to ecosystems often increase the availability of resources such as water, nutrients, space and prey for alien species (Diez *et al.*, 2012; Hellmann *et al.*, 2008). In Australian rainforests, severe cyclones cause catastrophic disturbance by opening canopy gaps, thereby facilitating the rapid recruitment and spread of alien woody-vines (e.g., *Thunbergia* spp., *Mikania micrantha* (bitter vine) and *Turbina corymbosa* (Christmas vine); Camarero, 2019). Hurricane Sandy in the United States caused catastrophic coastal dune erosion and thereafter an alien *Carex kobomugi* (Asian sand sedge) established (Charbonneau *et al.*, 2017). Also, heavy drought can cause fire activity (e.g., 2019-2020 mega-fires in Australia and 2019 California wildfires, **Chapter 1**, **Box 1.4**), resulting in enhancement of the spread of invasive alien trees from plantation forests (**section 3.3.4.5**).

Extreme climatic events may also often stress and cause catastrophic mortality of resident native species, resulting in decreasing biotic resistance of native communities to the establishment and subsequent spread of invasive alien species (Diez *et al.*, 2012; Hellmann *et al.*, 2008; **section 3.3.5**). In semi-arid shrublands of Chile, a study based on 130 years of precipitation data showed that extreme drought, associated with El Niño effects, led to increased alien plant cover at the expense of native plants (Jiménez *et al.*, 2011). Similarly, using a mesocosm experiment across a precipitation and continental gradient between Belgium and Israel, Jentsch *et al.* (2007) found that drier ecosystems showed decreased biomass production after extreme droughts, facilitating invasive alien species establishment. These climatic extreme events also affected the resilience of marshes and riparian ecosystems. In Mexico, the vegetation of San Jose del Cabo (estuary) is resilient to hurricanes, but the vegetation cover loss due to the increased runoff caused by stronger hurricanes generated clearings that favoured the establishment of invasive alien species such as *Arundo donax* (giant reed) and *Tamarix* sp. (tamarisk) (Shiba-Reyes *et al.*, 2021).

Extreme climatic events can also act as a driver affecting the decline of invasive alien species. For example, a heavy drought in North America between 1987 and 1988 has led to the declines of 10 alien insect herbivore species in the following few years (Ward & Masters, 2007). An extreme cold spell in southern Florida led to declines in the abundance of an alien species, *Centris nitida* (oil-collecting bee), previously introduced from Mexico and Central America (Downing *et al.*, 2016).

3.3.4.4 Carbon dioxide enrichment in air, water

The concentration of atmospheric CO_2 in 2019 was 45 per cent higher (410 ppm) than in 1750; and in part excess CO_2 released from anthropogenic sources has been taken up by the oceans, ultimately leading to decreasing pH levels (IPCC, 2021). Responses to increasing atmospheric CO_2 differ between species within terrestrial and aquatic environments.

For terrestrial plants, higher levels of CO_2 cause an increase in water use efficiency and fertilization effects that can enable greater biomass production leading to an advantage of C4 rather than C3 plants (generally benefiting native relative to alien species; Nowak *et al.*, 2004). Nevertheless, winners and losers depend on availability of nutrients and some fast-growing C3 species (such as annual grasses) may respond more strongly than slow-growing C3 herbs or C4 plants (Poorter & Navas, 2003). In arid and semiarid ecosystems invasive alien annual grasses have a competitive advantage under elevated CO_2 (Chambers *et al.*, 2014; S. D. Smith *et al.*, 2000), whereas in savannahs, native grasses may be replaced by woody alien species (Bond & Midgley, 2000; Gritti *et al.*, 2006). These performance effects can translate to increased spread of invasive alien plant species and increased CO_2 concentrations. For example, invasive alien *Phragmites* spp. (reed) benefit from higher CO_2 concentrations and as a result increased dispersal and productivity allowing these species to compensate for transpiration water loss in the coastal marshes of North America (Eller *et al.*, 2014). Similar patterns of increased performance at higher than ambient CO_2 concentrations have been found for other invasive alien plants including *Prunus laurocerasus* (cherry laurel; Hattenschwiler & Körner, 2003) and *Pueraria montana* var. *lobata* (kudzu; Forseth & Innis, 2004). Terrestrial animal responses to the rise in CO_2 will likely be indirect, based on the responses of plants, and thus are likely to be most evident for herbivorous invertebrates but will be dependent on the specific host plant, making generalizations difficult (Dukes, 2000).

One-third of the anthropogenic CO_2 has been absorbed by the oceans (J. Johnson *et al.*, 2016; Sanford *et al.*, 2014). Together with warming and altered ocean circulation, which reduce subsurface oxygen concentrations, the rising atmospheric CO_2 leads to ocean acidification (Doney *et al.*, 2012). The impacts of acidification are more pronounced in extreme regions such as in polar regions (Fabry *et al.*, 2009) and for coral reefs where calcareous corals and algae are replaced by noncalcareous algae (Hall-Spencer *et al.*, 2008). In these regions, invasive alien species that are tolerant of high CO_2 concentrations increase in abundance, as documented for macroalgal biological invasions in the northeast Atlantic (Brodie *et al.*, 2014). In the Mediterranean Sea, invasive alien genera (e.g., *Sargassum, Caulerpa* and *Asparagopsis*) spread to sites where native coralline algae are disappearing due to acidified waters (Hall-Spencer *et al.*, 2010).

3.3.4.5 Fire regime changes

In addition to direct human-induced changes to fire regimes (**section 3.3.1.5.2**; **Chapter 1**, **Box 1.4**), weather conditions that favour fire occurrence (i.e., hot, dry and windy events) have become more common in some regions due to climate change, a trend that is expected to occur in even more regions in the future (IPCC, 2021). Climate change is expected to lead to more extreme and frequent fires globally (Hoegh-Guldberg *et al.*, 2018), and there is evidence that climate change during the last decades has already increased fire activity, for example in western United States (Abatzoglou & Williams, 2016; S. E. Mueller *et al.*, 2020). Likewise, recent increases in fire frequency and severity in eastern Australia, including the unprecedented estimated area of over 10 million hectares burnt during the 2019-2020 season (Boer *et al.*, 2020; R. H. Nolan *et al.*, 2020), are consistent with predicted changes in the fire regime under climate change (Clarke & Evans, 2019; Lewis *et al.*, 2019).

Fire may facilitate establishment and spread of invasive alien plants that exhibit highly effective post-fire regeneration, and presence of these species may in turn lead to changes in fuel properties that ultimately increase fire activity, thus promoting positive feedback mechanisms to the detriment of native species (Aslan & Dickson, 2020; Brooks *et al.*, 2004; Gaertner *et al.*, 2014; Rodewald & Arcese, 2016; Serbesoff-King, 2003; **Chapter 1**, **Box 1.4**; **Chapter 4**, **Box 4.5**). Accordingly, by leading to longer fire seasons, shorter fire return intervals and/or higher fire intensity than were previously encountered, climate change may favour the establishment and spread of fire-adapted invasive alien species (Abatzoglou & Kolden, 2011).

The effect of climate change on fire regimes will likely be intensified in the future and drive the spread of *Bromus tectorum* (downy brome) in deserts and Mediterranean ecosystems in the western United States (Abatzoglou & Kolden, 2011; Balch *et al.*, 2013). Higher fire activity under climate change may also drive the spread of the African grass *Cenchrus cilliaris* (buffel grass) in the central rangelands and eastern woodlands of Australia (D. W. Butler & Fairfax, 2003; G. Miller *et al.*, 2010). The mechanism for the spread of invasive alien grasses under climate change both in the United States and Australia is an intensification of fire-invasive positive feedback loops promoted by invasive alien species in these ecosystems (i.e., grass-fire cycle), where increased production of biomass by invasive alien grasses leads to increased fire frequency, continuity and/or intensity and hence favours their spread (Balch *et al.*, 2013; D. W. Butler & Fairfax, 2003; Gaertner *et al.*, 2014; G. Miller *et al.*, 2010). In addition, fire-induced air currents associated with the recent extreme fires in Australia seem to have driven the introduction of invasive alien species to New Zealand, such as the pathogenic fungi *Austropuccinia psidii* (myrtle rust; Australian Government, 2021), and could possibly also favour the arrival of the *Agrotis infusa* (bogong moth) in the country (Warrant *et al.*, 2016).

There is evidence that increased fire activity under climate change may also directly drive the spread of invasive alien woody species. In Patagonia, a warmer and drier climate is implicated in the spread of alien pines and shrubs whose persistence is promoted by fire (Cavallero & Raffaele, 2010; K. T. Davis *et al.*, 2019; Raffaele *et al.*, 2016). In European and southern African Mediterranean ecosystems, changes in the fire regime under a warmer and drier climate change are expected to favour the spread of invasive alien tree species from the genus *Acacia* (e.g., *Acacia longifolia* (golden wattle); Souza-Alonso *et al.*, 2017).

There is very limited information on how changes in fire regimes under climate change may facilitate the spread of invasive alien animals. In freshwater ecosystems in the western United States, increased fire activity due to climate change may favour alien fishes, especially in degraded and fragmented landscapes (Dunham *et al.*, 2003). In these ecosystems, larger and more frequent fires under climate change tend to increase water temperature and decrease stream stability and connectivity, thus driving the spread of generalist alien fishes to the detriment of native Salmonidae fishes (Isaak *et al.*, 2010; Luce *et al.*, 2012), although the effect of fire as a driver affecting invasive alien species in this region may be species-specific and less significant in comparison to other anthropogenic disturbances (Sestrich *et al.*, 2011).

3.3.4.6 Sea level rise

Global mean sea level increased 0.20 m from 1901 to 2018, with an annual increase of 3.7 mm per year from 2006 to 2018 (IPCC, 2021). Sea level rise is caused by climatic factors affecting the thermal expansion of water and the melting of glaciers, permafrost and polar ice sheets (Hoegh-Guldberg & Bruno, 2010; Oppenheimer *et al.*, 2019; Rignot *et al.*, 2018). Rising sea level will likely lead to increased impacts from extreme weather events and storm surges, increased coastal flooding, higher high tides and increased saltwater intrusion into freshwater systems, altering environmental conditions along coastal zones (Nicholls *et al.*, 2014; Woodruff *et al.*, 2013). Few studies have assessed the direct effect of sea level rise as a driver in the context of biological invasions. However, it is likely that marine invasive alien species able to disperse by ocean currents (e.g., *Mytilus galloprovincialis* (Mediterranean mussel)) may be introduced to new areas due to increased inundation of coastal areas (McQuaid & Phillips, 2000). In Hawaii, the combination of sea level rise and high tide events resulted in habitat creation, facilitating the spread of invasive alien fish (e.g., tilapias) from fishponds to nearby anchialine pools (Marrack, 2016).

Sea level rise, *via* the effect of saltwater intrusion into freshwater ecosystems and increased water salinity, may also shift selection pressures and facilitate the establishment of invasive alien species. Evidence from coastal areas in the United States (K. Williams *et al.*, 1999), Australia (Traill *et al.*, 2011) and China (W. Wang *et al.*, 2015) show that sea level rise may alter soil chemistry and native vegetation patterns in coastal wetlands or native forests, selecting for species with a higher tolerance to saline habitats and where present, allow invasive alien species to dominate. Increased tolerance of the alien haplotype of *Phragmites australis* (common reed) has allowed it to spread through native salt marshes in the Atlantic and Gulf Coastal areas (Bhattarai & Cronin, 2014; Vasquez *et al.*, 2005). Similarly, *Osteopilus septentrionalis* (Cuban tree frog), an invasive alien species in the United States, is tolerant to increased salinity which can facilitate its spread and establishment in coastal environments (M. E. Brown & Walls, 2013). Verbrugge et al (2012) found that salinity tolerance of *Corbicula fluminalis* (Asian clam) and *Potamopyrgus antipodarum* (New Zealand mudsnail) was higher than for native species occurring in the River Rhine. However, models of changes in salinity due to rising sea levels in the freshwater ecosystem of the Everglades indicate a decrease in alien fish species biomass (Romañach *et al.*, 2019) compared to native species.

In coastal systems, the effect of rising sea levels on soil moisture in coastal dune systems can disrupt sediment transfer impacting dune formation processes and vegetation patterns. For example, in New Zealand, increased soil moisture disrupts the formation of dunes (Thomas *et al.*, 2018) and allows for their colonization by plants, including the invasive alien grass *Calamagrostis arenaria* (marram grass). In Australia, invasive alien *Thinopyrum junceiforme* (sea wheatgrass) is able to take advantage of increased soil salinity (Hilton *et al.*, 2006).

Sea level rise could also drive the intentional introduction of invasive alien species for the purposes of climate change adaption to reduce impacts of coastal erosion and infrastructure damage. For example, *Sporobolus* species, introduced to reduce the effects of coastal erosion (Ge *et al.*, 2015), have become widespread invasive alien species in China (An *et al.*, 2007). The introduction of *Calamagrostis arenaria* (marram grass) in Australia and New Zealand are further examples of alien species introduced for dune stabilization for coastal protection. The need for improved coastal protection from rising sea levels could see alien species being utilized in many parts of the world. Alternatively, the construction of hard surfaces for coastal protection against sea level rise can also facilitate the establishment of invasive alien species of seaweed (Geraldi *et al.*, 2014).

3.3.5 Invasive alien species

Although studying the role of invasive alien species as a direct driver of change in nature affecting invasive alien species might sound like circular reasoning, there is increasing evidence of the role that invasive alien species may play in facilitating other alien species **(Figure 3.21)**. The process by which facilitation among alien species potentially accelerates the accumulation of introduced species has gained its own term, "invasional meltdown" (Simberloff, 2006; **Chapters 1**, **2**, **4**).

3.3.5.1 Biotic facilitation

Invasive alien species can facilitate the establishment and spread of other invasive alien species through multiple direct and indirect ecological interactions **(Box 3.10)**. Direct biotic

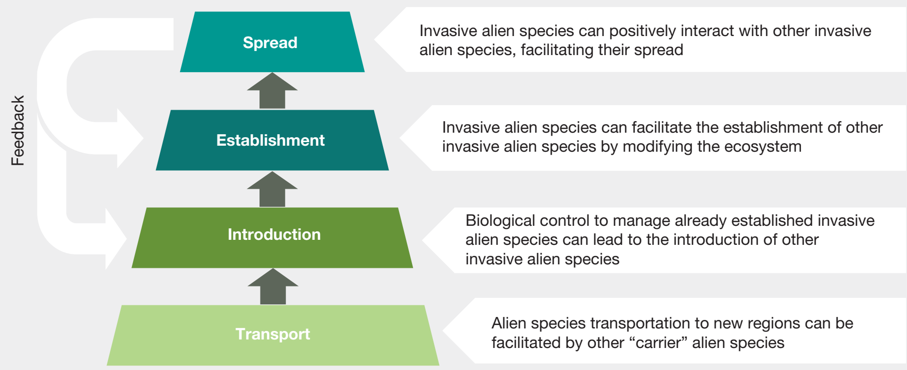

Figure 3 21 **Examples of the role of invasive alien species in facilitating additional invasive alien species across stages in the biological invasion process.**

Invasive alien species may facilitate further biological invasions by acting as pathways for other invasive alien species, by motivating the deliberate introduction of additional alien species for biological control, by modifying the ecosystem thereby facilitating the establishment other alien species, or by facilitating spread. Biological invasions can also negatively impact ecosystem functioning and resistance, causing feedback *via* facilitation of the introduction and establishment of additional invasive alien species.

facilitation often involves plant-animal interactions (e.g., pollination; e.g., Morales & Aizen, 2002), dispersal, (e.g., Mandon-Dalger *et al.*, 2004), plant-fungal interactions (e.g., mycorrhizal symbiosis; Dickie *et al.*, 2010), or animal-animal (e.g., ant-scale insect) mutualisms (Richardson, Allsopp, *et al.*, 2007; Simberloff & Von Holle, 1999; Traveset & Richardson, 2014), or even multitrophic interactions like those between alien herbivores dispersing alien fungi (e.g., mycorrhiza of alien trees; Nuñez *et al.*, 2013). However, alien species may also indirectly facilitate the establishment and spread of other invasive alien species, by modifying the biotic conditions of the recipient community (e.g., reducing competition or predation pressure by a third species, or increasing food resource availability), or abiotic attributes and ecosystem properties (e.g., by promoting habitat disturbance such as enhanced fire regimes; see **section 3.3.4.5**) increasing soil nutrients by nitrogen-fixing plants, etc.

The term "invasional meltdown" coined by Simberloff & Von Holle (1999), refers to the process by which alien species facilitate one another, magnifying ecological effects, leading to accelerating rates in the number of invasive alien species and magnification of impacts. In other words, invasional meltdown is the potential emergent result of a series of facilitations (Ricciardi, 2001). Therefore, although invasional meltdown has often been broadly used to refer to any kind of positive interaction among alien species in the peer-reviewed literature, this chapter refers to invasional meltdown *sensu* (Simberloff & Von Holle, 1999), and shows how this phenomenon is linked to facilitation among invasive alien species as a driver that may accelerate rates of biological invasions (**Chapter 2**), and synergistic impacts (**Chapter 4**).

A recent review based on 150 empirical studies, Braga *et al.* (2018), confirmed overall broad support for facilitative interactions among alien species (63.3 per cent of the studies) across multiple types of interactions (direct or indirect, unidirectional, reciprocal, or multi-species), ecological levels (individual, population, community and ecosystem), taxonomic groups and major habitat types. This evidence points to biotic facilitation among alien species as a major driver facilitating the establishment and spread of invasive alien species. However, they also found some exceptions to this general pattern, and have identified biases and gaps (see below). This section reviews the role of biotic facilitation among alien species as a driver affecting the different stages of the invasion process (Braga, Gómez-Aparicio, *et al.*, 2018; Gavira-O'Neill *et al.*, 2018; Jeschke *et al.*, 2012).

The transportation of alien species to new regions can be facilitated by other "carrier" alien species. For instance, plants relying on endozoochoric or ectozoochoric seed dispersal can be transported and introduced to new regions in the guts, fur, hoof or feathers of alien animals (Reynolds *et al.*, 2015; Van Leeuwen, 2018; Diaz Velez *et al.*, 2020). The alien mammal *Axis porcinus* (hog deer) disperses similar numbers of alien and native plant species' seeds through its faeces, thus greatly facilitating the dispersal of alien species in south-eastern Australia (N. E. Davis *et al.*, 2010), and horses transport alien seeds on their hooves (Gower, 2008). Indeed, facilitation is concomitant

Box 3 10 Three-way invasional meltdown: invasive alien ungulates disperse invasive alien fungi that facilitate pine invasions.

One example of invasional meltdown that involves belowground mechanisms of facilitation, is that of alien ungulates dispersing alien ectomycorrhizal fungi, in turn facilitating the invasion by alien pine trees **(Figure 3.22)**. Introduced pine trees have become invasive in many parts of the southern hemisphere and cause profound ecological, social and economic impacts. Pine tree establishment and growth are critically dependent on the interaction with ectomycorrhizal fungi, which provide nutrients, water and protection against pathogens, in exchange for plant carbon. Pine trees thus co-invade with alien ectomycorrhizal fungi. As ectomycorrhizal fungi disperse independently from pine trees, some ectomycorrhizal fungi species are able to disperse away from the original place of introduction, establish a spore bank, and make stands of native species more susceptible to pine invasions. In turn, invasive alien ungulates consume alien ectomycorrhizal fungal sporocarps and disperse the spores of some ectomycorrhizal fungi species through their faeces (Nuñez *et al.*, 2013). This mechanism of dispersal is crucial for the pine-ectomycorrhiza symbiosis both in the alien and native ranges fungi, especially for those ectomycorrhizal fungi that produce hypogenous sporocarps (i.e., truffle-like fungi), which are proposed to exclusively rely on mammal-mediated dispersal **(Figure 3.22)**. Invasive ungulates can disperse viable spores in high densities, far beyond the distance they typically disperse through wind (Horton, 2017). This scale of dispersal is important considering the scale at which biological invasion occurs. Although not all ectomycorrhizal fungi species survive this form of dispersal, evidence shows that those ectomycorrhizal fungi species that survive or even depend upon mammal-mediated dispersal are among the most invasive ectomycorrhizal fungi (Policelli *et al.*, 2019). Dispersal limitation of ectomycorrhizal fungi might be determinant for invasions of Pinaceae. The absence of dispersal vectors, such as ungulates, could act as an impediment for viable ectomycorrhizal fungi propagules to reach sites far from the propagule source, in turn hindering the invasion by the alien plant host or increasing its lag time.

Box 3 10

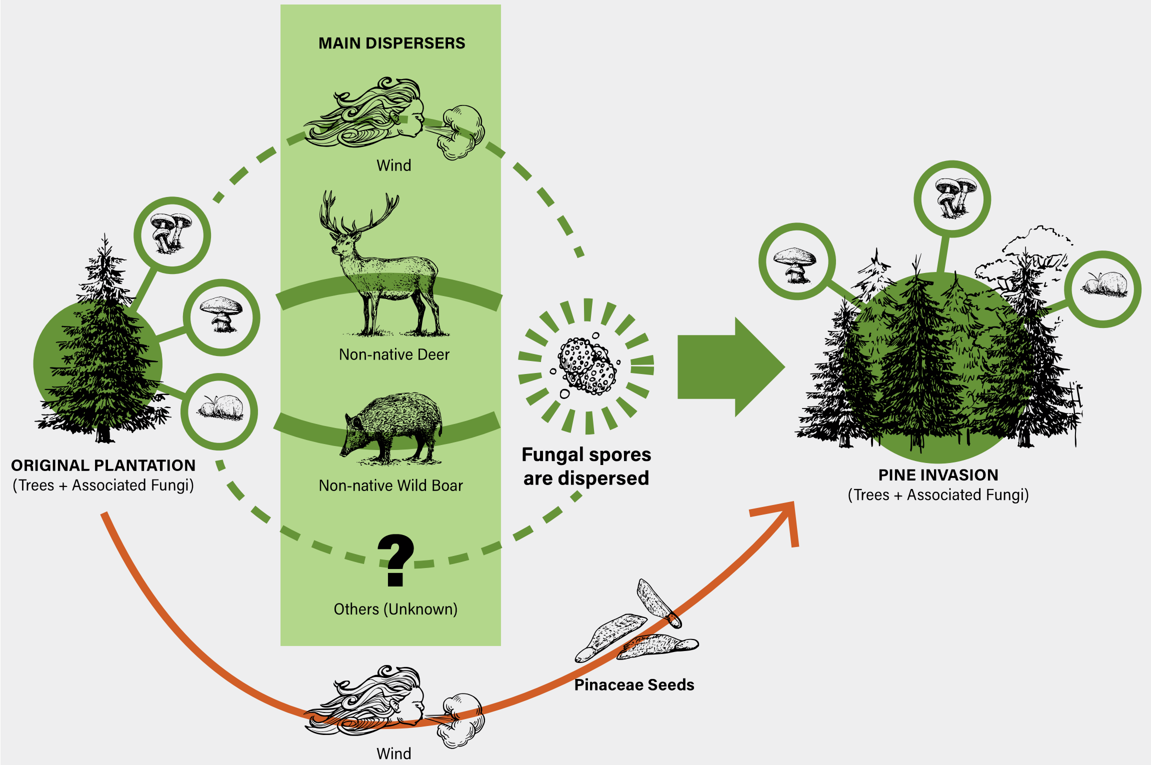

Figure 3 22 **Diagram of the three-way invasional meltdown between invasive alien pine trees, invasive alien ectomycorrhizal fungi and invasive alien ungulates.**

Pine trees need ectomycorrhizal fungi to successfully invade (thick middle arrow). Pine seeds are mainly dispersed by wind (bottom arrow). Spores from ectomycorrhizal fungi can be dispersed through wind (upper dotted line) but some ectomycorrhizal fungi species present in the pine plantation produce sporocarps that are eaten by invasive alien ungulates (wild boar and deer; medium thick lines). Ungulates transport the invasive ectomycorrhizal fungi spores further from the invasion source population compared to wind. Spores from some invasive ectomycorrhizal fungi can form long-lasting spore banks in the soil, making native stands more susceptible to pine invasion. More evidence is needed about other potential mechanisms of fungal dispersal (here represented by the question mark, lower dotted line), such as bird dispersal, or human dispersal which could also be important, especially over long-distances. with the uptake, transportation and introduction of invasive alien species that engage in obligated symbiosis with other organisms and in the co-introduction of alien parasites by their alien hosts (e.g., Arbetman *et al.*, 2013). As an example, frugivorous birds have been shown to simultaneously disperse three interlinked alien species: the seeds of *Ligustrum lucidum* (broad-leaf privet), its weevil granivore and a parasite of the weevil (Chen *et al.*, 2021). However, despite the importance of transport and introduction within biotic facilitation **(Figure 3.4)**, these initial two stages of the biological invasion process have been largely neglected in major studies and reviews about facilitation among invasive alien species or invasional meltdown (O'Loughlin & Green, 2017; Simberloff, 2006; Simberloff & Von Holle, 1999).

Once alien species have arrived in a new region, positive interactions with other alien species may be unidirectional or bidirectional. Unidirectional interactions include alien species facilitating any aspect of another's survival, reproduction, resource acquisition, or other factor that enhances establishment, population growth, or spread while the latter has no detectable influence on the former (a commensal relationship). With bidirectional interactions, both species have a reciprocal positive effect (mutualism). Multispecies interactions may be through direct and/or indirect effects (reviewed in (Braga, Gómez-Aparicio, *et al.*, 2018). According to Braga *et al.* (2018), most studies focused on unidirectional or multi-species interactions (58 studies each) and these generally found a high level of support for facilitation, while there were fewer studies on reciprocal interactions (34 studies) and these generally found a lower level of support for facilitation (Braga, Gómez-Aparicio, *et al.*, 2018). As an additional scenario, one alien species could facilitate the success of another at its own expense, such as through a predator-prey or parasite-host relationship; such exploitations are likely quite common, but are also rarely considered in studies examining facilitations (but see Grosholz, 2005; Ricciardi, 2001). Empirical evidence exists for multispecies interactions that affect the success of an invasive alien species or trigger the expansion of an alien species. For example, Grosholz (2005) showed that the invasion by a predator, *Carcinus maenas* (European shore crab), reduced the abundance of a native clam, which was the crab's preferred prey, by 10-fold,; this interaction released another introduced species, *Gemma gemma* (amethyst gemclam), from competition and thus allowed it to become superabundant, after having been present at low abundance for decades. However, while many studies have inferred invasional meltdown, few cases have demonstrated an accelerating rate of establishment or spread of invasive alien species and/or the synergistic impact of these invasive alien species. Heimpel *et al.* (2010) described a scenario of invasional meltdown where *Aphis glycines* (soybean aphid) increased the abundance of eleven invasive alien species including worms, shrubs, birds, beetles and animal and plant pathogens. A study by Ricciardi (2001) of the North American Great Lakes found that facilitative interactions among alien species were at least as common as antagonistic interactions, and that the rapid accumulation and synergistic effects of alien species, while best explained by increased propagule pressure (e.g., from shipping), was consistent with the prediction of the invasional meltdown hypothesis (Simberloff & Von Holle, 1999). Christmas Island, mentioned previously, provides the best documented case of invasional meltdown to date. After being introduced to the island several decades ago, *Anoplolepis gracilipes* (yellow crazy ant), persisted for decades at low density before its population exploded in the late 1980s. The ants had an antagonistic relationship with *Gecarcoidea natalis* (Christmas Island red crab), a keystone omnivore. The ants caused a reduction in populations of the crab, which resulted in increased tree seedling density and reduced leaf litter on the forest floor. Further, the depletion of *Gecarcoidea natalis* promoted yet another invasive alien species, *Lissachatina fulica* (giant African land snail). Simultaneously, in the forest canopy, the higher density of ants promoted population growth of introduced honeydew-secreting scale insects through a mutualistic relationship, which resulted in fungal growth and dieback of trees. This ecosystem transformation occurred in a period of only a few years (Green *et al.*, 2011; O'Dowd *et al.*, 2003).

Finally, Braga *et al.* (2018) identified biases in research effort. In particular, the majority of the studies focused on the individual and population levels (about 44 per cent each), with a lower representation of studies at the community (10.5 per cent) and ecosystem levels (1.5 per cent), and there are less studies addressing indirect effects (56 studies) than direct effects (87 studies). Regarding habitats, most evidence comes from terrestrial ecosystems (63.1 per cent) compared to fresh and marine ecosystems (21.5 and 15.4 per cent, respectively). As for taxonomic groups, more studies focused on plants and algae (89 studies), followed by invertebrates (83 studies) and vertebrates (51 studies). In the future, taking the importance and prevalence of alien-alien facilitation into account might lead to better prediction of the outcomes of biological invasions and effective prevention (**Chapter 5**). Moreover, while there have been many examples of invasive alien species facilitating one another, suggesting that invasional meltdown is possible in a broad range of ecosystems, there is thus far very little published evidence of an accelerated accumulation of invasive alien species attributable to these facilitations (but see O'Dowd *et al.*, 2003; Ricciardi, 2001; Simberloff & Von Holle, 1999).

3.3.5.2. Unintended consequences of management through biological control

Many empirical examples of the unintended consequences of management of biological invasions resulting in the introduction, establishment or spread of invasive alien species stem from the literature on early attempts at biological control (**Chapter 5**, **section 5.6.2.3**). Many of these historical high-profile cases report negative direct impacts on non-target native species by generalist predators or pathogens released as biological control agents (e.g., the release of cats and mongoose to control rodents, cane toads against agricultural pests and plant pests or diseases to control invasive plants). These examples are all from a time when biological control was implemented in an unregulated way, for example, with no requirement for risk assessment of the biological control agent (**Chapter 5**). A classic example is *Cactoblastis cactorum* (cactus moth) that was intentionally released on islands in the Caribbean in 1957 for the control of native *Opuntia* (pricklypear) species that were seen as a nuisance to tourists. However, the moth spread from the Dominican Republic to Florida, where it poses a threat to native *Opuntia* (Hinz *et al.*, 2019), and to the Yucatán peninsula where it was successfully eradicated (Senasica, 2019). It has currently spread across the south-eastern United States to Texas where it can enter Mexico again and threaten the over 100 native *Opuntia* species, many of which are endemic and constitute an important part of the Mexican diet and economy (Senasica, 2019).

Insects have also been released to control other insects and in some cases these biological control agents have become invasive alien species. Examples include two species of ladybird, *Harmonia axyridis* (harlequin ladybird) from Asia causing declines of native ladybirds in the United Kingdom and Belgium (Roy *et al.*, 2012) and in other countries worldwide (Roy *et al.*, 2012) and *Coccinella septempunctata* (seven-spot ladybird) from Europe impacting populations of native North American ladybirds (E. W. Evans *et al.*, 2011). The release of *Euglandina rosea* (rosy wolf snail) in Hawaii to control *Lissachatina fulica* (giant African land snail) also failed to lead to desired management outcomes but instead resulted in the intentional introduction of an invasive alien species (Cowie, 2001).

Rhinella marina (cane toad) was introduced into Queensland, Australia in 1935 from Hawaii to control insect pests of sugar cane and became an invasive alien species with direct and possible indirect impacts on non-target native Australian vertebrates (R. Shine, 2010). This is an example where science was ignored and a political decision was made to introduce *Rhinella marina* (M. D. Day *et al.*, 2021). Mammals have also been released as biological control agents with unintended consequences. *Herpestes javanicus auropunctatus* (small Indian mongoose) was introduced initially to control alien invasive rodents and snakes in the West Indies, Hawaiian islands and Japan, and has resulted in mammal and reptile extinctions (Hays & Conant, 2007). In aquatic environments, *Gambusia affinis* (western mosquitofish) and *Gambusia holbrooki* (eastern mosquitofish), native to the fresh waters of the United States, have been introduced worldwide as biological control agents of mosquito larvae, but are implicated in the decrease and loss of non-target native invertebrates as well as fish and amphibian populations (Azevedo-Santos *et al.*, 2017). In the marine realm, the sea urchin *Evechinus chloroticus* (kina) released as an augmentative biological control agent against the invasive *Undaria pinnatifida* (Asian kelp) showed substantial non-target effects on benthic communities, however these were localized and reversible (Atalah *et al.*, 2013). Conservation actions may also have unintended consequences in facilitating invasive alien species, as illustrated by the creation of beaver dams during the reintroduction of *Castor canadensis* (North American beaver) in Verde River, Arizona, United States, which shifted desert fish assemblages toward dominance by alien species (P. P. Gibson *et al.*, 2015; Reaser, 2003).

A global review of non-target impacts of weed biological control agents found that the proportion of intentionally released biological control agents causing non-target effects declined from 18.2 per cent prior to the 1960s to 9.9 per cent in the period 1991–2008 (Hinz *et al.*, 2019). Similarly, an analysis of all non-target effects of weed biological control programmes from 1969 to 2014 showed a risk factor of less than 1 per cent (Moran & Hoffmann, 2015). There was no evidence of non-target impacts from plant pathogens used for biological control (Suckling & Sforza, 2014).

3.4 ADDITIONAL DIRECT DRIVERS – NATURAL DRIVERS AND BIODIVERSITY LOSS

3.4.1 Natural hazards

Natural large-scale disturbances, such as hurricanes, earthquakes and tsunamis can facilitate the onward spread of alien species from an existing invaded range to new regions (Carlton *et al.*, 2017; **section 3.3.3.3**, **Box 3.8**) as well as encourage their wider spread within regions where they are already present as aliens (Bellingham *et al.*, 2005; **Figure 3.23**). Natural drivers have thus facilitated the wider establishment and spread of alien plants and animals within and beyond their known invaded range through acting as agents of secondary dispersal (e.g., Lovette *et al.*, 1999; Toepfer, 2012; Lee *et al.*, 2014; Massa *et al.*, 2014).

The roles of natural drivers apply to all regions and all realms. Natural disturbances such as hurricanes (**section 3.3.4.3**) have played a role in assisting the dispersal of alien animals (Andraca-Gómez *et al.*, 2015; Censky *et al.*, 1998; Johnston & Purkis, 2015), plants (Bhattarai & Cronin, 2014) and microbes (Feehan *et al.*, 2016), leading to expansion of their historical invaded ranges. A classic example of onwards dispersal of alien species *via* natural drivers is the crossing from Africa to the Americas by the *Bubulcus ibis* (cattle egret), whose introduction, establishment and further spread throughout the Americas has been linked to multiple weather events (Massa *et al.*, 2014). Wind and ocean currents offer new opportunities for colonization within and beyond the invaded range of both marine and terrestrial organisms (Munoz *et al.*, 2004); rafting during extreme weather events is a common example by which non-flying alien animals can be transported between islands, as has been documented for *Iguana iguana* (iguana; Censky *et al.*, 1998). As species' thermal barriers are being altered or lifted by climate change, ocean currents are contributing to the range expansion of alien species and colonization of previously inhospitable regions such as the Arctic (Chan *et al.*, 2019) and Antarctica (C. I. Fraser *et al.*, 2018). Disease outbreaks among *Strongylocentrotus droebachiensis* (green sea urchin) in the northwest Atlantic Ocean have been attributed to *Paramoeba invadens*, a pathogenic amoeba that is intolerant of the typical winter sea surface temperatures in the region. Evidence suggests that the amoeba originates in southern surface waters transported to the north Atlantic coast, and that disease outbreaks have occurred during hurricanes and unusual warm winter sea temperatures (Feehan *et al.*, 2016). Molecular and oceanographic evidence suggests that ocean currents regularly disperse rafting species thousands of kilometres, and that Southern Ocean coasts are biologically well-connected (C. I. Fraser *et al.*, 2022). If warm-adapted

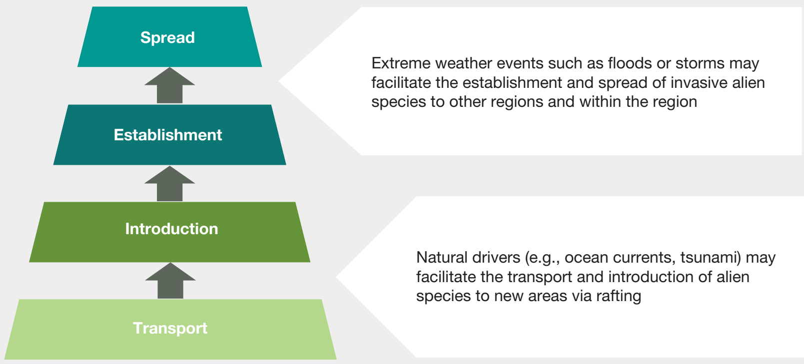

Figure 3 23 **Examples of the role of natural hazards in facilitating invasive alien species across stages of the biological invasion process.**

Natural hazards can facilitate biological invasions by acting as agents of secondary dispersal beyond and within the invaded range. Examples are chosen to represent relationships found across the invasion stages.

taxa frequently disperse to Antarctic waters, global warming could allow the region to become increasingly colonized by new species delivered *via* ocean rafting, especially during storms (C. I. Fraser *et al.*, 2018). These cases illustrate the capacity of natural drivers to facilitate colonization events, but also suggest an increasing influence of anthropogenic climate change as an amplifier of such dispersal opportunities, by, for example, altering or strengthening ocean currents, or by creating temporary hydrological connections (**section 3.3.4**).

The relative importance of natural drivers such as natural hazards in the range dynamics of alien species, however, are likely to be relatively minor. Natural long-distance dispersal events have evidently been sufficient to colonize remote oceanic islands in the prehistoric past, but are likely orders of magnitude less frequent than human-assisted, long-distance dispersal events (Ricciardi, 2007). Natural hazards typically move small numbers of propagules and are dependent on weather patterns and other environmental constraints. This is in contrast to modern human-assisted biological invasions in which enormous numbers of individual organisms and a broad diversity of species can be moved to virtually any region of the planet over short time scales (Ricciardi, 2007). The spread of alien species often involves a combination of human-assisted and natural drivers, of which the latter may be dominant at small spatial scales (Chan *et al.*, 2019; Medley *et al.*, 2015).

3.4.2 Biodiversity loss and ecosystem resilience

It is estimated that 25 per cent of all species globally are threatened by extinction and that 1 million species may become extinct in the following decades due to human interference, especially land- and sea-use change (**section 3.3.1**) and direct exploitation of natural resources (**section 3.3.2**) (IPBES, 2019). While this biodiversity loss has been the dependent variable in most previous IPBES assessments (IPBES, 2019), for invasive alien species it can also be seen as a driver that may facilitate biological invasions since reduced taxonomic or functional diversity of native ecosystems may reduce their biotic resistance and thereby facilitate the establishment and spread of invasive alien species (Levine *et al.*, 2004; **Figures 3.3** and **3.24**). A wide range of biotic interactions may confer resistance to biological invasions in native communities, including competition, predation, herbivory and disease, and all of these may be involved in constraining the introduction, establishment and spread of invasive alien species (Alofs & Jackson, 2014; Elton, 1958; Levine *et al.*, 2004).

Studies from terrestrial systems show that the presence and diversity of native vegetation, along with phylogenetic distance between the invasive alien species and resident community, can constrain plant invasions, implicating different modes of plant-plant competition for space as a powerful mechanism underlying biotic resistance to invasive alien species. For example, Byun *et al.* (2015) analyzed the interplay between abiotic constraints, propagule pressure and biotic resistance by conducting experiments to explore the *Phragmites australis* (common reed) invasion process, and found that maintaining native plant cover could confer invasion resistance, even when abiotic conditions changed (Byun *et al.*, 2015). Going *et al.* (2009) found that competition from a resident annual plant community had strong negative effects on the biomass and reproduction of invasive alien grass, such as *Avena barbata* (slender oat), *Bromus diandrus* (great brome) and *Hordeum murinum*

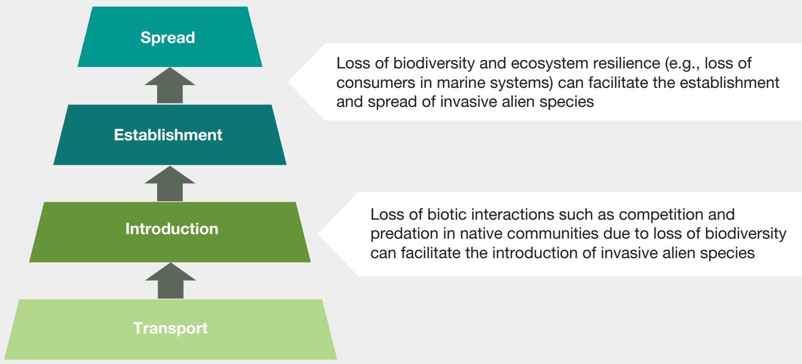

Figure 3 24 **Examples of the role of biodiversity loss in facilitating invasive alien species across stages of the biological invasion process.**

Biodiversity loss can facilitate biological invasions by reducing ecosystem resistance to invasion, which may facilitate the introduction, establishment and spread of invasive alien species.

(mouse barley), and that removing the resident communities increased the biomass and seed production of the invasive alien species by two-fold to ninefold. Elton's diversity-invasibility hypothesis proposes that taxonomic diversity in native communities confers additional resistance to invasive alien species because less niche space is available to alien species (Elton, 1958). In support of this hypothesis, Maron & Marler (2007) found that plant assemblages with higher plant species richness displayed lower invasibility (**Chapter 1**, **section 1.3.2**) than assemblages with lower species richness, and Zheng *et al.* (2018) found that the invasion success of *Chromolaena odorata* (Siam weed) correlated negatively with both biomass and species richness of the native community. A third idea related to biotic resistance is Darwin's naturalization hypothesis, which builds on Darwin's (1859) position that alien species will be more successful in a native community if they are more distantly related to native residents, because relatedness may indicate niche similarity (**Chapter 1**, **section 1.3.2**; Violle *et al.*, 2011). In support of this hypothesis, Zheng *et al.* (2018) experimentally established that success of the invasive tropical shrub *Chromolaena odorata* increased with functional distance to the native community. Similarly, Iannone *et al.* (2016) found, in a large-scale observational study of invasive alien species in forests across the eastern United States, that tree biomass and evolutionary diversity, but not species richness, was negatively associated with the establishment and dominance of the invasive alien species, and thus that evolutionary diversity is indicative of biotic resistance. In an experimental study explicitly designed to distinguish Darwin and Elton's hypotheses, Feng *et al.* (2019) found support for both ideas, as the effects of both phylogenetic and functional distance became stronger as species richness increased, and further analyses indicated that both competitive inequalities and niche differences between invasive alien and native communities may contribute to these responses.

Observed relationships between the taxonomic or functional diversity of native and invasive alien plants may be caused by mechanisms beyond direct plant-plant competition. For example, observed biotic resistance from native vegetation against invasive alien plant species may operate *via* soil pathogens that negatively affect the invasive alien species (Knevel *et al.*, 2004; van Ruijven *et al.*, 2003). Similarly, a study from south-western United States by St. Clair *et al.* (2016), found that native rodents suppressed invasion by *Bromus tectorum* (downy brome) while promoting native plant diversity after fire, providing strong biotic resistance to invasive alien plants through preferential seed and seedling predation on invasive alien species.

A meta-analysis of marine experiments revealed the same general trend of diversity-mediated biotic resistance as was observed in terrestrial systems; high native primary producer diversity in marine systems confers significant resistance to alien primary producers through competition, whereas low-diversity communities in the same marine systems often fail to do so (Kimbro *et al.*, 2013). However, unlike terrestrial systems, biotic resistance in freshwater and marine environments might to a larger extent be driven by consumption (Alofs & Jackson, 2014). Resident species at the top of the food chain can prevent invasion by alien species which are lower in the food chain. In freshwater systems in the southern United States, Parker & Hay (2005) found that native consumers (including crayfish, grasshoppers and slugs) preferred alien plants as a food source over native plants, conferring resistance to biological invasion. In another example, in China the native crab *Helice tientsinensis* effectively inhibits *Sporobolus* *alterniflorus* (smooth cordgrass) invasion in anthropogenic ditches, high marshes and estuarine mangrove forest by grazing seedlings and suppressing their density and survival (Ning *et al.*, 2019). In rainforest of Christmas Island, Indian Ocean, *Gecarcoidea natalis* (Christmas Island red crab) can kill the introduced *Lissachatina fulica* (giant African land snail), restricting the distribution of giant African land snails and thus conferring biotic resistance to biological invasions in undisturbed habitats on the island (Lake & O'Dowd, 1991).

3.5 MULTIPLE, ADDITIVE OR INTERACTING EFFECTS OF DRIVERS AFFECTING INVASIVE ALIEN SPECIES

The evidence that the majority of the Earth's ecosystems are subject to complex threats from several concurrent, interacting and exacerbating drivers of change in nature is unequivocal (IPBES, 2019). The net effect of drivers is often not additive, as drivers can reinforce or mitigate each other's effects (i.e., be synergistic or antagonistic; Fontúrbel, 2020; Jackson *et al.*, 2016; Pyšek *et al.*, 2020). Generalizing from studies of single drivers in isolation may therefore yield misleading conclusions (Bowler *et al.*, 2020). Interactions between multiple drivers of change are expected to jeopardize ecosystem functioning and biodiversity, and are a key concern for conservation and management (Cote *et al.*, 2016). As a special case, novel ecosystems (**Chapter 1**, **Box 1.5**), which contain new species combinations and/or altered ecosystem functioning (Hobbs *et al.*, 2006, 2009; Morse *et al.*, 2014; Seastedt *et al.*, 2008) can be more susceptible to biological invasions than more native ecosystems (Ogutu-Ohwayo *et al.*, 2016).

Associations amongst invasive alien species and other drivers of change in nature are generally understudied, and the degree to which biological invasions are affected by additive or multiplicative processes and interactions among drivers is therefore difficult to assess (**Figure 3.25**, **Chapter 1**, **section 1.3.3**). A recent review found that only 16 per cent of published research on invasive alien species examined associations with at least one other direct or indirect driver of change in nature, and less than 3 per cent considered associations with two or more additional drivers (Hulme, 2022). This section acknowledges the limited information on interactions between invasive alien species and other drivers of change in nature, and refers to a number of illustrative, rather than exhaustive, examples to highlight the importance of taking such interactions into account **(Box 3.11)**.

Indigenous Peoples and local communities recognize that most drivers of change on their lands do not act in

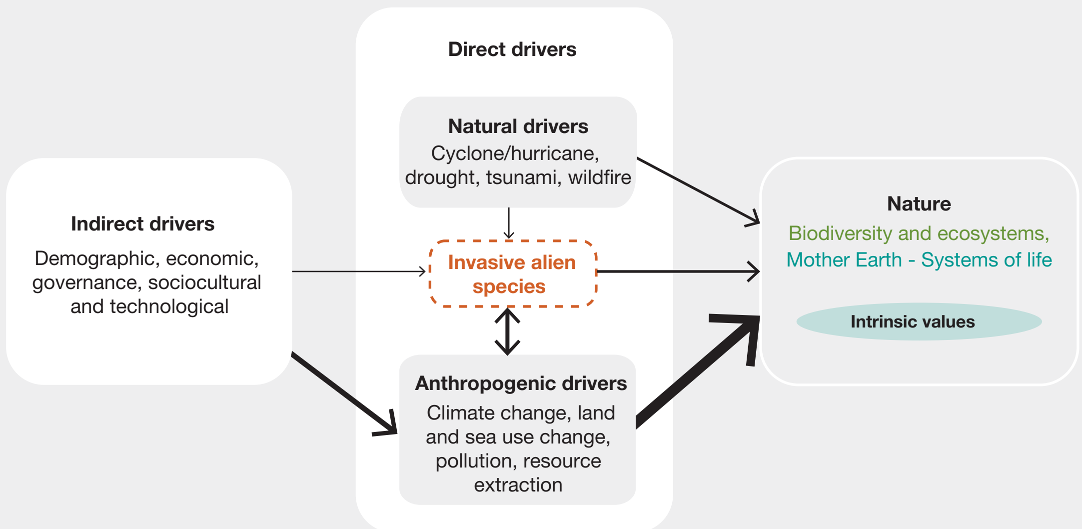

Figure 3 25 **Schematic representation of the links between indirect and direct drivers of change in nature in relation to their potential effect on invasive alien species (see Figure 3.3).**

The size of the arrows represents the available evidence in the scientific literature for the importance of the different links, as assessed though a bibliometric analysis of the literature (the absolute number of articles retrieved is reflected in the size of each arrow). Box 3 11 **Multiple interacting drivers trigger plant invasions in mountains.**

In the last two decades, evidence has highlighted the increasing number of alien plants establishing in mountain regions, despite mountains across the world differing greatly in terms of their biodiversity, climate, geology, land-use and other socioecological factors (e.g., T. Becker *et al.*, 2005; Dainese *et al.*, 2014; Guo, Fei, *et al.*, 2018; Khuroo *et al.*, 2007; Kueffer *et al.*, 2013; Marini *et al.*, 2012). In a standardized survey along elevational gradients in nine regions on four continents, more than 300 alien plant species were observed (Haider *et al.*, 2018).

Historically, agriculture and domestic grazing were probably the first and most extensive drivers that facilitated plant invasions in mountains. For example, species typical for European grasslands are widespread in the alien flora of mountains worldwide (McDougall *et al.*, 2011). However, as mountains have become more heavily developed, drivers such as infrastructure and anthropogenic land-use changes (including urbanization and the development of corridors such as roads, trails and railways) have synergistically supported the upslope movement of alien plants introduced at low and mid-elevations (Alexander *et al.*, 2011; Lembrechts *et al.*, 2017; Liedtke *et al.*, 2020; Rashid *et al.*, 2021; Yang *et al.*, 2018). Corridors provide a conduit for rapid movement of propagules aided by the continuous movement of vehicles and construction material (Rew *et al.*, 2018). Furthermore, the typically ruderal alien species benefit from the disturbed habitat conditions resulting from roadside construction and maintenance (Lembrechts *et al.*, 2016; Pickering & Hill, 2007; Seipel *et al.*, 2012).

In recent decades, and because of technological advances and higher economic and development pressures, mountain ecosystems have experienced a new phase of extensive land-use changes and infrastructure development, which has triggered the spread of invasive alien plants to even higher and more remote areas (Kalwij *et al.*, 2015; Rew *et al.*, 2018). Tourism in mountain areas has exponentially increased across the world (reviewed by Río-Rama *et al.*, 2019), increasing the development pressure in mountainous and alpine ecosystems. In most regions, there has been an increase in human settlements including housing and urbanization for tourism and recreation, as well as the expansion of infrastructure such as roads, railroads, powerlines and telecommunication towers. Overall, increasing land development, traffic and visitation rates have multiplied the chances for the introduction and establishment of invasive plant propagules at high elevations (McDougall *et al.*, 2011).

Figure 3 26 **Monte Baldo hosts an increasing number of invasive alien species.**

An increasing number of alien plants have been establishing in mountains like Monte Baldo throughout the European Alps (Dainese *et al.*, 2014). Photo credit: Katzwiekatzkann, WM Commons – under license CC BY 3.0.

Box 3 11

Climate change is expected to facilitate the expansion of invasive alien species to higher elevations both through direct and indirect effects. Climate change will reduce climatic barriers for generalist alien plants (Pauchard *et al.*, 2016), especially in regions which are not water-limited. Range shifts towards higher elevations have been reported, and alien plants appear to be moving up in elevation faster than native species (Dainese *et al.*, 2017). Increased disturbance due to, for example, higher fire frequency and intensity and insect and pathogen outbreaks triggered by climate change, will also play a role in promoting invasive alien species, especially in the middle elevations of mountains where forests will be more prone to invasion by woody plants (Franzese & Raffaele, 2017; Jactel *et al.*, 2020; Liebhold *et al.*, 2017). By reducing snow cover, climate change will promote the displacement of mountain ski facilities and resorts to higher elevations and into previously undeveloped areas. In addition, summer use of high elevation mountain resorts may be boosted in search for cooler places or "last chance tourism" (e.g., Kilungu *et al.*, 2019). The interactive effects of multiple drivers of change in nature affecting plant invasions are generally underestimated and primarily focus on climate change. However, interactions between climate change, infrastructure development, social values and land-use change will be informative because simple projections based solely on climate will be unreliable (Dainese *et al.*, 2017).

isolation in facilitating invasive alien species.[8] For instance, the interaction between economic and sociocultural drivers has been identified by Indigenous Peoples and local communities as responsible for the introduction and establishment of invasive alien species, as exemplified by the complexity and variability of societal and ecological processes facilitating the spread and establishment of *Prosopis juliflora* (mesquite; **Box 3.6**). Indigenous Peoples and local communities from Botswana, Ethiopia, Jordan and Kenya report that the main cause of the dispersal and spread of *Prosopis juliflora* is wildlife and livestock (Al-Assaf *et al.*, 2020; Bekele *et al.*, 2018; Haregeweyn *et al.*, 2013; IPBES, 2020; Mosweu *et al.*, 2013; Wakie *et al.*, 2016), which are linked to both sociocultural and economic drivers (pastoralist livelihoods). The Afar from Ethiopia now also use *Prosopis juliflora* as fuel wood, animal fodder and construction materials (Haregeweyn *et al.*, 2013) for economic reasons, which also contribute to its spread and establishment. In the Ramnad area of Tamil Nadu, India, sociocultural and land-use change led local communities to adopt charcoal-making, which promoted the spread of *Prosopis juliflora* through the reduction of grazing land and livestock holdings (Chandrasekaran & Swamy, 2016). Similar observations have been made for other species. For example, Indigenous Peoples and local communities in Ghana, West Africa and Himalayan India have observed the invasion of *Chromolaena odorata* (Siam weed; Amanor, 1991). Most of the Indigenous Peoples and local communities identify multiple drivers, such as the movement of humans and machinery, trade, land-use change, infrastructure development such as road construction and tourism, as important in facilitating the spread of this invasive alien species on their lands (Amanor, 1991; Braimah & Timbilla, 2002; Kosaka *et al.*, 2010; Timbilla & Braimah, 1993; Uyi & Igbinosa, 2013).

8. Data management report available at: https://doi.org/10.5281/zenodo.5760266

3.5.1 Land-use change and climate change

Most of the current knowledge on interactive effects of climate change and land-use change on biological invasions is informed by modelling studies designed to assess potential changes in species' distribution, with few experimental studies examining mechanisms based on demographic responses (e.g., L. C. Ross *et al.*, 2008). Modelling studies suggest that the relative importance of land-use change and climate change in facilitating biological invasions is highly variable and often species-specific or scale dependent (Febbraro *et al.*, 2019; Manzoor *et al.*, 2021). A general insight emerging from this work is that incorporating land-use change scenarios into climate change models can considerably alter the predicted outcomes of future biological invasions.

Climate change acts over broad regional and temporal scales, whereas land-use changes can have a much more local and immediate effect in response to commercial or land management decisions. For example, at the global scale, the future distribution of two major invasive alien plant species depended primarily on how their niches responded to climatic changes, with land-use change having a minor effect on distribution at this scale (Gong *et al.*, 2020). However, at smaller scales, several studies show that while future changes in temperature or precipitation patterns will exert a large influence on the establishment and spread of invasive alien plants, the rate of spread is often limited by the availability of suitable habitat (Taylor *et al.*, 2012), such as either cultivated or grazed land (J. V. Murray *et al.*, 2012; L. C. Ross *et al.*, 2008), urban areas (Nobis *et al.*, 2009) or the expansion of native ecosystems (Manzoor *et al.*, 2021). Interestingly, in some cases, the response of native vegetation to future climatic changes can enhance biological invasions. For example, a study from Wales found that the invasive forest understory shrub *Rhododendron ponticum* (rhododendron) is likely to decline under most climate and land-use scenarios, largely due to declines in coniferous forest cover, but is projected to increase under a scenario where ecosystem conservation leads to a substantial increase in coniferous forest cover (Manzoor *et al.*, 2021).

Increased fire activity may act synergistically with other climatic and land-use changes to drive the establishment and spread of invasive alien plant species (**sections 3.3.1.5.2**, **3.3.4**). For example, interactions among increased temperature, decreased precipitation and more frequent fires in recent decades have driven an upward spread of fire-adapted C4 invasive alien grasses (e.g., *Melinis minutiflora* (molasses grass)) along an elevation gradient in Hawaii (Angelo & Daehler, 2013). Higher atmospheric CO_2 levels have increased the productivity of invasive alien annual grasses in the western United States (Ziska *et al.*, 2005) and are predicted to favour the post-fire growth of African invasive alien grasses to the detriment of Australian native grasses (Tooth & Leishman, 2014). In the future, warmer minimum temperatures and other climatic changes in the western United States may also favour the establishment and spread of fire-adapted invasive alien grasses in previously unsuitable sites (Abatzoglou & Kolden, 2011; Martin *et al.*, 2015), although contractions of suitable habitat may also occur due to more extreme drought conditions (Albuquerque *et al.*, 2019). There is also concern that the interaction of climate change, fire activity and land management may promote grass-fire cycles and hence the spread of fire-adapted invasive alien grasses in disturbed forest ecosystems (Kerns *et al.*, 2020). Likewise, climate change, fragmentation and increased fire frequency have been shown to act synergistically to drive the spread of *Lantana camara* (lantana) in temperate forests in the Western Himalaya (Mungi *et al.*, 2018).

Few studies have investigated the interactions between land-use changes and climate change for invasive alien animals, invertebrates and microorganisms. Yet, the findings of existing studies often describe a prevalence of non-additive effects, reflecting those described above for plants. In an example from Italy, Febbraro *et al.* (2019), found that the potential distributions of four invasive alien squirrels (*Sciurus carolinensis* (grey squirrel), *Callosciurus finlaysonii* (Finlayson's squirrel), *Callosciurus erythraeus* (Pallas's squirrel) and *Tamias sibiricus* (Siberian chipmunk)) were reduced when the interactions between land-use and climate changes were included in models. In this case, climate-only models fail to account for lack of connectivity between habitats and limited overall habitat suitability, and may lead to an overestimate of the potential suitable habitat (Febbraro *et al.*, 2019). In Korea, the potential spread of an invasive alien insect *Thrips palmi* (melon thrips) in agricultural areas was shown to be influenced by rising temperatures in winter. Increased winter temperatures enabled a longer overwintering period, allowing the species to spread further across increasingly connected agricultural areas (Hong *et al.*, 2019).

Climate change and land-use changes may also interact by creating positive feedback loops, reinforcing biological invasions. For example, in the tropical dry forests of Bolivia experimental fires were shown to enhance the abundance of the invasive alien African grass *Megathyrsus maximus* (Guinea grass) in plots subjected to selective logging compared to unlogged areas, suggesting that increasing fire risk under climate change may interact with deforestation resulting from land-use change to promote the spread of this species (Veldman *et al.*, 2009). Similarly, in dryland areas in South Africa, degraded landscapes and road corridors invaded by alien grasses may alter the fuel characteristics sufficiently for fires to become a threat to an otherwise fire-absent vegetation type (Rahlao *et al.*, 2009, 2014). In these disturbed environments, land-use change and climate change interact to favour biological invasions.

3.5.2 Land-use change, climate change and nutrient pollution

While many studies comment upon the role of land-use change, climate change and nutrient pollution in the context of biological invasions, few explicitly capture interactions between these drivers or suggest causality for specific alien species introductions or stages of the biological invasion process. In fact, in many instances, invasive alien species are considered as a driver, rather than the response affected. In lieu of direct observations, paleoecological records may provide evidence for the interactive effects of land-use or sea-use change, nutrient pollution and climate change coinciding with an increase in invasive alien species. The analysis of a marsh sediment core spanning the last 1,100 years from Tivoli Bay in the Hudson River shows that climate shifts and other anthropogenic drivers (i.e., land-use change and nutrient input) occur simultaneously, with a fivefold expansion of invasive alien plant species such as *Typha angustifolia* (lesser bulrush), *Phragmites australis* (common reed) and *Lythrum salicaria* (purple loosestrife) (Sritrairat *et al.*, 2012). This study suggests that the increase in the number of invasive alien species is linked to European settlement impacts in this region, including higher disturbance, increased nutrients and sedimentation, along with warmer climate, however an explicit causal link between the different drivers and establishment of invasive alien species cannot be made.

A contemporary study of the seed recruitment of the invasive alien forbs *Bellis perennis* (common daisy), *Lolium perenne* (perennial ryegrass), *Poa pratensis* (smooth meadow-grass), *Taraxacum officinale* (dandelion), *Trifolium pratense* (red clover) and *Trifolium repens* (white clover) beyond their current invaded range in the subarctic Andes found that the species produce more biomass and flowers at higher nutrient levels and warmer temperatures and establish, grow and flower more in disturbed habitats than in undisturbed habitats (Lembrechts *et al.*, 2016). The study found no differences between the responses of these species when expanding in their invaded range in the Andes compared to expanding in their native range in the Scandes, suggesting that both plant invasions and natural range expansions in cold-climates are likely to increase with a combination of warmer climate, increased disturbance and increased nutrients (Lembrechts *et al.*, 2016).

In aquatic systems, the invasive alien *Phragmites australis* (common reed) is expanding throughout the Great Lakes of the United States (Great Lakes Phragmites Collaborative,

Box 3 12 **Land-use change, climate change and nutrient pollution interact to drive the introduction, establishment and spread of *Pontederia crassipes* across Africa.**

Pontederia crassipes (water hyacinth) is a fast-growing floating aquatic plant native to South America that has spread throughout vital freshwater bodies and wetlands of Africa, North America, Europe, Asia and Oceania since the late 1800s (Navarro & Phiri, 2000). Across Africa, this species has shown true exponential expansion by spreading over a large proportion of the water bodies with infestations getting worse as there is an increase in extreme climatic events in major water bodies like Lake Victoria in East Africa, Lake Nyasa in the Nile basin (especially around Lake Tana), the Zambezi River basin in southern Africa and the Tano lagoon and River Niger in West Africa. Connectivity among diverse water bodies has further facilitated the spread of water hyacinth in the region. Its spread is linked to eutrophication emanating from poor land-use management practices and is facilitated by environmental degradation and extreme climatic (i.e., temperatures, wind and floods) events (Navarro & Phiri, 2000; Téllez *et al.*, 2008; Thamaga & Dube, 2018). These extreme events facilitate the transport and introduction of water hyacinth in many freshwater ecosystems, and are also expected to alter natural surface water flow regimes, potentially further increasing the likelihood of water hyacinth and other invasive alien species establishing and spreading (Diez *et al.*, 2012; IPBES, 2019). Water hyacinth is expected to continue expanding into suitable habitat found in African ecosystems, with the rate and extent of the spread depending on disturbance from climate change and the nutrient pollution levels of the water bodies (Diez *et al.*, 2012; IPBES, 2019; Navarro & Phiri, 2000).

Figure 3 27 ***Pontederia crassipes* (water hyacinth) in Lake Victoria, Kisumu, Kenya.**

2022), with its introduction, establishment and spread promoted by road networks, agricultural activities that increase nutrient availability and climate change (Mazur *et al.*, 2014). In Lake Victoria, Africa, the distribution of the invasive alien *Pontederia crassipes* (water hyacinth) rapidly expanded during the 1980s, a period linked to eutrophication and climate warming (Hecky *et al.*, 2010; Ogutu-Ohwayo *et al.*, 2016; A. E. Williams *et al.*, 2005; **Box 3.12** . While currently its spread is reduced, fears remain that land-use changes in the catchment area, along with continued nutrient loading and climate warming, will result in a resurgence of water hyacinth **(Box 3.12)**. In the late 1980s, the Baltic Sea experienced a bloom of *Mnemiopsis leidyi* (sea walnut) and a collapse of anchovy stocks, both of which were linked to a complex interaction of increased eutrophication, a changing regional climate with more severe winters and fishing pressures (Oguz *et al.*, 2008). Changing salinity arising from the new Suez Canal (**section 3.3.1.3**, **Box 3.7**) opening in conjunction with climate change is facilitated the expansion of *Brachidontes pharaonis* (variable mussel)'s distribution across the Mediterranean Basin, with this expansion also being enhanced by eutrophication associated with local urbanization (Sarà *et al.*, 2018).

3.5.3 Trade, urbanization and land-use change

Although international trade can directly introduce invasive alien species in ballast water, contaminants of commodities or stowaways in containers (**section 3.2.3.1**), it also interacts with other drivers facilitating biological invasions including: direct exploitation of natural resources, pollution, climate change, land-use change and urbanization **(Figure 3.28)**. To illustrate aspects of these interactions, the following section examines the implications of the interactions between trade, land-use change and urbanization.

International trade is an important driver of urbanization since it encourages the agglomeration of economic activities (and hence labour) in specific urban areas, particularly areas that are associated with international transport hubs such as marine ports, airports or national borders (Tripathi, 2020). Cities that have a high number of global trade links tend to be highly urbanized and urbanization also increases with the level of agricultural imports and with exports of non-agricultural commodities (Thia, 2016). Urban areas also represent hotspots of alien species richness, which in part can be explained by the high rate of intentional introductions of alien species

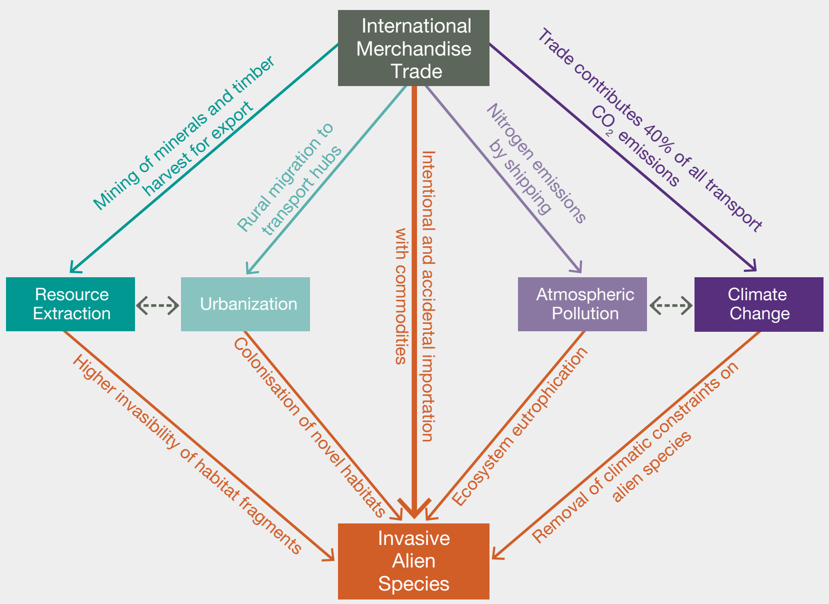

Figure 3 28 **Schematic illustration of how international merchandise trade interacts with other drivers of change in nature to influence the introduction and spread of invasive alien species.**

The thick arrow indicates the direct influence of international merchandise trade on invasive alien species, and thin arrows indicate how international merchandise trade affects other drivers which again may facilitate the introduction and spread of invasive alien species. Dotted lines represent interactions among drivers of change in nature. Adapted from Hulme (2021b), https://doi.org/10.1016/j.oneear.2021.04.015, under license CC BY 4.0.

either for amenity value (e.g., street trees) or as pets (e.g., parrots) that subsequently escape, but also by the higher international connectivity of large cities that facilitates unintentional introductions of alien species *via* ports and airports (Shochat *et al.*, 2010). In the marine realm, urbanized maritime infrastructure associated with ports (e.g., breakwaters, jetties and seawalls) does not function as a surrogate for natural rocky habitats but instead facilitates the establishment and spread of alien species (Bulleri & Chapman, 2010; **section 3.3.1.4**). For example, in coastal North America approximately 90 per cent of the alien species inhabiting hard artificial substrata have been reported from docks and marinas (Mineur *et al.*, 2012). Similarly, it can be expected that urbanization driven by international trade will lead to further development of land-based transport infrastructure such as rail and roads which may also facilitate the spread of alien species beyond the initial port of entry. The growth of urban areas also results in land-use change as natural and agricultural areas are fragmented and converted to housing. This environmental disturbance favours the persistence of generalist human-commensal species from around the world (Gavier-Pizarro *et al.*, 2010).

The extensive clearing of tropical forests in recent decades is in part driven by increased international trade in agricultural commodities and this trend is expected to continue due to further trade liberalization (Schmitz *et al.*, 2015). Increasing global demands for meat, animal feed and oil seed products have led to major changes in land-use in developing countries (Pendrill *et al.*, 2019). There is also a link between international trade in wood products (particularly roundwood timber) and declining national forest stocks, especially in developing countries in the tropics such as Indonesia and Cameroon (Kastner *et al.*, 2011). In addition, international trade increases demand for new products as in the case of the expansion of oil palm plantations in Latin America, which has occurred at the expense of other land-uses including tropical forests (Furumo & Aide, 2017). The resulting fragmentation of tropical forests also increases their vulnerability to biological invasions (Waddell *et al.*, 2020). Furthermore, new crops such as *Elaeis guineensis* (African oil palm) can themselves spread beyond cultivated areas to become invasive alien species in regions where they are not native (Zenni & Ziller, 2011).

3.5.4 Urbanization and pollution

Urbanization and pollution interact to facilitate biological invasions; invasive alien species are disproportionally found in urbanized areas with higher pollution compared to less polluted urban areas or polluted natural ecosystems. While urbanization promotes the transport and introduction and of invasive alien species both intentionally and unintentionally (**section 3.2.2.4**), pollution contributes to improve the chances of establishment and spread of an invasive alien species, which tend to be facilitated by nutrient-rich habitats (**section 3.3.3.1**). For example, in reef ecosystems, alien faunal distributions are linked to the presence of heavy metals, local population density and proximity to city ports; with invasive alien species being more common in areas with higher levels of pollution, while native species are less common under these conditions (Stuart-Smith *et al.*, 2015). In mangrove ecosystems in Nigeria, pollution and urbanization create forest gaps that enhance biological invasions, for example of *Nypa fruticans* (nipa palm; Nwobi *et al.*, 2020).

Urban areas generate and disseminate many types of pollutants, including nitrogen. Alien species are generally more tolerant to nitrogen pollution than native species (**section 3.3.3.1**), and in nitrogen polluted freshwater ecosystems in Hawaii, native goby species have declined while alien species are increasing (Lisi *et al.*, 2018). Urbanization generates runoff to aquatic ecosystems, which can carry many pollutants, and modifies their dynamics. An example is how pollution of freshwater environments following the application of road de-icing salts facilitates the survival and establishment of the invasive alien *Corbicula fluminea* (Asian clam) in New York, the United States, as this species is more tolerant to road salts than other native freshwater organisms (Coldsnow & Relyea, 2018).

Pollution can act directly by conferring advantages to more tolerant invasive alien species, but also by creating a competitive advantage for them by negatively affecting native populations. Human settlements generate domestic wastewater, agricultural fertilizer runoff, and effluents enriched with organic nutrients that, in coastal urban areas, often end up directly in the sea. In South Africa, these inputs of organic pollutants are associated with the bloom of *Ulva lactuca* (green laver) in Saldanha Bay (Mead *et al.*, 2013, **section 3.3.3.1**). In the Mediterranean Sea, high levels of urbanization are also linked with the degradation of coralligenous assemblages, compared to sites within natural protected areas and areas with lower rates of urbanization. This difference is, at least partially, associated with the increase of opportunistic alien species (e.g., algal species), which are more tolerant to urban-related pollution (Montefalcone *et al.*, 2017). In South East Australia, the heavily urbanized Port Jackson Estuary is one of the world's waterways most polluted by heavy metals and organic compounds as a result of antifouling paint, and this threatens the native *Saccostrea glomerata* (Sydney rock oyster), giving the more tolerant invasive alien *Magallana gigas* (Pacific oyster) a competitive advantage, and the invasive oyster, which also takes advantage of artificial substrates to establish has become more abundant (Scanes *et al.*, 2016). In coastal urbanized areas, copper, which is one of the primary active ingredients in antifouling hull paints, has become a common pollutant that increases in concentration as vessel traffic increases. A study carried out in Massachusetts proved that the invasive alien *Botrylloides violaceus* (violet tunicate) poses a competitive threat to the native *Aplidium glabrum* (tunicate) with regard to surface area growth when copper pollution is present. *Botrylloides violaceus* proved to be more tolerant to copper pollution (Osborne & Poynton, 2019). In Tasmania, expanding urbanization close to estuaries has resulted in an increase in pollutants from anthropogenic sources (e.g., marinas, storm-water drains, sewage outfalls and fish farms) that affect nearby benthic assemblages. Alien species were more abundant in sites near marinas and sewage outfalls (Fowles *et al.*, 2018). Increased focus on controlling pollution from marinas and sewage outfalls may thus limit the spread of alien species (Fowles *et al.*, 2018). In Lane Cove Valley, Australia, invasive alien plants are linked to areas polluted by phosphorus and heavy metals, which are pollutants linked with urbanization, and especially to areas where soil has also been previously disturbed (S. J. Riley & Banks, 1996).

Plastics are also a common waste product in urban areas, and exposure to plastics can change the behaviours of species. In Chile, Pinochet *et al.* (2020) studied invasive alien bryozoan species, such as *Bugulina flabellata* and *Bugula neritina* (brown bryozoan), that are frequently found in urbanized areas globally. These species tend to prefer plastic substrates, rather than wood or concrete, and exposure to plastic substrates could enhance their spread (**section 3.3.3.4**).

Finally, there are other types of pollution less frequently studied that are also linked to urbanization such as noise and light pollution. There are a few studies that assess the link between noise and light pollution in urban areas and invasive alien species. For example, the invasive alien *Hemidactylus frenatus* (common house gecko) in north-eastern Australia occupies a broader range of light environments than does the native gecko *Gehyra dubia* (dubious dtella). Experimental removal of the invasive alien gecko from places with light pollution, did not change the selection by native geckos for darker locations, which suggests cities are opening niches for invasive alien species (Zozaya *et al.*, 2015).

3.6 SYNTHESIS AND CONCLUSION

3.6.1 Literature used in this chapter and identification of knowledge gaps

A diverse strategy was adopted to identify and summarize the literature used in Chapter 3 (**sections 3.1.3** and **3.1.4**).[9] The varying approaches to reviewing the literature not only recognized the biases and gaps within the scientific literature linking invasive alien species with other drivers of change in nature (Hulme, 2022; **Box 3.13**), but also acknowledged the complexities in establishing cause-effect relationships between drivers and the transport, introduction, establishment and spread of invasive alien species (**sections 3.1.2** and **3.1.4**, **3.1.5**). Based on these search strategies, Chapter 3 summarizes the information from 1,183 scientific papers and other sources9 across indirect, direct, and other drivers of change in nature for the role of a total of 44 drivers in facilitating the transport, introduction, establishment and spread of invasive alien species across biomes, realms and IPBES regions (**sections 3.2** and **3.3**, **3.4**, **3.5**). Sections 3.2, 3.3, 3.4, 3.5 and 3.6.2 appraise and summarize the current state of knowledge on the role of drivers in facilitating biological invasions, whereas sections 3.1 and 3.6.1 outline the background and search strategies and summarize the knowledge base for the chapter.

Across the 1,183 studies identified and used in this report **(Figure 3.29)**:

- 30.4 per cent reported on indirect drivers of change in nature (sociocultural 2.2 per cent, demographic 9.5 per cent, economic 10.4 per cent, technology 5.9 per cent, governance 2.4 per cent);
- 72.1 per cent on linked to direct drivers of change in nature (land- and sea-use change 29.3 per cent, direct exploitation of natural resources 7 per cent, pollution 12.1 per cent, climate change 17.2 per cent, invasive alien species 6.5 per cent);
- 5.8 per cent on linked to other drivers (biodiversity loss 3.9 per cent, natural drivers 1.9 per cent).

Despite targeted searches to address how two or more drivers of change in nature interact to facilitate biological invasions (**sections 3.1.5**, **3.5**) fewer than 20 per cent of these studies reported on the role of more than one driver in facilitating biological invasions (**Boxes 3.12** and **3.13**).

9. Data management report available at: https://doi.org/10.5281/zenodo.5529309

Most studies were on invasive alien plants (52.8 per cent), which represents almost twice as many as for invasive alien vertebrates (28.9 per cent) or invertebrates (29.2 per cent), with fewer studies having been conducted on invasive alien microbes and fungi (12.3 per cent). More than half of the identified studies were from the terrestrial realm (66.3 per cent), whereas freshwater and marine systems were represented by, respectively, 20.2 per cent and 23.7 per cent of the studies. Plants dominated studies of terrestrial invasive alien species, whereas all macroscopic taxonomic groups were relatively evenly represented in the studies reviewed from the aquatic realms, with vertebrate studies being most numerous in the freshwater realm and invertebrate studies most numerous in the marine realm **(Figure 3.30A)**.

Reviewed studies mostly focused on drivers in the Americas (45 per cent), followed by Europe and Central Asia (36.6 per cent), with fewer studies from the Asia-Pacific region (34.5 per cent, noting that 23.2 per cent were from Oceania) and Africa (26 per cent). This trend was relatively consistent across all taxonomic groups **(Figure 3.30B)**.

For the majority of the studies analyzed in this report (1044 sources), it was possible to link drivers to one or more stages of the biological invasion process, with the majority of studies linking drivers to the establishment (70.5 per cent), spread (66.4 per cent) and introduction (53.5 per cent) of invasive alien species, whereas fewer sources explicitly linked drivers to transport (33.8 per cent). These numbers add up to considerably more than 100 percent, illustrating that most studies link drivers to more than one stage within the biological invasion process. The availability of studies on drivers varied across stages of the biological invasion process. Studies of the role of indirect drivers of change in nature in facilitating biological invasions tended to focus on links to transport and introduction of invasive alien species **(Figure 3.31A)**. This trend was especially evident for sociocultural and economic drivers, for which studies on their role in transport and introduction made up for two thirds (65 per cent) of studies on these two drivers across all stages of the biological invasion process. This pattern was consistent across all realms and taxonomic groups but is especially strong for microbes. In contrast, studies of direct (anthropogenic and other) drivers, reported

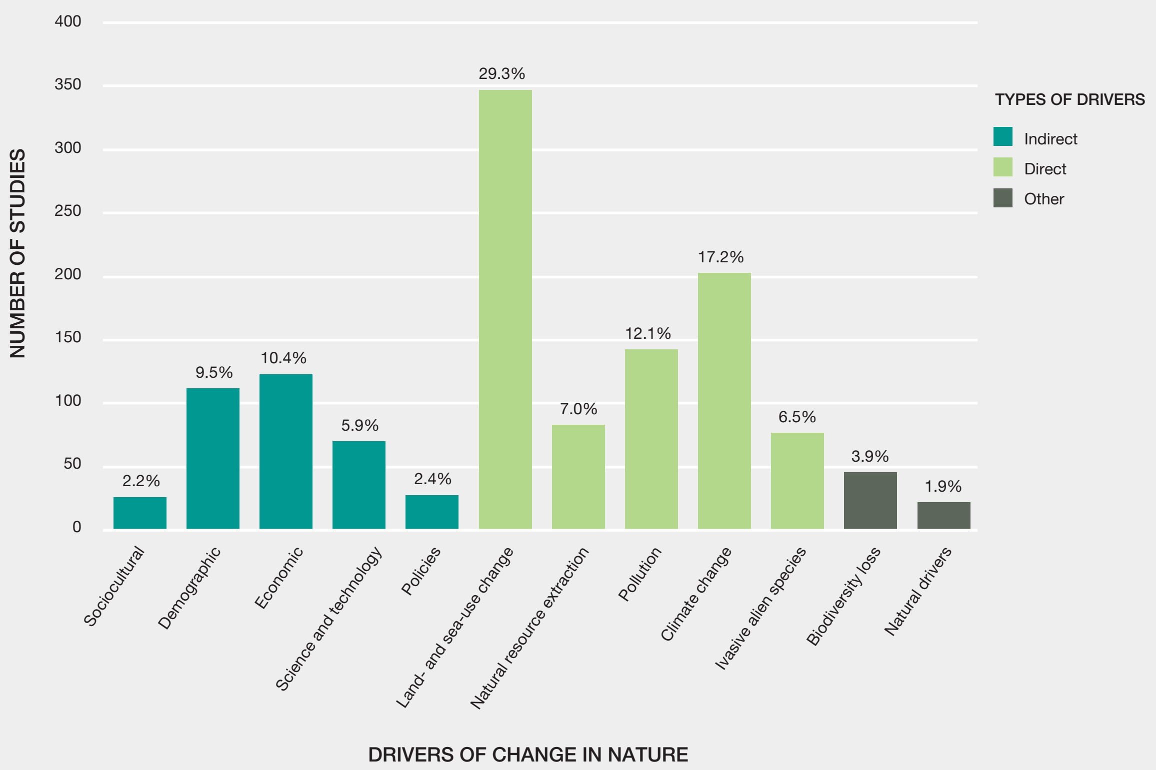

Figure 3 29 **Overview of the literature used for this assessment of the drivers of change in nature affecting biological invasions.**

The number of studies (y axis) in the literature base for Chapter 3 reporting on each driver of change in nature (x axis) in affecting biological invasions. The total number of studies is 1185. The underlying data for this figure is available at https://doi.org/10.5281/zenodo.5529309

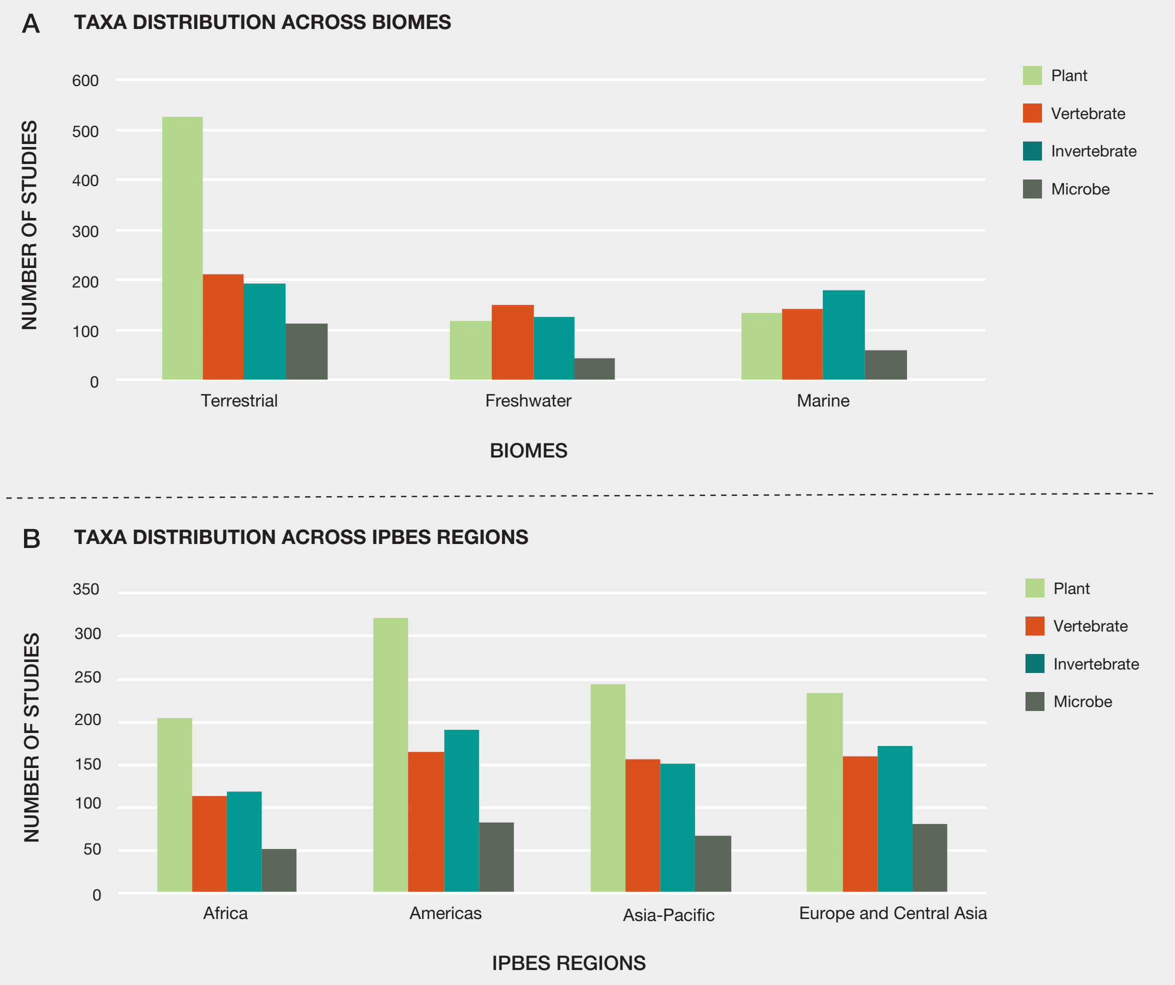

Figure 3 30 **Overview over the literature used for this assessment of the role of drivers of change in nature in affecting biological invasions across realms, IPBES regions and taxa.**

The number of studies in the literature base for Chapter 3 (y axis) reporting on the role of drivers of change in nature in facilitating invasive alien species categorized by realms vs. taxonomic groups (panel A.; x axis) and by IPBES regions vs. taxonomic groups (panel B.; x axis) (n = 1202 papers).The underlying data for this figure is available at https://doi.org/10.5281/zenodo.5529309

predominantly on links to the establishment and spread stages, a pattern that was especially evident for pollution, climate change, invasive alien species, biodiversity loss and ecosystem resilience, and for natural drivers, for all of which studies on their role in establishment and spread made up more than 75.9 per cent of all studies (**Figure 3.31B** and **C**). These patterns were less consistent across realms and taxonomic groups, however, as stronger links between direct or other drivers and establishment and spread were found in the terrestrial realm than in freshwater, whereas this pattern was largely absent in marine systems. Likewise, the link between indirect drivers and the early stages of biological invasion and direct drivers and later stages was strong for alien plants, but less evident for invertebrates and vertebrates, whereas studies of microbes predominantly reported on links to transport and introduction across all drivers. Three groups of drivers, demographic drivers, land- and sea-use change and direct exploitation of natural resources, stood out as studied in relation to all stages of the biological invasion process (**Figure 3.31A** and **B**). This was less evident for land-use and direct exploitation of natural resources in the terrestrial realm and for plants, where studies of establishment and spread dominate, and for demographic drivers for microbes, where studies of transport and introductions, dominated.

Information on the roles of drivers in facilitating biological invasions was largely sourced from primary studies (50.4 per cent), followed by reviews (40.9 per cent), whereas only a small number of studies were formal meta-analyses (3.6 per

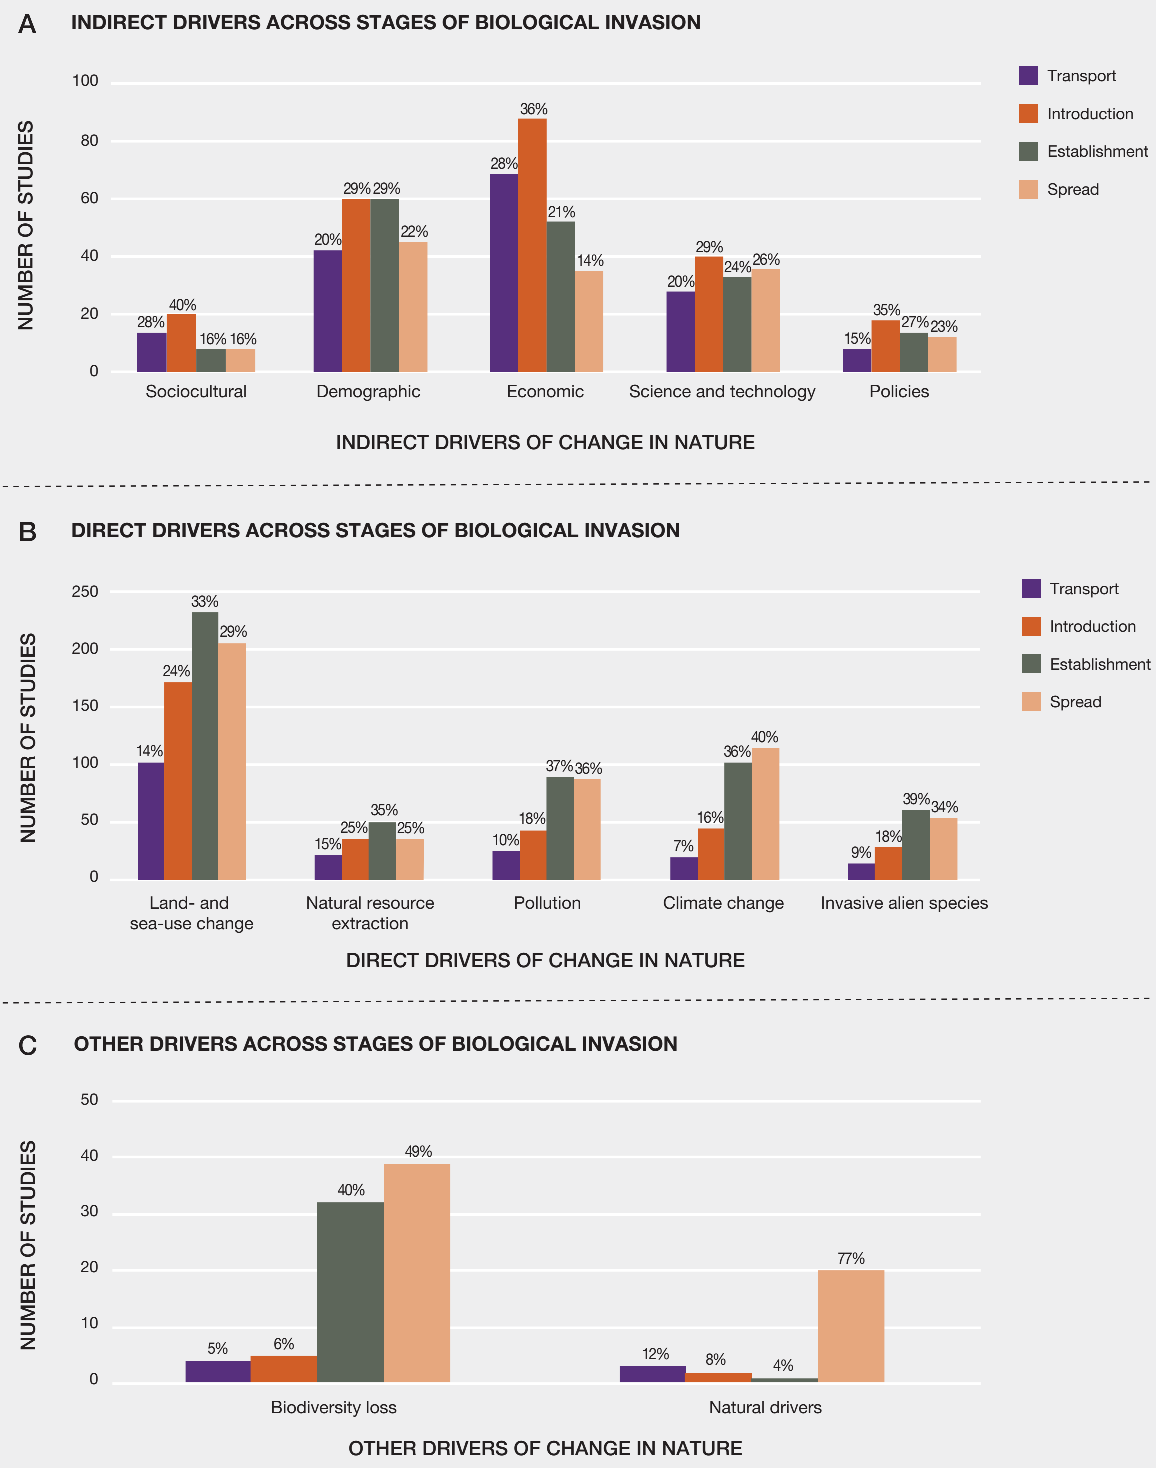

Figure 3 31 **Overview of the literature used within this chapter and specifically the role of drivers of change in nature in affecting invasive alien species across the biological invasion process.**

Summary of the literature extracted for Chapter 3 for assessing the role of drivers across biological invasion stages, showing the proportion of the studies of each driver that addresses the different stages in the biological invasion process. Note that studies used in the chapter that do not explicitly state stages of the biological invasion process affected are excluded from this figure, and that each study can address more than one stage of the biological invasion process (total of 1,183 papers). Chi-square analysis indicated

Figure 3 31

that the number of studies reporting effects on the transport and introduction of invasive alien species is statistically higher for indirect than direct drivers of change in nature ($p<0{,}001$), whereas the opposite is true for the establishment and spread stages. The number of studies is shown on the y axis, while the indirect (panel A.), direct (panel B.) and other drivers (panel C.) of change are shown on the x axis. For the number of studies for each driver, see **Figure 3.29**. The underlying data for this figure is available at: https://doi.org/10.5281/zenodo.5529309

cent). This suggests further structured synthesis and reviews are required to support the knowledge on the drivers facilitating biological invasions **(Box 3.13)**.

The outcomes of the chapter review with respect to data gaps and biases in the evidence available for assessing the role of drivers of change in nature in the context of biological invasions, are largely consistent with both the systematic review of scenarios and models[10] (**Chapter 1**, **section 1.6.7.3**) undertaken as part of this assessment **(Box 3.14)** and the bibliometric analysis of research effort undertaken by Hulme (2022) on drivers in relation to biological invasions **(Box 3.13)**.

10. Data management report available at https://doi.org/10.5281/zenodo.5706520

Box 3 13 **Impacts of direct and indirect drivers of change in nature on biological invasions are currently much less understood than other areas of conservation science.**

A recent assessment of the research effort into the role of indirect and direct drivers of change in nature facilitating invasive alien species concluded that the current knowledge is limited, and focuses on tractable drivers over those that require an interdisciplinary approach, with bias towards developed economies (Hulme, 2022). Between 2000 and 2020, 27,462 peer-reviewed journal articles were published addressing biological invasions of which less than 5,000 (or 18 per cent) examined the role of one or more drivers of change in nature. In contrast, out of a corpus of 110,087 research papers targeting biodiversity and ecosystem services, almost 40,000 (or 36 per cent) described the role of one or more drivers. Thus, the drivers affecting biological invasions remain less understood compared to other areas of conservation science.

Research on drivers of change in nature facilitating biological invasions reflects a strong bias towards direct drivers with only a small fraction of studies addressing indirect drivers (Hulme, 2022). While there have been calls for increased interdisciplinarity in the study of biological invasions, the percentage of articles addressing indirect drivers of change in nature has shown no significant increase over the last two decades, leading to an increasing bias in articles towards direct drivers of change in nature (Hulme, 2022). Drivers deemed likely to be important for biological invasion by invasive alien species, such as governance and direct exploitation of natural resources, were shown to be poorly supported by research effort. The considerable literature addressing national and international policies for conserving biodiversity (Le Preste, 2017) is not matched by similar studies tackling the governance of problems arising from invasive alien species (Hulme, 2021a).

Compared to developed economies, there were only about half as many articles affiliated with institutions in developing economies. This may significantly limit the opportunity for prevention and projection of future risk of invasive alien species in Africa, Asia and Latin America. Given the future importance of indirect drivers such as tourism, trade and infrastructure projects on the likely risk of introducing invasive alien species to developing economies (Hulme, 2015a), the paucity of studies on indirect drivers is particularly troubling. Developing economies harbour most of the world's biodiversity (Adenle *et al.*, 2015) but also face significant threats from indirect drivers of change in nature such as international trade (Lenzen *et al.*, 2012) as well as direct drivers in the form of invasive alien species (Early *et al.*, 2016). Developing economies have also been identified as sources of many of the world's invasive alien species that have the potential to reach nearly all terrestrial biomes (Measey *et al.*, 2019). Thus, there is an imperative to improve the knowledge of drivers of change in nature in developing economies not only to protect their own national natural heritage but also prevent further biological invasions globally. The similarity between the results from the diverse literature review strategy in Chapter 3 and a systematic bibliometric analysis (Hulme, 2022) support the view that Chapter 3 adequately captures current knowledge of the drivers in facilitating invasive alien species.

Box 3 14 Representation of drivers in scenarios and models.[11]

Previous IPBES assessments have evaluated how various tools and techniques such as scenarios and models have been used to better understand the impacts of drivers on nature, nature's contributions to people and good quality of life (IPBES, 2016b, 2018e, 2018c, 2018d, 2019). For this assessment a systematic review was undertaken to evaluate the patterns and trends in published research on invasive alien species that included both scenarios and models (**Chapter 1**, **section 1.6.7.3**). In total 778 papers were reviewed (from an initial set of 30,299). Drivers were included as a scenario feature within the review with information captured on the number and type of driver. The results of the review showed that most papers focused on only one driver (77 per cent of 778 papers). Climate change was the most commonly included driver (62 per cent of all observations; **Figure 3.32**). The studies that focused on two or more drivers often included climate change or invasive alien species. Many of the drivers identified in **Chapter 3** **(Table 3.1)** were poorly represented, as drivers such as demographics, governance, pollution, direct exploitation of natural resources, values and technology accounted for less than 2 per cent of the observations. The lack of studies focusing on interactions amongst drivers is a gap that could limit understanding of the outcomes of biological invasions alongside other drivers of change in nature.

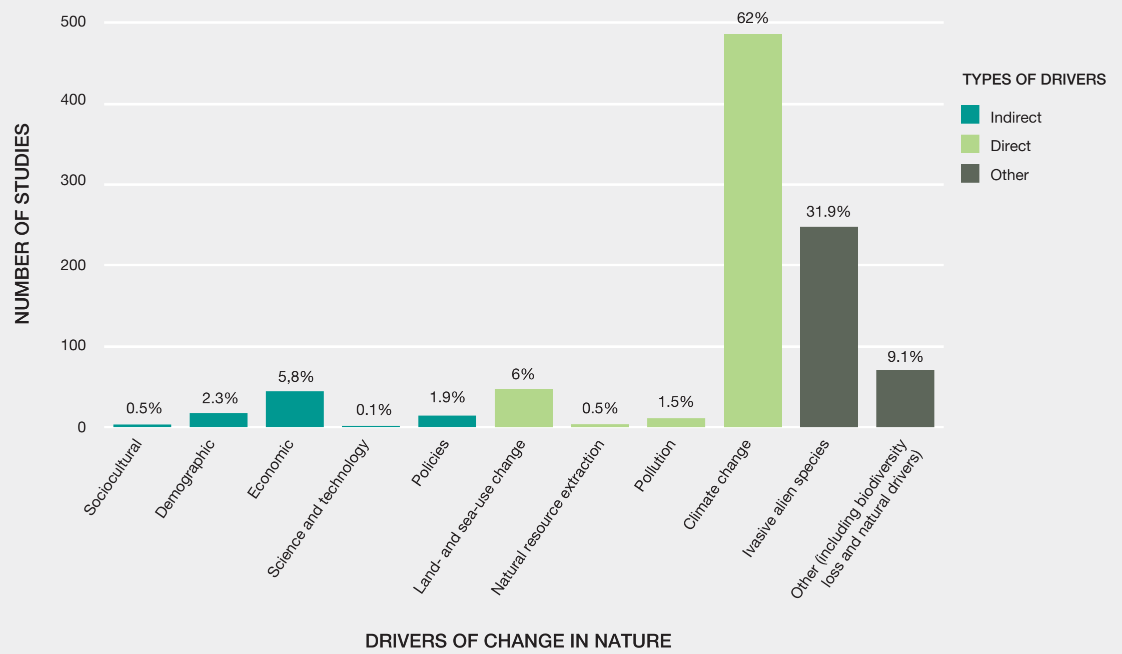

Figure 3 32 **Representation of drivers (per cent) of the observations for each driver across the papers included in the scenarios and models review noting some papers included multiple observations.**

The number of studies is shown on the y axis, and the different drivers of change in nature are shown on the x axis. A data management report for this figure is available at https://doi.org/10.5281/zenodo.5706520

The dominance of climate change as a driver in most studies is explained by the prevalence of correlative models which invariably include climate change scenarios (e.g., scenarios from the Intergovernmental Panel on Climate Change; IPCC) as a factor to project the occurrence or potential distribution of species. The majority of papers focused on exploratory scenarios, that examine a range of plausible futures based on the potential trajectory of key underlying scenario features. The results of these studies provide some insights in relation to future directions for the development of scenarios and models in invasion science (e.g., Lenzner *et al.*, 2019; Roura-Pascual *et al.*, 2021). Future studies may be able to address the current gaps and include the other cross-cutting themes highlighted in this assessment such as Indigenous and local knowledge (**Glossary**) and good quality of life (e.g., Obermeister, 2019), which would improve our understanding of the patterns and trends in drivers of change in nature and how these affect biological invasions.

11. Data management report available at https://doi.org/10.5281/zenodo.5706520

3.6.2 Synthesis

The relative importance of drivers of change in nature in facilitating biological invasions was quantified based on a consensus approach involving an expert-based assessment by the authors of the chapter for each invasion stage across and within realms (terrestrial, freshwater, marine) and broad taxonomic units (microbes, plants, invertebrates, vertebrates).[12]

Overall, the expert-based consensus approach assessed economic drivers as the most important in facilitating biological invasions worldwide (average 21 per cent importance, across all realms and taxonomic units, and stages of the invasion process), followed by land- and sea-use change (16 per cent), demographic drivers (10 per cent), climate change (9 per cent), sociocultural drivers and policies, governance and institutions (each 8 per cent), pollution (7 per cent), direct exploitation of natural resources and invasive alien species (each 5 per cent), biodiversity loss, natural hazards and science and technology (each 4 per cent). The major drivers identified are consistent with indigenous and local knowledge **(Box 3.15)**.

The consensus approach further reveals a clear shift in relative importance of the drivers over the stages of the biological invasion process **(Figure 3.34)**. The transport and introduction of invasive alien species are primarily facilitated by economic drivers, followed by land- and sea-use changes, with some evidence for an additional role of sociocultural drivers, demographic drivers, and policies, governance and institutions. In contrast, land- and sea-use change is the overriding driver responsible for the establishment and spread of invasive alien species, followed by climate change, pollution, and to some extent economic drivers and biodiversity loss. Thus, indirect drivers are identified as the most important in the early stages of the biological invasion process while direct drivers dominate in the later stages.

Patterns are relatively consistent across realms, but with some variation **(Figure 3.34A)**. Economic drivers and natural drivers are considered relatively more important and sociocultural and policy, governance and institutional drivers less important for facilitating the transport of invasive alien species in the marine realm, whereas demographic drivers are more important for the transport of invasive alien species into the terrestrial realm. There is little difference between realms in the relative importance of drivers facilitating the introduction stage. Policies, governance and institutional drivers are more important in facilitating the establishment of invasive alien species, while sociocultural drivers and biodiversity loss are less important in the marine realm, whereas demographic drivers are relatively more important and direct exploitation of natural resources less important in the terrestrial realm. Finally, the spread of invasive alien species is relatively less affected by demographic drivers in the marine realm, more affected by sociocultural drivers in freshwater systems, and less affected by pollution but more affected by biodiversity loss in the terrestrial realm.

There is more variation across taxonomic units than realms **(Figure 3.34B)**. Sociocultural drivers are consistently more important for facilitating alien plants early in the invasion process and for vertebrates across all stages, and less important for microbes and invertebrates. This pattern likely reflects the importance of intentional introductions of plants and animals for human amenity values, both linked to subsistence and to cultural values (**sections 3.2.1**, **3.2.3.2**, **3.2.3.3**, **3.3.1.1**). Demographic drivers are relatively more important for the transport of microbes than other taxonomic groups, whereas economic drivers are relatively less important for the introduction of plants and more important for the spread of plants and vertebrates than for the other taxonomic groups. This latter finding is likely linked to the relatively higher importance of land-use changes for the introduction of plants along with intentional introductions of alien vertebrates for hunting and farming (**sections 3.3.1.1**, **3.3.2.1.1**, **3.3.2.1.2**). Pollution is assessed as relatively more important for the introduction of microbes and less important for the establishment of invasive alien vertebrates and the spread of invasive alien invertebrates and vertebrates. In contrast, climate change is deemed relatively more important for the introduction, establishment and spread of microbes compared to other taxonomic groups.

These patterns illustrate some of the complexity in how drivers of change in nature facilitate biological invasions. The variation across stages, taxonomic units and realms is partly related to the biophysical characteristics of the specific processes and systems. As examples, trade and travel operate mainly through both the intentional and unintentional transport of invasive alien species across regions; harvesting and restocking for harvesting are more important in aquatic than terrestrial systems (**sections 3.2.3.1**, **3.3.2.1**) and respond to variation in human impacts (such as, land- and sea-use being more important for plants and pollution within aquatic systems and less important for vertebrates; **sections 3.3.1.1**, **3.3.3**).

12. Data management report available at https://doi.org/10.5281/zenodo.7861162

Box 3 15 Identification of drivers by Indigenous Peoples and local communities.[13]

The IPBES framework acknowledges diverse knowledge sources in assessments, and in particular the central position of Indigenous Peoples and local communities in providing situated understanding of biological invasions. Assessment authors thus carried out an extensive cross-chapter review of literature to identify Indigenous and local knowledge related to invasive alien species (**Chapter 1**, **section 1.6.7.1**). In total 131 studies were reviewed, and data on drivers was collated, including both the number and type of driver identified along with any comments or additional information.

In most cases, Indigenous Peoples and local communities identified at least one driver that had facilitated the invasion of the reported alien species (84 per cent of 131 papers). Land-use change was the most commonly included driver (identified in 40 per cent of all papers), but Indigenous Peoples and local communities generally judge indirect drivers of change in nature as relatively important in facilitating biological invasions, with economic drivers (32 per cent), policies, governance and institutions (24 per cent) and sociocultural drivers (21 per cent) as the three next-ranked drivers **(Figure 3.33)**. In the majority of studies (68 per cent), Indigenous Peoples and local communities identified more than one driver facilitating biological invasions, the average number of drivers being 2.25 (range 1-7). Of the studies, 72 per cent reported on the spread of invasive alien species, 18 per cent on their establishment, and 11 per cent on their introduction, with no studies reporting on the transport stage of the invasion process.

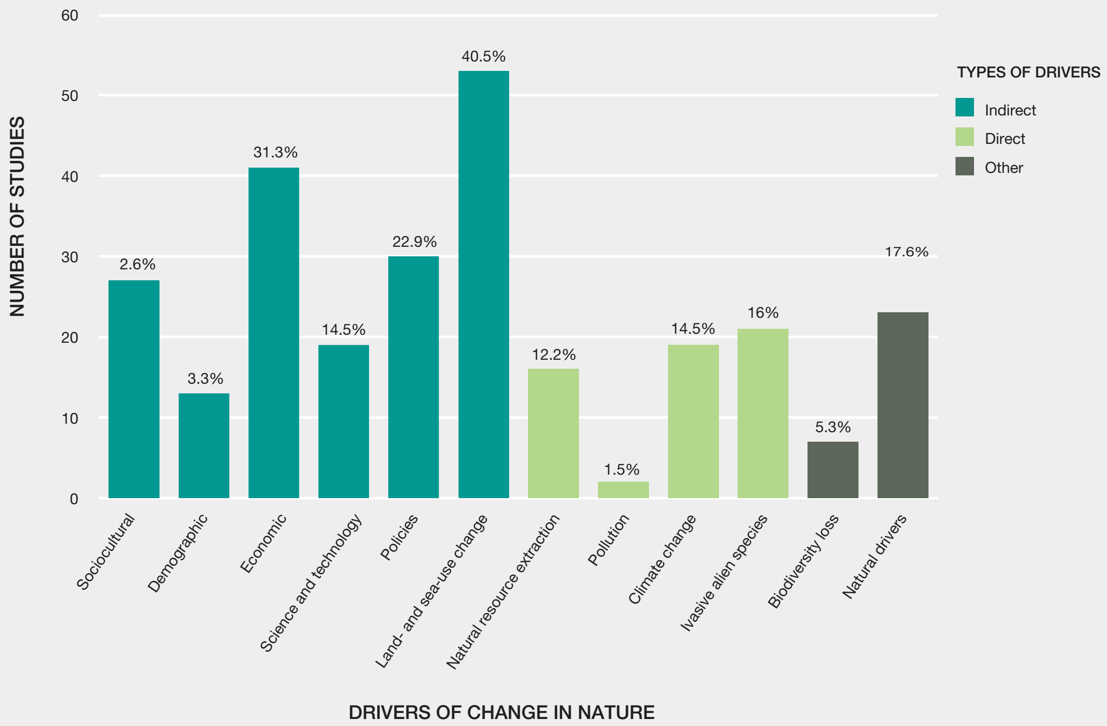

Figure 3 33 Representation of the role of each driver in the studies included in the literature review on Indigenous Peoples and local communities and invasive alien species (numbers of reported cases across 131 references) in facilitating biological invasions, noting most papers included multiple cases.

The number of studies is shown on the y axis, and the different drivers of change in nature are shown on the x axis. Data management report available at https://doi.org/10.5281/zenodo.5760266

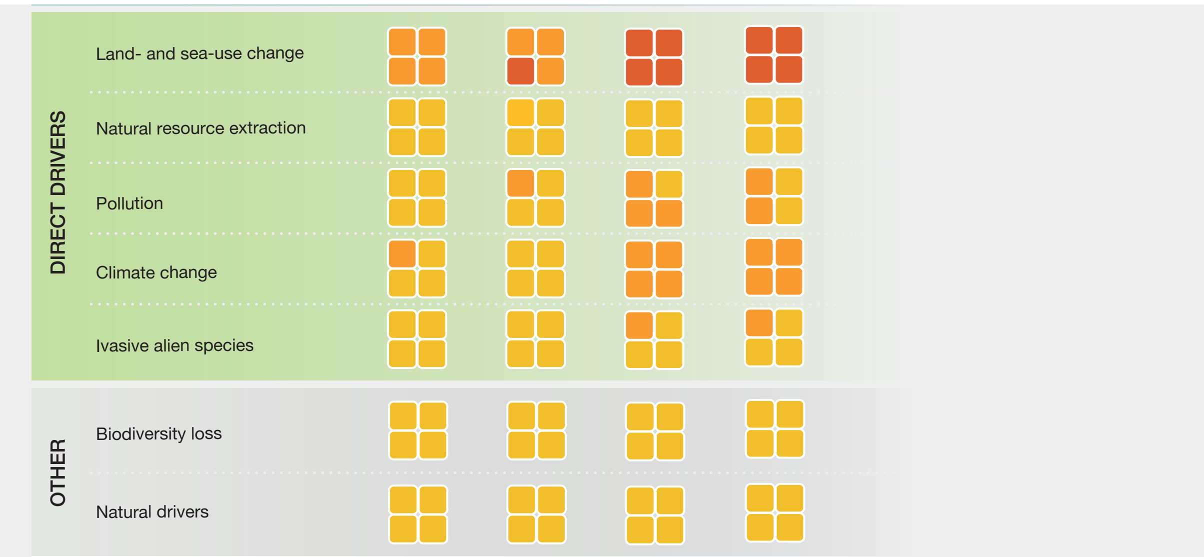

Figure 3 34 **Assessment of the relative importance of indirect and direct drivers of change in nature in facilitating invasive alien species across stages of the biological invasion process, by A) biome (terrestrial, freshwater, marine) and B) taxa (microbes, plants, invertebrates, vertebrates).**

Separately for each realm and taxonomic unit, the Chapter 3 experts (coordinating lead and lead authors, fellows), scored the relative importance of each driver (out of 100 points) for each of the four stages of the invasion process. The scores of all panel members were then averaged to produce an overall consensus assessment, based on which the authors were allowed to adjust their individual scores (i.e., using a Delphi method approach). A data management report for this figure is available at https://doi.org/10.5281/zenodo.7861162

3.6.3 Conclusions

Indirect and direct drivers of change in nature play significant but varying roles across all four stages in the biological invasion process **(Figure 3.34)**. There is a clear shift from the early stages (transport and introduction), where indirect drivers of change in nature play overriding roles, and the later stages (establishment and spread), where direct drivers dominate. The transport and introduction of invasive alien species are primarily facilitated by economic drivers (**section 3.2.3**), in particular, international trade, primarily though maritime commerce, which has caused both intentional and unintentional transport and introduction of many invasive alien species in both terrestrial and aquatic realms, followed by land- and sea-use change (**section 3.3.1**), with other drivers playing smaller but still significant roles **(Figure 3.34)**. Land- and sea-use change is the overriding driver for the establishment and especially spread of invasive alien species, followed by climate change, pollution and to some extent demographic and economic drivers **(Figure 3.34)**.

There is variation in relative importance of drivers across realms and taxonomic groups, partly related to the biophysical characteristics of the specific systems (such as better connectivity in aquatic than terrestrial systems) and partially related to variation in human impacts. Sociocultural drivers are consistently more important for plants and vertebrates than for microbes and invertebrates across all stages of the invasion process **(Figure 3.34)**. This pattern probably reflects the importance of intentional introductions for human amenity value. Recent research on the role of drivers of change in nature in facilitating biological invasions has focused on the direct drivers, climate change and land-use change, whereas economic drivers are the most studied indirect driver. The importance of governance and sociocultural perspectives in shaping biological invasion remains understudied. Strong biases also occur in the biomes and taxonomic groups examined, with the majority of studies dealing with terrestrial temperate ecosystems relative to other biomes, and plants relative to other organismal groups (**section 3.6.1**). The evidence base for the role of direct and indirect drivers on invasive alien species is largely drawn from developed nations, particularly Europe, the United States and Canada as well as Australia and New Zealand. While most indirect and direct drivers of change in nature affect biological invasions across all regions and ecosystems, the magnitude of their effects will differ and the lack of detailed information for the Arctic and developing nations, especially sub-Saharan Africa, tropical Asia and South America, is of concern.

Intensification of drivers and the acceleration of biodiversity loss and ecosystem degradation will have consequences for biological invasions in the future. It is becoming clear that climate change will increasingly shape future trends in invasive alien species, potentially with a significant temporal lag (**Chapter 2**, **section 2.2.1**), and will modify the role that other direct and indirect drivers might play in facilitating biological invasions. Furthermore, ecosystems may become more vulnerable to biological invasions as invasive alien species themselves decrease biotic resistance to further biological invasions and/or biodiversity is lost (**sections 3.3.5**, **3.4.2**). All these concurrent changes in drivers and ecosystems are indicative that past patterns of biological invasions may not be effective in informing future invasion patterns. Of particular concern is the lack of understanding as to how different drivers of change in nature interact to affect biological invasions across the invasion stages.

Few drivers act in isolation (**sections 3.1.5**, **3.5**), and there are potentially many interactions among drivers that are likely to lead to future biological invasions scenarios never previously experienced. For example, international trade also influences other drivers of change in nature that facilitate biological invasions by intensifying urbanization around major trade ports, driving resource extraction to meet international market demands and increasing atmospheric and aquatic pollution (**section 3.5**). Similarly, land- and sea-use change has led to changes in disturbance regimes and habitat degradation, which can decrease biotic resistance to the establishment and spread of invasive alien species (**section 3.3.1**). Increasing and expanding trade, travel and urbanization are major drivers implicated in the introduction and spread of invasive alien species worldwide that at the same time facilitate ecosystem degradation, which in itself is a direct driver facilitating biological invasions (**section 3.1.2**). However, fewer than 5 per cent of published studies examining the role of drivers in facilitating biological invasion addressed more than one driver (**section 3.6.1**).

Intensification in many co-occurring drivers of change in nature in combination with interactive effects amongst drivers increase the risk of positive feedbacks exacerbating biological invasions in the future. Addressing these complexities can be achieved through interdisciplinary collaborations including scientists and policymakers. For example, future scenarios can be used to explore how economic, policy and demographic changes alongside and in response to climate change, land- and sea-use change, or pollution might lead to greater risk of biological invasions (i.e., the patterns described in **Chapter 2**). Such scenarios could then enable identification of the specific conditions, situations and combinations of drivers that are key in facilitating biological invasions, and that would therefore be critical to address in order to reduce threats and impacts from invasive alien species (**Chapter 4**). Only by investing in building these links between science and policy can risks of unintended policy outcomes, that lead to environmental degradation and biodiversity loss, be identified and avoided (**Chapters 5**, **6**). Better orientation and coordination of national and international research on drivers in relation to both their actual importance as well as their policy relevance in relation to biological invasions by invasive alien species is therefore key to addressing biological invasions in the future.
